As the physiological phenomena observed in persons dead from *hanging* and *strangulation* are nearly the same, we shall consider them together in the present section, pointing out the differences between them as we proceed.

Notwithstanding the authorities of Boerhaave, Morgagni, and Portal, who imagined that apoplexy was the immediate cause of death in hanging, it is now generally admitted that the event is owing to suffocation. This opinion is confirmed by the experiments of Gregory and Brodie, from which it appears that if an artificial opening be made into the trachea of an animal, below the ligature by which it is suspended, it will continue to live. But we must admit that other injuries are sometimes inflicted, of themselves sufficient to account for death, such as compression of the nerves of the neck, and fracture or dislocation of the spine. With respect to the former, Dr. Paris remarks, "Although the pressure of a ligature on the nerves of the neck cannot be considered as the immediate cause of death in hanging, yet Mr. Brodie has very justly observed that if the animal recovers of the direct consequence of the strangulation, he may probably suffer from the effects of the ligature upon the nerves afterwards. Mr. Brodie passed a ligature under the trachea of a guinea-pig, and tied it tight

* Traité des Exhumations Juridiques, t. ii. p. 83.

† Annales d'Hygiène pub. et de Méd. Lég. t. v. p. 429.

on the back of the neck with a knot: the animal was uneasy, but nevertheless breathed and moved about. At the end of fifteen minutes the ligature was removed; on the following morning, however, it was found dead. On dissection no preternatural appearances were discovered in the brain, but the lungs were dark and turgid with blood, and presented an appearance similar to that which is observed after the division of the nerves of the eighth pair. 'I do not,' observes Mr. Brodie (manuscript notes), 'positively conclude from this experiment that the animal died from an injury to the eighth pair, but I think that such a conclusion is highly probable; and it becomes an object of inquiry whether a patient, having recovered from hanging, may not in some instances die afterwards from the injury of the par vagum.'"* Fracture or dislocation of the spine, when they do take place, must of course contribute to the speedy death of the individual; but these accidents are very rare, even when the fall is great, as in public executions. In numerous instances that have come under the observation of the writer, this cause of death was never observed. As in the case of drowning, two questions present themselves for solution by the medical witness: 1. whether the individual was suspended before or after death; 2. whether it was an act of suicide or of murder. An individual found suspended may have been killed in different ways; first, he may be hung up after having been murdered; and again, he may have committed suicide by hanging after having previously tried to destroy himself by other methods, in which he has failed, as by fire-arms, cutting the throat, &c. In the first case we might be led to mistake murder for suicide, and in the second suicide for assassination. It is necessary, then, to be aware of the signs by means of which death by strangulation in general may be distinguished, in whatsoever manner it may happen. These are lividity and distortion of the countenance, protrusion of the eyes, which are frequently suffused with blood, projection and wounding of the tongue by the teeth. The latter depends upon the position of the rope: if it be below the cricoid cartilage, the tongue is pushed out; but if it presses above the thyroid cartilage, it is carried along with the os hyoides backwards. In addition, we have the mark of the cord around the neck forming a livid depressed circle; the fingers usually bent, the nails blue, and the hands nearly closed, with swelling of the chest, shoulders, arms, and hands, and sometimes ecchymoses in these situations; also semi-erection of the penis, and emissio seminis. Cases of death by hanging occasionally present themselves in which the countenance is pale; this arises from the suddenness of death in some individuals, and particularly if the spine be dislocated. On dissection, the body presents nearly the same appearances as those described as caused by drowning, with the exception of water in the air-passages. A bloody mucus issues from the mouth and nose; but this is very different from the froth of drowned persons. The principal vessels of the head and neck are filled with blood, and sometimes ruptured. With respect to the bruised mark of the rope round the neck, it is stated by M. Klein* to be an uncertain sign,—an opinion founded on fifteen cases of suicide by hanging, in all of which it was wanting. Remer† of Breslau has more lately investigated this subject on an extended scale, and out of one hundred cases collected by him, eighty-nine presented the sugillation on the neck in an evident manner. In one case, instead of ecchymosis, the skin was found of a yellowish brown colour, like parchment; in two others the skin was excoriated; in another putrefaction prevented any certain examination; and in nine cases it is expressly mentioned that ecchymosis was wanting. It follows from this, that out of one hundred hanged persons, nearly one-tenth were found without a bruised mark. But if this proportion is sufficiently great to induce medical jurists to withhold unlimited confidence in this sign, it is at the same time too small to destroy the validity of the general rule, that such impressions are found in hanged persons. In all the cases that have come under the observation of the writer, the mark of the rope was most distinct. These were all executed criminals, in whom, from the nature of the ligature and the height of the fall, such impressions might be expected; but even in the most unfavourable circumstances the ecchymosis has been strongly marked. Remer‡ mentions that it has taken place notoriously in those found strangled in a position in which either the feet or the knees had not left the ground. In all the instances observed by us, the ecchymosis did not occupy the part of the skin with which the rope was in contact, but formed two lines on either side of it, one above, the other below; while the intervening portion, the part actually compressed by the cord, resembled dark-coloured parchment.

It is quite necessary that the medical jurist should not be content with the discovery of a blue ring on the neck, but that he should cut into it, in order to examine the extent of the extravasations, and the injury done to the parts in its neighbourhood. The height of the fall must cause a difference in the injuries inflicted on the parts composing the neck. When the individual falls from a considerable height, as in public executions, the lesions produced are very extensive. Dr. Houston§ has published an account of some dissections of criminals in whom the similarity of injury is most remarkable. "Both the individuals were strong plethoric men, executed for murder. Their death was evidently caused by strangulation. The cervical vertebræ were unbroken, and the spinal marrow and brain presented no trace of injury. In both, the sterno-mastoid muscle, on the right side (the opposite to that on which the knot of

* *Paris and Fonblanque*, Med. Jur. v. ii. p. 44.

‡ Loc. cit.

§ Dublin Hosp. Reports, vol. v. p. 317.

the rope was applied) was ecchymosed, contused, and broken; that of the left side was only slightly bruised. The os hyoides and thyroid cartilage were completely severed from each other. The omo-hyoid, sterno-hyoid and thyro-hyoid muscles, were so bruised and lacerated, that only some stretched shreds of them remained to hold the parts together. The thyro-hyoid membrane was also torn across, and the epiglottis, pulled from its root at the back of the thyroid cartilage, had passed up with the os hyoides and tongue into the back part of the mouth. The skin alone remained unbroken, and interposed between the rope and the cavity of the pharynx. This was the only region of the neck which gave evidence of much injury; the great vessels and nerves all escaped unhurt. In two other criminals, which more lately I have had an opportunity of examining, precisely the same effects had been produced by the rope on the soft parts of the neck, and without any injury to the brain or spinal marrow." The preparations from which the above statement is taken are preserved in the museum of the Royal College of Surgeons, Dublin. The semi-erect condition of the penis, and emission of semen, are signs which, although frequently met with, are not constantly found in hanged persons. Thus Klein, in the memoir alluded to, states he did not perceive them in any of the instances examined by him, and Remer found them only in the proportion of three to four. In some of the cases examined by the writer they were wanting, but in the majority there were evident traces of excitement of the organs of generation. The practice adopted by worn-out libertines, of causing themselves to be half hanged in order to arouse their dormant generative power, is a proof that some effect is produced on these organs by suspension. But as erection is not constantly found in hanged persons, we cannot accord to this phenomenon much value as an indication of death by strangulation, unless when accompanied with other characteristic signs. It adds, then, to the certainty of this kind of death, but it is no proof when it exists alone, for it has been found in other forms of violent death; and its absence is no proof of the contrary. A remarkable proof of the occurrence of this phenomenon in hanging is given by M. Guyon,* surgeon-major at Martinique, who attended the execution of fourteen persons, with a view of ascertaining the truth respecting the disputed subject of emission. Being situated near them at the place of execution, he observed the penis of all become erect at the moment of strangulation, and immediately after five of them made water abundantly. An hour after execution he found in nine of them the penis in a state of semi-erection, and its canal filled with a kind of matter with which the shirt was too profusely impregnated to allow it to be supposed that it came from any other organ than the prostate.

* Anderson's Quarterly Journal of the Medical Sciences, vol. ii. p. 151.

The second question is, whether it was an act of suicide or of murder. It is admitted by most medico-legal writers that this is a difficult and unlikely method of committing murder, unless the assailants be numerous and powerful. Dr. Smith remarks, "It is perhaps not going too far to say that a man cannot be hung alive by others, unless his hands be previously tied, and probably his legs also." Accordingly, when a body is discovered hanging, the first impression is usually that the individual has hung himself. But this opinion should not be confirmed until an accurate investigation has been made into all the external circumstances connected with the occurrence. It should first be ascertained that death has been caused by strangulation; for it has happened that crafty murderers have destroyed their victim in some other manner, and then suspended the body in order to create the suspicion of suicide. But supposing strangulation to be recognized, particular attention should be paid to the part of the neck which bears the impression of the ligature, and the kind of mark left by it. Thus, if we find the track of the cord to be low down, and to pass horizontally round the neck, while another and fainter impression exists at the upper part, taking an oblique course, it should excite suspicion that manual strangulation had been resorted to in the first instance, and that the body had been hung up after death. An examination of the dress and person of the deceased will sometimes aid the inquiries of justice by pointing out the signs of resistance and struggling, or robbery. It is necessary, however, to judge of any marks of external violence with great caution, for although they may generally be esteemed proofs of homicide, they may have been purely accidental, or have been inflicted by the individual previous to voluntary suspension. De Haen records the case of a person who, while hanging, inflicted several wounds on his face; and Ballard* mentions a case of suicide, in which the individual first cut his throat partially. The following interesting case is related by Dr. Male:† "An apprentice-boy in my neighbourhood, working alone in an attic, tied one end of a rope loosely round his neck, whilst his master was from home, probably without any intention of destroying himself, and twisted the other round the projecting part of the top of a door, the planks of which were irregular and somewhat divided; a small stool, on which he stood, slipped from under him, when he fell forwards, striking his temple against the corner of a box which cut him to the bone; he lay along the floor, his head and shoulders only elevated a few inches above it; the cord not being tied had run nearly its whole length, and then caught between the planks of the door, in which state he died. The wound was magnified by popular rumour into many, and vengeance was denounced against the innocent master, who was accused of having first killed and afterwards suspended the boy. On examining the boy, the mark of

* P. 409.
† Juridical Medicine, p. 243.

the cord was found to extend from ear to ear; the vessels of the brain were turgid, the thyroid cartilage broken, the nails blue, and the hands firmly closed. From this and other important circumstantial evidence, the coroner's jury were convinced that the charge was unfounded." It should be recollected that a person may be hanged accidentally, and therefore the usual verdicts of insanity, or felo de se, are not to be given in all cases where proofs of homicide do not exist, without due caution. A remarkable instance of this kind is related by Dr. Gordon Smith,* which occurred in April 1821, in Northamptonshire. A girl, aged thirteen, was swinging in a brewhouse, and near the rope used by her for that purpose was another for the purpose of drawing up slaughtered sheep. In the course of the exercise her head got through a noose of this second cord, which pulled her out of the swing, and kept her suspended at a considerable height until dead. We have said above that it is difficult, without an overwhelming force, to hang an individual against his will; but, on the other hand, it is surprising with what facility death may be accomplished by this means, in situations which at first view would seem to preclude its possibility. The late Prince of Condé, who committed suicide on the 27th of August 1830, was found hanging to a window-shutter, with his feet touching the ground and his knees bent. The attitude in which the body was found raised some suspicion of foul play, and a most accurate investigation of all the circumstances connected with the event was instituted, from which it appeared to have been a case of voluntary suicide. An interesting memoir† on the subject was published in January 1831, in which are related several instances of self-destruction by hanging, where the bodies were found in the most extraordinary situations and attitudes, accompanied with plates of the same. In one, a man was found in a granary hanging by a cotton handkerchief made fast to a rope which stretched across; the knees were bent, so that the legs formed a right angle backwards; the feet were supported on a heap of grain, over which the knees hung at a distance of a few inches. In another, a prisoner was found hanging to the bars of a window so low that he was nearly sitting on the ground; he had previously tied his hands together. In a third, the body was found in a vertical position, with the heels resting on a window-stool. In a fourth, an Englishman, a prisoner in Paris, hung himself in his cell, which was an apartment with an arched roof, and at the lower part of it was a grated window, the highest part of which was not near the height of a man; nevertheless he hung himself to this grating, and was found almost sitting down, with his legs stretched out before and his hips within a foot and a half of the ground. In a fifth, the attitude of the body was similar to the first: the man had suspended himself to a large iron pin driven into the wall to support the bed-curtains, and his feet, bent at a right angle, rested on the bed, while his knees approached it within a few inches. In a sixth, the point of suspension was so low that the person (a female) was obliged to stretch out her legs, one before resting on the heel, the other behind resting on the toes, in order to accomplish her purpose. In a seventh, a female was found stretched at the foot of her bed, the legs, thighs, and left hip, lying on the floor; the upper part of the body was raised, and suspended by a cord fixed on the neck, and fastened to the hospital-bed. There are other cases recorded in the memoir alluded to, of persons found hung in equally extraordinary situations, but we think it unnecessary to particularize them. A few years ago, a man aged seventy-five, destroyed himself at Castle Carey, by fixing a cord round his neck while sitting on his bedside, leaning forward till his purpose was accomplished. His wife, who had for years been bed-ridden, and therefore not likely to have been fast asleep, was in the room during the transaction, and knew nothing of what was going on.* In order to show the power of the will and firmness of resolution in certain suicides, we quote the following case from Remer, (loc. cit.) "Une femme alla, avec l'intention de se pendre, de la chambre où ses enfans se trouvaient, dans celle où ils couchaient. Sa fille aînée, agée d'environ huit ans, la suivit bientôt, et la trouva pendue; la fille exerça tant de tractions sur sa mère pour la détacher, qu'elle y parvient en rompant le lien. Alors la mère, qui avait toujours la corde au cou, repoussa son enfant dans la première chambre, la reprimanda, et lui ordonna, ainsi qu' à ses frères et ses sœurs, de rester où ils etaient, revint sur ses pas, et se pendit une seconde fois. Les enfans allaient chercher du sécours, mais il n'était plus temps." From these cases we learn how quickly consciousness must be destroyed in this form of death; for were it not so, some exertion would be made by the individuals to save themselves after the experiment had been tried to a certain extent.

Strangulation, properly so called, differs from hanging in the individual not being suspended; but whether death be caused by suspension or a ligature drawn tight, or by the hand alone, or any other pressure on the trachea, the physiological phenomena are the same. Strangling is a more common method of committing murder than hanging, arising from the greater facility with which it is accomplished. A remarkable instance of this is that of Dr. Clench, who was strangled in a hackney-coach in London, in 1692, by two men, who called him out in the night under pretence of taking him to visit a patient. After driving about the city for more than an hour the two individuals left the coach, and the coachman found Dr. Clench sitting in the bottom with his head against the cushion. He was quite dead, and had a handkerchief bound about his neck, in which was a piece of coal placed just over the windpipe. The coach-

* Principles of Forensic Medicine, p. 236.

† Annales de Hyg. pub. et de Méd. Lég. tom v. p. 156.

* Beck's Med. Jur. by Darwall, p. 283.

man had not the slightest knowledge of the transaction, having heard no noise while driving the carriage.

The appearances presented by strangled persons, when a ligature has been employed, do not differ much from those already detailed as characteristic of death by hanging. The position of the rope-mark constitutes the chief point of distinction; if it is not at the upper part of the neck, there can be no doubt the person was not hanged, dislocation of the neck is not to be expected, but the cartilages of the larynx and trachea frequently suffer. The track of the ligature in strangling is horizontal, and usually rather low down on the neck. A question has arisen as to the possibility of strangling being resorted to for the purpose of suicide. Upon this subject Foderé remarks, "Je dirai relativement au second chef de la question, qu'en général les impressions circulaires laissées par la simple strangulation forment seules une présomption d'homicide, parcequ'il n'est guère possible de se donner la mort par ce moyen, les mains cessant de faire force au moment ou la compression commence à s'exercer."* Notwithstanding this opinion he relates a case communicated to him by Desgranges of Lyons, on which the Society of Medicine were consulted, and replied that voluntary strangulation was possible. The case was that of an individual found strangled in a hayloft by a handkerchief which had been tightened by a stick. Another case of a similar description is given by the same author. One of a more recent date is recorded by Dr. Dunlop,† on the authority of a navy-surgeon, a friend of his. A Malay, who on board of a man-of-war in the East Indies had made repeated attempts to commit suicide, at last succeeded by the means alluded to. He tied a handkerchief round his neck, and with a small stick twisted it several times, and then secured it behind his ear to prevent its untwisting. Jealousy was the cause assigned for the act. The well-known case of General Pichegru, who was found strangled in prison, in Paris, during the consulate of Buonaparte, gave rise to various suspicions; and the rarity of this form of suicide, together with a general disbelief in its possibility, served to strengthen the common fame of that day, that he had been thus privately murdered in order to avoid the risk of a public trial. Certainly the condition in which the body was found seemed to point to such a conclusion. It was lying in bed on the left side, in an easy attitude, with the knees bent, and the arms lying down by the side, with a black silk handkerchief twisted tightly round the neck by means of a stick passed under it. The cheek was torn by the ends of the stick in its rotations. In allusion to this case Remer‡ observes: "Je n'ai d'ailleurs ici aucune intention de me constituer le défenseur d'un homme qui a trop versé de sang pour ne pouvoir pas prendre facilement sur lui un meurtre de plus. Bien mieux, j'accorde que ce genre de mort n'est que très rarement le résultat d'un suicide, mais je doute que sur cette seule considération, et sans autres preuves plus fortes, on puisse absolument affirmer qu'il y a eu meurtre." Indeed, when we consider the number of cases that occur, of suspension, some of which we have mentioned, where the position in which the body is found establishes with what promptitude the loss of sense must have taken place, or how strong the desire of self destruction must have been when the resolution was once taken, we think it is going too far to deny the possibility of death by voluntary strangulation, however cautious we may be in receiving testimony on the subject.

Persons destroyed by manual strangulation exhibit, instead of the circular ecchymosis on the neck, irregular patches corresponding to the fingers of the assailant. We must not expect, however, to find the internal mark of suffocation so distinct as in cases of hanging, because the closing of the air-tube not being so complete, the functions of respiration and circulation go on in some measure for a longer time. Traces of violence on the chest and limbs are also frequently observed in consequence of the struggling and force employed in the act.

Death by *smothering* is nearly allied to the former. It consists in cutting off the supply of air to the lungs by forcibly closing the mouth and nostrils. This form of death is more usually accidental than intentional, because, unless in the case of very young or old feeble persons, it is a difficult method of committing murder. Children have been smothered in bed accidentally, by the nurse or a pillow, overlaying them in such a manner as to close the mouth and nostrils. Persons in a state of intoxication may be smothered accidentally by falling with the face in mud, shallow water, or the like, and being unable to extricate themselves they perish by suffocation. But drunken persons are also easily destroyed by intentional smothering, of which the woman Campbell murdered by the notorious Burke and Hare in Edinburgh in 1828, furnishes a melancholy example. This was the last of three charges of murder laid in the same indictment as having been committed within six months in the same way, and for the same purpose, of supplying subjects for the anatomists' dissecting-room; and there is now no reason to doubt that, in conjunction with their two accomplices who turned king's evidence, they had carried on the dreadful trade of human butchery to a far greater extent. The direct evidence of the manner of death, as derived from the testimony of the accomplices, was that Burke and Hare were fighting together, when the deceased, in attempting to part them, was struck down by Hare to a sitting posture on the floor; that Burke, as soon as he had overpowered his companion and thrust him on the bed, threw himself on the deceased, kept her down by the weight of his body, and covering her mouth and nose with one hand while he applied the other under her chin, held her thus for ten or

* Méd. Lég. tom. iii. p. 174.
† Beck's Med. Jur. by Darwall, p. 290.
‡ Ann. de Hyg. et de Méd. Lég. t. iv. p. 186.

fifteen minutes till she was dead. The most remarkable appearances presented by the body when examined two days after death, were the following:—joints flaccid; features composed, red, and rather more turgid than natural; lips affected with dark livor; conjunctivæ of the eyes, even in the horizontal position of the body, much injected with blood; a little fluid blood on the left cheek, proceeding apparently from the nostrils; tongue not protruded or torn by the teeth; the scarf skin under the chin much ruffled, and the surface of the true skin dry and brown when denuded, but without blood or surrounding ecchymosis; integuments every where very free of lividity except on the face; no effusion of blood or laceration of the parts around the windpipe; no injury of the cartilages; the os hyoides and the thyroid cartilage farther apart than usual, in consequence of stretching of their interposed ligament: on the inside of the windpipe some tough mucus, not frothy, with a few points of blood between it and the membrane, which last was healthy; organs within the chest perfectly natural; the lungs remarkably so, and unusually free of infiltration; blood in the heart and great vessels, and indeed throughout the whole body very fluid and black, and accumulated in the right cavities of the heart and great veins. There were some appearances of violence on the limbs and in the spinal canal, unnecessary to notice, as they were the effects of injuries after death, caused by forcibly doubling up the body to enclose it in a box. Upon this case, Dr. Christison* (from whose admirable and detailed account we have extracted the foregoing) very justly observes: "A conviction has gained ground among the public, and has been encouraged by the sentiments currently expressed in society by some medical men, that the signs of suffocation generally, and as they existed in the body of the woman Campbell in particular, are so obvious and characteristic that they would of themselves, and independently of a knowledge of collateral circumstances, at once attract the attention of a professional person conversant with anatomy, and excite a very strong and well-grounded suspicion of the cause of death. This idea, if erroneous, must have a pernicious tendency in various ways. A sufficient reason for my taking notice of it is, that it may throw medical inspectors off their guard, by leading them to expect strongly-marked appearances in every case of death by suffocation. That such appearances are very far from being always present, should be distinctly understood by every medical man.

"In the body of the woman Campbell no person of skill, whose attention was pointedly excited by being told that from general circumstances murder was probable, but the manner of death unknown, could have failed to remark signs that would raise a suspicion of suffocation. But if his attention had not been roused,—if, for example, he had examined it in the anatomical theatre of an hospital, without knowing that suspicions from general circumstances were entertained regarding it, he might have inspected it even minutely, and yet neglected the appearances in question. Nay, a person of skill and experience would have been more likely to do so than another, because every one who is conversant with pathological anatomy must be familiar with such or similar appearances as arising from various natural diseases."

For persons found dead from *noxious inhalations, poisoning*, and *wounds*, see the articles Asphyxia, Toxicology, and Wounds, Death from.

Persons found burned.—In cases where bodies are found dead with traces of extensive burning upon them, the medical jurist to whom the investigation may be committed, has some delicate and interesting questions to solve. This difficulty has been of late years increased, by the admission of the possibility of spontaneous human combustion, and he is now expected to state—1st, whether burning was the cause of death or not, or, in other words, whether the body was burned before or after death; 2d, whether the burning was spontaneous or ordinary combustion. It is much to be feared that a want of information respecting the peculiarities of these different cases, has led, even in times not very remote, to the condemnation of innocent persons. "On a vu dans le courant du dixhuitième siècle, condamné à périr sur l'échafaud, un malheureux habitant de Rheims, accusé d'avoir assassiné sa femme, et de l'avoir ensuite brulée, afin de se dérober au supplice, qui l'attendait; et M. Vigné a jetté des fleures sur la mémoire de l'infortuné Millet, dont la femme sujette à l'ivrognerie, fut trouvée le 20 Février 1725, presque entièrement consumée dans sa cuisine, à un pied et demie du foyer."* Two cases related by Dr. Christison,† on the authority of the late Dr. Duncan, appear to us of a similar nature. In each the prisoner was accused of having murdered his wife, and burnt the body afterwards to conceal the murder. "The first was the case of a man, Gilchrist, who was condemned and executed at Glasgow. The prisoner and his wife lived on tolerably good terms, but used to take fits of rambling and get drunk for days together. At last, on one of these occasions, after their return home in the evening, the people who lived in the floor above them heard a noise like that of two persons struggling, and soon afterwards a rattling or gurgling and moaning, as of one choking or bleeding to death. They so strongly suspected that all was not right that they called down to Gilchrist through the floor that they were afraid he was killing his wife. In no long time they were further alarmed by the smell of fire and the filling of the house with smoke; upon which they went down to Gilchrist's apartment and demanded admission. After some delay he admitted them, and in doing so appeared to have come out of an inner room, where he said he was asleep in

* Edinburgh Med. and Surg. Journal, vol. xxxi. p. 243.

* Foderé Méd. Lég. tom. iii. p. 204.

† Edin. Med. and Surg. Journ. vol. xxxv. p. 316.

bed. On letting them in, he stumbled over the body of his wife, who lay in the outer apartment quite dead, kneeling before a chair and very much burnt. In these circumstances the prisoner was accused of having murdered her and then burnt the body to conceal the manner of death; while, on the contrary, he alleged he had gone to bed tired, and knew nothing of what had befallen her till he was awakened by his neighbours, and that he presumed her clothes had caught fire while she was intoxicated and burnt her to death. The medical gentlemen who had been appointed to examine the body, merely reported that they found the body so much burnt that they could learn nothing from it as to the cause of death. The general evidence was all against the prisoner. He was accordingly condemned, although the precise manner of his wife's death was not proved even presumptively, and the sentence was put in execution; but to the very last he vehemently and solemnly denied that he was guilty." The second case occurred to Dr. Duncan within the same year, at Leith. "The general evidence was of the same nature as in the case of Gilchrist, but even stronger against the prisoner. He lived on bad terms with his wife. On the evening of her death she returned home at a late hour with a lighted candle, after getting some whiskey at a neighbour's. At this time the prisoner was in bed; but some time afterwards there was heard a considerable noise, like that of struggling, and of chairs pushed up and down the room; and after this the man was heard in an adjoining bed-room, endeavouring to quiet his child, who was crying. Presently the neighbours were alarmed by a strong smell of fire proceeding from the prisoner's apartments. At last a man forced his way in by breaking the window. On entering he found the room full of smoke, and observed something burning red in a corner, over which he instantly threw a pitcher of water, and which proved to be the body of the woman burning on the hearth." Dr. Duncan was present at the examination of the body under the sheriff's warrant, and reports as follows. "We found some parts of the body, especially the belly, burnt to a cinder. We then examined the parts on which the fire had acted more moderately, namely, the face and extremities, and here there was every mark of vital reaction; some spots were merely red and inflamed; others scorched to a hard transparent crust, but surrounded with distinct redness, and a great many blisters filled with lymph perfectly different from those produced on the dead body, which are not filled with a fluid, but with air or vapour. In short, we found appearances exactly similar to those of fire on a living body, and therefore we reported as our unanimous opinion that the deceased was burnt to death." As there was no proof of the prisoner's having set fire to her, he was not found guilty, but the jury returned the intermediate verdict of *not proven*.

It is worthy of remark, that although the possibility of spontaneous combustion was not mooted at the time of these occurrences, yet the acute mind of Dr. Duncan led him to perceive something extraordinary in the phenomena which presented themselves; and he particularly comments upon the violent and destructive action of the fire, compared with the small quantity of combustible matter consumed. In neither case was there any trace of burning in the house or furniture, and in the last the woman was found on the hearth with part of her clothes unburnt, and a chair from which she had fallen quite entire. She was dead when the neighbours entered, and in the dark the body was discovered by a red light issuing from it.

Upon reviewing these cases, particularly the last, we cannot avoid agreeing with Dr. Christison, that the body was in that singular state in which it is apt to undergo spontaneous combustion; it being difficult to explain otherwise the great extent of injury inflicted. It is not our intention at present to enter into a discussion of the theory of spontaneous human combustion, that subject having been already most fully and ably treated of in a former article, (see COMBUSTION, SPONTANEOUS); but we wish to direct the attention of practitioners to that interesting phenomenon, in order that they may be prepared to detect it when it occurs; and we have mentioned the instances just quoted as examples in which a knowledge of this peculiarly morbid condition of body might possibly have saved the lives of innocent persons.

Was the body burnt before or after death?—This question can only be solved by a reference to the phenomena which are known to occur on the application of a burning heat to a living and a dead body, and by observing those indications of vital reaction which are peculiar to the former, and remain visible after life is extinct. We are indebted to Dr. Christison* for some interesting experiments and observations made for the purpose of arriving at a more certain knowledge of these phenomena; particularly with a view of ascertaining whether the effects of a burn on a living body can be imitated immediately after death by the application of heat. It appears that the most immediate effect of the application of heat to a living body is a blush of redness to a considerable extent around the burnt part, removable by gentle pressure, disappearing in no long time, and not permanent after death. Next to this in order (according to the author quoted), and occurring most generally at the very same time, is a narrow line of deep redness, separated from the burnt part by a stripe of dead whiteness, bounded towards the white stripe by an abrupt line of demarcation, passing at its outer edge by insensible degrees into the diffuse blush already described, but not capable of being removed like it by moderate pressure. In every instance in which Dr. Christison watched the effects of the actual cautery, as well as in those cases observed for him by others, this deep crimson line appeared in a very few seconds, sometimes in five,

* Edin. Med. and Surg. Journ. vol. xxxv. p. 321.

generally within fifteen, and once only so late as thirty seconds. Dr. Christison never failed to observe this appearance on the bodies of persons burnt a few hours before death, forming a line on the entire skin near the burn, from a quarter to half an inch in breadth, and about half an inch from the burn. Blistering is the next appearance in point of order, but it is not a very constant consequence of a burn if life be extinguished a few minutes afterwards. When the heat is applied by means of a scalding fluid, blisters usually appear in a very few minutes. Yet sometimes, in very extensive burns of this kind, especially in young children, there is no vesication at all in many hours. "It follows, then, that the only effects of burns which appear immediately after the injury and remain in the dead body, are, first, a narrow line of redness near the burn not removable by pressure, and, secondly, blisters filled with serum; that the former is an invariable effect; but that the latter is not always observable when death follows the burn in a few minutes."

In order to try whether these appearances could be imitated by the application of burning substances after death, Dr. Christison made the following experiments:

1. In a stout young man who had poisoned himself with laudanum, a very hot poker and a stream of boiling water were applied to the skin of the chest and inside of the arm one hour after death.

2. A stout young woman died in ten or twelve days of a low typhoid fever, and at her death was but little attenuated. Ten minutes after death boiling water was poured in a continuous stream on the breast and outside of one of the legs.

3. A very powerful, athletic young man poisoned himself with laudanum. Four hours before death a tin vessel filled with boiling water was closely applied on several parts of the anus, and a hot smoothing iron was held to the outside of the hip-joint. Half an hour after death a red-hot poker was applied to three places on the inside of the arm. The body was examined in thirty-eight hours. "Some of the spots burnt during life presented a uniform blister filled with serum; on two there was no blister, but the cuticle was gone, and the true skin dried into a reddish translucent membrane, at the edge of which there were drops of serum, and also particles of the same fluid dried by evaporation. Round all these spots there was more or less scarlet redness, particularly round the two spots last mentioned. A bright red border, half an inch wide, surrounded the whole burns; and the redness was not in the slightest degree diminished by firm pressure. The spots burnt *after death* were some of them charred on the surface, and not elevated; two presented vesications, but the blisters were filled with air, the cuticle over them dry and cracked, and the surface of the true skin beneath was also quite dry. On the white parts of the skin there was no adjacent redness." Similar appearances were presented in the two former experiments to those now mentioned as the effects produced after death. Three other experiments were made on amputated limbs immediately after operation, with results of a similar nature. From these experiments it appears that the application of heat to the body, even a few minutes only after death, cannot produce any of the signs of vital reaction formerly described; and that a line of redness near the burn, not removable by pressure, and likewise the formation of blisters filled with serum, are certain signs of a burn inflicted during life.

Was the burning spontaneous or ordinary combustion? We have already referred to the article SPONTANEOUS HUMAN COMBUSTION for an account of this extraordinary phenomenon and its probable causes. It is remarkable that by far the greatest number of victims to this accident are females. Sixteen out of seventeen cases related by Kopp, and all those, amounting to eight, given by Lair, were of this sex. In like manner the four cases mentioned by Dr. Apjohn as having occurred in Ireland, were all old women, and in all the use of spirituous liquors had been carried to a great extent. This kind of combustion penetrates the body with extraordinary rapidity, and the flame which accompanies it is with difficulty extinguished by water: but although it acts so rapidly and extensively on the body, it is observed that objects in the neighbourhood, unless those in actual contact with it, are not attacked. The trunk of the body is the part that suffers most, being generally almost entirely consumed, while the head and extremities are more spared. The rapidity and depth of these combustions, together with the small quantity of other surrounding combustibles consumed, contrast strongly with the slowness observed when bodies are burned on a funeral pile or at the stake, and lead us to understand that similar effects cannot be the work of criminal intention, for when burning is resorted to in order to conceal crime, its operations are infinitely more slow, more imperfect, and extend more to surrounding objects, than in cases of spontaneous combustion.

Persons found dead from cold.—Death from this cause is by no means rare in countries where the winter is very severe, as we learn from accounts of travellers in Siberia, Lapland, Switzerland, &c.: and even in these countries, when the winter is unusually severe, cases occur which equally illustrate the destructive effects of cold. If such accidents happen at a distance from inhabitated places, in snow and frost, they are generally too strongly marked by circumstances to be mistaken. But they may occur in populous places, and even in large cities, and are then more liable to misconstruction and suspicion. "The degree of cold necessary for the production of its fatal effects varies in a very remarkable degree with the strength and circumstances of the individual to whom it is applied, as well as with the rapidity of the cooling process. In some instances we find man enduring an extreme degree of cold with but little inconvenience, whilst in others we see him perishing in a temperature at which

water retains its fluidity."* There is a very striking description of the effects of cold in the account of the first voyage of Captain Cook. When the Endeavour was off Terra del Fuego, Sir Joseph, then Mr. Banks, Dr. Solander, and some others of the company, wished to make a botanical excursion to a mountain that appeared but a short distance from the shore. They set out, twelve in number, including domestics. An intense cold soon seized them, which they were encouraged to resist by Dr. Solander, who had crossed the mountains separating Sweden and Norway, and knew the fatal effects of yielding to its influence. He assured them that whoever sat down would sleep, and that whoever slept would never waken. Nevertheless, he was himself the first to yield to the desire for sleep, against which he had warned the rest. He begged to be allowed to lie down; he stretched himself, and slept some time upon the ground covered with snow, and it was with great difficulty that his friend Banks could rouse him to go a quarter of a mile to a fire which he had lighted. A black servant of Mr. Banks lay down also, replying to the threats of death held out to him, that he only desired to be allowed to sleep and die. Dr. Solander, when aroused at the end of five minutes, had almost lost the use of his limbs, and his feet were so shrunken that his shoes fell off. It was not possible to waken the negro, and he perished with another negro who had been left for a moment with him to assist him. All the persons in the expedition felt the effects of the cold more or less, but the whites were all saved, even Mr. Buchan, a painter, who had a fit of epilepsy, to which he was subject.

In this example, as well as from more recent observation in the polar seas, it appears that a great degree of cold, particularly when joined with fatigue, produces in the body a stupor and numbness almost insupportable, and that the ardent desire to sleep arising from this stupor is such that it cannot be conquered by the fear of the consequences. We also perceive that men least accustomed to cold are those who most readily sink under its influence, as we find the negroes dying while the whites were saved; and also that strength of mind and body tended much to enable the sufferer to resist, since Sir Joseph Banks, a man endowed with great moral and physical energy, was the one who suffered least of the whole party. The same cause will enable animals to sustain cold with impunity. For instance, among hybernating animals, as the dormouse and marmot, it has been observed, in experiments made to ascertain the cause of their sleep, that the most vigorous are the most susceptible of invigoration by heat; and that they are least readily thrown into a state of slumber by artificial cold during summer. Foderé, who was a Swiss, says that whilst inhabiting his native mountains, all the cases of death of this nature whose histories he could discover, were of sickly persons, children, old men, or females. From the experiments of Mr. Brodie, to ascertain the source of animal heat, it is plain that the temperature of animals is in some way or other dependent upon the integrity of the functions of the nervous system; and hence the power of an animal to resist cold will be determined by his power of generating heat. Now it is found that any cause by which the powers of the nervous system are impaired favours the action of cold upon the body; and for this reason an individual labouring under the effects of a narcotic may be killed by a degree of cold that otherwise would have been quite supportable. It is for this reason, also, that intoxicated persons perish in severe cold more readily than those whose nervous system is not so impaired. Dr. Paris* notices two instances that occurred in London, a few winters back, of drunken persons being taken to the watch-house, and there not being any charge against them they were dismissed by the constable of the night, and perished in the streets. A military friend of his communicated to him an instance where, out of a great number of troops who were exposed to intense cold, the only one who perished was under the influence of intoxication. This was also exemplified on a large scale in the disastrous retreat of the French troops from Russia, for we learn from La Beaume's account that intoxication seemed to insure death.

Mr. Brodie is inclined to think that cold probably destroys the principle of vitality equally in every part, and does not exclusively disturb the functions of any particular organ. This opinion is supported by the experiments of Dr. Chassat.

In case of persons found dead from cold, if the accident be recent, attempts may be made to restore life. The application of heat should be very gradual; and artificial respiration may be tried with a prospect of utility. Internal stimulants should be cautiously administered after signs of returning animation are apparent.

Persons found dead from hunger.—Food being necessary to the maintenance of life, it is plain that its deprivation cannot be endured for any length of time without causing death, and those cases of long fasting, or of refraining altogether from food for years, have all turned out to be impositions. It has, however, been ascertained that the want of nourishment is borne differently by different persons, a difference depending on age, health, constitution, sex, &c. Thus, a great number of persons doomed by some calamity at sea or elsewhere to perish by this dreadful death, do not all die at the same time, but some, according to their constitution, have the sad privilege of surviving their companions in misfortune. Young persons bear hunger worse than old, and sooner sink under its influence,—a fact no less correctly than beautifully illustrated by Dante in his description of the sufferings of Count Ugolino and his children, four in number, all enclosed in a dungeon together, and condemned to death by starvation. The father is represented as surviving until the

* *Paris and Fonblanque*, Med. Jur. vol. vii. p. 59.

* Loc. cit.

eighth day, having witnessed the death of his sons in the order of their age, beginning with the youngest. We see that in general, of the two sexes, women bear the privation of food more easily than men; thus, in all accounts of long voluntary abstinence, three-fourths or more of the individuals are of the female sex. Women usually do not consume much, and all being equal as to age and health, they require much less nourishment than men. The power of resisting hunger varies also with the total privation or otherwise of water. Redi * made many experiments to discover how long animals could live without food. Of many fowls that he kept without eating or drinking, none passed the ninth day. He gave to one as much water as it chose, of which it drank freely and often during sixteen days, and it did not die until the twentieth. Dogs in like manner lived much longer when allowed water. But it would appear from a number of instances, that the moisture of the atmosphere of the place in which an individual may be confined may compensate in some degree for the want of drink. Foderé relates an instance where three women in Piedmont were overwhelmed by snow, and shut up in a narrow stable without any provision for thirty-eight days, and at the end of that time were rescued alive; and he thinks it probable that they owed their preservation to the moisture of the place of their confinement; the absorbents on the skin being thus able to derive a certain portion of fluid for the use of the system. Chaussier reports the case of some workmen who remained fourteen days without eating or drinking, shut up in a deep damp quarry by the sudden falling in of the roof. They were withdrawn at the end of that time, with a small feeble pulse, scarcely any heat, and just a spark of life remaining, which was with difficulty kindled. The absorption of moisture had sustained them as it did the women at Bergamoletto. A very striking instance of the power of water to prolong life occurred in the case of Luc Antoine Viterbi, who starved himself to death in prison in Corsica.† From the fifth to the sixth day, to hunger insensibly succeeded the much more grievous suffering of thirst, which became so acute, that on the sixth, without ever deviating from his resolution, he began to moisten his mouth occasionally, and to gargle with a few drops of water to relieve the burning pain in his throat; but he let nothing pass the organs of deglutition, being desirous not to assuage the most insupportable cravings, but to mitigate a pain which might have shaken his resolution. Until the tenth the thirst became more and more intolerable, when, overcome by excess of pain, he seized the jug of water and drank immoderately. On the thirteenth, the unhappy man thinking himself at the point of death, again seized the jug and drank twice. On awaking on the morning of the fourteenth, and finding his powers restored, he fell into a rage with his keepers, protesting that they had deceived him, and then began beating his head against the wall of his prison, and would inevitably have killed himself had he not been prevented. During the nineteenth, the pangs of hunger and thirst appeared more grievous than ever; so insufferable indeed were they, that for the first time Viterbi let a few tears escape him, but his invincible mind instantly spurned this human tribute. On the twentieth, he declared to the gaoler and physician that he would not again moisten his mouth, and feeling the approach of death he stretched himself, asking, as on a former occasion, whether he was well out, and added, 'I am prepared to leave this world.' Death did not this time betray his hopes. On the twenty-first Viterbi was no more.—In this interesting case, which we have here abridged, we perceive the effect of a small portion of fluid in producing vigour in a body worn out by abstinence. There can be no doubt Viterbi would have died much earlier if he had not made use of the water. In the examination of bodies dead from hunger, the following characters are usually observed. There is general emaciation of the body, together with an acrid fetid odour. The eyes are open and red, the tongue and throat dry, and the intestinal canal is empty. The gall-bladder is usually filled with bile, which exudes and tinges the neighbouring viscera. The lungs are shrivelled, and all the other organs healthy. It is thought by Foderé that some conjecture may be drawn as to whether the person has been totally deprived of water or not; for according to the experiments of Dumas, the dogs which he killed by thirst had the viscera inflamed, and the blood thick and coagulated—phenomena which did not present themselves in the bodies of those dead from hunger alone.

Persons found dead from lightning.—Death from this cause is sufficiently common to warrant a consideration of it in this place. Its phenomena may be studied by observing those of common electricity, as it has been sufficiently proved that they are identical. The human body is alike affected by both, and death, whether it be occasioned by the discharge of an electrical battery or by that of a thunder-cloud, exhibits effects precisely analogous. Two theories respecting the manner of death by lightning are extant, the first that of Mr. Hunter, the second of Mr. Brodie. Mr. Hunter supposed that when death is thus occasioned, there is an instantaneous and total destruction of the vital principle in every part of the body, and that the muscles are therefore relaxed and incapable of contraction; that the limbs do not stiffen as after other forms of death, nor does the blood coagulate, and that putrefaction is rapidly set up. On the other hand, Mr. Brodie concludes from his experiments, given from his manuscript notes by Dr. Paris,* that an instantaneous extinction of vitality does not take place, but on the con-

* Osservazioni intorno agli Anim. viventi, No. 3, 4.

† *Paris and Fonblanque*, Med. Jur. v. ii. p. 69.

* Med. Jur. vol. ii. p. 64.

trary the functions of the brain are those on which the electric shock exercises its primary influence. In one of his experiments an electric battery of six jars having been charged with electricity, the shock was made to pass through a guinea-pig in the longitudinal direction from the head to the tail. The animal immediately fell on one side insensible, as if stunned; a convulsive action of the muscles of the extremities was observed, but did not long continue, and the function of respiration was not interrupted. In a few minutes sensibility was restored and the animal recovered. In another experiment a shock from nine jars was passed in the same manner through another guinea-pig. The animal immediately fell on one side, exhibited a convulsive action of the voluntary muscles of the limbs, but uttered no cries, and although attentively watched, no signs of respiration could be discovered after the shock had passed through. Three minutes afterwards Mr. Brodie opened the chest, and found the heart acting with regularity and vigour about eighty times in the minute, and circulating dark-coloured blood. The peristaltic motions of the intestines were also visible, and the muscles obeyed the galvanic stimulus.

In this experiment it is plain that neither the irritability of the muscular system at large nor that of the heart was destroyed by the shock, but death took place as from a severe injury of the head and destruction of the functions of the brain. In this case Mr. Brodie remarks, that if the lungs had been artificially inflated, the action of the heart might have been maintained, and the animal probably restored to life.

When a discharge of lightning strikes a human body, it may affect the surface and produce vesications, which most commonly, according to Mayer, pass in the direction of the spine; or it may penetrate a particular part of the body and act locally. The clothes are not unfrequently torn, and buttons, coin, or other metallic substance melted, but occasionally cases are met with where the clothes are uninjured. Death has sometimes occurred when the thunder-cloud has appeared to be at a considerable distance. This is accounted for by supposing it to be a discharge of electricity from the earth to the cloud, which had become negatively electric, constituting what is termed the returning stroke. All discharges of electricity occur in consequence of the approach of two bodies in opposite states of electrical excitement. When a substance excited positively is brought near another in its natural state and insulated, the electric equilibrium of the latter is instantly disturbed, the parts nearest to the former become negative, and the distant ones positive. If the body is not insulated, its electricity passes into the earth, and the whole becomes negatively electric. If, on the contrary, the exciting body be negative, it causes the contiguous parts of a body in its vicinity to become positive. Hence it is established as a law, that an electrified body tends to produce in a contiguous substance an electric state opposite to its own. The electricity developed in this way is said to be induced, or excited by induction. The construction of the Leyden phial is upon this principle; when the inside of the jar is rendered positive by contact with the prime conductor, the outside, if in communication with the earth, parts with electricity and becomes negative; both surfaces are therefore electrified, but in opposite states; and if a communication be established between them by a good conductor, the excess of electricity instantly passes along it, and both sides of the jar return to their natural condition. Now when a negatively electric cloud approaches the earth, all objects in its vicinity are positively excited, and when it comes within striking distance,—that is, so near that the tendency of the electricity to pass from the positive to the negative body overcomes the resistance of the intervening portion of air,—the equilibrium is restored with a report and a flash of light, exactly as in the discharge of the Leyden phial. If a person is found in an open place or under a tree shortly after a thunder-storm, with the ordinary appearances mentioned above, we may attribute his death to lightning, and particularly so if the metallic substances about him are found melted and his clothes torn or burnt, while dissection exhibits no other cause of death.

(T. E. Beatty.)

PERTUSSIS.—See Hooping-Cough.

PHARYNGITIS.—See Throat, Diseases of.

PHLEBITIS.—See Veins, Inflammation of.

PHLEGMASIA DOLENS.—Some of the hypothetical names which have, up to the present time, been employed by authors to designate the disease which forms the subject of this article, are—*Œdema Lacteum*, *Œdème des Nouvelles Accouchées*, *Dépôts Laiteux*, *les Infiltrations Laiteuses des Extrémités Inférieures*, *Hysteralgia Lactea*, *Metastasis Lactis*. As it has been demonstrated by the researches of recent pathologists that the swelling of the affected limbs, and all the other local and constitutional symptoms of this affection, invariably depend on inflammation of the iliac and femoral veins, we propose to substitute the term *crural phlebitis* for phlegmasia dolens, and the other names which have now been mentioned and were in general use before the true nature of the disease was ascertained.

We shall consider *crural phlebitis* as it is observed, 1. in puerperal or lying-in women; 2. in women who have not been pregnant; 3. in the male sex.

1. *Crural phlebitis in puerperal women.*—In the works of Hippocrates, Rodericus a Castro, and Wiseman, we find obscure notices of this disease. Mauriceau was, however, the first author who distinctly pointed out its characteristic symptoms, and he referred the swelling of the lower extremities to a reflux upon the parts of certain humours which ought to be evacuated by the lochia, of which he says, "le gros nerf de la

cuisse s'abreuve quelquefois tellement, qu'il en peut rester à la femme une claudication dans la suite."* It is not improbable, from the manner in which Mauriceau has expressed himself in this passage, that he had actually felt with the finger the indurated and inflamed femoral vein in the upper part of the thigh, which he mistook, however, for a nerve, as some other observers seem to have since done, for an inflamed absorbent. When the disease was accompanied with great fever, difficulty of respiration, pain, and tension of the abdomen, he considered the affection to be dangerous in proportion to the severity of these symptoms.

A more full account of crural phlebitis was published, not long after Mauriceau, by Puzos and Levret, both of whom considered the swelling of the limbs to depend on a deposit of milk in the part.

Puzos states that it is a painful and protracted, and sometimes a fatal disease, and that it occurs most frequently about the twelfth day after delivery, though sometimes as late as the sixth week. He also observed that one limb only is at first affected, and that the pain and swelling commence in the groin and superior part of the thigh, and descend along the course of the crural vessels to the ham, and thence along the calf of the leg to the foot. He observed, likewise, that the disease attacked the other limb, and that it presented the same appearances as the first affected. The extent of the mischief, he remarks, is readily recognized by a painful cord formed by the infiltration of the cellular tissue which accompanies the crural vessels. "C'est dans l'aine et dans la partie supérieure de la cuisse, que le dépôt commence à donner des signes de sa présence par la douleur que l'accouchée y ressent; et la douleur suit ordinairement le trajet des gros vaisseaux qui descendent le long de la cuisse; elle est même plus vive dans tout ce trajet. On reconnoit l'étendue du mal par une espèce de corde douloureuse que forme l'infiltration du tissu cellulaire qui accompagne ces vaisseaux, et l'enflure se joint presque toujours à la douleur."† Puzos recommended repeated venesection, cathartics, and sudorifics, and various local applications, as warm fomentations, and embrocations of oil of almonds with ammonia.

Levret's description of crural phlebitis strikingly coincides with that of Puzos, and he refers the disease to the crural vessels in so direct a manner, that it is singular he did not discover its precise nature. When the disease attacks one side, a tumour more or less considerable, he observes, is found on examination in the iliac fossa. The cord of crural vessels is also painful through a great part of its course. "On distingue même souvent, dans toute son étendue, de petites tumeurs olivaires qui l'entourent ça et là."‡

‡ L'Art des Accouchemens, p. 932, 2nd edition, Paris, 1761.

In a manuscript copy of Dr. William Hunter's Lectures, taken in 1775, no account is given of this disease; but from the following note, written by Mr. Cruickshanks to Mr. Trye, at the time he was engaged in the publication of his work on the subject, it is evident that Dr. Hunter had seen cases of crural phlebitis, and was convinced that the opinions of Puzos and Levret respecting the nature of the disease had no solid foundation. "They have imputed the swelled leg, which happens after lying-in, to a dépôt de lait, but it is not: to something wrong in the constitution; the patient is first seized with pain in the groin, the pulse becomes smart, and the part becomes tender, the pain and tenderness get gradually lower down, and the muscles are stiffened into hard bumps, and an œdema frequently succeeds the inflammatory swelling. It is generally called a cold, but it is not. In some it is over in a short time, in others it will last some months; it generally does well."

In the year 1784, Mr. White of Manchester published an "Inquiry into the nature and cause of that swelling in one or both of the lower extremities which sometimes happens to lying-in women," and he suggested or adopted the opinion that the disease depends on obstruction, detention, and accumulation of lymph in the limb, or on some other morbid condition of the lymphatic vessels and glands of the affected parts. He considered it to arise from some local accident during labour, and to be a purely local disease. Mr. White saw fourteen cases, either during or subsequent to the attack; but as none of them proved fatal, an opportunity was not afforded him to determine the truth of his hypothesis by an examination of the actual condition of the different textures of the affected extremities.

An essay on the swelling of the lower extremities incident to lying-in women was published in 1782, by Mr. Trye of Gloucester, in which he referred the symptoms to rupture of the lymphatics as they cross the brim of the pelvis under Poupart's ligament. Six cases came under the observation of Mr. Trye, and in all recovery likewise took place. He clearly perceived, although he was not able to explain the fact, that an intimate relation subsists between puerperal fever and the swelled leg of lying-in women. Dr. Ferriar soon after maintained, without the slightest evidence, that there is a general inflammatory state of the absorbents in this disease.

Dr. Hull published an essay on phlegmasia dolens in 1800, in which he satisfactorily shewed that it was impossible to account for the phenomena of the disease on the supposition that the lymphatics were affected independently of a considerable primary affection of the sanguiferous system of the limb. He considered the proximate cause to consist in an inflammatory affection producing suddenly a considerable effusion of serum and coagulating lymph from the exhalents into the cellular membrane of the limb. All the textures, muscles, cellular membrane, lymphatics, nerves,

glands, and bloodvessels, he supposed to become affected.*

It is a remarkable circumstance in the history of crural phlebitis, that nearly a century and a half should have elapsed from the time when it was first clearly pointed out by Mauriceau, before an opportunity was presented of ascertaining by dissection the precise nature of the disease. There had indeed been opportunities to determine the accuracy of the different hypotheses which had been advanced, but these were neglected, and the seat of the disease and its commencement in the uterus were imperfectly understood until the writer of this article ascertained by dissection the true nature and origin of the complaint.†

In January, 1823, M. Bouillaud related several cases and dissections in which the crural veins were obliterated in women who had suffered from a swelling of the lower extremities after delivery; and M. Bouillaud distinctly stated that he considered obstruction of the crural veins to be the cause, not only of the œdema of the lower extremities in lying-in women, but of many partial dropsies.

"Elizabeth Perfu, æt. 38, was received," he says, "into the Hospital Cochin two months and a half after her delivery. She had tuberculous phthisis, and the left lower extremity was infiltrated with serum. She died in three months, and on opening the body the veins of the affected extremity were found plugged up with a very old, red-coloured, easily broken-down fibrinous coagulum, which extended into the common iliac vein. The vena cava and the other veins were healthy, and contained more or less liquid blood."

Marguerite Colliere, æt. 30, was delivered by the forceps in the Maternité, about the end of January, 1822. She entered the Hospital Cochin on the 20th March following, having the left lower extremity greatly swollen and infiltrated with serum. She died on the seventh day after. An enormous abscess was found in the pelvis, which appeared to have commenced on the left side of the cavity before and within the psoas muscle. All the surrounding parts were extensively disorganized. The coats of the left iliac veins were thickened, and their interior layers were altered in structure, and converted into a lardaceous substance. The whole of the veins of the inferior extremity were plugged up with a solid friable clot.

M. Bouillaud observes that Chaussier and Meckel had both before related cases of swellings of the lower extremities in puerperal women, where the crural veins had been found inflamed and obstructed.‡

In May, 1823, the valuable essay of Dr. Davis on phlegmasia dolens was read before the Medical and Chirurgical Society, subsequently published in the twelfth volume of the Transactions. Although the cases of M. Bouillaud were published four months before Dr. Davis's paper was read, it does not admit of dispute that Dr. Davis was the first who proved by dissection that phlegmasia dolens depended on inflammation of the iliac and femoral veins. So early as 1817 a fatal case occurred to him, which was examined by Mr. Lawrence, in which the iliac and femoral veins were found inflamed and obstructed. Two other cases were recorded by Dr. Davis, and another by Mr. Oldknow, in all of which there were proofs of the previous existence of inflammation of the crural veins.*

For six years after the publication of the cases of M. Bouillaud and Dr. Davis, pathologists remained in doubt whether these cases should be considered as examples of genuine phlegmasia dolens, or be viewed as essentially different diseases, and analogous in their nature to those formidable attacks of phlebitis which sometimes succeed to venesection and wounds. In opposition to the views of Dr. Davis, it was forcibly urged that if phlegmasia dolens depended on inflammation of veins, three out of four patients would die; whereas death does not take place in one case in an hundred where that disease is distinctly marked. Even that distinguished pathologist, Mr. Lawrence, who had examined the first fatal case which occurred to Dr. Davis, declared, in the Medical and Chirurgical Society, as late as 1828, that he was fully convinced, from what had subsequently fallen under his observation, that Dr. Davis's views were incorrect, and that phlegmasia dolens did not arise from inflammation of the iliac and femoral veins. Dr. Davis has communicated no additional information on the subject since 1823, and he is still of opinion that the inflammation commences in the common iliac, and not in the veins of the uterus, and that the disease is produced by the pressure of the gravid uterus during pregnancy.

In none of the cases of Dr. Davis does it appear that any attempt was made to trace the hypogastric veins to the uterus, though it is now certain, from what is known respecting the progressive changes witnessed in cases of phlebitis, that the alteration of structure which he has described must have originated in the veins of the uterus.

Thus, then, none of the writers who have been hitherto quoted have made any allusion to phlegmasia dolens commencing in the uterine veins; and even M. Velpeau, the latest continental author on the subject, has given it as his opinion that the affection of the veins is not the primitive disease, but is the consequence of the inflammation and suppuration of the articulations of the pelvis, with which he observed it to be frequently combined. The puriform fluid found within the veins he supposes to have been introduced into their cavity by absorption, and not to have been the effect of inflammation, nor the cause of those affections of the articulations, which is now known

* An Essay on Phlegmasia Dolens, by John Hull, M.D. Manchester, 1800.

† Pathological Researches on Inflammation of the Veins of the Uterus, Med. Chirurg. Trans. vol. xv. 1829.

‡ Archives de Médecine, tom. ii. Janvier, 1823.

* Med. and Chirurg. Trans. vol. xii. 1823.

to be the case. How far this opinion was incorrect we need not now point out.

It is due to Mr. Guthrie to mention, that in a paper on inflammation of veins after amputation, published in the Medical and Physical Journal for 1826, he suggested the importance of tracing the veins from the common iliac of the affected side down to the uterus, and expressed a suspicion that the disease would be found to originate in that organ.

All the authors who have treated of phlegmasia dolens describe it as commencing, in the great majority of cases, subsequent to the tenth day after parturition, with symptoms of uterine irritation and constitutional disturbance of a low typhoid character, and with pain and swelling in one extremity only. They have assigned various reasons for these remarkable peculiarities, in the period and mode of development of the disease, as pressure of the gravid uterus on the iliac veins during gestation, the change in the distribution of the blood from the sudden removal of this pressure, exposure of the extremity to cold, suppression of the lochia, deposits of milk in the limb; all of which, taken singly or combined, are insufficient to account for the phenomena; and the occurrence of the disease after menstruation, abortion, and the malignant affections of the uterus, proves that these causes are neither necessary nor sufficient for its production.

The numerous cases and dissections of which the writer of this article has published detailed histories in the Medical and Chirurgical Transactions, and in a recent work on the "Pathology and Treatment of some of the most important Diseases of Women," offer a more satisfactory, and, he trusts, a conclusive explanation of the phenomena. They demonstrate that if inflammation be excited in the uterine branches of the hypogastric veins, it may continue to spread along these until it reaches the common external iliac and femoral veins, and by the morbid changes induced in them give rise to all the subsequent symptoms.

The two following cases are here introduced, not merely because they were the first in which crural phlebitis was distinctly traced into the uterine veins, but as they afford good examples of this affection in its most mild and most severe forms, and illustrate, better than any general description could do, the phenomena of the disease, and the alterations of structure produced by inflammation in the hypogastric and crural veins.

A patient of the British Lying-in Hospital, who had been suffering for some weeks before delivery (May 8, 1829) from the usual symptoms of tubercular phthisis, experienced, on the 4th June, a sense of soreness in the left groin, which gradually extended along the inner surface of the thigh to the ham, and from thence along the posterior surface of the leg to the foot. She stated that for two days before the occurrence of pain in the groin, she had felt great uneasiness in the region of the uterus; that this suddenly quitted the hypogastrium and passed into the groin, and that from thence it extended downward along the inner surface of the thigh to the leg. The limb became swollen twenty-four hours after the invasion of the disease.

The whole left inferior extremity is now affected with a hot, painful, colourless swelling, no where pitting on pressure, except over the foot. The thigh is fully double the size of the other, and any attempt to move the limb produces excruciating pain along the inner surface of the thigh; and the pain excited by pressure along the tract of the femoral vein is so acute, that the condition of the vessel cannot be ascertained. Several branches of the saphena major above the knee are distended and hard; pulse 120; respiration quick and laborious; tongue peculiarly red and glossy; diarrhœa continues. 10th. Pulmonary affection aggravated. The limb continues extremely painful, and is still more swollen. The groin is so tender that she cannot bear the slightest pressure over it. The same is the case with the inner surface of the thigh. The branches of the saphena are still hard and painful. 11th. The femoral vein, under Poupart's ligament, can now be felt indurated and enlarged, and it is exquisitely painful when pressed; as is the inner surface of the thigh, the ham, and the calf of the leg. There is comparatively little tenderness along the outer surface of the limb. 17th. Diarrhœa, emaciation, colliquative sweats, and difficulty of respiration increasing. The left inferior extremity is still much swollen; but there is less pain in the groin and in the course of the femoral vessels. Died on the 24th.

Dissection.—Thorax. Adhesions between the pleuræ on both sides. Scarcely a portion of lung could be observed which did not contain tubercles in various stages of their growth. The right and left superior lobes contained several large tuberculous excavations. The vena cava and right common and external iliac veins were in a sound state. The *left common external* and *internal iliac* veins were all impervious, and had undergone various alterations of structure. The common iliac, at its termination, was reduced to a slender tube, about a line in diameter, which was lined with a blueish slate-coloured adventitious membrane. The remainder of the common and the external iliac veins were coated also with a dark-coloured membrane, and their centre filled with a brownish ochrey-coloured tenacious substance, rather more consistent than the crassamentum of the blood.

The left hypogastric or internal iliac vein was in the same condition, but in some places reduced to a cord-like substance, and its cavity throughout completely obliterated. The branches of this vein, taking their origin in the uterus, and usually termed the uterine plexus, were found completely plugged up with firm red coagula. From the commencement of the branches of this plexus of the hypogastric vein to the termination of this vein in the iliac, the whole had become thickened, contracted, and plugged up with coagula and adventitious membrane of a dark blue colour.

The same changes had taken place in the uterine plexus and trunk of the right hypogastric vein, from the uterus to its unusual termination in the left common iliac vein. The coats of the left femoral vein were thickened, and closely adherent to the artery and surrounding cellular substance; its whole interior lined with an adventitious membrane, and distended with a reddish-coloured coagulum. The same morbid changes presented themselves in the deep and superficial branches as far as they were examined down the thigh.

A woman, aged forty, who had been delivered of twins a month before, and had nearly perished from flooding, and subsequently from an attack of uterine inflammation, was seized on the 27th August 1829, with a violent fit of cold shivering, followed by pyrexia and pain in the right iliac region and groin. In the course of the two following days, the pain increased in severity, and extended down the inner surface of the thigh towards the ham, and the whole leg and thigh became much swollen. 29th. The whole right inferior extremity affected with a general intumescence, and completely deprived of all power of motion. The temperature of the limb, particularly along the inner surface, much higher than that of the other; but the integuments retain their natural colour, and do not pit on pressure. The femoral vein, for several inches under Poupart's ligament, is very distinctly felt enlarged, and is very painful when pressed. Out of the course of the crural vessels little uneasiness is produced by pressure. In the right side of the hypogastrium there is also great tenderness; pulse 120; tongue furred. She appears pale and depressed, and complains of deep-seated acute pain in the lower part of the back when she attempts to move. From this period until the 22d September, when she died, she suffered from repeated fits of shivering, which occasionally assumed a regular intermittent form; there was diarrhœa, with brown tongue; the glands in the right groin became much enlarged, and the left inferior extremity became affected in a manner similar to the right.

Dissection. The veins presented nearly similar appearances to those observed in the preceding case. The divisions of the vena cava were in this instance both affected. On the left side the cavities of the iliac and femoral veins were filled with a dark purple coagulum, their coats being not much thicker than natural; whilst on the right side the coats of these veins were dense and ligamentous, and the cavities blocked up by adventitious membranes, or lymph of a dull yellow colour. The lower part of the vena cava, for the space of two inches, as well as the right common iliac, was obstructed by a tough membrane of lymph surrounding a soft semi-fluid yellowish matter. The right common, external, and internal iliac veins were imbedded in a mass of suppurating glands, the purulent fluid of which had escaped into the adjacent cellular membrane, and forced its way downwards in the course of the psoas muscle, as low as Poupart's ligament. The right hypogastric vein was reduced to a small impervious cord, and its branches were distended with coagula of lymph of a bright red colour. The right femoral and its branches were in like manner impervious, their coats being greatly thickened, and their interior occupied by coagula. The cavities of the left common external iliac and hypogastric veins contained soft coagula, disposed in layers which adhered to the inner tunic of the vessel.

The trunk of the left hypogastric vein was contracted, its coats somewhat thickened, and its branches filled with worm-like coagula. The spermatic veins were healthy. The cellular membrane of both lower extremities was infiltrated with serum.

The *causes* of uterine and crural phlebitis have already been pointed out in the article Puerperal Fever. Inflammation of veins, it was there observed, rarely takes place in any part of the body where it cannot be referred to a wound or to some specific cause externally applied to the coats of the vessels. In uterine phlebitis the inflammation cannot, it is true, be traced in all cases to the semilunar shaped orifices in the lining membrane of the uterus which communicate with the sinuses where the placenta had adhered; yet it scarcely admits of a doubt that the frequent occurrence of the disease arises from the orifices of these veins in the lining membrane of the uterus being left open after the separation of the placenta, by which a direct communication is established between the cavities of these veins and the atmospheric air, in a manner somewhat analogous to what takes place in amputation and other extensive wounds.

The veins which return the blood from the uterus and its appendages may be either wholly or in part inflamed; generally, however, the inflammation attacks the spermatic veins alone, and for the most part the one only on that side of the uterus to which the placenta has been attached: and it may confine itself to a small portion of the vessel, or extend throughout its whole course from the uterus to the vena cava. The same is the case with regard to the hypogastric veins, one only being generally affected. These veins are, however, rarely inflamed in comparison with the spermatic; and this would seem to depend on the latter veins being invariably connected with the placenta, to whatever part of the uterus it may happen to be attached.

In eight of the twenty-three cases of puerperal crural phlebitis which have come under the writer's immediate observation, the disease has commenced between the fourth and twelfth days after delivery, and in the remaining fifteen it appeared subsequent to the end of the second week after parturition. In most of the patients there was either an attack of uterine inflammation in the interval between delivery and the commencement of the swelling in the lower extremity, or there were certain symptoms present which are to be regarded as

characteristic of venous inflammation, viz. rigors, headach, prostration of strength, a small rapid pulse, occasional paroxysms like those of ague, nausea, loaded tongue, and thirst.

The sense of pain, at first experienced in the uterine region, has afterwards been chiefly felt along the brim of the pelvis, in the direction of the iliac veins, and has been succeeded by tension and swelling of the part. After an interval of one or more days, the painful tumefaction of the iliac and inguinal regions has extended along the course of the crural vessels, under Poupart's ligament to the upper part of the thigh, and has descended from thence in the direction of the great blood-vessels to the ham. Pressure along the course of the iliac and femoral vessels has never failed to aggravate the pain, and in no other part of the limb has pressure produced much uneasiness. There has generally been a sensible fulness perceptible above Poupart's ligament before any tenderness has been experienced along the course of the femoral vessels; and in every case at the commencement of the attack, we have been able to trace the femoral vein proceeding down the thigh like a hard cord, which rolled under the fingers.

A considerable swelling of the limb, commencing in the thigh and gradually descending to the ham, has generally taken place in the course of two or three days, and in some cases immediately after the pain has been experienced in the groin. In other cases the swelling has been first observed in the ham or calf of the leg, and has spread from these parts upward and downward until the whole extremity has become greatly enlarged. The integuments have then become tense, elastic, hot, and shining, and in most cases where the swelling has taken place rapidly there has been no pitting upon pressure or discoloration of the skin. In several well-marked cases, however, of crural phlebitis, at the invasion of the disease, the impression of the finger has remained in different parts of the limb, more particularly along the tibia; but as the intumescence has increased, the pitting upon pressure has disappeared, until the acute stage of the complaint has passed away. At the onset of the disease we have also observed, in several cases, a diffuse erythematous redness of the integuments along the inner part of the thigh and leg. In one individual only has suppuration of the glands taken place in the vicinity of the femoral vein; but in several, by an extension of the inflammation, the inguinal glands have become indurated and enlarged. In some women the inflammation of the femoral vein has appeared to be suddenly arrested at the part where the trunk of the saphena enters it, and the inflammation has extended along the superficial veins to the leg and foot. The swelling and pain in these instances have been greatest along the inner surface of the thigh, in the course of the saphena veins. In most cases of crural phlebitis, not only the whole lower extremity, but the nates and vulva have been affected with a glossy, hot, colourless, and painful swelling, which has not retained the impression of the finger.

The power of moving or extending the leg has been completely lost after the disease has been fully formed, and the greatest degree of freedom from pain has been experienced by the patients in the horizontal posture, with the limb slightly flexed at the knee and hip joints. The severity of the pain and febrile symptoms has usually diminished in a few days after the occurrence of the swelling; but this has not invariably happened, and we have seen some individuals suffer from excruciating pain for many weeks, or through the whole period of the acute stage of the disease.

The duration of the acute local symptoms has been very various in different cases. In the greater number they have subsided in two or three weeks, and sometimes earlier, and the limb has been then left in a powerless and œdematous state. The swelling of the thigh has first disappeared, and the leg and foot have more slowly resumed their natural form. In one case, after the swelling had subsided several months, large clusters of dilated superficial veins were seen proceeding from the foot along the leg and thigh, to the trunk; and numerous veins as large as a finger were observed over the lower part of the abdominal parietes. In some women the extremity does not return to its natural state for many months or years, or even during life. In the summer of 1831, a lady was placed under our care for an affection of the left lower extremity, who, forty years before, had suffered from an attack of crural phlebitis in the same side. The left leg and thigh had remained larger and weaker than the other during the whole of this long period, and was liable to suffer severely from fatigue, and slight changes in the atmosphere. This lady was attended in her confinement by a celebrated London accoucheur, who was so strongly impressed with a belief of the truth of the doctrine of Puzos respecting milky deposits in crural phlebitis, that he ordered the infant to be kept night and day at the breasts, lest the milk should make its way into the thigh.

In four cases of this affection, after the acute symptoms had begun to subside, the same appearances were observed in the iliac and femoral veins of the opposite extremity, and the other thigh, the leg, and the foot became similarly affected. In two individuals only has the disease attacked the same extremity twice. In one woman an interval of twelve years elapsed between the first and second attack.

Dr. Hull has given the following description of the disease.* "It has in many instances attacked women who were recovering from puerperal fever, and in some cases has supervened, or succeeded to thoracic inflammation. It not uncommonly begins with coldness and rigors. These are succeeded by heat, thirst,

* On Phlegmasia Dolens, p. 133. Manchester, 1800.

and other symptoms of pyrexia; and then pain, stiffness, and other symptoms of topical inflammation supervene. Sometimes the local affection is from the first accompanied with, but is not preceded by febrile symptoms. Upon other occasions the topical affection is neither preceded by puerperal fever nor rigors, &c.; but soon after it has taken place, the pulse becomes more frequent, the heat of the body is increased, and the patient is affected with thirst, headach, &c. The pyrexia is very various in degree in different patients, and sometimes assumes an irregular remittent or intermittent type.

"The complaint generally takes place on one side only at first, and the part where it commences is various; but it most commonly begins in the lumbar, hypogastric, or inguinal region, on one side, or in the hip or top of the thigh, and corresponding labium pudendi. In this case the patient first perceives a sense of pain, weight, and stiffness in some of the above-mentioned parts, which are increased by every attempt to move the pelvis or lower limb. If the part be carefully examined, it generally is found rather fuller or hotter than natural, and tender to the touch, but not discoloured. The pain increases, always becomes very severe, and in some cases is of the most excruciating kind. It extends along the thigh, and when it has subsisted for some time, longer or shorter in different patients, the top of the thigh and the labium pudendi become greatly swelled, and the pain is then sometimes alleviated and accompanied with a greater sense of distention. The pain next extends down to the knee, and is generally the most severe on the inside and back of the thigh, in the direction of the internal cutaneous and crural nerves; when it has continued for some time, the whole of the thigh becomes swelled, and the pain is somewhat relieved; the pain then extends down the leg to the foot, and is commonly most severe in the direction of the posterior tibial nerve; after some time the parts last attacked begin to swell, and the pain abates in violence, but is still very considerable, especially on any attempt to move the limb. The extremity, being now swelled throughout its whole extent, appears perfectly or nearly uniform, and it is not perceptibly lessened by an horizontal position, like an œdematous limb. It is of the natural colour, or even whiter; is hotter than natural; excessively tense and exquisitely tender when touched; when pressed by the finger in different parts, it is found to be elastic, little if any impression remaining, and that only for a very short time."

After describing the manner in which the constitutional and local symptoms subside, Dr. Hull further observes, that "hitherto the disease has been described as affecting only one of the inferior extremities, and as terminating by resolution or the effusion of a fluid that is removed by the absorbents; but unfortunately it sometimes happens that after it abates in one limb, the other is attacked in a similar way. It also happens in some cases that the swelling is not terminated by resolution. For sometimes a suppuration takes place in one or both legs, and ulcers are formed which are difficult to heal. In a few cases a gangrene has supervened. In some instances the patient has been destroyed by the violence of the disease before either suppuration or gangrene has happened."

2. *Crural phlebitis in women who are not in the puerperal state.*—The cases which have been related in the work already referred to, prove that inflammation of the iliac and femoral veins is a disease not peculiar to women who have recently been delivered, but that it may also arise from suppressed menstruation, malignant ulceration of the os and cervix uteri, and other organic diseases of the uterine organs.

In a lady aged thirty-one, whose case has been recorded by Tommasini, the catamenia were suddenly suppressed from immersion of the body in cold water. Headach, fever, and swelling of one of the limbs took place, and in three months she was attacked with great anxiety, prostration of strength and spirits, and other signs of a severe disease. The pulse was frequent and irregular, and there was great anxiety in respiration; the blood drawn was buffy. Phlebitis of the inferior extremity manifested itself. The pulse became intermittent, the veins of the limb painful and turgid, and the skin covered with spots of a dark colour. The sense of oppression increased, and death took place about four months after the commencement of her illness. On dissection, the lungs were found inflamed. In the limb affected, the coats of the saphena, sural, popliteal, crural, and iliac veins were thickened, injected, and filled with coagula of blood, which in some parts of the crural veins appeared to be changed into a fleshy substance. The coats of the iliac above the crural arch, to the bifurcation of the vena cava, were much thicker than the other veins, and more injected, without any manifest collection of purulent matter. The arterial system was healthy; the condition of the internal iliac and uterine veins has not been described, although there can be little doubt the effusion originated in the uterus.*

In four cases which have come under our observation, inflammation of the iliac and femoral veins, giving rise to all the phenomena of phlegmasia dolens, has followed the sudden suppression of the catamenia from exposure to cold.

In the first there was great tenderness of the hypogastrium and left thigh, a rapid feeble pulse, delirium, brown tongue, vomiting, exquisite pain in several of the joints both of the upper and lower extremities, and abscesses formed in different parts of the body.

In the second case, which occurred in a young lady, the whole left inferior extremity was swollen, hot, and painful, but not discoloured. The femoral vein was felt under Poupart's ligament like a large hard cord, and pressure over it and along the course of the iliac veins of the same side produced great

* *Tommasini*, Saggio di Pratiche Considerazioni fatte nella Clinica Medica di Bologna, p. 317.

suffering. The affection presented the same characters as in puerperal crural phlebitis, and could be distinctly referred to the sudden suppression of the catamenia.

In another case, referable to exposure to cold, the disease occurred in both lower extremities.

In the article (Edema it is observed that in women suffering from amenorrhœa, œdema is one of the most common attendants. In these cases there is considerable tenderness in the course of the femoral veins, the most common site of this tenderness being just before the vein pierces the tendon of the triceps to pass into the ham, and probably depends on some inflammation of the vessel. (See (Edema.)

From cases which we have likewise related, it appears that uterine phlebitis sometimes follows abortion, and that it has taken place and proved fatal after the removal of a polypus of the uterus by ligature. Tenderness in the course of the venous trunks of the lower extremities, and œdema of the limbs, have also in several cases been traced to some external injury inflicted on the uterus.

The first case of crural phlebitis from malignant ulceration of the os uteri came under our notice nearly four years ago, and for several weeks before death the patient experienced great tenderness in the course of the left femoral vein, with a tense swollen state of the limb. On opening the abdomen, the peritoneum covering the intestines and liver was found to be inflamed, with an effusion of purulent fluid into the abdominal cavity. The os, cervix, and a great part of the body of the uterus, had been destroyed by phagedenic ulceration, and extensive openings had formed in the bladder and rectum. On the left side, between the remaining portion of the uterus and the pelvis, to the brim of which it firmly adhered, was a spongy cancerous mass, enclosing within it the branches and trunk of the hypogastric vein and artery, and a considerable portion of the common and external iliac veins. When cut into it presented a spongy texture, and a thick whitish purulent fluid escaped as if from numerous cells, but which were subsequently ascertained to be cavities of veins. A portion of the common and external iliac veins was lost in removing the parts from the body. What remained of the common iliac was reduced to a slender tube, which was partially coated on the inner surface with an adventitious membrane of a black colour.

The commencement of the external iliac was also contracted so as to be impervious, and lined with a dark-coloured false membrane. The common superficial and deep femoral veins were all plugged up with firm red coagula, the coats thickened, and the inner surface lined with adherent false membranes.

The cellular texture of the limb was loaded with serum; but in other respects it was healthy, as were the other tissues.

From these and similar cases which have since occurred to the writer, to Mr. Lawrence,* and to Dr. Blundell, it appears not only that inflammation of the veins of the uterus may be produced by malignant ulceration of the os and cervix uteri, but that this inflammation may extend along the internal to the common, external iliac, and femoral veins, and thus give rise to all the phenomena of crural phlebitis, as observed in puerperal women.

3. *Phlegmasia dolens in men.*—It has recently been ascertained that this disease, in the male sex, may commence either in the hemorrhoidal, vesical, or in some of the other branches of the internal iliac veins, in consequence of inflammation or organic changes of structure in one or more of the pelvic viscera. Crural phlebitis in men arises much more frequently, however, from inflammation being excited in the superficial veins of the leg, extending upward and involving the great venous trunks of the thigh and pelvis. External injuries, exposure to cold and moisture, and ulcers, are the most frequent causes of inflammation of the saphena veins. Amputation may also excite crural phlebitis, both in the veins of the same side and in those of the opposite extremity. Tumours, by pressing upon the vena cava and iliac veins, may also give rise to the disease.

The following observations will illustrate, though in a less perfect manner than might be desirable, this interesting part of the pathology of veins.

Mr. Lawrence examined the body of a man who died in St. Bartholomew's Hospital of cancer of the rectum, and he found the iliac veins inflamed and obstructed. The affection not having extended into the veins below Poupart's ligament, none of the usual symptoms of crural phlebitis manifested themselves.

In two cases of crural phlebitis, related by Mr. Holberton, the patients died of phthisis, with diarrhœa and ulcerations of the bowels. In the first case the examination was imperfect, but in the second the writer traced the left hemorrhoidal veins close to the spots of ulceration in the mucous membrane of the rectum, and the coats of these vessels were unusually thickened, and exhibited other marks of previous inflammation.*

The patient whose case has been recorded by Dr. Forbes, likewise died of phthisis and suffered from diarrhœa. The internal iliac vein was not traced to the rectum, but Dr. Forbes has recently stated to us his belief that the mucous membrane of the lower intestines was ulcerated.†

Dr. Cheyne observes in his Report of the Whitworth Hospital, which contains an account of dysentery, that "it is worthy of remark that a swelling occurred in several of the patients, both males and females, resembling the phlegmasia dolens in all respects but in its connexion with parturition."

Dr. Tweedie has related cases of fever which were followed by painful swellings of the lower extremities, which also in all essential circumstances resembled phlegmasia dolens; but as

* Med. Chir. Transact. vol. xvi. p. 59. 1830.

* Med.-Chir. Transact. vol. xvi. part i. p. 70.

† Ibid. vol. viii. p. 293.

these patients recovered, the condition of the veins or the intestines was not ascertained.*

Drs. Graves and Stokes have subsequently related cases of painful swellings of the lower extremities after fever, which presented all the usual symptoms of phlegmasia dolens, and were considered by them to be identically the same diseases. In both, they remark, œdema occurred unattended by redness, but accompanied by increase of heat with great tenderness and pain, and followed for a considerable time by impaired motion of the limb. In both diseases the swelling and the other symptoms are frequently not confined to any one portion of the extremity, but extend uniformly over the leg and thigh. In both diseases, however, we have also often observed that the pain, heat, and swelling occupied particular parts of the limb, while the rest was comparatively free from disease. Thus, in some cases a portion of the thigh was extensively engaged while the leg and foot remained in the natural state, and after some days the diseased action seemed to change its place, and successively attacked the other portions of the limb, without, however, any precise order in the mode of succession.†

In the spring of 1833 a case of chronic dysentery came under the observation of Dr. Macann, in which phlegmasia dolens took place a short time before death. On dissection, the common, external iliac, and femoral veins of the left side were found to be completely obstructed, and their coats extensively disorganized by inflammation. The writer is indebted to his friend Dr. Forbes for this valuable specimen of inflamed veins, which was presented to Dr. Forbes by Dr. Macann, previous to his departure for the West Indies. In the short notice of the case it is stated that both lower extremities were swollen. It has not been ascertained whether the condition of the lining membrane of the rectum was examined by Dr. Macann, or if he attempted to trace the hemorrhoidal veins to their commencement.

In Dr. Cheyne's cases of dysentery it is highly probable the disease commenced in the hemorrhoidal veins, and from the frequent occurrence of inflammation and ulceration of the intestines in continued fever, we are disposed to think the affection had the same origin in the cases of Drs. Tweedie, Graves, Stokes, and Macann.

A man, whose case is recorded by Cruveilhier, had a sound introduced into the bladder for retention of urine, occasioned by a swelling of the prostate. Pain was experienced soon after in one of the lower extremities, and the veins became painful and distended like hard cords. The patient died, and all the different degrees of phlebitis were observed in the veins of the limb. There can be little doubt, M. Cruveilhier observes, that inflammation of the prostatic or vesical veins had been induced by the introduction of the instrument in this case, but the examination not having been conducted with a view to ascertain this point, it was not positively determined.

More frequently, both in the male and female sex, the inflammation does not commence within the pelvis, but originates in the superficial veins of the limb, and gradually extends upwards to the large deep venous trunks.

Mr. C. Hutchison has related the history of an interesting case of phlegmasia dolens in a gentleman who received a blow on his right shin, immediately over a branch of the saphena vein, by a small piece of timber accidentally falling upon it. The accident was followed by considerable swelling and inflammation all over the limb; pain was felt in the direction of the upper third of the saphena before it actually dips to unite with the femoral vein. The whole leg and thigh soon became enlarged and inflamed, and many months after the acute symptoms had subsided, when we examined the limb with Mr. Hutchison, Sir Gilbert Blane, and Dr. Gairdiner, there could be no doubt that the saphena and femoral veins had become completely impervious from inflammation.*

Sir A. Cooper performed an operation for varix of the saphena vein, which was followed by inflammation of the coats of the vessel and all the symptoms of phlegmasia dolens.

The following fatal case of crural phlebitis induced by exposure of the limb to cold and moisture, has been recorded by Drs. Graves and Stokes. A young man, of a strong habit, was employed for two successive days in working in a ditch, and was consequently obliged to stand in water above his knees during that time. On the following day he became affected with lassitude, vertigo, and general weakness, and complained of severe pain in the right thigh. These symptoms continued for seven days, when he was admitted into the Meath Hospital. His countenance was anxious and depressed, the tongue furred; thirst, headach, urine scanty, turbid, and high-coloured; pulse ninety-six, skin mottled with petechiæ. In addition to these general symptoms, the respiration was laboured and unequal, with some cough; face very livid. But his chief complaint was a severe pain in the upper and anterior part of the right thigh, which was greatly aggravated by motion or pressure. He had also severe pain in the left hypochondrium.

At this time no swelling of the limb whatever could be detected; but in the course of two days the upper portion of the thigh became evidently swollen, the part being extremely tender, but not at all red. The pain of the side continued, and extensive bronchial and pneumonic inflammation was detected. General bleeding and very free leeching to the limb was employed. The blood was not inflammatory, and no relief was experienced by the patient. The swelling of the thigh increased; calomel and opium were freely exhibited, but without any effect. The typhoid symptoms increased, and the patient died on the fourth day after his admission.

* Edin. Med. and Surg. Journal, vol. xxx.
† Dublin Hospital Reports, vol. v. p. 29.

* Med. and Chir. Transactions, vol. xv. 1829.

On dissection, the right lower extremity was found to be tense and swollen in its superior portion, while the leg and foot were slightly anasarcous. The sac of the pericardium contained some sero-purulent fluid; and that portion covering the auricles and great vessels was vascular, and in many cases covered with coagulable lymph. Both lungs were in a state of extreme sanguineous congestion, with commencing solidity in their posterior inferior portion, and general inflammation of the pleura. The bronchial mucous membrane was universally red, and the tubes filled with frothy mucus.

The vena cava contained a few portions of a substance of a granular appearance, friable, and of a yellowish colour. This did not adhere to the vessel, which otherwise appeared healthy. In the external iliac vein, however, just above Poupart's ligament, there was a large concretion of a similar nature nearly plugging up the vessel, and extending into some of the minute collateral branches. The lining membrane was red, and in one point adhered to the coagulum. No puriform matter could be detected. The femoral and popliteal arteries were healthy. The cellular tissue of the limb was œdematous. The condition of the saphena vein where it enters the femoral is not described, although the inflammation most probably originated in the superficial vessel.

On the 2d of February 1832, the body of an aged man was brought into the dissecting-room of Webb-street school. The whole left inferior extremity was much swollen, and a chronic ulcer was observed over the tibia. The coats of the saphena vein along the leg and thigh were found, on examination, to be much thickened, and plugged up with coagula of blood and lymph. The left common and external iliac and femoral vein to the ham were all completely obstructed with coagula of blood and lymph, and lined with adventitious membrane. The lower part of the vena cava, to the extent of three inches, was filled with a soft yellowish coagulum of lymph, which adhered to the inner coat of the vein. The coats of the principal arteries of the left lower extremity were ossified.

In April 1832 Sir Henry Halford read an account at the College of Physicians of crural phlebitis as observed in the late Earl of Liverpool. The attack commenced many years before; and it is highly probable, from a circumstance stated to us by Sir A. Cooper, that it was induced by exposure to a current of cold air, which passed through an open window and fell upon the lower extremities when but thinly clothed, his lordship being at a crowded levee. The left groin, thigh, and leg were affected; and in the acute stage of the complaint, leeches and the usual antiphlogistic remedies had been employed by Dr. Pemberton and Sir A. Cooper. Lord Liverpool subsequently died from an affection of the brain; and on examining the body, the left iliac, femoral, and saphena veins were found to have undergone changes of structure similar to those which have previously been described as occurring in puerperal crural phlebitis. Sir Henry Halford related two other cases of crural phlebitis in men. They were similar to the case of the Earl of Liverpool, and were succeeded by marked tendency to head affection. In none of the cases of crural phlebitis which have fallen under our observation, has any remarkable slowness of pulse or tendency to disease of the brain been observed. Even where the vena cava and both iliac and femoral veins have become completely impervious, the blood has been returned to the heart without difficulty, and no affection of the brain has taken place.

In a patient of the British Lying-in Hospital, who had suffered much from varicose veins in the latter months of gestation, inflammation of the saphena veins of both lower extremities came on two days after delivery with most severe constitutional symptoms. From the left knee to the ankle on its inner surface, the integuments were hot, and swollen, and tense, and in several places large patches of a dark red colour were observed over the superficial veins, which being laid open in two places, a considerable quantity of purulent fluid was discharged. Where the swelling and tension were least, the superficial veins could be felt distended like hard cords; as could also the saphena through its whole course upward from the ham to its junction with the femoral vein. In the course of this vein there was considerable swelling; and the integuments in this situation, as far as the middle of the thigh, were hot and of a dark red colour.

The symptoms which characterise venous inflammation in its most severe forms took place, and she sank on the fourteenth day after delivery. Dr. Sims assisted us in inspecting the body, when the following morbid appearances were observed. The left lower extremity was very much enlarged. The cellular and adipose membranes from Poupart's ligament, along the inner surface of the thigh and leg to the ankle, were indurated, vascular, and infiltrated with a red-coloured serous fluid. Several abscesses were observed in the cellular membrane immediately beneath the skin in the calf of the leg, and an extensive collection of pus had formed in the interstices of the gastrocnemii muscles. The branches of the saphena in this situation were converted into solid impervious cords; and the coats of this vein, from the knee to its junction with the femoral, were thickened and contracted, and in the lower part the cavity was nearly obliterated. The saphena vein was lined with an adventitious membrane of considerable thickness, which was easily separated from the inner coat. Its opening into the femoral vein, though reduced in size, was pervious; and the coats of the deep femoral vein, from this point to the ham, were thickened and contracted. The inner membrane was rugous, and of a deep red colour; but no deposit of lymph was observable, and its canal was pervious. The femoral vein above the termination of the saphena, and the whole of the external iliac,

were thickened and slightly contracted in their dimensions, and lined with a thin coating of lymph. These vessels were pervious, and the common and internal iliac exhibited no sign of disease. The intestines were inflamed; and on the ascending colon there was a small part in the state of sphacelus.*

We have related other cases of inflammation of the saphena veins of less severity, occurring in puerperal women, where the swelling, heat, and tension were confined to the course of these vessels; and it is now clearly ascertained that the whole limb does not become affected when the iliac and femoral veins have remained pervious. The preceding and other cases likewise prove that the inflammation in crural phlebitis, when violent, is not limited to the coats of the veins, but may extend to the cellular membrane, glands, muscles, and other contiguous tissues.

In July 1830 the author was indebted to the kindness of Dr Ashburner for the opportunity of observing the progress of an interesting case of crural phlebitis in a female about the middle period of life, who had not been pregnant for several years. A small ulcer above the left internal malleolus gave rise to inflammation of the saphena and femoral, and probably of the iliac veins, and the whole limb became affected with a hot, shining intumescence.

Sir Charles Bell has informed us that he has observed upwards of twenty cases of painful swellings of the superior extremities in women afflicted with cancer of the mammæ. He has been accustomed to refer these swellings to obstruction of the lymphatics, or to compression of the veins by the induration and enlargement of the glands of the axilla. No opportunity has yet occurred to determine by dissection whether or not the painful swelling of the arms is to be attributed in such cases to inflammation and obstruction of the veins; but this has been rendered probable by the facts already related respecting the effects produced on the iliac veins by malignant ulcerations of the uterus. It is rendered still more probable by the following observation of Laennec: "that it is not uncommon to find the veins in the neighbourhood of a cancerous breast filled with pus, either pure or mixed with blood; sometimes fluid, at other times more or less inspissated, and occasionally of the degree of consistence of an atheromatous tumour."†

Treatment.—Puzos recommended repeated and copious venesection for the treatment of phlegmasia dolens; but in all the cases which we have witnessed, there has been so much feebleness of pulse and prostration of strength that we have not ventured to draw blood from the arm. There are cases, however, occasionally met with where the symptoms are immediately relieved by a general bleeding. An example of severe crural phlebitis after delivery recently occurred in the practice of Dr. Duffin, where the abstraction of twenty ounces of blood seemed at once to break the force of the attack. In a great proportion of cases venesection is not required, and we are to trust for the relief of the inflammation to the repeated application of leeches above and below Poupart's ligament, in the course of the crural veins. From two to three dozen of leeches should be applied immediately after the commencement of the disease, and the bleeding should be encouraged by warm fomentations, or by a bread and water poultice to the part. Should the relief of the local pain not be complete, it is requisite soon to re-apply the leeches in numbers proportioned to the severity of the attack, and to repeat them a third or even fourth time at no very distant intervals, should the disease not yield.

Some patients experience greatest relief from the use of warm cataplasms to the limb; others derive most advantage from the application of cold, or of a tepid evaporating lotion.

The bowels are often much disordered in this disease; but the employment of strong acrid cathartics is always injurious. Repeated small doses of calomel and antimonial powder should be given with some mild purgative, not only with the view of correcting the disordered state of the bowels, but to subdue the local inflammation and the great constitutional disturbance usually present. It is of importance, also, to administer saline and diaphoretic medicines, and to procure rest and relief from pain by anodynes, until the acute symptoms pass away: the diet should be the same as that usually allowed to patients who are labouring under inflammatory and febrile diseases. We have seen no advantage derived from the use of digitalis in any stage either of uterine or crural phlebitis. Dr. Sims has informed us that the painful swelling and tension of the limb, in a case of phlegmasia dolens, were strikingly relieved by puncturing the skin in different parts with a fine needle.

When the acute inflammatory symptoms have passed away, the limb remains in a weak œdematous state, and great uneasiness is often experienced from congestion of blood in the veins. Until the collateral branches, which are to carry back the blood to the heart, become enlarged, it is impossible by any means we possess to afford complete relief. Much benefit may, however, be derived in this stage of the complaint from the occasional application of a few leeches to different parts of the limb, and by preserving it in the horizontal position. We have seen mischief produced by having recourse too early to remedies intended to promote the absorption of the fluid effused into the cellular membrane. Blisters, frictions, stimulant embrocations, and bandages to the limb, are only useful when the inflammation of the veins has wholly subsided, and other vessels have become so much enlarged as to carry on the circulation of the blood in the extremity without interruption.

We have not perceived any sensible benefit accrue from the use of mercurial ointment and iodine in crural phlebitis, and we consider the local abstraction of blood at the commencement

* Medical and Chirurgical Transactions, vol. xv.

of the attack to constitute by far the most important part of the treatment.

PHYSICAL DIAGNOSIS.—See Symptomatology.

PITYRIASIS, from *πίτυρον*, *bran*, denotes a cutaneous affection in which irregular patches of the cuticle, varying much in size, appear covered with thin branny or minute powdery scales, which fall off and are soon succeeded by others. This disease is not contagious, and is seldom productive of inconvenience to the patient; it never terminates in crusts or excoriations, but, if neglected, it may alter its character and degenerate into porrigo. During health, the cuticle over the whole body is constantly undergoing changes, peeling off in minute fragments, while a new and sound surface is formed below. Of this we have sufficient proof in the scales which are daily detached from the scalp by the hair-brush, and those which are always seen on drawing a black silk stocking off the leg. Now when this process of exfoliation is greatly increased on particular spots and patches of the skin, it constitutes the most simple form of pityriasis. There are several varieties of this affection.

1. *Pityriasis capitis.* (Dandriff of the head. Dartre furfuracée volante, *Alibert.)* This eruption is seen on the scalp and eyebrows of infants and sometimes of old men; on the temples and forehead it has a white mealy appearance; but on the occiput it consists of distinct flat scales, semi-transparent, and of a light brownish colour. In children it is occasionally connected with imperfect nutrition, but most frequently originates from a mere want of cleanliness. In adults and the aged, dandriff of the head accompanies the falling off of the hair, which so often takes place during convalescence and under chronic disease. This form of eruption sometimes occurs also on the chin and other parts of the face, when they exhibit patches of a rough and mealy appearance; it is occasionally the result of indigestion, but more frequently of some local irritation, as acrid soap or a rough-edged razor.

Treatment.—This eruption, when on the scalp, in general yields readily to removal of the hair, washing of the affected parts with soap and water morning and evening, and anointing them afterwards with some mild cerate. All causes of local irritation must be removed, the general health attended to, and a plentiful supply of wholesome nourishment afforded, should that appear to have been deficient.

The other forms of pityriasis are more remarkable for the discoloration of the skin which attends them than for the mealy or branny desquamation of the cuticle; and hence, although Willan, Bateman, and other English writers have considered them as species of pityriasis, Alibert,* Rayer,† and Biett‡ arrange them among the *ephelides*, or *tan-spots*. We prefer adhering to the arrangement of our countrymen, because we have always observed some exfoliation of the cuticle in these forms of pityriasis, at least during the height of their course; and because they differ from true ephelis in appearing especially on those parts of the body which are not exposed to the sun's rays. Three varieties have been distinguished by the names of *versicolor*, *rubra*, and *nigra*.

2. *Pityriasis versicolor.* (Chequered dandriff. Ephelides hepatiques; chloasma pseudo-porrigo; maculæ hepaticæ; leberflechte.) This is characterized by yellowish or light brown spots, and sometimes large patches of the most irregular outline, branching into the healthy coloured surface, or enclosing portions of it; not in the least elevated, and usually covered thinly by fine powdery scales. The colour varies in intensity according to the greater or less vascular turgescence of the skin, and when this is much excited, verges into the reddish tint of the succeeding variety. The most frequent seats of this eruption are the front of the chest and upper part of the belly; it appears also on the neck and back, and sometimes on the shoulders and arms. It is seldom productive of any discomfort, except under particular circumstances of excitement, when it is accompanied by itchiness of the skin on the patient becoming warm in bed; and should the stomach be disordered, this occasionally proves very troublesome. But the great source of uneasiness is more commonly in the mind, from the fears of the patient, who sees in this affection what he imagines to be the copper-coloured blotches of a confirmed venereal infection. Many times have we been consulted by persons affected with the light brown and red varieties of pityriasis under this impression, and not a few of them had been subjected to prolonged courses of mercury and sarsaparilla,—we need not add without benefit. The difference between pityriasis and syphilitic eruptions is abundantly well marked, the latter being of a darker and more coppery hue, distinctly elevated above the surface, and leading ultimately to the formation of crusts and ulcerations—appearances which are not observed in any form of pityriasis.

A diversity of opinion exists respecting the anatomical seat of pityriasis versicolor; Dr. Willan§ states that the rete mucosum or cutis is always affected in this disease, the brown stain being still perceptible after the cuticle has been removed; while Dr. Bateman,‖ on the other hand, asserts that in some cases he has seen the discoloured cuticle peel off at intervals in a thickened state, leaving a new cuticle underneath of a red hue. But to this latter statement it may be fairly replied, that when the cuticle becomes thickened and thus

§ On Cutaneous Diseases, vol. i. p. 194.
‖ Synopsis, p. 47.

peels off, the disease has lost the genuine characters of pityriasis versicolor. With a view to decide the question, we applied a blister to a portion of skin affected with this disease. After the cuticle was wholly removed, the mottling still remained; but the patches, instead of being tawny, were now changed to a deeper red than the rest of the excoriated surface; thus proving to our satisfaction that the anatomical seat of pityriasis versicolor lies beneath the cuticle.

It is rarely in our power to trace the occurrence of this cutaneous affection to any satisfactory cause; we have sometimes seen it connected with a feeble digestion and indifferent health; but on other occasions nothing of this kind could be observed. An opinion held by some, that it is dependent on disease of the liver, probably originating in the name *maculæ hepaticæ*, is certainly quite groundless. Bateman has observed this eruption in a severe form to follow the free use of spirits while fasting, and exposed in an open boat; and Dr. Willan speaks of various sources of irritation of the stomach and skin as possible causes of this disease, such as acid fruits, mushrooms, sudden alternations of temperature, violent exercise with flannel next the skin; but the whole of these are more likely to give rise to urticaria than to pityriasis.

Treatment.—It must be acknowledged that we have not much power over this disease by internal remedies; and after the patient has been satisfied as to its innocence and the absence of all syphilitic taint, he often ceases to think of it, and allows time, if it will, to work a cure. Should the disease seem to have originated from any irritation either of the cutaneous surface or of the alimentary cavities, its cause must, if possible, be removed without delay: when the digestion is impaired, light tonics are to be used, as infusion of calumba with sulphuric acid, or small doses of sulphate of quinia; the bowels are to be regulated, and a milk and nourishing diet enjoined, with abstinence from spirituous liquors, and a very guarded use of wine and ale, if any be allowed. When itching exists, a spirit lotion with borax or alum, or acetate of lead or zinc, will be found useful; or, what rarely fails to give relief, a lotion with hydrocyanic acid. The vapour-bath at a moderate temperature will serve to equalise the cutaneous circulation, and soften the branny spots. In our hands nothing has proved so effectual in restoring the natural colour and functions of the parts as a lotion of chloride of lime or soda, varying in strength according to circumstances. The success which has attended this application has exceeded our expectations; but whether its effects are to be regarded as the result merely of a stimulus, or of its bleaching property, admits of question.

3. *Pityriasis rubra* (red dandriff). This differs from the preceding species chiefly in the redness of its colour, and the greater excitement of the surface which attends it. It is more uniformly accompanied by heat, itching, and general languor and restlessness, and may be considered as remotely allied to psoriasis diffusa, although altogether free from elevation above the surface, and vastly more mild in all its symptoms. On its decline, it leaves sallow faded stains marking the parts which were affected. The anatomical seat of pityriasis rubra is certainly deeper than the cuticle; its red colour evidently depending on the injected state of the vascular tissue lying beneath.

Treatment.—We have never in any case of red dandriff found the irritation such as to require the abstraction of blood; but in every instance the bowels should be opened by mild purgatives, and those which correct acidity. A soothing or slightly astringent lotion, such as those already described, ought to be applied to the affected parts, and any cause of cutaneous irritation immediately removed.

Dr. Bateman has recommended a diaphoretic plan of treatment,—antimonials, with decoction of the woods, and the warm sea-water-bath; and he adds that he has found benefit from small doses of the *tinct. veratri.*

3. *Pityriasis nigra* (black dandriff; ephelide scorbutique). This is an exceedingly rare disease; so much so that Dr. Willan had not seen it at the time of his publication, and Dr. Bateman does not appear to have ever met with it. Alibert has described it under the name quoted above, and figured it as it affects the hands (plate 27 bis). The cases seen by Dr. Willan occurred in children born in India, and brought to this country. The disease commenced in a partially papulated state of the skin, and terminated in a black discoloration, with slight furfuraceous exfoliations: it sometimes affected half a limb, sometimes the fingers and toes.* In allusion to the foreign origin of this species of pityriasis, we may mention a curious dusky mottling of the skin, which is seen in the children of mulatto women by European fathers, when they approach, as they sometimes do, to the fair complexion of the European. It seems as if patches of the dark hue of the mother shone through the pure skin of the father; and it is chiefly perceptible when they are heated with exercise, or the skin otherwise increased in vascularity.

Some years ago we had the good fortune to see a case of pityriasis nigra. The patient was an unmarried female, aged forty-five, a native of Scotland, her parents Scotch; and she had never travelled to any distance beyond the precincts of her native city. The skin of her arms, legs, bosom, and neck, but especially the last, was of a dark tint like that of a mulatto, but varying in different parts in depth of hue; and scattered over the dusky surface were many white spots, from which crusts appeared to have separated; and on other parts some crusts appeared still adhering. Both the white spots and the mulatto-coloured surface were slightly sealy. With this disease was combined an eruption of scabies affecting severely the hands, from the itching of which she suffered great an-

* *Bateman*, Synopsis, p. 49.

noyance. The disease had existed for some months; and at the time when it commenced she was reduced to a state of great misery and destitution. By the employment of sulphur frictions, the warm bath, and a plentiful supply of nourishing food, the natural colour of the skin was nearly restored after the lapse of some weeks; but we are ignorant whether a complete cure was in the end effected. This case confirms the remark of Dr. Bateman, that the disease is the result of misery and filth, but not his opinion that both the disease and its cause are wholly unknown in this country.*

Treatment.—Our first object in pityriasis nigra is to clear out the bowels by mild purgatives, and thoroughly purify the surface of the body with soap and water. A course of tonic aperients, with the regular use of the warm water or vapour bath, should then be prescribed, while the patient is put upon a moderate allowance of nourishing food. As his appetite and strength improve, the quantity of food is to be increased, and the warm-bath exchanged for sulphur fumigations; or if the disease prove obstinate, recourse ought to be had to the cautious employment of the arsenical liquor, and the external use of the chloride of lime or soda, as in pityriasis versicolor.

(W. Cumin.)

PLAGUE, from πληγὴ, Gr. *plaga*, Lat. *a blow* or *wound;* th. πλήσσω, *to strike*.—This is the name of a well-known and extremely fatal disease, which is endemic in Egypt and certain other countries bordering on the Levant, and has made frequent and destructive irruptions into Europe. The malady thus designated is called *pestis* and *pestilentia* by the Latin writers, λοιμὸς by the Greeks, *la peste* by the French, *pestilenza* by the Italians, and *pest* by the Germans, which last name is not unfrequently bestowed upon it by ourselves. It is a curious fact that these words have each in their respective languages a signification distinct from the primary one, and expressive of various kinds of moral and physical evil, the malignancy of the disease in all situations being thus evinced by its suggesting the same analogy to people differing widely in physical constitution and mental habitudes.

The words plague, pest, and pestilential, and their corresponding terms in different tongues, have frequently, even when applied to diseases, a sense considerably vague. The disease we are about to treat of has always been comprised in these terms, but other maladies have been similarly designated, with which, probably, it had no quality in common excepting that of being extremely diffusible and fatal; and hence by *morbi pestilentiales* we are not always to understand a form of plague in a strict sense of the word. This want of precision of language is very conspicuous in Hippocrates and his commentator Galen,† whose idea of a pestilential disease appears to have corresponded very nearly with that which we express by the term epidemic; and a similar want of accuracy is perceptible in the writings of the Arabians, from whom we might for obvious reasons have expected the greatest precision.

The subject was so much obscured by the vague application of terms, that even at so late a period as 1775 the Faculty of Medicine of Paris proposed the following queries as the subject of a prize essay: "*If plague be a distinct disease*, what is its character? and what are the means of treating and preventing it?" —queries which were thought to have been successfully solved by M. Paris of Arles. We need scarcely observe, what is now universally admitted, that the characters of plague are as distinctive as those of small-pox, measles, scarlatina, or any other disorder.

This disease is endemic in Egypt, and very often exists in adjacent territories; but the former country is unquestionably the great source whence it extends its ravages into surrounding districts; and a very learned and ingenious writer is of opinion that there only is it ever engendered, and that in other regions it is always an alien.* In Egypt it is said to arise every autumn, and to prevail till the beginning of June of the succeeding year: its ravages then cease, and its contagion is extinguished or remains in abeyance during summer, to be again called into existence or activity in the autumn. The vernal equinox is the period of the greatest fatality of the disease. About this time, we learn, southerly winds blow with great violence. They last ordinarily three or four hours, and are frequently renewed daily for fifty successive days. They are very warm, passing over the burning deserts which border Egypt on the south, and they are, moreover, loaded with putrid emanations exhaled from the animal and vegetable substances which are decomposed in the lakes formed by the retiring of the waters of the Nile, or in the cemeteries which its inundation has reached. At this sickly season, diseases of all kinds assume a malignant character: it was at this season, that after the great inundation of 1801, the plague committed the greatest ravages among the inhabitants of Cairo and Upper Egypt. In June the wind blows from the north, and being cooled in traversing the Mediterranean, renders that season the most refreshing and salubrious of the year, during which no sickness manifests itself.†

It was to be expected that a disease eminently contagious should be occasionally diffused through countries having incessant intercourse with the land of its origin; and we find it repeatedly visiting the people paying allegiance more or less direct to the Ottoman Porte, and not unfrequently ravaging Constantinople. Formerly it penetrated into more northern climes. Previously to the year 1665

it usually invaded England, as Sydenham informs us, at intervals of from thirty to forty years; but since the cessation of the celebrated epidemic of that year, which destroyed eight thousand inhabitants of London in the course of one week, though two-thirds of the population had previously fled from the city, it has not been seen in Britain. In other European countries it has much more recently manifested itself. Marseilles, which had previously suffered twenty severe visitations in the course of seventeen centuries, was ravaged by it in 1720; Moscow suffered a severe infliction in 1771 and 1772; and within the present century it prevailed at Noja in the Neapolitan dominions, in 1815 and 1816; it appeared in the Lazaretto of Venice in 1818, and at Gressemberg in Silesia in 1819. But with these exceptions it has been for a century generally confined to Africa, the land of its origin, and to those portions of Asia and Europe which own the Ottoman sway.

Symptoms.—The following definition will suffice to convey a general idea of plague, although, as is usually the case with nosological definitions, it does not comprise certain cases sometimes observed, which form exceptions to the ordinary character of plague:—an exanthematous disease, the eruption consisting of buboes, carbuncles, and pustules, white, livid, or black, distributed in various parts of the body, and generally attended with malignant and very fatal fever.

Various divisions have been proposed by systematic writers; but there is every reason to think that there is no difference existing between cases of the disease which can be regarded as specific, all the varieties being found intermingled in the same epidemic. Plague possesses two prominent characteristics—fever and eruption, both of which are found in fully formed cases; but examples of the existence of one of these symptoms without the other are not of unfrequent occurrence. The cases in which the eruption is wanting constitute the most rapidly fatal type of the disease; whilst, on the other hand, bubo occurring without constitutional disturbance is the slightest form in which this disorder, usually so fatal, can exist. Between these extremes there are various shades of intensity discernible, which, as well as the most severe and the mildest type, we shall endeavour to depict.

The following sketch of the most rapid and intense form will remind the reader of malignant typhus, and of cases of the ordinary exanthemata, in which the system is so entirely overwhelmed that the eruption fails to appear, or displays itself but faintly. The patients are sometimes attacked suddenly with a loss of strength, a sense of confusion or weight in the head, occasional giddiness, oppression about the præcordia, and extreme dejection of spirits. They are inclined to be silent, and shew great anxiety in their aspect, but make little or no complaint, and, either having no febrile symptoms or such as are very obscure, are considered by the persons about them as indisposed in a slight degree. Death takes place in such cases sometimes within twenty-four hours, or occasionally on the second or third day. Neither buboes nor carbuncles appear, and it is rare to find suspicious marks of infection on the dead bodies.*

Others, who are at first attacked in the same manner as the foregoing, become in a few hours more manifestly disordered. Their eyes become muddy, the surface of the body cold; they grow drowsy and lethargic, and complain of pain at the heart. As the distemper advances, they often lose the power of speech; the skin seldom recovers its warmth, or, if it does, there is a mere irregular flushing, which soon gives place to cold and clammy sweats. The pulse sometimes remains nearly in its natural state, but is generally low and quick. Patients are by turns delirious, confused, and sensible, but the comatose disposition is the most prevalent. Towards the close there is incessant inquietude. Buboes rarely appear, and in those only who survive the third day; petechiæ, vibices, or broad, livid, roundish spots occur sometimes, but are not common, and the two latter are seldom visible till after death. All the cases of this description which fell under Dr. Russell's observation were fatal, the patients generally dying on the second or third day, a very few living till the fifth.†

This intense form of the disease is most frequently observed at the commencement of an epidemic of plague, when it generally possesses the greatest malignancy. At a later period the following more mild but still dangerous variety is that which is most commonly met with.

The disease commences with coldness sometimes amounting to shivering, which is speedily followed by fever, accompanied occasionally with vomiting, and uniformly with giddiness and pain of the head; but rarely at first with delirium, and scarcely ever with a comatose disposition. The fever increases during the latter part of the day and the following night, but there is a perceptible remission, though by no means a cessation, of fever the following morning. In this form of disease, buboes and carbuncles generally make their appearance the first day, and it is not unusual to see successive eruptions of them appear throughout the disorder.

As the second day advances, there is again an exacerbation of fever; some of the sick are harassed by vomiting; there is distressing headach; the tumours are painful; there is confusion of thought, occasionally a slight disposition to coma; and the muddy eye, so characteristic of the disease,—in which Dr. Russell says muddiness and lustre are so strangely blended together—manifests itself. The skin is hot, the pulse frequent, the tongue dry; the patient is anxious, restless, and complains of pain or oppression about the heart. As night approaches, the feverish symptoms are aggravated; the heat is more intense; the pulse

* *Russell*, History of the Plague at Aleppo in 1760, 1761, and 1762. p. 96.

† Ibid. p. 97.

less full, but very quick; the jactitation is great, the eye very muddy, and the patient is disposed to incoherent raving or to stupor. Sweat breaking out early in the morning of the third day always brings a mitigation of the symptoms, and sometimes proves completely critical, but more commonly produces only a remission so favourable as to encourage the expectation of a more perfect crisis on the fifth. But where the patient neither sweats nor experiences a sensible remission on the third day, as is sometimes found to occur without perspiration, danger is always to be apprehended. During these remissions, it should be observed, the pulse becomes slower, softer, and more full, especially after perspiration; and though the eyes still remain muddy, the anxiety and disquietude abate, the intellectual faculties are clearer, and the patient finds himself in every way better.

There are again exacerbations on the third and on the fourth day. A remission takes place on the morning of the latter of these days, preceded by perspiration, but rarely so profuse as that which takes place on the third. The exacerbation of the fourth day is more severe, especially towards night, than that of the second and third, and continues intense till perspiration appearing on the morning of the fifth, and increasing to a profuse sweat of various duration, leaves the patient faint and languid, but in every other respect manifestly relieved. After this day the subsequent exacerbations become slighter and slighter, and, the buboes generally advancing favourably to suppuration, little or no fever remains after the beginning of the second week, excepting symptomatic heats occasioned by the eruptions. But where the sweat on the fifth day proves imperfectly critical, milder exacerbations, which usually decline with gentle perspirations, continue to recur till the seventh day, when a second profuse sweat places the patient beyond all danger.

The formidable symptoms which generally occur on the second day in this form of the disease, sometimes do not take place till the third or fourth, and hence it sometimes happens that those who for some days seem to be slightly affected suffer a tedious illness or die contrary to expectation, while more alarming attacks terminate favourably. In the latter case the event remains doubtful till the fifth day; in the former till the end of the week. At these periods a conjecture as to the result may be made with tolerable success; though cases sometimes occur in which matters remain in suspense some days longer.

A much more severe and fatal form of plague, constituting the second class of Dr. Russell, begins generally with slight shivering or sense of cold, which is soon succeeded by fever, accompanied with giddiness, headach, vomiting, and sometimes purging. The fever increasing towards night, the face becomes flushed, the eyes glisten, and the patient either becomes delirious, or drowsy and comatose. The pulse in this stage usually continues full and strong, and though the tongue is not dry, the thirst is excessive; but the stomach retains little of the liquid taken, and the patient, harassed by the vomiting and other symptoms, passes a very unquiet night. There is an abatement of the symptoms on the succeeding morning; but the pulse is frequent and more or less full, the skin is hot and dry, and the patient dejected. As the day advances, there is an exacerbation, the accession of which is accelerated by vomiting and especially by diarrhœa, which frequently supervenes at this time. The symptoms during this exacerbation are muddy eyes and a peculiar confused expression of countenance, quick pulse, sometimes low and fluttering, but rarely intermitting; a whitish, but rarely a parched tongue; the external heat moderately feverish, or occasionally intense in irregular flushings; pain at the heart or oppression about the præcordia; burning pain at the pit of the stomach and incessant inquietude. The more or less rapid progress of these symptoms denotes more or less danger; but when to these are joined a faltering in the tongue or loss of speech, while the surface of the body, losing its natural or feverish heat, becomes cold and damp with clammy sweats, death is inevitable, though perhaps the fatal moment may still be at some distance. In certain cases, especially where vomiting has been severe, and where diarrhœa or hemorrhage adds to the debility, the third day proves fatal; but the disease is more commonly protracted two or three days longer, advancing so far regularly to its termination that each subsequent night proves worse than the preceding, and in the day the remissions are so transient and obscure as to leave no room for hope.

Few of the sick recover from this form of plague, whether the disease be left to itself or treated methodically; neither does the result appear to be materially influenced by the course of the buboes. They generally appear on the second day, sometimes on the third, and occasionally later. Suppuration does not take place, and the tumours, advancing or not towards this state, have no visible effect in hastening or retarding the termination of the disease. Carbuncles, as well as petechiæ and vibices, are occasionally met with.*

In the cases of which the eruption constitutes the principal feature, either buboes or carbuncles form, and frequently both occur in the same subjects. The patients are so little indisposed as to be able to walk about the streets or labour at their accustomed avocations, unless prevented by the inflammation of inguinal buboes. Even in more intense forms of the disease, the prostration of strength is in some cases slight; for in the expedition into Syria of the French army of Egypt, several soldiers affected with plague were able to march during a considerable length of time,† and Diemerbroeck relates many examples of which he was an eye-witness, of infected

* *Russell*, p. 101.

† *Fodéré*, Dictionnaire des Sciences Médicales, vol. xli. p 77.

persons walking within a few hours of their death.*

The pestilential bubo is a swelling of the glands of the groins, the axillæ, the neck, or of the parotid itself; though tumours in this last situation are sometimes named distinctively parotids. Buboes are at first small and deeply seated; they are more or less painful, but never entirely indolent, and they advance towards the surface, and in some cases to suppuration, with various degrees of rapidity. They terminate either in resolution, suppuration, or gangrene, but this last termination is rare, though examples of it are recorded by authors;† and it is remarked that it rarely takes place in the cellular tissue, but merely in the gland itself, and hence that it can be ascertained only by dissection.‡ It is considered in all cases a fatal termination. There is a general opinion that the suppuration of buboes, if not essential to the safety of the patient, is in the highest degree conducive to his recovery; but it having been repeatedly observed that buboes never begin to inflame externally, or to show signs of approaching suppuration till the fever is manifestly on the decline, and restoration to health having taken place in innumerable instances though buboes did not undergo this process, there is every reason to think that too much importance has been attached to it, and that it is at most rather a sign than a cause of recovery. Buboes are rarely solitary, two, three, or four existing in the same subject; and this circumstance, their complication with carbuncle and other forms of eruption, and the antecedent and concomitant symptoms which generally exist, will secure us from confounding them with syphilitic swellings. It should be remarked, moreover, that pestilential bubo in the groin generally affects the glands in the vicinity of the crural vessels, though it sometimes appears in the situation of the ordinary venereal tumour.

Besides buboes situated in glandular parts, tumours to which the same name has been given are found in various situations, as on the head, the nape of the neck, the shoulders, the thorax, the vicinity of the umbilicus; in short, they may appear in almost any part of the body or limbs.§ During six or eight days they are small hard bodies which do not involve the superjacent skin; but subsequently to this period they become protuberant, and the integument is inflamed. They sometimes disperse, but more frequently suppurate, though more slowly than the glandular bubo. They are numerous, from five to nine generally existing in one subject. Dr. Russell calls them spurious buboes.

Carbuncles may form in any part of the body, and they are not unfrequently observed in the integument covering buboes. Various forms of them are described, but it is probable that varieties have been multiplied by observers depicting the same species in different stages of its progress. They commence generally in a pustular form, but occasionally like a vesication of the size of a horse-bean, filled with a dusky-yellow or blackish fluid. In the more advanced stage they are hard and very painful, speedily becoming gangrenous, and forming eschars, which tend to spread and rapidly destroy the skin, and sometimes muscular and tendinous parts. They occasionally exist in considerable numbers on the same patient. When recovery is approaching, suppuration takes place round the edges of the eschar, which, separating, leaves an ulcer of greater or less depth, discharging abundantly for some time and then gradually healing; but in fatal cases the eschar remains dry, with little appearance of being cast off.

There are other cutaneous affections observed in plague: of this kind are petechiæ, at first of a pale or purplish red, and subsequently livid; a certain marbled appearance of the skin, evanescent till towards the close of the disease, the variegating colours being of a pale faint blue or darkish red, and an erysipelatous efflorescence remaining visible for a short time. Narrow streaks of a reddish purple or livid colour are sometimes observed; and when they affect the face, they give a frightful appearance to the countenance, producing such an alteration of features, and so disguising the patient, that he can scarcely be recognized by his acquaintances. Vibices or weals, and large blue or purple spots, the maculæ nigræ of authors, occur in the more depending parts of the body sometimes shortly before death, but they are more frequently not discoverable till after this event, and in both cases probably result from the infiltration into the subcutaneous cellular membrane of the blood attenuated by the disease.

Morbid anatomy.—In a disease considered highly contagious, a deficiency of information on this head is to be expected, and we find that writers on plague are more copious on any branch of the subject than this. Some authors have, however, endeavoured to illustrate the nature of the disease by dissection, but it must be acknowledged without much success. Deidier made many dissections of persons dead of plague at Marseilles in 1720; but the only material result of his labours was the discovery that the gall-bladder was extremely loaded with black or greenish bile.* Another observer of the same epidemic informs us that in some bodies every thing was found in a natural state, and in others that nothing was discovered but slight traces of inflammation of the intestines, which, the writer remarks, were certainly produced in the last moments of the disease.† Savaresi, in his Topography of Damietta, relates that in three

cases the only morbid appearances were the lining of the intestinal canal and the stomach being covered with a yellowish mucus, and a general hardness of the conglobate glands.* Certain individuals have expected to derive information regarding the nature of the disease from the condition of the blood; but the humoral pathology does not appear to have furnished results more satisfactory and uniform than the inspection of the solids; the blood having been found in various states, namely, of a natural consistence and appearance, unduly liquid, and inflammatory or sizy.† In conclusion, we are compelled to acknowledge that plague is one of the numerous diseases in which the changes during life leave no determinate trace after death to explain their nature or the cause of their fatal issue.

Nature of plague.—This dreadful disease, like others of the febrile class to which it belongs, evidently results from the introduction into the system of a morbific poison; but much obscurity prevails with respect to the part of the frame which it first affects, and many of the pathological changes which it ultimately produces. The external inflammations and the fever are the only parts of the disease of which we have distinct knowledge. It has already been stated that examples occasionally occur of the absence of one or the other of these phenomena, the imperfection of medical definitions being exemplified by plague as by many other diseases. This imperfection, resulting from the variable phenomena with which the physician is conversant, so markedly contrasted with the uniformity presented by nature to the philosopher, or which in his experiments he can form for himself, does not invalidate the substantial accuracy of the definition, which comprehends an immense majority of cases, and excludes only what may be justly considered as the exceptions to the rule. Many persons have been disposed to look beyond the manifest symptoms of the disease to the interior changes of which these are only the signs or the effects; but it is to be feared that there has been more of speculation than of cautious induction from facts in the opinions these individuals have published to the world; or at least that they have made a portion only, and this the smaller portion of cases of plague, the representatives of the whole class. M. Broussais informs us that the causes, the symptoms, and the changes observed in the bodies of those who die of plague, show that the digestive canal is the seat of *the inflammation which constitutes the disease*. If petechiæ, carbuncles, and inflammations improperly called buboes, appear, these symptoms are only according to him, as in typhus, the effects of the sympathetic irritation of the skin and cellular membrane, of which irritation the heat of the climate favours the development.‡ According to this view, the eruption hitherto deemed characteristic of plague is a mere contingency, and the inflammation of the digestive canal is exalted from an occasional occurrence into the constitment of the disease. It has apparently escaped this writer's observation that the eruption which he attributes to the influence of heat has accompanied the disease in every climate in which it has manifested itself,—in our own in winter,* for example; and that the affection of the intestines is indicated only in a small proportion of cases, either by symptoms during life, or by the pathological condition of parts after death. The analogy between the petechiæ, which only occasionally appear in typhus, and the characteristic eruption of plague, is too remote to identify these diseases, though we would willingly admit that they are in some degree related, as all febrile disorders are, to each other. Professor J. P. Frank places plague in the same genus with continued nervous fever, which is, he says, a fever occasioned by causes acting especially on the nervous system, and which escape the observation of the senses; and this fever, he informs us, may be complicated with gastric and other inflammations,†—an opinion in which we fully concur with him; though we do not agree in thinking plague a mere variety of continued nervous fever or typhus, but, on the contrary, we deem it an independent disease which preserves its character in all climates and situations in which it may exist.

The strongest analogy with plague which we have any where found occurs in the following example of disease, induced, as it would appear, by exposure to the effluvia of common putrefying animal matter.

An American merchant-ship was lying at anchor in Wampoa Roads, 16 miles from Canton. One of her crew died of dysentery. He was taken on shore to be buried. No disease of any kind had occurred in the ship from her departure from America till her arrival in the river Tigris. Four men accompanied the corpse, and two of them began to dig a grave. Unfortunately they began in a spot where a human body had been buried about two or three months previously. The instant the spade went through the lid of the coffin, a most dreadful effluvium issued forth, and the two men fell down nearly lifeless. It was with the greatest difficulty their companions could approach near enough to drag them from the spot, and fill up the place with earth. The two men then recovered a little, and with assistance reached the boat and returned on board. On the succeeding morning, they presented the following symptoms: very acute head-ach, with a sense of giddiness and dimness of sight, (which had existed more or less from the moment of opening the grave); eyes of a peculiar muddy appearance; oppression about the præcordia; dull heavy pain in the regions of the

heart and liver, with slight palpitation at times, and fluttering pulse; sense of extreme debility, with occasional convulsive or spasmodic twitchings of the muscles of the lower extremities; nausea; slight diarrhœa; rigors, succeeded by flushings of the face, neck, breast, and upper extremities; tongue white and much loaded; pulse from 110 to 120, weak and irregular; urine scanty and high-coloured, and skin sometimes dry, sometimes covered with a clammy sweat. On the fourth day from the commencement of the attack, numerous petechiæ appeared over the breast and arms, and in one of the patients a large bubo formed in the right groin, and another in the axilla of the same side, which speedily ran to suppuration. To one, the disease proved fatal on the evening of the fourth day; to the other, on the morning of the fifth.

On examination after death, in both cases the vessels of the brain were found loaded, and an effusion of lymph existed between the tunica arachnoidea and pia mater; there was an unusual quantity of fluid in the ventricles, and upwards of three ounces of dark-coloured liquid at the base of the brain. The optic nerve of the right side, in one of the patients, was surrounded, where it emerges from the thalamus, by a portion of gelatinous matter, and appeared thickened and discoloured; and the surface of the brain was very vascular. The heart in both cases was much enlarged, and distended with blood. In one case, five ounces of a dark-coloured fluid flowed from the pericardium when slit open, and the vessels on its internal surface were gorged with blood, and this was indeed the case throughout the whole portal circle. The stomach, near its pyloric orifice, was thickly beset, in one case, with small purple-coloured spots. The intestines in several places assumed a brownish appearance, as likewise the omentum. There were numerous petechiæ on the surfaces of both bodies. In one of the cases the medulla spinalis, in the dorsal region, to the extent of three or four inches, was of a light brown colour; and in the other case it exhibited evident marks of congestion throughout. Most of the inguinal and axillary glands were enlarged and hardened, and several of them, when cut into, contained a light straw-coloured matter. No other morbid alteration of structure existed.

One of the two men not immediately engaged in digging the grave was attacked on the eighth day from his being on shore. The symptoms resembled those in the preceding cases. For three days previously to the avowed attack of illness there had been pain and enlargement of one of the inguinal glands, which at the period he was visited had acquired the size of a hen's egg; and early in the disease the breast and arms were covered with petechiæ. By active treatment this person recovered, as likewise did the fourth man, who had slight indisposition of no decided character.*

* Medico-Chirurgical Review, N. S. vol. ii. p. 202 et seq.

Systematic writers have generally been more struck with the analogy between plague and eruptive diseases than with its relation to typhus or any form of idiopathic fever, and hence it is universally found in nosologies placed among the exanthemata. But this analogy is not so complete as to cause it to be ranked among diseases which attack persons but once in the course of their lives. Popular opinion in the Levant, where plague may be considered almost endemic, imposes this limitation on the disease,—an error not destitute of advantage, as it prevents the sick from being deprived of the requisite attendance; and the kind of confidence it is calculated to inspire is to a certain extent justifiable, as second attacks are unquestionably rare. Dr. Russell informs us, for instance, that he met with only twenty-eight examples of well-ascertained re-infection in four thousand four hundred pestilential cases. This accurate observer cautions us, however, against regarding this as the precise proportion in which second attacks occur, there having been no plague at Aleppo for eighteen years previous to the appearance of the epidemic he describes; and he found great difficulty in obtaining accurate information, after so long a lapse of time, as to the sickness of his patients, or their exemption from disease, during the former visitation, and the number stated must be understood to comprise the double attacks which took place from 1760 to 1762 only.

This opinion of the liability of sufferers from plague to second attacks is not universal among writers on the subject. The Chevalier Butel, for instance, is of opinion, from personal observation, that an attack of plague in Egypt furnishes complete exemption from all future accidents of the same nature, though, with some inconsistency, he subsequently quotes the case of an English physician (perhaps he alludes to Dr. Whyte) who died of the natural disease six months after an attack he had inflicted upon himself by inoculation.*

Authors on plague, however, who at all advert to this question, are almost unanimous in regarding second attacks as, at least, occasional, if not frequent occurrences. Diemerbroeck mentions several, and, among others, that of a Chevalier Schabhals, a bold and rash man, who was attacked with the prevailing disease, indicated by violent fever, a bubo in the groin, and three carbuncles, from which he had the good fortune to recover. He consequently became so presumptuous as to neglect all precaution, and was again attacked, five weeks after his complete convalescence, with the malady, of which he died before the sixth day.† There is reason to think that some writers have exaggerated the proportion of second attacks from not having duly discriminated such attacks from relapses; thus it has been urged in evidence of the frequency of second invasions, that *convalescents* employed as nurses about the sick, both at Marseilles and with the French army in Egypt, were

* Journal Universel, Jan. 1826.

† De Peste, lib. iv. hist. 37, 45.

frequently attacked and perished; but a sufficient number have been noticed by judicious observers to warrant our concluding that plague does not impart that kind of security from second invasions which is afforded by small-pox and certain other exanthemata.

Diagnosis.—Difficulty will never be experienced in discriminating a well-marked example of plague from any other disease, provided the practitioner have an opportunity of observing it throughout its course; for the buboes, carbuncles, and other external affections attending it, constitute, with the intense fever, a group of phenomena which belongs only to this malady. But, on the first appearance of an epidemic, a difficulty, arising from various circumstances, has not unfrequently been experienced in pronouncing on the character of the disease. In the first place it often happens that the early cases belong to the intense type, in which death occurs before the characteristic eruption has time to display itself; and, again, even in cases which ultimately assume the normal form of the disease, a certain period elapses before buboes, carbuncles, or other external marks appear. The symptoms on which, the eruption excepted, most reliance is placed for discriminating plague, are the peculiar inflamed appearance of the eyes, which was previously mentioned, swelling of the tongue, difficulty of articulation, and tottering gait. Of these phenomena, the Chevalier Butel declares that the two first are never absent in any case of plague; but it seems more than questionable whether they belong so exclusively to this disease, that we could pronounce from them alone on the nature of any case we might witness, especially at the commencement of an epidemic, unless our diagnosis were aided by extrinsic circumstances, such as our being aware of the arrival of persons or goods from infected districts, of the sufferers having had intercourse with such persons, or having been exposed to effluvia from the goods, &c. Should such circumstances be shewn to have occurred to the subject of a suddenly fatal disease, it would certainly be advisable to act on the assumption of its being pestilential, and to take the precautions which the safety of the community requires. Prudence would dictate also that suspicious cases which do not terminate so rapidly, should be kept secluded for a period sufficiently long to allow their real character to manifest itself, especially if the disease occurred in a country or district of which the geographical or commercial relation with territories in which plague was prevailing was such as to render its importation a probable event.

Mortality and prognosis.— Plague is one of the most fatal diseases which afflict human nature; and the general prognosis in the event of its introduction into any place must be in the highest degree unfavourable, unless the early cases admit of being so totally secluded that any general contamination of the inhabitants may be prevented. Very accurate statistical details, from which we may estimate the amount of ravage it generally commits in proportion to the number affected, or to the population of the place or district in which it prevails, are scarcely to be procured, since plague has not proved in modern times a disease of the more civilized nations of the world; and it is only among a civilized people, and at a very recent period, that any thing like very precise records of the fatality of disease is to be found. But such information as we possess leads to the conclusion that of those attacked with plague, fully fifty per cent. perish. At Marseilles, for example, in 1720 and 1721, it is calculated that of a population of 90,000, 40,000 fell victims to the disease, though more than 10,000 are supposed to have escaped infection;* whilst the following returns from the hospitals, and, as it would seem, from certain corporate bodies, show a rate of mortality higher than this general average.

	Received.	Died.
L'Hôpital de la Charité, from the 3d of October to the end of February	1013	585
L'Hôpital du Jeu de Mail, from October to the 3d of July.....	1512	820

Of 100 manufacturing hatters, there died 53; and of 134 house-carpenters, 84. The tailors, who were in number 138, lost 78. Of the shoemakers, who were 200, there died 110; the cobblers were reduced from 400 to 50; and of 500 and odd masons, there perished 350. Of persons in a still lower station of society, such as porters and chairmen, the mortality was very great indeed; scarcely a sixth part remaining at the close of the epidemic.†

In the capital of our own country the ravages of plague have occasionally been very great. Thus, of the last five epidemics, those which prevailed between the close of the sixteenth and the latter part of the seventeenth century, there perished in that of 1593, between March and December, 11,166; in that of 1603 the mortality amounted, between the same periods, to 29,992; in that of 1625 to 34,754; in that of 1636, commonly called, not from the amount or rapidity of its fatality, but from its having lasted twelve years, "the great plague," 11,000 died between April and December of the first year, and in that of 1665 the mortality for the same period amounted to 69,602.‡ But the estimates transmitted to us furnish neither the proportion of deaths to the number treated, nor to the amount of population amid which plague prevailed; for it was so customary for individuals to fly from London on its first appearance, that population returns, however accurate, fail to supply the requisite information on the second point. Defoe (but

* Traité de la Peste, p. 464.

† Relation Historique de la Peste de Marseille, p. 437, 438.

‡ Graunt's Natural and Political Observations, &c. London, second edition, 1662. A Collection of very valuable and scarce Pieces relating to the Plague, p. 81, London, 1721. London's Deliverance predicted by John Gadsbury. London, 1665. Russell on the Plague, p. 274, 275.

we do not regard him as very precise authority) estimates at two-thirds the proportion of the population of London which fled in 1665. Thus much seems certain, that these returns record a difference in the amount of mortality in the same place, but in different epidemics, which no supposable variation, either in the amount of stationary population, in the number of fugitives, or in both conjointly, can possibly explain.

It thus appears that we are deficient in statistical details whence to draw a general prognosis, and that, even if we possessed them of the utmost accuracy, (epidemic visitations of the disease varying so much in intensity even in the same district,) they would not furnish secure grounds for estimating the probable danger to a population from an attack of plague. Observers, however, are almost unanimous in marking in every epidemic three periods at which the fatality, and consequently our predictions, must vary. At the beginning of a pestilence, the disease, though less diffused than it subsequently becomes, appears in its most fatal form; during the increase and height of an epidemic, though many more persons are attacked, the comparative mortality is diminished; and during its decline there is a decrease at once in the numbers attacked and the proportion of deaths. A curious anomaly is, however, pointed out by Dr. Russell in the last-mentioned law of the disease, namely, that persons in constant communication with the sick, who have resisted infection in the most contagious stages of the pestilence, are sometimes attacked in its decline.*

The circumstances which, independently of the period of an epidemic, should influence our prognosis, must be found in the age and general constitution of patients and the symptoms of the disease. On the former head it is important to remark that young, robust, and vigorous adults are more prone to plague, and are more frequently its victims when attacked, than feeble and valetudinary males, and women and children.† Women often appear to owe their recovery to the supervention of menstruation; but it may be questioned whether this occurrence is not rather an indication of returning health than the cause of it. Of the different forms of the disease which we have endeavoured to describe, that in which the febrile commotion is slight, the system appearing to be overwhelmed from the commencement, and not possessing sufficient vigour to throw out the eruption, is the most hopeless; whilst in the mildest degree of the disease, indicated only by the existence of bubo, a favourable result may be always calculated on, unless some gross error of regimen be committed to aggravate a slight into a serious disorder. In an affection of an intermediate degree of intensity, the result can rarely be predicted in an early stage. When there is an amelioration of symptoms with subsidence of delirium on the fifth day, we shall generally find a critical and favourable termination on the seventh; and it is commonly remarked that the fact of the patient's surviving till the eighth furnishes grounds for a favourable prognosis. Intense fever with unabating delirium, attended by the three forms of eruption,—buboes, carbuncles, and petechiæ,—indicates a very dangerous disease, from which recoveries are rare, death frequently occurring from the third to the fifth day. Inferences as to the result may be sometimes drawn from individual symptoms. A copious eruption of buboes is not deemed unfavourable; but buboes and carbuncles conjointly in great numbers betoken a dangerous disease, and one which the constitution frequently proves unable to contend with; and the prognosis is still more unfavourable if petechiæ are superadded. A firm and resisting bubo is a good omen, even though it should have a carbuncle in the centre; whilst one of a soft and yielding consistence is thought to be less favourable. Hiccough, convulsions, cardialgia, diarrhœa, and colliquative sweats, are grounds for an unfavourable augury.

Causes.—So much were early observers of this disease impressed with the evidence of its infectious nature, that in the writings of many of them, the words plague and contagion are used synonymously;* and from this kind of metonymy considerable confusion pervades the works of certain able authors, and among others those of Dr. Read. But how conclusive soever this evidence may be to the majority, there have existed persons, both in ancient and modern times, disposed to deny its validity; and on this account we think it advisable not to confine ourselves to the bare assertion of the fact that plague possesses a contagious property, but to adduce examples of it which may prove of sufficient force to convince those who might be influenced by the doctrines of certain very well-intentioned but dangerous speculators.

We have already quoted the opinion of M. Foderé, that plague may be generated by the abundant endemial causes existing in Egypt, which this writer in common with many others regards as the father-land of the disease. Having had no opportunity from observation of verifying or refuting this opinion, we shall leave it a matter undecided, whether all the visitations of plague arise from a permanent stock of human contagion, occasionally re-

* On the Plague at Aleppo, p. 262.

* —— patet et pestem esse omnium morborum qui contagione serpunt, etiam ad distans, contagiosissimam, unde à nostris contagionis solo nomine subauditur. *Guill. Beaumontensis*, de Peste, lib. i. 1629.

La peste, uno dei piu terribili mali che possano affligere il genere umano, benche non sia propriamente lo stesso che il contagio, pure suole avere fra noi il nome di contagio perche toccare i corpi, o l'aria degli appestati; o le merci, o robe, loro, se ne infettano i sani, con piu forza e strage che non accade in altri morbi epidemici et attaccticci—il perche contagio suo l'anche appellarsi la peste. *Muratori*, Della Peste, edit. 4. 1743.

ceiving increments from the subjects of the disease, when the atmospheric influence is favourable to its diffusion, and occasionally lurking in fomites to burst forth at a suitable season; or, whether the malady is engendered from time to time by the endemial causes we have mentioned, and there is consequently a reproduction of the contagious principle in Egypt. But though disposed to leave this question undecided in the case of Egypt or other eastern realms in which plague seems to be naturalized, we must express an opinion that its appearance in Western Europe has been owing to imported contagion—an opinion which is supported by a host of the greatest authorities that are to be found on this or any other question of pathology. Sydenham, though by no means inclined to exaggerate in any case the influence of contagion, and considering the co-operation of a peculiar atmospheric disposition or constitution essential to the diffusion of plague, yet thinks this pestilential constitution inadequate to its production without importation by fomites or the arrival of a diseased person from an infected district.* To the authority of Sydenham might be added that of Mead and others of the greatest reputation in medicine; but in a question of this nature we prefer, to the weight of great names, facts illustrative of its importation, and of its possessing contagious qualities not exceeded by those of any disease whatsoever, and sufficient to account for its diffusion through countries not guarded against it by rigorous quarantine.

The proofs we shall adduce of contagion will be derived principally from the history of the plague at Marseilles in 1720, this being one of the most accurately reported of European epidemics. Its importation into the city appears to have taken place by means of a vessel commanded by Captain Chataud, which left Seyde with a rich cargo on board on the 31st of January, her bill of health being clean, by which is meant that both the place and the ship were free from the disease at the time of sailing; but it was afterwards learnt that it existed avowedly in the town a few days after. The vessel then touched at Tripoli, which is near Seyde, and has constant communication with it, in order to undergo some repairs. Here additional goods were taken on board, and some Turks embarked to be conveyed to Cyprus. One of these Turks fell sick and died in a few days. Two sailors who touched the dead body sickened and died after a short illness, and in a few days other two persons, one of whom was the surgeon of the vessel, took the disease and likewise died. The captain, becoming alarmed, secluded himself from his crew, and three more men falling sick, and there being now no surgeon on board, the vessel was put into Leghorn. The disease of the three men last attacked was fatal at Leghorn, and Captain Chataud received from the medical men of the place a certificate that they died of pestilential fever. The ship reached her ultimate destination, Marseilles, on the 25th of May, and was put under quarantine of merchandise for forty days. On the 27th another of the crew died. At this time three other vessels from the same suspected places arrived, those of Captains Aillaud and Fouque, and the bark of a second Captain Aillaud. On the 12th of June the vessel of a Captain Gabriel likewise reached Marseilles from the same ports. These ships had all foul bills of health, declaring that at the time of their departure there was a suspicion of plague. The goods of all these vessels, as well as those from Captain Chataud's ship, were landed in the infirmaries for purification.

The disease and mortality continued on board of the first vessel. On the 12th of June the individual placed on board as a guard during the quarantine died, and on the 23d a cabin-boy sickened, and at the same time two porters employed in the purification of the goods, and subsequently a third similarly occupied with those of Captain Aillaud. The disease in all these persons was the same, and all died in two or three days. On the 5th of July two porters, shut up with the merchandise of Captain Chataud, were attacked, and had buboes in the axillæ; and some days after the priest who administered the sacrament to these men died. The passengers from all these vessels, even those from Captain Chataud's ship, were admitted into the town on the 14th of June with their baggage and private merchandise, after their persons and goods had undergone *fumigation*.*

The first case in the town occurred on the 20th of June, and on the 28th of the same month a tailor was attacked and perished, with his whole family, after a few days' illness. On the 1st of July a woman named Ligazière, living at the foot of the Rue de l'Escale, was attacked with the disease, and had a carbuncle on her nose; and immediately after a woman named Tanouse, in the neighbourhood, took the disease, and had buboes, and from her the whole street appeared to become contaminated, the contagion invading first the houses adjoining that of Tanouse.†

It was from this street (Rue de l'Escale) that the disease was introduced into the Hôtel Dieu, through which its progress is one of the strongest evidences of contagion that is to be found any where recorded. This hospital was closed against pestilential cases and all that had communication with them, it being intended to reserve it for the patients who occu-

* Interea aëris dispositionem quantumvis λοιμώδη pesti suscitandæ per se imparem esse vehementer suspicor; quin pestilentiæ morbum alicubi semper superstitem aut per fomitem, aut per pestiferi alicujus appulsum, e locis infectis in alios deferri; ibidemque, non nisi accedente simul idoneâ aëris diathesi popularem fieri.—*Sydenhami Opera*, sect. ii. cap. ii.

* The expression in the original is "parfums." The nature of these perfumes is not mentioned, but the author of the Relation Historique censures the quarantine department for their excessive confidence in them, and the neglect of ventilation. Relation Historique de la Peste de Marseille, p. 35.

† Ibid. p. 26—38.

pied it at the time of the breaking out of the disease, those who might be attacked with other disorders besides plague, and between three and four hundred children (enfans trouvés) who were its permanent inmates. A woman, who had escaped from the street we have mentioned, applied for admission, and either the characteristic marks of plague not having appeared, or having escaped the observation of the examiners, she was supposed to labour under ordinary fever, and was received into the house. She was conveyed by two girls into the women's apartment, and the principal nurse changed her linen. On the following day the two girls sickened, and died after an illness of six or eight hours; on the day after this the nurse became ill and died almost as suddenly. From these four patients the disease spread rapidly through the house, and *all its inmates*, directors, confessors, physicians, surgeons, apothecaries, and all the other officers, servants, and nurses *perished*, excepting thirty of the children, who were the sole survivors from a number of persons amounting to between five and six hundred.*

The effect of seclusion was exemplified in the case of the convents of nuns, all of which cut off communication with the town, and remained exempt from the disease throughout the whole of the pestilence. The Poor-House (La Charité) adopted the same precaution, and enjoyed the same exemption till the end of September. It was then converted into a pest-hospital, its original inmates being removed with the exception of a few who were retained as nurses; of these almost all perished.† The exemption imparted to religious communities by seclusion was strikingly contrasted with the ravages of the disease amid the orders of ecclesiastics who were employed in offices about the sick. Of the order of capuchins, who furnished a great number of confessors to the town and hospitals, forty-three perished, out of the whole body of fifty-five.‡

The contagious nature of plague is strongly exemplified, in the early stage of epidemics, by the gradual manner of its diffusion, the paucity of the attacks at the commencement, and their slowly increasing in frequency, till, foci of contagion being multiplied, vast numbers are invaded at the height of the disease. The rarity of the early invasions at Marseilles, and the havoc it ultimately committed, have been described. A similar mode of progression is observable in all epidemics of plague. In that of London of 1603, the number of deaths were progressively as follows: in March 11, April 26, May 83, June 362, and July 2999; in that of 1625, in March 23, April 85, May 224, June 954, July 5887; in that of 1636, April 37, May 162, June 440, July 456, August 1239, September 3856; in that of 1665, April 2, May 43, June 1060, July 5667.

We need not, as it appears to us, enlarge further on the evidence of contagion in plague, enough having, we trust, been adduced to convince the most sceptical. It appears transmissible from individual to individual in all the ascertained modes in which diseases are thus communicated; by contact, inoculation (from the matter of buboes), through the atmosphere, and by fomites. Observers have endeavoured to illustrate certain obscure points in these different modes of transmission. Thus, with regard to the matter of buboes or of sinuous ulcers consequent on them, it has been conjectured that its contagious property ceases before the healing of the sore; but no precise conclusion having been attained regarding the period when this cessation takes place, Dr. Russell advises that all pestilential ulcers should be held infectious till after the expiration of two months from the first attack, and the patient secluded accordingly. The contagious distance from the person of the patient has been matter of discussion, some persons imagining that a degree of proximity almost equivalent to contact is necessary for the communication of plague; but there is reason to think that this circumscription is much narrower than facts justify us in drawing it; though it is probable that the effluvia when once transmitted into pure air are soon blended with the common mass, and suffer such alteration as renders them innocuous at no great, though not an ascertained, distance from the patient. At what period of the disease the communicable property commences, and how soon after convalescence it ceases, are points which may be considered quite undecided. The most accurate observers are of opinion that consciousness of receiving infection, a feeling occasionally discerned in ordinary contagious fever, does not occur in plague.* When received, it does not hang ambiguously about a person in any case for more than two or three days, but its operation once announced by visible signs of disorder, the progress of the disease is rapid, there being a difference in this from the course frequently observed in typhus, in which the effect of contagion on the system is frequently manifested by slight indisposition, sometimes lasting for weeks, previously to the complete formation of the disease. (See Contagion.)

It would be desirable to ascertain the duration of the latent period of pestilential contagion from its reference to the safety of intercourse between infected and healthy districts; but the information to be obtained on this important question is of a very unsatisfactory nature. Only at the beginning of a pestilence, when foci of contagion are rare, can any attempt be made to illustrate it, and hence the data are too scanty to furnish a conclusion which can be implicitly relied on. Dr. Russell has known the disease sometimes manifest itself a few hours, and in some cases two or three days after intercourse, and is disposed to consider that infection rarely remains latent beyond ten days; but he acknowledges that wider experience is required to determine positively the latter point. The period during which conta-

* *Russell*, p. 302.

gion may adhere to unventilated goods appears as unascertained as the latent period in the case of persons; but many circumstances lead to the belief that it is of considerable length.

The question has been raised whether dead bodies have an infecting power, and M. Desgenettes answers it positively in the negative; but there is much reason to think that this decision is too general, however warranted by the experience of its author. During the pestilence at Marseilles burying the dead was found so dangerous an operation that free persons could not be procured to perform it even for an enormous recompense, and consequently the galley-slaves were employed on a promise of liberty when the duty should be completed. They were sent out in detachments. The first, consisting of twenty-six, were all attacked with the disease in two days, and successive numbers were sent on the duty, till, from the 20th to the 28th of August, one hundred and thirty-three had been employed, when the officers of the galleys refused to send any more, almost the entire number furnished being either sick or dead. It was likewise observed in the plague of London of 1665, that officiating at funerals was an office fraught with extreme peril.

Certain conditions of the atmosphere influence the diffusion of the contagion of plague, or the susceptibility of bodies to be affected by it. Of these the most manifest is temperature, extremes in this respect checking, and warmth within a certain degree appearing to favour, the propagation of the disease. It hence occurs that the abatement of pestilence in the east takes place during the heats of summer, and in Europe in winter. Popular superstition among the Christians resident in Europe fixes on St. John's day as the exact period of the cessation of pestilence: we scarcely need remark that this opinion is much more precise than is justified by facts. The following, according to the most accurate observers, is the ordinary course of the diminution and ultimate disappearance of plague in the Levant. There is a manifest abatement of the disease at the commencement of the summer heats, and in proportion as these continue and increase, cases become more and more rare, and finally cease; while contaminated goods lose at the same time, as we are informed, their infecting property. The uniformity in this course is so great that Christians who shut themselves up during pestilence almost always come abroad in June, the instances being very rare in which they remain confined to July. Epidemics in Europe have generally commenced in spring, or in the beginning of summer. Autumn has frequently been the period of their greatest prevalence and fatality, and they have either been totally extinguished in winter, or have then received a very considerable check, and have finally ceased in the early part of the ensuing spring. The great plague which prevailed in London from 1636 to 1648 presents an exception to this rule; but during this extensive period there was invariably a diminution of cases in winter, though at no time a cessation of the disease.

Independently of manifest atmospheric conditions, that inscrutable state of the air to which the term epidemic constitution has been applied so much influences the propagation of plague, that certain very experienced writers have denied its possessing a communicable property unaided by this atmospheric peculiarity. In illustration of this view, Dr. Russell informs us that experience in Turkey, where generally no precautions are taken in times of pestilence, clearly evinces that in a certain state of the air a communication with infected places may subsist without any material consequence. The return of plague at Aleppo happens at irregular periods; the intervals are of considerable but unequal length; and in these the commerce with Egypt, Constantinople, and Smyrna, remains uninterrupted. In the intervals between 1744 and 1760, and from 1762 to 1780, the plague raged several times in the places now mentioned, without affecting Aleppo; and even in two or three years subsequent to 1762, though it was at Marash, as well as other places not far distant, with which Aleppo has continual intercourse, no instances were discovered of communicated infection, and this exemption continued notwithstanding that infected families from some of these places took refuge in the town. It would appear, moreover, that this constitution, favourable to the progress of plague, varies considerably in degree. Thus we learn from the able author last quoted that the progress of plague at Aleppo was exceedingly restrained in 1760; it was much more vigorous in 1761; it raged with great fatality in 1762, and in this year was finally extinguished, though there was no appreciable difference in the state of the seasons in the respective years to explain the varying diffusion of the disease or its ultimate extinction. To the cessation of this atmospheric condition, which is known only by its influence on the propagation of disease,* is to be ascribed the occasionally sudden and otherwise inexplicable disappearance of plague in oriental countries where no disinfecting process is employed. Much, too, that ought rather to be attributed to a change in this latent state of the atmosphere, is frequently ascribed in other countries to disinfecting processes, which are in truth rarely so general or efficient as to account for the cessation of pestilence.

Treatment.—There are few points in medicine on which greater discrepancy of opinion prevails than the mode of treatment to be adopted for conducting patients safely through this dangerous disease. Remedies which are the favourites of one class of observers, in the hands of others prove to be fraught with danger. Bloodletting, emetics, and other heroic measures, are alternately lauded as cures and

* At vero quæ qualisque sit illa aëris dispositio, a quâ morbificus hic apparatus promanat, nos pariter ac complura alia, circa quæ vecors ac arrogans philosophantium turba nugatur, planè ignoramus. *Sydenhami Oper.* sect. ii. cap. ii. p. 107.

censured as poisons. We believe that had any of the remedies the reputation of which has been so fluctuating, been announced as cures for any of our ordinary epidemics, such as small-pox, scarlatina, or continued fever, without reference to the period or type of the disease in which they were to be employed, the testimony for and against them would have proved equally conflicting. The general treatment of any epidemic, independent of that required to combat local lesions, may be comprised, if we mistake not, in few words:—We must deplete the excited, and stimulate and support the sunken and collapsed; and in an immense majority of instances the condition requiring the former means, if it exist at all, will be found in an early stage of the disease; that demanding the latter will occur in an advanced period.

The best authorities inform us that bloodletting is to be employed at the very commencement of the disease, if the pulse possess sufficient force to render such a proceeding prudent; and some are of opinion that a second bleeding may be occasionally admissible; but that very judicious observer, Dr. P. Russell, cautions us against performing any bleeding after the third day. He mentions, however, one case* in which bleeding was successfully performed on the third day from both arms at once, though the patient, a female, had been bled the preceding day. The presence of buboes, which Sydenham and others have regarded as a valid objection to bloodletting, from a dread that the operation might occasion their recession, ought not, we are assured by more recent authorities, to prevent its employment, as neither the eruption nor progress of these tumours is injuriously influenced by it. Dr. P. Russell, indeed, remarked, that where the pain of buboes was excessive, bleeding was necessary to moderate that and other inflammatory symptoms, for till the fever declined, these tumours never advanced kindly to suppuration.

Many cases, however, occur, in which the collapse of the system is so well marked from the commencement that the employment of bleeding is manifestly inadmissible, and emetics are then thought the most suitable remedies. Should the first emetic dose fail to act, it is advisable to repeat it after the interval of an hour or an hour and a half. Full vomiting, we are assured, especially if bilious matter or worms were discharged, was found so efficacious during the prevalence of plague at Aix in Provence, that almost all from whom such matters were ejected recovered, whilst those on whom the emetic failed to operate perished.† It is probable that the failure of emetics was not so properly the cause as the token of death, as it indicated an extremely collapsed state of the system, of which the sensibility was almost annulled by the vehemence of the disease.

Purgatives are generally regarded as suspicious remedies, from the tendency to diarrhœa being so general in the disease, and its very fatal effects; and practitioners concur in declaring costiveness to be less prejudicial in plague than other febrile disorders. The irritability of the bowels is so great, and hypercatharsis is consequently so liable to be produced by the more active purgatives, that we are advised to empty the bowels at the commencement of the disease by means of the most lenient of the class, such as cassia pulp, manna, or rhubarb, with cream of tartar. Sir Brooke Faulkner, however, employed calomel and jalap, without intimating that inconvenience resulted from the practice.*

Among the older physicians, the object of whose practice was to eliminate from the blood the noxious principle on which they conceived the phenomena of the disease depended, the more heating diaphoretics, such as contrayerva and serpentaria, were favourite remedies, whilst their operation was aided by excluding the air, heating the apartment, and heaping the patient with bed-clothes. This method of treatment, so injudicious in any febrile disorder, is now universally abandoned by European practitioners. Some of the more cooling sudorifics, as liquor ammoniæ acetatis, and saline draughts, are customarily given by many physicians, and by some are thought to be beneficial. Dr. P. Russell says that saline draughts given in an effervescing state are much more efficacious in checking the retching which is sometimes a distressing accompaniment of plague than that of ordinary malignant fevers.

It has been stated that diarrhœa is a very common and very dangerous symptom. The judicious observer we have so frequently quoted, Dr. P. Russell, informs us that he was at first unwilling to administer opium for its relief, from an apprehension of aggravating the stupor or comatose disposition; but finding that this effect did not follow its employment, he used it in 1762 much more freely than he had done in former years, and in general remarked that where he succeeded in stopping the looseness early in the disease, the patient became more alert and sensibly better. In the more advanced stage, however, we learn from the same writer, astringents and opiates rarely checked or suppressed the diarrhœa. Inflammation of the intestines being one of the few pathological appearances generally recorded by authors, there can be little doubt that the diarrhœa which accompanies plague indicates some inflammatory affection of the bowels, and that local bleeding, from the integuments of the abdomen or anus, and perhaps subsequent blistering, would be found important auxiliaries in its treatment.

Coma and other affections of the brain it is customary to combat by means of blisters between the shoulders, to the nape of the neck, temples, and occiput.† It is extremely probable that the dread of drawing blood, which is so general among those who treat this disease, is the reason why local bleeding is not

* On the Plague at Aleppo, case ciii.
† *Sauvages*, Classes Morborum, vol. ii. p. 368.

* Treatise on the Plague, p. 238.
† *Sir B. Faulkner*, loc. cit. p. 241.

conjoined with the counter-irritants to subdue the cerebral affection. From the symptoms we have detailed of the intellectual disorder in plague, there can be little doubt of its depending upon the same causes as that which accompanies other malignant fevers, and that the same method of treatment would be found applicable to both.

Certain remedies of the general febrile state, besides those already mentioned, have been tried by European practitioners in this disease. Cold affusion is thought by Sir B. Faulkner to present a considerable prospect of benefit if applied at the very commencement: this writer, however, it should be remarked, speaks from a very limited experience of its effects. Several writers speak favourably of mercury; some on merely speculative grounds; others from the analogy, real or presumed, between plague and other disorders in which they have observed that this mineral is useful; Mr. Stafford from considerable experience. This gentleman declares that, when his regiment was infected, thirty or forty cases of axillary tumour recovered under its use, and he relates at length five severe cases of plague, of which three recovered under mercurial treatment. The mode of administering it was internally in the form of calomel, and by inunction. The statements of this writer seem to show that the mineral may be serviceable in the treatment of the disease.*

Should the vital powers appear to be failing at any period of the disease, wine and cordials are administered, and many writers advise that they should be accompanied by tonic medicines, of which calumba, bark, and serpentaria are those most usually resorted to.

Friction with oil has been praised as a means of curing the disease by inducing diaphoresis, and likewise as a preservative from infection. The property of inducing diaphoresis it certainly possesses; but its power of curing the disease is questioned by numerous authorities. A writer, whom we have often quoted, Sir B. Faulkner, is equally sceptical as to its prophylactic powers. On this point he remarks: "there are so many instances of persons living in the closest intercourse with the infected who escaped without the use of oil, and so few well-attested cases of persons having come into actual contact with pestiferous matter who were protected by oil alone, that I cannot hesitate to conclude that the opinion of its possessing any independent or certain prophylactic efficacy is destitute of foundation."† Vaccination has been recommended as a means of prophylaxis. The last quoted writer furnishes us with the following forcible argument against its claim to such a property. "I took pains," says he, "to ascertain whether those who had recently been vaccinated were rendered less susceptible; and I found that the instances of its inefficacy were every where numerous, of which I may mention rather a striking one, which was communicated to me by a Maltese surgeon, who was much employed in the plague, namely, that of a numerous family who had been recently vaccinated, the whole fell sacrifices to the prevailing contagion, with the exception of the parents, who had never undergone the operation."* For the prophylactic means to be adopted, we beg to refer to the articles CONTAGION and DISINFECTION.

The general plan of diet is the same as in other febrile disorders. Of preparations of animal food nothing stronger than chicken broth should be allowed; the rest ought to consist of preparations of farinaceous or leguminous vegetables, ripe fruits, and simple diluents, such as lemonade, toast-water, or tea.

The local treatment of buboes should be limited to the application of warm emollient poultices. By the older writers, who erroneously conceived that the suppuration of buboes was the cause rather than the effect of the abatement of the fever, various irritating measures were resorted to for accelerating the process, but sounder pathological views have occasioned them to be abandoned. When suppuration has taken place, the matter may be left to discharge itself spontaneously, or the lancet may be employed to give exit to it. Should the original aperture be too small, it should be dilated, as its narrowness is apt to give rise to sinuses. If the carbuncles require topical treatment at all, it should be of the same simple nature as that of the buboes. Prior to the forming of the eschar a mild poultice only is required: subsequently a slightly stimulating dressing, such as unguentum resinæ, or the same with oleum terebinthinæ, may be interposed between the tumour and the poultice.

(Joseph Brown.)

PLETHORA, πληθώρα, *fulness.*—Before entering on the discussion to which this article is appropriated, the writer wishes to guard himself against a misconception that has at times been inconsiderately formed respecting the doctrines maintained in it. Though connected with the foundations of all pathology, they are by no means intended to represent the whole of it. Pathology regards living actions, which depend on organized structure, and this both derives its nutrient elements from the blood, and returns to it the effete matter which the nutrient deposits displace. This connexion, subsisting without intermission so long as life endures, is so intimate, that whatever affects the condition of the blood must immediately concern the well-being of the whole frame; whence every approach to a correct pathology of the circulation must contribute to the establishment of sound principles, and improve medical science. But pathology embraces more than the mere lesions of the blood or of its circulatory apparatus: there is a nervous system as well as a vascular, which cannot be over-

* Cases by Mr. Stafford, quoted by Sir B. Faulkner, p. 245-253.

† Op. cit. p. 232.

* Op. cit. p. 233.

looked. We wish it, therefore, to be understood that in the following doctrines of plethora we have not the slightest intention of establishing an exclusive pathology, or of claiming for the facts and reasonings adduced a higher importance than they intrinsically merit.

The term *plethora* but ill expresses the state of constitution which it is used to designate, yet it would be difficult to substitute one more correct and appropriate. Indeed, no concise term could convey the compound idea which requires to be represented, and which involves the conception not so much of the quantity of the circulating fluid, as of the relative proportions of its constituent parts. The term hyperæmia, as being of similar import, would not be preferable even if it were not otherwise appropriated. It is applied to denote local accumulations of blood arising from congestion or determination, in which the phenomenon results solely from the increased quantity of blood, without reference to its quality, and is, consequently, expressed with correctness by a term representing such excess.

Plethora, though inducing a morbid condition of the body, has not in general been designated a disease, nor treated of by practical writers, save in connexion with some special malady attendant on or derived from it. Linnæus has given it a place in his nosology in the class *Deformes* and order *Decolores*, and thus defines it: "Rubedo corporis a distensis vasis sanguineis, cum dyspnœa." Sagar also admits it in the class *Cachexiæ*, and order *Intumescentiæ*, giving not only a definition but a description also: "Intumescentia universalis, proportionata et æquabilis ex abundantia sanguinis." "Amystidis et ventris cultus, pulsus plenus aut suppressus, venarum amplitudo conspicua, æstus et gravitas totius corporis, respirandi difficultas, lassitudo spontanea, stupor artuum, somni turbati, partes epidelio tectæ rubentimæ, temperamentum sublaxum, sanguineum." The former of these would seem to denote rather special disease of the lungs, and the latter to characterize obesity. Neither is calculated to convey a clear or correct notion of the morbid condition which excess of blood occasions. As this condition is present in many diseases, and actually gives rise to several; and as, even in cases where it does not exist, it is of importance to be assured of the negative, it cannot but be deemed an important part of pathological science to trace the circumstances which generate a state of plethora, and the phenomena which indicate it, so as to be prepared both to recognize it when present, and to apply means suitable and adequate for its correction.

Disease is considered to exist when there is any observable deviation from health in any of the functions or structures of the body. When the whole constitution is disturbed or depraved, without any part being more prominently affected, the disease is said to be general or constitutional, and according to its character is called either febrile or cachectic. If any function or organ be particularly disturbed, a name is thence affixed; and if an organ or function suffer without apparent disturbance of the general health, the disease is pronounced local. On such views have classifications of diseases been formed, yet are they wholly wanting in that precision which the productions of a nosological arrangement should indisputably possess.

When morbid symptoms of any kind arise, it is necessary to consider not only the morbid lesions which immediately produce them, but also the deviations from health in which these morbid lesions themselves originate, tracing these back to the point where deviation from health first occurs. By such investigation only can the history of disease be rendered complete, or its true pathology be established.

It is easy to understand why the investigation of disease has for the most part commenced with that period when a nosological malady is considered as formed. Until this period arrives medical aid is rarely sought for, the patient's consciousness of indisposition being aroused only when the functions of health become so impeded as to fail sensibly in their accustomed exercise. The accession is then referred in general to some exciting cause, real or imaginary, and is considered as having commenced at the time when the imputed cause was supposed to operate, a state of previous good health being assumed. Thus suddenness of accession has been regarded as a character of most acute diseases, and the period when the accession has been first observed has been regarded as identical with the commencement of disease. Yet it may be doubted whether any disease, excepting such as results from a morbific poison, ever takes place suddenly or without previous derangement of general health, cognizable by its appropriate manifestations, and capable of being corrected so as to obviate the morbid accession to which it leads. If this can be demonstrated, it is clear that this introductory stage of disease is of the highest importance, as being that to which prophylactic treatment can be most beneficially directed, and also as forming a part of the ensuing disease essential to its complete history, and without a knowledge of which its intimate nature or the series of morbid changes never can be thoroughly understood.

In tracing the progress of plethora, and the derangements of function which it occasions, it is necessary to commence at that point where the equable and temperate exercise of all the functions of life constitutes the state which we denominate health. By this means physiology becomes connected with pathology; the actual transition of health into disease is elucidated; and a light is thus shed on morbid processes which no other source of investigation can supply. When disease has made a certain advance, and continued a certain time, so complex are the derangements resulting, that without some clue for unravelling their intricacies, an exposition of them is in vain attempted, and, as the history of physic abundantly shews, conclusions the most opposite may be arrived at in inquiries directed to the same end. This could not be the case if the several morbid changes, as occurring in the respective func-

tions, were marked in their regular progression, so as to determine, when any one presented, what were its antecedents, what would be its consequents. Were this knowledge clearly possessed, each symptom of disease would be discriminated as belonging to a determinate train of morbid actions; and however obscured it might be by contingent or derivative disturbances, it would point out unequivocally the appropriate means of its own correction. With such accurate knowledge we should not see such ambiguity prevailing as that in certain maladies some practitioners enjoin bloodletting where others give opium and ammonia.

Almost all systematic and theoretical writers have left their inquiries incomplete; with each an important stage of the diseases of which they respectively treat remains unexplained. This stage embraces the interval between the first deviation from a state of health, and the occurrence of the special lesion of which each has taken cognizance; and it is chiefly to this stage that we purpose to direct attention in the following pages.

The constant, unremitting exercise of the functions, the aggregate of which constitutes all that we know or can conceive of life, is attended with a physical expenditure which daily nutrition replaces. The nutritive matter taken into the stomach, and which forms the chief support of animal life, undergoes several successive changes in its passage through the body; it is digested, assimilated to the animal juices, deposited in the several structures for their appropriate nutrition, and finally, when no longer fit for supporting their healthy actions, is taken up by the absorbents and carried out of the system by appropriate excretories. It is obvious that there is a natural proportion between the ordinary waste of the body and the supply of fresh nutritive matter, and that if the latter be either too sparing or excessive, the functions of life must undergo some deviation from their healthy exercise.

Considerable variations are liable to occur in the quantity and quality of food which any individual consumes, in the assimilating processes by which what is taken into the stomach is animalised and fitted for repairing the waste of the system, and in the several secretions in which the blood is expended. If more food be assimilated than the ordinary waste of the body requires, a state of repletion must be the natural and inevitable result. But repletion may also take place under a moderate and even abstemious use of food, when, from sedentary habits, inactive life, or other cause, appropriation of blood by the nutrient and other secretions is languid and inefficient. As repletion, then, may take place under very different circumstances, so is its presence marked by different phenomena. Whenever it arises, one of two consequences is sure to result; either it excites the several functions, if sufficiently healthy and vigorous, to increased actions leading to its speedy appropriation and removal; or, if these be weakly and unable at the moment to institute and support those increased actions by which the redundant matter is to be appropriated and expelled, then, oppressed by a labour to which they are unequal, they manifest a decline of even their ordinary power, and all the outward phenomena of debility are displayed. To discriminate this state from one of real debility arising from exhaustion of animal power or from defective nutrition, is a matter of practical importance not inferior to any which medical science may be engaged in illustrating.

When redundancy of nutriment takes place in a healthy constitution, its earliest effects manifest what may be termed rather exuberance of health than a state of disease. The several functions of the body are more vigorously performed, the nutrition of its several structures is more abundant, and it acquires increase of bulk, especially if the habits of life are not of an activity capable of increasing excretion to a degree proportionate to the nutriment inordinately supplied. And if the excess be casual or inconsiderable, the self-adjusting powers of the body are amply sufficient to dispose of it so as to prevent the transition of healthy actions into diseased. If from extent or continuance the excess be such as to urge these powers beyond a certain point, then their conservative energies fail, and irregular actions of various kinds take place, laying the foundation of a large proportion of the specific diseases to which the human body is liable. The general character of diseases so induced is inflammatory. They are marked by a quickened circulation, increased heat, and a more or less depraved state of the several functions. According to the predisposition of the system, hereditary or acquired, to the accidental weakness of particular parts, or to the casual excitement to which the body may be exposed, is the specific form of the ensuing disease determined. For this diseased condition the means of essential relief are, depletion and abstinence; the one to remove or abate the original cause of distemper,—the other to prevent its recurrence. There can be little doubt that the process of nature here referred to, though generative of what we term disease, is yet intrinsically sanative; its object being to dispose by increased energies of that which the ordinary powers are unable to appropriate, and the continuance of which is inconsistent with their healthful exercise.

When repletion occurs in a habit of less natural vigour, the self-adjusting powers are not so successful in effecting early restoration; and inflammatory actions are more tardy in their accession. The interval which precedes the occurrence of morbidly increased actions is one of peculiar interest, because its phenomena are of an equivocal character, resembling in many respects those which belong to a very different state of the system, and hence liable to be misunderstood; and more especially because they have hitherto been very imperfectly investigated.

The two kinds of plethora here described may be conveniently distinguished by the terms *absolute* and *relative*; the former implying that the redundancy exceeds what the

healthy state of the individual constitution would require or bear; the latter that, without being absolutely excessive, it is relatively so in reference to the deficient powers of the constitution for appropriating or otherwise disposing of it. Absolute plethora would thus correspond with the *plethora ad molem*, *ad vasa*, *ad venas* of systematic writers; and relative plethora to the *plethora ad vires*. With respect to the *plethora ad spatium*, or that referred to reduced capacity of vessels, the actual quantity remaining the same,—or the *plethora ad volumen*, arising from increase of bulk without actual increase of quantity, it would serve but little purpose to notice them in a practical treatise; the former being resolvable into relative plethora, and the latter, if it ever take place, being only a transitory effect of a temporarily operating cause, such as increased temperature, by which the volume of the blood was supposed to be expanded. The distention of vessels, however, from which this expansion was inferred, was much more probably occasioned by the excitement of the arterial system caused by the stimulus of heat. It is questionable whether a real plethora ad volumen ever occurs except in the instance of persons ascending great heights, at which the diminished pressure of the atmosphere seems to give rise to some such effect.

The subject of plethora might be comprised under the heads of absolute and relative; but its discussion would not then be complete, for so continually is nutritive plethora combined with another source of vitiation of the blood, that it is impossible to do justice to the one subject without at the same time illustrating the other. This vitiation takes place when under moderate nutrition there is defective excretion; in which state the system is oppressed, not so much by the quantity of nutriment, or the labour of disposing of it, as by the load of excrementitious matter with which the blood is overcharged. The phenomena and treatment of this condition of the body are also of high interest, and deserving attentive and mature consideration; for unless its nature be clearly understood, the treatment must be purely empirical, and its success precarious and incomplete. Each of these morbid conditions will now be considered; and the discussion will, we trust, assist in reconciling some of the apparent anomalies and inconsistencies with which medical practice is so frequently charged.

I. To the first of these conditions, or that of absolute plethora, belong all the cases of pure inflammation which we daily witness. It is usual, when these occur, to refer them almost exclusively to the exciting cause which may have immediately produced them. Yet the fallacy of the conclusion must be obvious when we reflect that, of several individuals exposed to the same exciting cause, scarcely two will be affected alike. From exposure to cold, for instance, one will be attacked with catarrh, another with rheumatism, a third with inflammation of the bowels, a fourth with sore throat; while by far the greater number will escape altogether. Were the exciting cause solely chargeable with these several effects, they would unquestionably be marked with greater uniformity. The truth is, that the exciting cause produces its effect because the body exposed to it is prone to be morbidly affected in consequence of its own previous derangement; and the specific form of the disease is determined, partly by the operation of the exciting cause, but chiefly by the predisposition of the parts affected to undergo those morbid actions to which the general indisposition of the system and their own partial weakness render them liable.

To distinguish by its appropriate phenomena that condition of an apparently healthy body which subjects it to be affected by slight exciting causes, must be an important part of medical knowledge. This state and these phenomena the writer of this article endeavoured to explain and illustrate at some length several years ago. He then made known the course of inquiry by which he was led to investigate these phenomena, and to trace them backwards to the point where health first passes into disease. His earlier observations were conducted on what occurred in his own person, at a time of life when he was prone to severe attacks of inflammation, and when regard for his safety compelled him to watch vigilantly the premonitory indications so as to anticipate the approach of inflammation, and by timely interference avert its more severe accessions. By close attention he was enabled to detect those indications in certain derangements of functions, sufficiently clear and undeniable when noticed, but which might, on superficial examination, be overlooked or regarded as trivial and insignificant. The success of his early endeavours to arrest advancing disease encouraged him to observe still more closely, and detect at still earlier periods, the morbid actions introductory to inflammation; in which way he progressively ascended to the higher links in the chain of causation, availing himself always of the knowledge thus acquired so as to apply means of relief at the earliest period when a necessity could be perceived; and with such effect that he succeeded thoroughly in subduing a liability to inflammation, from which he had suffered repeatedly and severely for several years. Engaged in hospital duties of some extent, he had ample opportunity of making corresponding observations in a tolerably wide field of practice; and the result was a full confirmation of all that the experience of his own case had taught him. From the principles thus deduced, the writer has derived much valuable guidance in the investigation and treatment of disease for more than twenty years; an experience which may be considered as justifying some confidence in now again submitting them to the profession through the medium of a work devoted to practical medicine. To detail here the analytic processes of inquiry from which this experience was derived would extend the present article beyond its allotted limits. Premising, therefore, that it was from research so

conducted the following information was obtained, we shall proceed to state synthetically what we believe to be the course of morbid actions consequent to and resulting from redundancy of nutritive matter in the blood, both absolute and relative.

We have stated that absolute plethora is the parent of pure inflammation. If there be no plethora, inflammation will not be excited by slight causes; or if it be aroused through the operation of an exciting cause, it will be mild and easily subdued. The severity of inflammation, too, will, *cæteris paribus*, be proportionate to the degree of plethora pre-existing. Previously to the occurrence of febrile or inflammatory action, there is always a sensible interval of disease marked by evidences of diminished power in the arterial system, the oppressed and irregular actions of which evince its inadequacy to carry on the circulation with its wonted vigour. The pulse, if examined, will be found low, oppressed, irregular; which state passes progressively into one of permanently increased action or fever. Multiplied observations have satisfied us both that the stage of disease here mentioned precedes that of febrile action, and that the morbid actions indicated by the pulse succeed each other in the order here announced; the first being that of feebleness or overloaded power, the second of irregularity, and the third of permanently quickened circulation. It has been already stated how incipient plethora, when the redundancy is no longer disposed of by the healthy action of the several organs of appropriation, and when these can no longer perform steadily the increased labour, gives rise to the state of feebleness now under discussion. To comprehend the nature of these several changes is not difficult, it being readily explicable by reference to well-known laws of vital action.

When redundancy of nutritive matter first occurs, its immediate effect is to promote more vigorous circulation, and to excite to increased actions the several capillaries, especially those engaged in nutrient secretion. The peculiar stimulus of the nutritive matter excites these actions; their end is to dispose of the redundancy by natural appropriation, and the effect on the frame in the first instance is only that of increased volume and exuberant health. But to all vital actions, and the degree to which they can be continuously sustained, there is a limit; and when increased beyond this they after a time become relaxed, sinking even below the natural standard. By incipient plethora increased actions are excited which at first differ from perfectly healthy actions only in degree. In time, however, and especially if the plethoric state be kept up by excessive nutriment, they become enfeebled and abate; then it is that the pulse, which antecedently was fuller and stronger than natural, first becomes low and oppressed. The disposal of redundancy by increased action of healthful processes proving inadequate, from inability of the vital powers, to continue it, other efforts are now needed; and as these, though in their tendency corrective of what is amiss, no longer resemble the healthy actions, they must be considered as morbid; disease being the result of their institution. While we thus regard them, however, we should never lose sight of the corrective tendency which originally belongs to them, nor fail to profit by the curative indications which the efforts of nature point out. The minute changes so induced we pretend not wholly to explain, though many of them are readily intelligible; but the cognizable phenomena are sufficiently obvious to mark their connexion and dependency, and thus to establish a rational theory of the course which nature pursues.

Relief by increased nutrient secretion not sufficing, a more general excitement seems now required, the object of which may be to call into more vigorous exercise the several excretories; and a state of generally increased or febrile action ensues. The state of irregularity is obviously the transition from the state of feebleness to that of permanently increased action or fever; and the end of the latter is to get rid of the original cause of disturbance. It is in proof of the correctness of these views that if in the stage of feebleness depletion and abstinence be resorted to, the feebleness disappears, natural vigour is renewed, and health is restored, without any febrile action being instituted; while if this state be treated with stimulants and nutritive diet, febrile or inflammatory action is sure to result. We wish here to observe that in these remarks we use the term *fever* to denote, not any of the specific diseases known by that name, but simple pyrexia, characterised by a quick pulse, hot skin, and furred tongue, being the constitutional state attendant on the ordinary phlegmasiæ, and so generally, through a radical misconception, denominated symptomatic fever. As the stage of feebleness is relievable by evacuations and abstinence, so are those of irregular action and of febrile excitement to be remedied by the same means; and if these be duly employed, any or all of these morbid conditions may be promptly corrected without specific disease or local lesion of any kind ensuing. But if they be not employed, and more especially if, through misconception, stimulants be used and nutritive diet continued, then febrile action becomes more determinately aroused, and some specific disease of an inflammatory character is engendered: or else, if the constitution be, from natural inertness or the extent of labour to be performed, unequal to the effort necessary for generating a state of fever in inflammation, the general health progressively declines, the powers of life become enfeebled, and the constitution finally sinks under some of the complicated forms of chronic disease. When under the former of these results active fever or inflammation occurs, it is in general speedily subjected to medical treatment; and as opinions vary but little respecting the measures to be pursued under such circumstances, while the urgency of disease requires them to be employed with proportionate vigour, it seldom happens that

this stage of disease is improperly treated, at least so far as regards the use of evacuants. At this time the propriety and necessity of active treatment and of depletory practice are admitted on all sides; yet previously to the acute attack a deviation from a healthy state existed, which admitted of detection, and which as clearly indicated the propriety of some depletion, though it might not demand it so imperatively, nor require it to the same extent, as when the acute attack had supervened. Were this introductory stage relieved by adequate depletion and other suitable means, there can be little doubt that the accession of acute disease might in every instance be averted, or at least so greatly mitigated as to be free from all danger.

It appears from all that has been stated, that incipient plethora in a healthy constitution excites at first only increased energies of healthy functions, manifested in the increased bulk and more florid aspect which such persons usually present, and in the evidences of more vigorous circulation which the pulse affords; that this state of increased healthy action, if urged too far, declines into one of diminished power, still evinced by the pulse, which then becomes low, oppressed, and irregular; and that, if these progressive changes be overlooked or unrelieved, a state of permanent excitement succeeds, such as constitutes fever or inflammation. It is obvious, then, that the increase of bulk and more florid aspect in which so many exult as evincing sound health, and which they endeavour by all the aids of good living to promote, is not a source of unmixed congratulation; but that, on the contrary, it deserves to be regarded with no slight suspicion, as actually verging on consequences by which both health and life may be forfeited. Up to this period, however, disease cannot be said to have commenced, however it may be approached; and reduction of diet, with free bowels and increase of active exercise, would suffice for getting back to sounder health without any need of medical interference. When abatement of healthful energies becomes evinced by a low and oppressed pulse, diseased actions may be said to commence, and when the stage of irregular action ensues, sensible progress may be considered as made towards the establishment of febrile action and inflammatory disease. When these latter result, medical aid and active discipline are indispensable; but up to this period much may be done by mere reduction of diet and a free state of bowels to avert the pending mischief. This condition of the body will be further illustrated, when the practical treament required for its relief comes under discussion, the course of enquiry rendering it necessary to proceed now to the consideration of the second division of the subject, or that of relative plethora.

II. In relative plethora the earlier deviations from a healthy state take place so gradually, and the constitutional efforts are so feebly exerted, that for a long time they are nearly unnoticed. Health is observed to be less perfect; there is occasional languor and disinclination to the customary exertions, with irregular distribution of blood as marked by coldness of feet and variable countenance; the bowels are irregular, the appetite is capricious or fails, and both flesh and strength decline.

At the earlier periods of this state the pulse will be found weak, often irregular. Sooner or later a febrile or inflammatory state ensues, marked by a quickened circulation, some increase of temperature, and a white or furred tongue. This state may continue for an indefinite period, and be subject to frequent fluctuations; most frequently in course of time some part more particularly suffers, a local ailment arises which excites attention, and to which, when discovered, the constitutional indisposition is most commonly ascribed. In order to judge correctly of this condition of plethora, it is necessary to mark particularly the accordance of its phenomena with those which absolute plethora presents, especially in the changes which the pulse undergoes. This, here also, is at first feeble and oppressed, then irregular, and finally it becomes permanently quickened.

As the incipient lowness of the pulse is the symptom which so generally misleads, conveying the impression of debility, and suggesting the employment of tonic and stimulant remedies, it is highly necessary to distinguish it from a pulse of pure debility. Happily there are other circumstances besides the pulse to direct the judgment in this respect; other obvious derangements co-exist, displaying a harmony of symptoms, which, taken collectively, establish beyond a doubt the existing condition of the vascular system. But the language which they speak is not always understood; their warning voice is unheeded; and the deceptive lowness of pulse is suffered to counteract the evidences which the other co-existing symptoms display. On this account it is that we dwell so much on an accurate discrimination of the indications which the pulse affords; not so much for the positive evidences which it furnishes—for there are others much less equivocal, and far more worthy of being relied on—as that, when this peculiar lowness exists, it shall not be suffered to bias the judgment or to divert the practitioner from those measures by which alone the morbid condition referred to can be corrected. A little accuracy in the mode of examination, with attention to the impressions made on the finger, will readily detect the peculiarities which we have stated; and when familiarised to the touch by habitual perception, there can be little difficulty in distinguishing them. In the condition of which we are treating, if firm pressure be made on the artery, it will be found to resist beyond what its apparent feebleness would indicate, and, on gradually withdrawing the finger, to rebound with a force much greater than would at first be imagined. If the pressure and relaxation be a few times alternated, the sensation will be rendered more distinct. This inherent

firmness is sufficiently indicative of the condition existing, and affords the best assurance of depletion being well borne. As we before stated however, and as will be hereafter more distinctly pointed out, there are other evidences to confirm what the pulse proclaims.

The state of irregularity of the pulse also requires precision in determining both its character and extent. It may be perceived as affecting both the force and frequency of the pulsations; and the irregularity of force, or that in which the artery makes a few strong pulsations, as if by a transient effort, and again relapses into a state of oppressed and diminished action, indicates, so far as we have been able to discover, a nearer approach to febrile or inflammatory excitement than the irregularity of frequency only; repeated observation of which fact has led us to infer that this stage of irregularity is the connecting link between the stages of feebleness and of permanently increased action, and that it consists of the early but yet imperfect efforts of the vascular system to form this latter stage; for when the febrile or inflammatory action is fully formed, the irregularity is no longer perceived.

The decline of power incident to a plethoric state of circulation has not been overlooked by theoretic or practical writers, however they may have failed to mark the order of succession which the phenomena present in the initiatory stage of disease, or to have deduced from these conclusions capable of affording practical guidance. Dr. Gregory, who has faithfully represented the state of physiological and pathological science as they existed when he wrote, notices distinctly both the weakness of the circulating organs and the inordinate burden imposed on them by a state of plethora. "Multa mala à nimia plenitudine oriuntur. Homo nonnunquam fere opprimitur, hebes, languidus, debilis fit, neque ipsa quæ sanguinem movent organa ad tantum onus impellendum valent. Pulsus languet, et aliquando syncope, et vertigo, et palpitatio observantur. Sæpius vero vasa nimis distenta, ad motus præter solitum vehementes et abnormes proclivia fiunt." Here the facts are explicitly stated, but the connexion of the state of debility with that of increased action is not traced, while symptoms, which belong to more advanced periods of disease, and arise from ulterior derangements, are intermixed, creating confusion. And, further, the stage of permanent excitement is regarded rather as the result of over-distention of vessels, than of the stimulus of redundant nutritive matter over-exciting the vital powers.

As the succession of these several stages may be observed taking place naturally, so may the changes be accelerated and displayed by means of medical treatment; for if the constitution be long oppressed, and have long endured the stages of feebleness and irregularity, moderate depletion has the effect of relieving the vital powers, so as to bring on the period of increased action much sooner than it would otherwise occur. This effect is strikingly exemplified by Dr. Watt in his valuable treatise on diabetes; in which he has shewn that the pulse may be raised from the extreme of depression to vigorous action by free bloodletting, and that under this process the blood itself becomes changed from a dark grumous mass, scarcely coagulating, to the blood of active inflammation, with firm coagulum and thick buff. Changes similar to those recorded by Dr. Watt we have had repeated occasion to witness both in diabetes and in cases where no urinary affection existed; and for many years we have been accustomed to refer them to the pathological state of the vascular system which we are now endeavouring to explain. This state also will require further illustration when its practical treatment comes to be considered; but ere we pursue the subject of nutritive plethora further, it is necessary to notice the vitiation to which the blood is liable from its becoming overcharged with the excrementitious matter carried back to it by the absorbents, which in the ordinary course of health ought to be regularly expelled, but which, under impaired energies or interrupted functions of the excretory organs, accumulates in the blood, oftentimes to a considerable extent, vitiating its quality, unfitting it for healthful nutrition, and oppressing and debilitating all the powers of life. The necessity for noticing this state arises from its being continually combined in various proportions with the condition of relative plethora, the progress of which it sensibly impedes, and the phenomena of which it complicates and obscures.

III. In the morbid condition which we are now to notice, the deviation from health takes place still more gradually than in relative plethora. Indeed, so insidious is its advance, that, not producing any immediate or special disease, and marked only by change of aspect and some abatement of wonted powers, it is for the most part overlooked, or at least undergoes no adequate investigation. Combined as it is, too, with relative plethora in every proportion, and by its debilitating effects even ministering to this latter, it becomes confounded with derangements of a character essentially different, and the influence which it exerts both in generating and modifying disease, fails to be recognised. It arises from defective excretion; and as exercise is the natural stimulant for exciting the various excretions to an adequate performance of their functions, this condition more peculiarly occurs in the sedentary and the indolent. It is characterised by great sallowness of aspect and duskiness of skin; the pulse is low and compressible; the surface of the body is in general harsh, dry, and deficient in natural transpiration; the tongue is for the most part moist and clean; the appetite capricious, often voracious; the alvine evacuations are inveterately foul, exhibiting no traces of healthy secretion; the urine is high coloured, depositing a dark sediment, and often very fetid; even the perspiration has frequently an offensive odour, and gives a dusky tinge to the linen which absorbs it. The state here described has not escaped

observation, having been noticed by medical writers, and even ascribed by them to the causes here assigned. Ramazzini more than a century ago represented distinctly this condition of body, as induced in certain artificers by sedentary habits and inactive life, explicitly referring the sallowness of aspect and depraved health, together with certain defœdations of the skin, to the *excrementitious* matter of the body being imperfectly discharged. In his work, "De Morbis Artificum," ch. xxx. he remarks, "Scabiosi quoque decolores, ac mali habitus esse solent sedentarii artifices, sarcinatores potissimum, ac mulieres quæ suis in laribus die ac nocte, ut victum sibi quæritent, acu operantur, hæ enim mala inexercitatos comitantur; nam vitium capit sanguis ni moveatur corpus, *unde illius excrementa in cute restitant, et universus corporis habitus vitiatur.*" Again he states, "Mala igitur intemperie et multa vitiosorum succorum redundantia laborare solent hujus modi artifices, ob vitam sellulariam quam degunt, ac præsertim sutores. Non sic tamen multi alii artifices qui sedendo operantur, uti figuli, textores, qui brachia et pedes, totumque corpus exercent ac propterea saniores sunt, ut *quibus sanguinis impuritates facilius per hujusmodi motum discutiantur.*" Here are represented as distinctly as words can convey, both the accumulation of excrementitious matter resulting from inactivity and defective excretion, and the depravation of habit to which such redundancy gives rise.

The manifestations now noticed as belonging to excrementitious redundancy are intermixed in every proportion with those of relative plethora, the two conditions mutually reacting on each other. Arising, however, as they do from totally different sources, it is highly necessary to discriminate them so as to impute to each what belongs to it, and thus render the practical treatment more definite and precise. No symptom marks the existence of excrementitious excess in the blood more signally than the obstinate foulness of bowels so often encountered in various maladies, and which no employment of purgatives seems to correct. If by their use such relief be given to the system as empowers it to make a febrile or inflammatory effort for impelling blood into the capillaries, renewing more active processes of secretion, and thus ministering to its own relief; if the pulse become quicker and firmer, the tongue white and loaded, with such evidences of increased activity of circulation as to warrant the use of small bleedings, these, if employed with sound discretion, and adapted to the powers of the constitution, will, in conjunction with the excited powers with which they are used to co-operate, do more to correct the morbid condition of the bowels, and thus restore healthy evacuations, than any use of purgatives however judiciously managed or perseveringly employed. This fact we have so often witnessed, that when this state of bowels is found to resist purgative treatment, we have for many years been accustomed to resort to the moderate use of the lancet, as the most effectual auxiliary of purgatives that can be employed. Bloodletting, however, in this morbid condition of the system, requires much caution and a clear conception of the principles on which its employment is founded, to guide its use; for if resorted to at too early a period, while the powers of life are still torpid and inert, or if pushed even a little beyond what those powers can bear, much mischief and formidable exhaustion may result. Some tendency to renewed excitement ought perhaps to be manifested ere the lancet is used; but when this presents, then small bleedings will contribute to rally the dormant powers far more effectually than the most potent tonics.

In the transition here noticed of the sluggishness of system belonging to a state of excrementitious redundancy, into the excited power manifested by febrile action, it cannot fail to be observed how closely the latter corresponds with what has already been described as occurring in relative plethora. In fact, so far as the state of excitement is concerned, the conditions are identical, displaying the same pathological phenomena, and ministering to the same end, the only difference being the modification which any great degree of excrementitious accumulation produces in the actions and symptoms; which after all is a difference more in degree than in kind; for when relative plethora has existed for any time, excrementitious accumulation is sure to become combined, it being the direct product of the debility and imperfect excretion incident to this morbid condition.

The consideration of excrementitious redundancy might with propriety have been included in that of relative plethora, were it not that the separate notice of it renders its nature and phenomena more clear and explicit. For practical purposes, however, the two states cannot in our conceptions of them be disunited, for relative plethora gives rise to excrementitious redundancy; and when any high degree of the latter primarily occurs, it is most probably incapable of correction without the intervention of those sanative efforts which the constitution itself makes when aroused into febrile excitement. To promote these efforts, not merely by exciting enfeebled powers with stimulants, as is too much practised, but by diminishing their labour, and thus rendering them more adequate to its performance, through the cautious abstraction of blood, and the establishment of more efficient excretions, is the process by which the objects of the medical practitioner will, in numberless instances, be best attained. To pursue this course, however, requires unbending integrity on the part of the practitioner, and firm confidence on that of the patient. It is opposed by many prejudices; it works not like a charm, and extravagant expectations of instantaneous results would not be realised. Time is required for its success; it is nature that effects the cure, and her operations are not to be hurried. They, however, who are willing to abide by her slow but sure exertions, and who value the re-establishment of perfect health more than the temporary alleviation of some partial ill, will be amply

repaid in the fulfilment of their more rational desire, so far as it is attainable by human means; and we can confidently say, from the experience of a life which has for above thirty years been devoted to medical science and practice, that the satisfaction which we have derived from witnessing the renovation of health and strength thus effected, has surpassed even that which the signal relief of acute disease by active treatment, and the consequent saving of life, has ever afforded.

Treatment.—We proceed now to consider the practical treatment of the three several conditions to which we have directed attention, namely, absolute plethora, relative plethora, and excrementitious redundancy.

1. *Absolute plethora.*—In this condition, including the diseases to which it gives rise, we may trace three progressive stages. The first embraces the period which precedes febrile or inflammatory excitement; in the second, febrile excitement exists unaccompanied by any prominent local affection; and in the third is superadded some local inflammation, or other partial derangement, constituting what is usually deemed a specific disease. When the latter arises, it no doubt reacts on the constitution, aggravating the several disturbances in proportion to the importance and the degree of derangement of the organ or function specially affected. But if the series of morbid actions here represented be that which nature follows, it is clear that they are much in error who ascribe what is miscalled sympathetic fever to the local disease coexisting, which, instead of exciting the attendant fever, is only its direct product.

The phenomena which mark the incipient stage have been already noticed and explained; and it was stated generally that the proper treatment for correcting this morbid condition consisted essentially of depletion to remove the plethora, and abstinence to prevent its recurrence. And this treatment, if timely employed, would always suffice. Indeed, in the very early periods, abstinence alone would, by cutting off the supply of inordinate nutriment, give effectual though slower relief. But were this otherwise, inasmuch as they who become so affected are still considered as enjoying perfect health, it would be useless to lay down rules of treatment to which none would be likely to resort or conform. Indeed, we should be reluctant to lay stress on this initiatory stage, if doing so were to induce any suspicion of a wish to bring under medical discipline those who probably exult in their not requiring its unenviable interference. Even if it were in our power, therefore, to arouse every such individual to a full sense of his approximation to disease, and of the dangers to which this exposes him, we should hesitate to give rise to such incalculable misery as a perpetual watchfulness over the feelings of health could not fail to occasion; for though many might, by timely precaution, avert diseases that would otherwise ensue, the constant anxiety to which numbers would be unnecessarily consigned by the prevalence of such impressions, however correct, would greatly counterbalance any good that could result. It is of consequence, however, that medical men should have a just conception of this state when subjected to their observation, so as not to be misled by delusive appearances; and it is of the highest importance, when, as continually happens, acute and dangerous maladies have a tendency to return, to be aware of the premonitory signs that mark an approaching accession, so as to employ in time the means necessary for averting its recurrence. To precautions of this kind, as formerly mentioned, the writer was indebted many years ago for his own preservation and reestablishment of health; since which period he has had ample opportunity of proving, by extensive application of the principles now inculcated, the value and efficacy of such timely prevention.

When the stage of disease now under consideration is subjected to medical treatment, the means of relieving it are simple in the extreme, consisting only of moderate bloodletting, occasional purging, and reduced diet, with a speedy return to such exercise as may be required for keeping the several secretory and excretory organs in the adequate and healthful discharge of their functions. By these means, pursued without any sensible impression on the general strength, and scarcely an interruption of ordinary avocations, may this condition be effectually relieved, and the dangers to which it leads successfully averted. It may conduce to accuracy of conception to explain here what is meant by *moderate bloodletting*. The object is to remove a certain portion of the circulating fluid in order to diminish the proportion which the nutrient matter bears to the watery solvent. This latter is so readily absorbed and carried into the circulation, that the actual volume of the blood becomes speedily restored. For the relief of incipient plethora it will in general suffice to abstract twelve or sixteen ounces of blood at a time, the evacuation being repeated as circumstances may require, both the amount and the repetitions being dependent on the individual constitution. In the case of the writer, when suffering under this stage of plethora, much larger depletion was required; above thirty ounces being often taken from the arm without the evacuation being otherwise felt than in the relief which it afforded. If the necessary relief happened to be postponed, so as to approach the period of active fever, the bloodletting required to be of still larger amount. At such time there was generally some uneasy sensation, caused by certain local determinations of blood to which the writer was subject; and when this existed, blood was usually suffered to flow without regard to quantity, until the uneasiness subsided. If the evacuation stopped short of this effect, the relief was incomplete, and a speedy repetition of venesection was sure to be required, and to a greater amount. From this free use of the lancet, guided as it was by a definite purpose, and bounded by certain limits, though these were not measured by quantity, the writer never in any instance suffered injury such as is so often ascribed to large bleedings, and he is

quite satisfied that by observing the rule which has been stated, more effectual relief was obtained, and that morbid actions were restrained with less ultimate loss of blood, and less prostration of general powers, than if blood had in the first instance been sparingly taken.

The principle of carrying bloodletting to the extent of making some impression on the constitution, and thus arresting the progress of morbid action, we shall have to consider more fully when we come to treat of its employment in active inflammation. We may here, however, cursorily remark, that when morbid actions of an inflammatory kind prevail to such extent as to demand direct depletion by bloodletting, effectual relief is not afforded unless the sufficiency of the depletion is manifested by some impression on the vital powers; for under high and active inflammation, twenty, thirty, forty ounces or more, may be abstracted without making any impression, when the loss of a few ounces more will, by inducing a disposition to syncope, at length arrest completely the inflammatory action, and repress the violence of disease. In such case, if the depletion be regulated by regard to the quantity of the blood taken rather than the effects resulting; and if from vague apprehension of injury it stop short of that relief which ought alone to set limits to it, the morbid action is left unsubdued, and much greater loss of blood is required eventually to allay it; and this with considerable risk of its then failing to accomplish its end; for independently of the hazard of allowing inflammation to continue in any organ essential to life, it should ever be borne in mind that in proportion to the time during which morbid action of this kind is suffered to continue unrestrained, will be the difficulty of finally subduing it; and consequently, that whenever active inflammation arises, it can never be too soon nor too effectually arrested.

From ample experience of the correctness of these views, we have long been convinced that when active inflammation occurs in a robust and vigorous frame, copious depletion in the earlier stages is the surest means of saving animal power and of accelerating perfect recovery. In the initiatory stage of plethora, however, such active measures are not needed. The object here is to reduce the quantity of blood as the most direct means of altering its quality; there is no inordinate action to subdue; and however moderate the depletion, it must give relief proportionate to its extent, the ground gained being afterwards maintained by other evacuations and abstinence. But when, from continued or increasing plethora, the second stage or that of febrile action ensues, then the principle which we have noticed becomes directly applicable. When the oppressed pulse passes into a state of irregularity, and thence into one of permanently excited action, as manifested by a quickened circulation, hot skin, and white tongue, active depletion becomes necessary, and it requires to be regulated on the principle now stated. At this time, too, other auxiliary remedies are needed. Of these purging is the most direct and most powerful, and saline purges, which produce copious watery discharges from the bowels, are among the most effectual. Several neutral salts and antimonial preparations are also valuable, as cooperating in the general purpose by the increased secretions to which they incite the kidneys and skin; and by the judicious administration of these several remedies, in conjunction with low diet, may this second stage in general be promptly and effectually relieved. The mode of exhibiting these remedies is so familiarly known and so continually practised in the treatment of the several phlegmasiæ, which so much prevail, that it would be superfluous here to enter into further details.

When local inflammation becomes superadded to the febrile excitement, we have then to consider not only the general plethora and febrile condition of the system, but also the state of the organ or part locally affected. If it be an organ essential to life, then the utmost activity of practice is required to guard against the danger arising from its functions being suspended or impeded, and from the disorganization of structure which continued inflammation is sure to induce.

It would exceed our province to notice here every local inflammation with which a predisposed body is liable to be assailed. For the purpose of illustration, therefore, we shall confine our remarks to two of the more urgent, and, by particularizing the treatment which they require, exhibit the principles of practice so clearly as to render them easily applicable to every corresponding case that can occur. With this intent we shall select two organs of primary importance, the brain and the lungs. When active inflammation of either organ is manifested by its appropriate symptoms, the necessary treatment must be promptly and vigorously applied, for the danger arising from suspended or impeded function is considerable, and both the obstinacy and danger are enhanced in proportion to the delay of the necessary depletion, and the insufficiency of its early employment. If bloodletting be not early and vigorously employed, such derangement of structure may quickly ensue as to destroy life, or permanently unfit the organ for the discharge of its ordinary functions. The effect of bloodletting in this case is twofold; by the quantity of blood abstracted it diminishes plethora, and by its influence on the moving powers it moderates or subdues the arterial actions by which inflammation is upheld. As inflammatory action in such cases cannot be too soon arrested, and as suddenness of depletion greatly promotes its speedy effect on the moving powers, the blood should be taken from a large orifice, in a full stream, and with the body erect. To be effectual, the depletion should be carried to the extent of making sensible impression on the local symptoms of either head or chest, and this will be found to coincide almost uniformly with abated action of the artery as felt at the wrist. When under the flow of blood the pulse falters, the lips become pale, and the face be-

dewed with perspiration, bloodletting may be confidently relied on for yielding all the relief which this truly potent remedy is capable of affording. The quantity necessary to produce this effect varies greatly. The writer has himself lost from forty to fifty ounces at one bleeding, and has nevertheless required a repetition to smaller amount within a few hours. We have known much larger bleedings employed in urgent disease with only salutary effect and without a single bad consequence resulting. As cases of extreme violence are those in which inadequate depletion would prove most fatal, it is necessary to notice the amount to which bloodletting may under urgent necessity be safely carried. Happily such cases are not the most frequent, and in the more moderate instances which most prevail, evacuations much more moderate will suffice. When by one or two bleedings, so conducted as to make impression on the moving powers, the more urgent symptoms are alleviated, the repetitions may then be regulated so as to keep within the bounds of all possible risk of excess.

If the plethora be considerable and the fever continue high, it may still, even though the local symptoms have yielded, be requisite to take more blood, so as to bring back the circulation to a healthy standard, and subdue remaining excitement, or relapse of inflammation may occur. By such means, combined with the auxiliary remedies already noticed, and assisted by the topical treatment suited to each local disease, a state of the most imminent danger may be speedily changed to one of perfect safety, provided organic lesion has not yet taken place.

The practice here inculcated may possibly appear to some bold and hazardous, but we can confidently appeal to the experience of those whose opportunities of treating active inflammation have been greatest, for the soundness of the principles which we advance, and for the perfect safety of the measures enjoined. We willingly admit that the ordinary course of medical practice may be carried on by less active treatment, for a large proportion of ordinary cases requires no more; but when urgent disease occurs, the attempt to dispense with proportionate activity of treatment can lead only to fatal results or tediously protracted disease. We have purposely dwelt on the severe rather than on the milder instances, in order to shew more clearly and forcibly what the principles are on which the treatment should be conducted. As the symptoms of each case, and the constitution to be acted on, denote the activity required, and thus guide the practitioner in the use of his remedies, there can be little hazard of the representations here made misleading any one into a rash or excessive use of bloodletting.

It may not be amiss here to take notice of two consequences, either of which may attend a very full bloodletting, namely, syncope and convulsion. They are prone to occur when much blood is taken, and especially when the patient is bled in an erect posture. There seems little room to doubt that both arise from the vessels of the brain being too much emptied, the enfeebled action of the heart being insufficient to re-fill them; and, as is familiarly known, recumbency of the body, which allows the blood to return to the brain with less of the heart's impulse, is the direct, and, we may add, uniformly effectual remedy. It has happened that patients bled to syncope have not revived; but this has been of rare occurrence, and when it has taken place, we should strongly suspect that blood must have been drawn beyond all prudent bounds, or that the propriety of taking any blood was questionable. We have witnessed many instances both of syncope and of convulsion, and can truly affirm that we never saw a single case in which injury of any kind resulted. We are no advocates, however, for bleeding to syncope, and never direct it, although, if urgent disease were to be arrested, we would go to the verge of it, for the reasons already assigned. Convulsion is an effect more formidable in appearance than syncope; and yet, though we have frequently seen it so induced, we have never known harm attend it. In its effect of lowering arterial action, we regard it as perfectly analogous to syncope, and for all that we have seen, equally innocuous. Yet, as it is always alarming to the bystanders, and as neither it nor syncope is necessary to ensure the full effect of bloodletting in subduing inflammation, we would willingly avoid both. There is a caution which we wish here to suggest to those who may have occasion to draw blood largely, namely, never to leave a patient so depleted until placed in a recumbent posture. The following case, of recent occurrence, will illustrate what we mean. We were requested to visit a man who had been seized with apoplexy some hours before. We found that he had been promptly bled, and to a large amount. The quantity of blood which we saw could not be under seventy ounces; it was thickly buffed in the earlier drawn portions, and we saw no reason to doubt the propriety of its abstraction. Having bled the patient, the medical attendant, pressed by other engagements, went away, directing him to be placed in bed as soon as possible. Circumstances prevented this being done, and when we arrived he was still sitting in the chair in which he was bled, held there by four stout men, whose united efforts were required to restrain the horrible convulsions which recurred every quarter of an hour or twenty minutes: he had been in that state for nearly two hours! His countenance was ghastly, the eyes glassy, lips livid, and breathing irregularly laborious. We had him instantly laid on the ground, and as speedily as possible transferred to bed; nothing more was required, for circulation soon returned, the pulse again became distinct, the countenance calm, with returning colour to the lips, and the breathing tranquil. This was an extreme case, being by far the worst we had ever witnessed. The bloodletting was unusually large, and severe convulsions continued at intervals for nearly two hours, owing to the im-

prudent continuance of the erect posture. Yet so little injury did this man suffer, that in less than ten days he walked to his physician's house, free from complaint, to thank him for having visited him.

It should be recollected that in the practical remarks hitherto offered, we have had in view inflammatory complaints only as they occur in absolute plethora, consequently in their most active and violent degree. In this state they require large depletion, and there is always ample power to sustain it, the danger being that of falling short of the quantity necessary, rather than of exceeding it. Diseases of the same species, however, occur in every condition of the system, and according as they take place in feebler constitutions, and are marked by less violence of symptoms, may measures of less energy be trusted to for their relief. It is from not noticing the differences of constitution or the degree of general plethora present under attacks of local inflammation, that so much diversity of opinion has prevailed among medical practitioners respecting the extent of depletion required. From peculiarities of local districts some practitioners never encounter diseases of this violence. They accordingly find that copious depletion may be dispensed with—that, if employed, it sinks the powers of life, and lessens the chance of recovery, and thence they somewhat hastily conclude that the active treatment pursued by others is rash and unnecessary. Diseases of this languid character may be supposed to prevail most in large and crowded cities, where the habits of life are sedentary and luxurious, and where inflammatory complaints are connected more with relative plethora than with absolute. Perhaps London may be taken as the best exemplification of this remark, and it is very generally believed that there the corresponding diseases do not bear the activity of treatment which the provincial practitioners find indispensible. We have it asserted, however, from high authority, that this is a misconception, and that no such difference exists, at least to the degree represented; for that London citizens both require bleeding as freely and bear it as well as the residents of any other district. The subject, however, will come more appropriately into the next section.

2. *Relative plethora.*—This variety being of more frequent occurrence than absolute plethora, and having connected with it a greater number of diseases, the consideration of it is still more important, and entitled to closer attention. In it, too, the progress of morbid action is more gradual, and the constitutional efforts to rectify existing derangements are more varied and more general. Hence the character of the disease produced by or incidental to this condition is complicated, and their elucidation proportionally difficult.

The earlier phenomena, being less conspicuous, attract less attention, and the equivocal character which they frequently present being liable to misconception, it becomes important to illustrate clearly the real nature of this condition, to exhibit distinctly the phenomena which characterise it, and to point out accurately the practical treatment suited to its relief, in order to prevent the highly injurious practical errors to which misconception in this respect so continually gives rise.

In relative plethora, as in absolute, the earliest deviation from health is marked by evidences of diminished power in the general circulation. The pulse becomes low and oppressed, and the general powers enfeebled. When from natural feebleness of constitution, or the absence of excitement, this incipient stage is prolonged for any considerable time, the impaired energies and deficient exercise of the several excretory functions give rise to more or less of excrementitious accumulation, and a combination of these opposite conditions results. More frequently, however, this stage passes into that of increased action, and some congestion, inflammation, or other local malady becomes manifested. A hard and frequent pulse, increased heat of skin, and whiteness of tongue, mark the formation of the second stage; and if in moderate degree, and unexasperated by stimulants, this may, in constitutions not predisposed to any particular malady or local lesion, continue for months or even years without any specific disease ensuing, and with only progressive deterioration of general health. We have so often met with this state clearly characterized, that we have been in the habit of distinguishing it by the term *constitutional inflammation*, meaning thereby to designate general inflammatory action in the system unattended by local inflammation.

All the phenomena which belong to this stage are of an inflammatory character. Blood drawn frequently exhibits a thick buffy coat, with cupped and with contracted edges, and the treatment of inflammation is that which alone affords effectual relief. If taken at an early period, moderate depletion and antiphlogistic regimen will speedily correct it; but if neglected or improperly treated by tonics and stimulants for any length of time, it becomes more difficult to remove, acquiring obstinacy from its continuance, and through the congestions and local determinations which are prone to occur during its progress, laying the foundation of various specific diseases of the worst kind. The treatment of the several stages requires to be discussed at some length, and copiously illustrated.

Absolute plethora in its simplest form and earliest stage may be relieved by artificial means, without any excitement of the system being necessary to co-operate in the restoration of health. This the writer has unequivocally experienced in his own person, and he has thus been enabled to satisfy himself of a fact which is not often subjected to medical observation. In relative plethora it is questionable whether the capillary congestions, and other derangements of minute structure and function attendant on this condition, be removable without some sensible effort of the constitution, and whether febrile excitement in some degree be not a necessary agent in effecting recovery. That it is often contributory to this end, we enter-

tain no doubt. These observations have direct relation to the practice suited to the several stages. Should the earlier of these, in consequence of the decline of health to which its long continuance gives rise, come under medical cognizance, sparing depletion to lessen the redundancy, with moderate excitement to arouse the energies of the system, will be the most judicious and suitable treatment. Under extreme feebleness of pulse and great muscular debility, it may be prudent to commence with gentle excitement, watching carefully the time when increased action in the pulse manifests that renewed energy which will both justify and bear direct depletion. We are certain from much observation, that when the pulse becomes irregular, blood may be taken not only with safety but advantage, and that the relief afforded will be speedily manifested by the increased fulness and tone which the pulse acquires. For this purpose the earlier bleedings should be small; from four to six ounces may suffice to commence with. The repetitions will of course depend on the effects, and it is a subject of interest inferior to none which pathology presents, to mark in the extreme cases of such condition how progressively under repeated venesection the pulse rises, and the buffy coat is displayed on the blood. Some striking instances of this we have recorded in another place. In an enfeebled and emaciated boy labouring under diabetes, 209 ounces of blood were drawn in twelve successive bleedings, the blood becoming changed from a dark grumous coagulum of loose texture to the thickest and firmest buff; and the strength of the body increased from feebleness hardly admitting of an erect posture, to a degree of vigour which enabled him to hold the plough for several hours a-day. It may afford a clearer conception of this condition, and shew the ability which the body acquires through bloodletting of bearing copious depletion, to present here a tabular view of the successive venesections practised in this case, with their amount, intervals, and the character of the blood drawn.

No.	Date.	Amount.	Quality of blood.	Total amt. at each period.
1,	Nov. 6,	12 oz.		12 oz.

In another case, of a weakly and delicate female, without any special disease or local ailment save pains irregularly alternating in the head and chest, 106 ounces were taken at seven bleedings, with similar changes of blood, and as well-marked improvement of general strength. Such instances must be deemed conclusive of the fact that the state of constitution which we are endeavouring to illustrate has a real existence. In these cases the early symptoms were those of seeming debility; yet if this had been such as is generally imagined, life must have been inevitably destroyed by the means employed. If, then, there are states of disease marked by considerable debility, in which the constitution not only bears depletion without sinking, but acquires very considerable accession of strength under copious evacuations, it surely must be of the first importance to medical science to scrutinize such conditions of the system, and acquire juster notions of its real nature than are generally entertained.

When by the judicious combination of small bleedings and moderate excitement, assisted by other evacuations, the system is aroused to greater energy, and a state of febrile excitement ensues, the treatment of this must be conducted on principles with which all are familiar. When a hot skin, quick pulse, and furred tongue present, no practitioner is deceived, or fails to resort to proper remedies. Our great object is to direct attention to the earlier and more obscure stages, to shew their connexion with the febrile state, and to demonstrate the correspondence which prevails in the treatment which they respectively require. The earlier the advance of such disease can be detected, the less will the interposition of art be needed, and the more effectual will it prove both in correcting the febrile state, and averting the local injuries which continued febrile action will always sooner or later induce. There are occasions when this vigilance in detecting the incipient deviations from health is of the very first importance; a signal instance of which we shall briefly notice, as illustrating what it is wished to impress, and as proving the soundness of the principles by the efficacy of the treatment which they dictated, perfect recovery having taken place under circumstances which seemed to augur a very different result. A young woman applied to the writer above three years ago with ovarian tumour, accompanied with great inflammatory action both local and constitutional. Active treatment was employed, and the progress of the disease arrested. Continued attention, however, was required to keep down inflammation, and both bleeding from the arm and cupping were in constant requisition. Auxiliary means were freely employed, but bloodletting was the remedy which gave most decisive relief. So sensible was she of the advantage, and so intelligent in noting the premonitory indications which marked the necessity of depletion, that she was accustomed to ask for the lancet or cupping-glass, specifying her reasons for thinking they were needed; and on these occasions she was invariably right. To detail minutely a case which was subjected to medical discipline for so long a time, would be tedious and unsuited to our present purpose. It may suffice to say that the constitutional state tended throughout to inflammatory action, and that by the fluctuations of this the local disease was influenced. The tumour advanced so as to form a consi-

derable prominence in the right hypogastrium. Cupping, leeching, blistering, were all employed, and eventually a caustic issue was established over it. So much relief was obtained that she was occasionally discharged from the hospital in order to recruit her general health. After a short absence, however, she was sure to return with renewed disease both local and general. It being sufficiently manifest that the local excitement was always preceded by febrile action, the propriety of looking closely after the latter was apparent. If fever was not speedily arrested, the tumour became active and increased; when by early bloodletting febrile action was reduced, the tumour remained quiescent. Early bleeding was therefore the remedy most worthy of reliance, and it was resorted to accordingly, with due caution, but determined perseverance. And here we were happily assisted by one well-marked evidence of renewed plethora and approaching fever that never deceived us. Ere pain was felt in the seat of disease, or any of the ordinary indications of fever presented, a dark narrow dry stripe appeared on the centre of the tongue. If this were unheeded, it soon expanded at the tip, and spread slowly towards the edges. By a moderate bleeding this was promptly removed, and its sure attendants, general fever and local pain, were averted. By steady perseverance in the treatment here noticed, all disease was eventually removed; and within these few days we have seen this person in perfect health, and without a vestige of tumour remaining. We have no hesitation in attributing the fortunate result to bloodletting, and also to this being regulated on the principles which it is the object of this essay to inculcate. We may add that it never required to be carried to the extent of making even a temporarily injurious impression on the general powers of the constitution.

We have stated that the stage of febrile excitement is preceded by certain changes in the pulse indicative of its approach, and also that we are not under the necessity of judging solely from this evidence, for that other derangements coexist, which evince a harmony of symptoms, and that the whole collectively furnish indisputable proof of the actual condition of the vascular system. On the peculiarities of pulse we are not anxious to dwell, further than to give a seasonable warning that they be not suffered to bias the judgment through fears of an unreal debility. In judging of the approach of febrile excitement we are accustomed to rely more on the state of the tongue than on that of the pulse. When the constitution is assuming a disposition to febrile excitement, ere this is announced by the pulse, still feeble and compressible, the tongue presents a peculiar whiteness strongly characteristic and expressive, being distinct from any apparent secretion, and obviously resulting from some defect of capillary circulation in the tongue itself. This whiteness we have often seen disappear under bloodletting ere the arm was tied up. To describe it more particularly would be useless; to be known it must be seen, and they who are accustomed to inspect inflammatory tongues will at once recognize the condition to which we allude. We know not a stronger or surer evidence of incipient febrile excitement than this appearance of the tongue presents, and when it exists we should consider some abstraction of blood both justifiable and necessary. It appears, then, that bloodletting is suited to each stage of relative plethora. In the stage of feebleness when long protracted, small evacuations of blood relieve the oppressed constitution, thus enabling it to form the stage of febrile excitement which seems so necessary an agent in correcting the several derangements of the system. When used for this purpose, the early depletions should never be large, from four to six ounces being oftentimes as much as can with propriety be taken. According as febrile excitement advances, more copious depletion will not only be borne but required. The object of the incipient bleedings is not to make that impression on the moving powers which is necessary for the abatement of inflammatory action, but merely to abstract a portion of the circulating fluid, and thus lessen the plethora by which the system is oppressed. The blood may therefore be taken from a small orifice and in a recumbent posture. According as the period of excitement approaches, the effect of depletion in hastening its advancement becomes more manifest; and indeed it is a matter of familiar observation to surgeons, that even while the blood yet flows from the vein, the arterial powers so sensibly increase that the tardy and sluggish stream, which at first only trickled down the arm, becomes converted to a full and vigorous jet, the blood being oftentimes propelled to a distance of several feet. When this degree of increased action is displayed, blood may be more freely taken, and antiphlogistic treatment more rigorously pursued.

During the advanced stage, the object of venesection is both to abstract blood and to moderate inflammatory action by the direct impression which this remedy makes on the arterial system. Wholly or suddenly to subdue this action is not here intended, unless there be also local inflammation of a hazardous kind. The abstraction of eight or ten ounces will often suffice; that of twelve, sixteen, or even twenty will very frequently be well borne.

When local inflammation is superadded, then the extent and frequency of bloodletting must depend on the urgency of symptoms present, the importance of the organ principally affected, and the danger of this sustaining injury such as would be either immediately fatal to life, or ultimately subversive of health and vigour. Though in this state of constitution bloodletting is the remedy most essential, and which most effectually arouses the sanative energies of the system, yet other means are required for co-operating in the general purpose, and for re-establishing the several functions of life in their healthful and efficient exercise.

Next in power to bloodletting as an evacuant is purging, and this requires to be employed

with much discrimination, if the full benefits of it are to be obtained. The objects of it here are both to deplete the system, and to restore to healthful efficiency the excretory processes connected with the alimentary canal, which, in the early stages of relative plethora, are always inadequately performed. Simple as the process seems to be by which the bowels are evacuated, we scarcely know a term in medicine more vaguely employed than that of purging. It is continually used to express processes essentially different, and which require to be accurately distinguished from each other. By observing closely the effects of different purgatives and the nature of the discharges produced by them, we may perceive some well-marked differences in their modes of operation. Those of one class simply evacuate the feculent contents of the bowels; those of another excite the various exhalent arteries, producing watery stools; and those of a third stimulate the mucous follicles which so abundantly line the intestines, causing them to throw off the mucus which they so copiously secrete. When the bowels are merely inactive, their secretions healthy, and no constitutional disease present, the simple aperients of the first class suffice to obviate costiveness and prevent feculent accumulations. Medicines of the second class are indicated, when, besides unloading the intestines, it is expedient to abate arterial action, or allay fever by abstracting fluids from the system. Those of the third are required when mucus, inordinately secreted, accumulates so as to clog and obstruct the secretory vessels themselves, and also when this accumulated mucus, acting as a foreign body, becomes instrumental in exciting or aggravating disease. The particular medicines belonging to each class will readily present themselves to every practitioner, and need not here be specified; neither is it important to distinguish them by any very accurate arrangement. The same medicines will act differently on different habits and under different circumstances, and it is the effect, not the medicine producing it, that is the chief object of consideration. On the simple aperients we have little to remark; they form a most useful class of remedies, and may be combined with the second and third classes, so as to assist in producing every species of alvine discharge. The several aperient neutral salts are well known as the principal purgatives for producing watery stools. When increased discharges of mucous secretions are required, our chief reliance is on certain preparations of mercury and of antimony. The stomach, forming part of the alimentary canal, requires itself to be occasionally unloaded, which is effected by emetics. And here too we should distinguish between those emetics which simply discharge the floating contents of the stomach, and those which cause it to throw off increased mucous secretions. Even though vomiting be not resorted to, the mucous secretions of the stomach may yet be expelled by combining with purgatives such preparations of antimony as have an emetic operation. Consistently with these views it would appear that the most perfect evacuation of the whole canal must be that procured by combining medicines of each class, and accordingly we find the purgatives in most general use so constituted. When full purging is required to allay fever or lessen arterial action, no practice is more common than to give at night a suitable dose of extract of colocynth or of aloes, which are simple aperients, combined with calomel and antimony, medicines that expel mucous secretions, and followed next morning by a saline purgative, which, while it accelerates the operation of the previous dose, produces also copious watery stools. When these latter are not required, but yet a state of disordered intestinal secretion is manifested, it is often expedient to correct this latter gradually, the nature and activity of the cathartic employed being suited to the particular design; and whether it consist of colocynth, calomel, and antimony, or of rhubarb, blue pill, and ipecacuan, the same principles govern its administration, and similar effects, differing only in degree, are produced. With these principles to guide the employment of purgative remedies, they may be so administered as to prove most powerful auxiliaries of bloodletting in the several stages of relative plethora. In the earlier stage, simple aperients, combined with mild doses of mercury and antimony, are the most suitable. According as the febrile stage succeeds, saline purges may be more freely employed; and when fever becomes active, or local inflammations arise, these are indispensable. In proportion as the mucous secretions are accumulated or depraved—and they become signally so whenever the earlier stage of relative plethora has been of long duration—then must those combinations be employed which most effectually deterge the loaded membrane, and restore the secreting vessels to their natural condition.

A consideration of the several changes that take place in the body under febrile excitement, and a more minute observation of the immediate effects produced by increased arterial action on the several secretory and excretory organs, will shew the value and importance of purgatives in a still clearer point of view, and lead to a more discriminative employment of them.

A certain degree of arterial action being necessary to the healthy exercise of the secretory and excretory functions, it might be reasonably supposed that increase of such action would lead to a more energetic performance of these functions, and increased formation of what they respectively secrete,—a supposition which the evidence of facts amply confirms, one of the earliest effects occurring in a state of febrile excitement being an increased secretion of the natural mucus which lines the stomach and intestines. Of the existence of such superabundant mucus during inflammatory complaints sufficient proof is afforded in the discharges brought off by appropriate evacuants, or occasionally by the natural efforts. With respect to the stomach, if the examination of its rejected contents be superficial, it may mislead, for the mucus, if of recent secretion, being clear and

colourless, is not readily distinguished from the surrounding fluid. Its tenacity, however, furnishes a ready means of detecting and demonstrating it, for if a rod or wire of any kind be drawn through it and elevated, it will raise from the watery fluid, discharged by vomiting, the mucus diffused through it, and sufficiently display its dense and viscid nature. Similar secretions go forward at the same time through the whole intestinal canal, as evinced by the quantity of mucus which a dose of calomel, or of calomel and antimony, administered under these circumstances, expels. And to the power of these medicines in dislodging such secretions is owing much of the efficacy so long and so justly attributed to them in the cure of acute diseases. The increased secretions proceed immediately from the greater activity of the secerning vessels. These again derive their excitement from the greater abundance and more stimulant quality of the blood conveyed to them; and the effect of their increased action is to correct the stimulant property of the blood, by disposing of the nutritive constituents which render it unduly stimulant, and thus to allay indirectly their own inordinate actions. Hence the relief of the constitution by means of the improved quality of the blood may be fairly considered the final cause for which these secretions are increased, for which febrile excitement is generated. In this view we can perceive the importance of purgatives, not only as general evacuants, but also as specially promoting those curative efforts by which nature herself endeavours to throw off redundancies and minister to her own relief.

The want of sufficient attention being given to the peculiar effects produced by different purgatives may account for much of the uncertainty and indecision that have prevailed in the employment of them. This part of medical practice, indeed, has been much improved of late years; and the labours of several modern writers, of whom Dr. Hamilton and Mr. Abernethy are preeminently distinguished, have done much to assert for it the importance due to it. Still much remains to be investigated respecting it. If the mucous matter be recently formed, and in no great quantity, a common purgative will suffice to remove it, together with all such feculent lodgements as the bowels may contain. A source of injurious irritation is thus removed; the various secretory and excretory vessels are disencumbered of an oppressive load, and left free to perform their natural functions, or to renew their sanative efforts; and the process of nature instituted for the removal of redundancy and restoration of health goes uninterruptedly forward. If the mucous secretions be of older formation, consequently more viscid and tenacious and less easily expelled, the common purgatives fail to give relief, and a doubt is thus often cast on the propriety of employing purgative treatment. The patients may be misled, as many continually are, by false experience; but the practitioner should not fall into this error. The fault lies not in employing purgatives, but in not suiting those given to the effect required; for if a suitable preparation of mercury or antimony be in such case combined with the simple aperient, the result will rarely occasion disappointment. If saline purgatives be given with the intention of cleansing the intestines at a time when they are coated with viscid secretions, the purpose will be very imperfectly answered, while, if persevered in when general evacuation is no longer needed, and there is no febrile action to call for their use, they fruitlessly exhaust strength and do sensible injury. Even the powerful remedy which a combination of calomel, antimony, and drastic purgatives supplies, may be misapplied, and if rashly given when the bowels are irritable, with little mucus present, distress and injury may result, and an useful remedy thus fall into unmerited disrepute. In fine, by neglecting to ascertain the precise nature of the evacuation required, and to apply with accuracy the remedy suited to effect it, we must ever run considerable risk of disappointment in the effects expected from purgatives, and of so misapplying them as really to do injury in cases where purging, judiciously regulated, is the best if not the only means of cure. The quantity of mucus secreted in the stomach and intestines under febrile excitement, which implies a general increase of vascular action, is often considerable. It lines the whole canal, and when accumulated (and more especially when inspissated by long retention) is the cause of many powerful medicines passing through without producing their ordinary effects; for in consequence of the interposed mucus, the medicines come imperfectly or not at all in contact with the living fibre on which alone they can act. They pass, therefore, as if either the living fibre were torpid or the medicine inert, when neither supposition would be correct. This is signally the case with respect to the stomach, the accumulated mucus of which is often thrown off like a dense membrane. In this state of stomach we have oftentimes given tartarised antimony in grain doses quickly repeated to the extent of twelve or fourteen, ere vomiting could be excited, the matter discharged furnishing abundant evidence why such inordinate quantity was needed. We mention the circumstance here in order to enforce the expediency of judging on all occasions, not from the quantity of medicine administered, but from the effect produced; and, as the principle applies no less to the bowels than to the stomach, to impress the indispensable necessity of a constant inspection of the alvine discharges, without which it is impossible to form an accurate judgment either of the propriety of purging, the selection of purgatives specially indicated, the extent to which their operation should be carried, or the period for which their use should be continued.

It has been shewn that the derangements of circulation incident to a state of plethora, whether absolute or relative, manifest an uniformity which serves to mark the nature of the morbid changes induced, and to illustrate the processes which nature institutes in her endeavours to effect her own relief. Redundancy of nutritive matter first excites the healthy functions to in-

creased energy, tending to its appropriation by natural secretion: when too much urged this energy abates, and feebleness of arterial action ensues; to this succeeds a state of general excitement, such as is expressed by the term fever; and finally, some local congestion or inflammation occurs, producing what is called a specific disease. From this view the dependency both of the general fever and local affection on the constitutional state is at once perceived; and the treatment by which these are severally relieved acquires thence a clearness and consistency which no speculative theory of disease has ever yet imparted. For absolute plethora in its simple state, it has been shewn that depletion and abstinence, the remedies directly suggested by a knowledge of its cause, are those which experience proves to be most efficient, and which may alone give full relief. For the active fever and local inflammation induced by this condition, the same means are essential, and are still the most powerful of all that can be employed; though when these derivative maladies occur, other evacuations besides that of blood are needed, it being here required to call forth the energies of all the excretories of the system in aid of those constitutional efforts by which the febrile excitement is aroused. In relative plethora the morbid condition of the system is less simple, yet it still corresponds with the other throughout. Owing to the duration of morbid actions antecedently to the occurrence of febrile excitement, the constitutional derangements are more extensive; more functions are depraved; the difficulty of restoring these severally to a healthy state is increased; and a longer time is required to correct their aberrations and renovate their powers. During this period, too, various disturbances, originating in depravation of nervous function, become intermixed with the ordinary symptoms, complicating and obscuring the whole. To these latter we shall have occasion to advert more particularly by-and-bye. In absolute plethora the purpose is simple. If the redundancy of nutriment be diminished, and a fresh supply withheld—in other words, if bloodletting and abstinence be carried to the requisite extent, the powers of nature, thus relieved, are amply sufficient to re-adjust all that is amiss, and perfect health becomes restored.

No artificial stimulus is here needed to arouse the natural powers; but, on the contrary, the chief care is to restrain them within salutary bounds. In relative plethora, while depletion and adaptation of diet are equally necessary as in positive, more care is necessary for maintaining in due activity the several secretories, and some degree of stimulant treatment requires to be combined, in order to excite and support those increased energies of the system by which alone this condition can ever be thoroughly rectified. Ordinary stimulants, however, which merely excite the heart and larger vessels, are inadequate to this end. Nay, they do mischief; for they lead to no effectual exercise of power, and from that which they do excite, exhaustion rather than benefit results. The great deficiency of power which here prevails is in the capillary vessels, and to depravation, abatement, or suspension of their functions, may all the coincident derangements of the frame be readily traced. The two most essential processes of animal life are nutrition and excretion. These are exclusively performed by capillary vessels, on the due energy of which they are dependent. When from any debilitating cause these minute vessels fail in power, or become obstructed, both nutrition and excretion must become impeded; and hence we can understand why emaciation often takes place, even where there is a redundancy of nutritive matter in the general circulation, available for nutrition if the capillaries could so dispose of it. It is hence also intelligible, how a debilitating impression made on the system has, through abatement or suspension of the capillary function, the direct effect of throwing back on the mass of blood that which in ordinary course the capillaries would have disposed of, and of thus inducing a state of relative plethora. It is clear from this view, that the object of treatment in relative plethora is not merely to remove the relative excess, although this demands its full share of attention; but also to renew the activity of the capillaries, in order, first to re-establish their healthy functions as essential to the well-being of the general constitution; and secondly, by thus providing for the just appropriation of the nutritive matter supplied by the blood, to restore that balance between appropriation and supply without which health cannot subsist, and which the occurrence of plethora, however induced, never fails to disturb. We have stated that ordinary stimulants, which produce but transient excitement of the heart and larger vessels, are not the remedies here needed. What we require is an agency which, without exciting inordinately the general circulation, is capable of acting on the capillary vessels, and of arousing them to a renewal of their several functions both secretory and excretory. Such a remedy we happily possess in mercury, which is signally endued with this peculiar property, and which, in consequence, affords a powerful agency in relieving the larger bloodvessels, when overcharged, from part of their excessive load, by causing it to be diffused more freely through their numerous and wide-spreading ramifications; and when the aggregate capacity of the minute vessels thus expanded and restored to the exercise of their natural functions, is estimated, there will be little difficulty in comprehending how mercury proves so powerful an auxiliary of bloodletting in relieving an overcharged state of the general circulation, as well as in correcting the congestions and other derangements to which this state gives rise. If the effects of mercury on the animal frame be examined, it will be seen that, however diversified, they all correspond in one respect—namely, in evincing increased action of capillary vessels. Mercury has the effect of increasing almost every secretion, and by capillary vessels all secretion is performed. It promotes transpiration by the skin, diuresis, and secretion of bile; it more especially excites the salivary glands; and there is reasonable ground of con-

jecture that it similarly affects the pancreas, to the increased secretions of which gland mercurial diarrhœa has been with some plausibility ascribed. It increases the intestinal discharges independently of its direct action on the bowels when taken internally, for mercurial frictions are well known occasionally to purge. In every effect which mercury induces this common character is observable, that capillary action is more or less excited. Now a renewal of capillary action is what has been shewn to be needful for correcting the derangements incident to relative plethora, and hence the inestimable value of this remedy when judiciously administered, in restoring to health those who suffer under such derangements.

In absolute plethora the febrile action aroused suffices to impel blood into every extreme vessel, and thus to equalize circulation by extending it to every part where nature requires its full activity; and to effect this seems to be the great end for which febrile excitement is instituted by nature. In relative plethora this effort is more feeble, the natural powers being weaker, (indeed it is in this natural weakness that relative plethora has its origin;) and as every day but adds to the labour to be performed, while under the general depravation of habit the natural powers tend to further decline, we have little difficulty in comprehending why this state does not become aroused to those energetic efforts which are so often witnessed in the active fever of absolute plethora. To excite such effects then by the peculiar stimulus of mercury becomes an essential part of the treatment of relative plethora; and when in the correction of this state mercury is used with the necessary discrimination, and in aid of bloodletting, no course of medical treatment can be more successful, nor more strikingly illustrative of the principles by which it is guided, than that which this combination of depletory and stimulant agency supplies. The principle here adduced is confirmed by all that we know of the action of mercury, whether in its abuse or its use. Consistently with the views here presented, this action ought to be salutary only when the labour to be performed is not beyond what the animal powers are capable of sustaining. If the labour be too great, if inordinate plethora prevail, then must the excitement of mercury fail to effect its object, and the animal powers, exhausted by the vain effort, must still further decline. This operation of mercury corresponds exactly with the course of active fever where no bloodletting is employed. The powers exercised are in either case considerable, but the labour is disproportionate, and they sink under it. But if the labour be lightened by lowering the nutritive quality of the blood, (and this can only be effected with the necessary promptitude by bloodletting,) then will both febrile action and that of mercury accomplish all that is required from them.

We must here call attention to a physiological truth which requires to be borne in mind. When nutritive matter is introduced into the blood, if it find not an outlet by artificial bloodletting or natural hemorrhage, it must go through the processes of secretion and excretion ere it can be again expelled. If it be so redundant as to require these functions to be inordinately exercised in disposing of it, the respective organs lose power, and from the over-excitement sink even below the natural standard. Bloodletting, by lowering the quality of the blood, and lessening the proportion of its nutritive constituents, supersedes much of this inordinate and unnecessary labour, and thus actually saves animal power instead of expending it. In absolute plethora this is all that is required, for the natural powers thus relieved are fully equal to accomplish their own work. But in relative plethora the case is somewhat different. Here, while the nutritive matter of the blood is relatively redundant, requiring to be reduced, the animal powers are also enfeebled, and the several functions dependent on the capillary vessels are all more or less depraved. In addition, then, to reducing the nutritive matter by abstracting some blood, it is here necessary also to excite both the general powers and the capillary actions, in a way more effectual than simple febrile excitement can accomplish. Here mercury comes appositely and powerfully in aid, and by its direct influence on the capillary vessels effects what the natural powers, even when aroused into febrile excitement, would under such circumstances be unable to perform.

An analogy has been traced between the action of mercury and febrile excitement; and if this be followed up by closer observation, the respective processes will appear little short of identical, the only difference being in the excitant by which these processes are instituted and maintained. In absolute plethora the redundant nutritive matter suffices to arouse the system to corrective efforts: in relative this is inadequate, and the excitement of mercury is needed for stimulating to due activity the arteries, more especially in their minuter ramifications. This it effects in a way so closely corresponding to febrile action, that when the full effect of mercury is produced, it would be difficult to show that its phenomena differ essentially in any respect from those of fever. There are induced a quick pulse, hot skin, white and furred tongue, muscular debility, increased secretions, attenuation,—in short all that characterises simple fever. And further, if this state be neglected or maltreated, it passes into one which exhibits the whole train of typhoid symptoms—black and dry tongue, accumulation of sordes on the teeth, prostration of power, high nervous excitement, and finally death. These consequences are attributable, not to any necessary effect of the remedy, nor to any poisonous properties inherent, but to the constitution not being prepared by sensible depletion for its safe and salutary exhibition. When mercury is administered in unreduced plethora, and especially when its use is rashly urged, the effects are precisely such as result from febrile excitement, when, besides being inordinate in degree, it fails in its corrective agency. The excited powers, exhausted by their efforts, fall into a state of collapse, the object for which

they were exercised is not attained, the capillary actions are either not renewed, or if renewed they are overworked, and thus again enfeebled; they are consequently incapable of ministering to the general restoration as they would do if their healthful functions were re-established; and the consequence is, that the constitution is left in a far worse state by the effort than if it were not made. Far different is the result when either febrile excitement or the action of mercury is regulated by the guidance which sound principles supply. If plethora be reduced, and a state of active secretion be maintained, then may either febrile action, or that of mercury, be rendered conducive to the restoration of health, through renovation of functions such as seem almost beyond the reach of other influences.

The evils occasioned by neglect of the principle here inculcated are abundantly displayed in the history of syphilis; and we believe that all experienced surgeons are now agreed on the danger of administering mercury in an overcharged constitution.

Enough has now been stated to display the principles which should guide the employment of mercury in the treatment of relative plethora, and of the manifold diseases incident to this condition of the frame; and from long and extensive experience and close observation, both of diseases and the operation of remedies, we can confidently affirm, that if the principles here inculcated be applied to the elucidation of diseased conditions; if in these the attendant state of constitution be regarded rather than the specific disease, and at all events in connexion with it; and if the treatment indicated by the foregoing principles be employed so as to correct the constitutional derangements, many an apparently formidable malady will insensibly subside without requiring any specific treatment to be directed towards it, its surest corrective being the removal of the causes in which it originated, and by which it was upheld.

The practical application of these principles in the treatment of relative plethora is simple in the extreme. If the diseased condition be of recent occurrence, and the depravation of capillary functions slight, very moderate evacuations and renewed activity of the secretory and excretory functions, with regulated diet, will suffice to restore health. But if the plethoric state have continued so long as to deprave materially the general habit; if the capillary functions have been so long inactive as to have become indisposed to a renewal of their healthy energies; if the secerning vessels have through their abortive efforts become obstructed and powerless; and if, through congestion or subacute inflammation, structural changes have commenced in any of the organs or tissues, then these simple means must fail, and some constitutional effort, such as is exerted under febrile excitement, is necessary for restoration. But as natural febrile action is in this case inadequate to effect what is required, we here need the artificial excitement which mercury supplies to accomplish the purposes which medical treatment has in view. The indications by which the use of mercury is to be guided are neither obscure nor equivocal. If there be the debility of incipient plethora, moderate evacuations will relieve the vital powers, and enable them to display their inherent energies. When febrile action is thus aroused, the course of procedure is clear, and if the powers called forth be adequate to effect perfect restoration, no artificial excitement can be needed. But should it be, as in the larger proportion of such instances will prove to be the case, that the natural powers are feeble and inadequate to maintain the curative processes by which a healthy state of capillaries is to be renewed; if the obstructions be considerable, and the indisposition of the capillaries to a renewal of their natural exertions be clearly marked, then is the stimulus of mercury indispensable, and for this end there exists not in the wide range of medicinal agency a remedy possessed of powers so certain or so manageable. We have medicines which emulate some of its properties; antimony promotes many of the capillary secretions; iodine promises to afford much valuable aid of a corresponding kind; but so far as our present knowledge extends, we have no medicine entitled to rival mercury in the properties which the foregoing observations ascribe to it. When a soft, calm, and firm pulse evinces a healthful state of circulation; when the several secretories and excretories cease to display in their products a morbid condition; when under these changes the general feelings improve, and health progressively amends, it is quite needless to exceed the means by which a change so favourable has been effected, and far better is it to trust to this slow but sure process of amendment, and await the time necessary for completing it, than by over anxiety for more rapid progress hazard the disappointment which too sedulous endeavours might occasion.

But when the constitutional efforts do not make perceptible advance in the removal of general indisposition and local derangement; when the pulse continues oppressed, the skin dry, the tongue irregularly coated or otherwise unhealthy, the excretions morbid, the aspect sallow, and the general feelings unrelieved, then if depletion have been employed, and carried to the extent which sound experience justifies, it becomes absolutely necessary to resort to that agency which mercury supplies, and to administer at intervals small and unirritating doses of this mineral so as to excite the animal powers to the efforts necessary for relief.

It occasionally happens that in this use of mercury too much excitement follows, and from this circumstance its inexpediency has been at times somewhat hastily inferred. The occurrence may no doubt proceed from the medicine being unsuitable; but it may also take place either from plethora not having been sufficiently reduced, or from the medicine being too freely administered. In these latter instances further depletion and reduction of dose are what reason would direct. Precipitately to withdraw the remedy under such circumstances,

without trial of the expedients here proposed, would be little reconcilable with that knowledge of the operation of mercury which all should possess who venture to prescribe it. In general it is advisable to continue its use until its constitutional effects are evidenced by slight affection of the gums; but this is not indispensable, for we have often seen its curative effects obtained without any soreness of mouth being induced. Much minute detail on what is called the alterative effects of mercury, and the modifications which its exhibition continually requires, might here be introduced, but it would encumber an article already too long, and it cannot be needed.

No morbid condition can more clearly illustrate the operation of mercury than that which the advanced stages of continued fever present. Such cases have often been consigned to us as hospital patients when the early treatment had proved unsuccessful. The phenomena of this stage of the disease we need hardly describe. Great emaciation, prostrate powers, a feeble and rapid pulse, black and dry tongue, lips and teeth covered with sordes, insensibility, with a train of corresponding symptoms, characterise this stage. Yet, appalling as is the condition here presented, we never despair of it, provided no organ essential to life have yet suffered irreparable injury. Stimulants to recruit power are of course needed; but the chief agent for exciting the several secretory and excretory vessels, and for renewing the activity of the capillaries generally, is mercury. By small doses of this, repeated at suitable intervals, the pulse is rendered fuller and firmer, the secretions improve, the tongue becomes moist and clean, sordes separates from the teeth and lips, consciousness returns, appetite revives, and sleep is restored. Large doses are not needed; from one to two grains of calomel, given three or four times in the twenty-four hours, will generally suffice. Aperients and nourishment are of course required, and wine to such extent as the existing debility may demand. This effect of mercury we have so often witnessed that we can entertain no doubt either of the correctness of what is here stated, or of the agency to which the amendment is owing. No subject in pathology can be more interesting than the progressive development of power and improvement of function which such a case presents. It has repeatedly occurred to us to see so much reaction thus aroused as to require actual depletion of blood at late periods of the disease to relieve the local determinations which resulted. In the same subject we have been obliged to apply leeches alternately both to the head and chest, in order to allay the respective local excitements. That these resulted from the use of mercury we were well assured, but, instead of withdrawing it under a false alarm, we relieved the local disturbances by depletion, continuing a guarded use of the mineral so long as its specific agency was required for the re-adjustment of the system.

The accordance of the principles maintained throughout this article with the best established doctrines of idiopathic fevers cannot fail to be perceived by those who have given to this latter any particular attention. Dr. J. Armstrong, in his excellent treatise on typhus, distinguishes three stages in the disease, namely, those of congestion, reaction, and collapse. It is in confirmation of his accuracy that a corresponding succession, differing only in the intenseness of each stage, may be traced in every instance where simple inflammatory action arises,—a circumstance which claims for his theoretic views a high credibility, by shewing that the essential phenomena of continued fever do not result from any peculiarity of character imparted by its special cause, but that they correspond accurately with the successive processes which nature institutes in the simplest febrile disturbances of the animal frame.

Even the minuter observations which we have made on the changes of the pulse, and which were derived from the examination not of idiopathic fever but of incipient plethora, correspond with what Dr. Armstrong states as occurring in the congestive stage of typhus, among the symptoms of which he notices "a quick, low, struggling pulse, *changeable as to frequency, and even irregular as to force.*" But the most impressive illustration of the debility connected with internal congestion, and of the effect of copious bloodletting in relieving it, is, perhaps, that which is furnished by the epidemic, or, as it is commonly termed, spasmodic cholera.

In the pamphlet published by the London General Board of Health, by authority of the Privy Council, the following passage occurs: "But the remedy which is described to have been most uniformly successful, when it could be used, is bleeding, and this even in cases where the pulse was scarcely perceptible at the wrist. This practice seemed to apply itself to the root of the disease, by relieving the congestion of the venous system, which was invariably found loaded on examination after death, and which congestion (though only an effect of the first impression made by the attack of the disease on the constitution) appeared to be the immediate cause of death. In the lighter cases, or in those of a severe nature which came under medical treatment before the pulse at the wrist was lost, or had become fluttering, bleeding was attended with the most decided advantage. The oppression of the chest, the burning heat of the præcordia, the spasms, the vomiting and purging, are stated in some instances to have ceased at once; at others, on a repetition of bleeding. In such as allowed a free abstraction of blood these effects very uniformly occurred; but even in some, when the pulse was indistinct, bleeding was successful, if it could be carried to the extent of eighteen, twenty-four, or thirty ounces, the pulse rising in power and becoming more distinguishable in proportion to the flow of blood. If the pulse in this state of feebleness was distinct enough to give the finger the feeling of oppression, bleeding was almost always successful. The blood drawn was black, whether procured from a vein or an artery, and flowed with great difficulty,

commonly first coming from the vein in drops, and gradually in a stream; but before it could be induced to flow with freedom the patient often required warm baths, frictions, external and internal stimuli, to produce a sufficient quantity for his relief. If a small quantity only could be procured, the heart seemed to feel the loss without being relieved, the bulk of the blood actually circulating being reduced, while the great mass of it, congested in the inferior and superior vena cava, did not make its way to the heart. The effect of bleeding was mechanical, and acted only as removing an obstruction to the passage of the blood from the distended venous system; and if not carried far enough to remove this impediment and allow the large veins to empty themselves into the heart, such weakness was produced as is occasioned by the loss of blood in a constitution worn out by disease." This statement of the Board of Health we adduce in preference even to the authorities from which it was derived. It was the result of deliberate and mature consideration of all the information which public records and private testimony could supply; it was issued to the public under a responsibility which must have precluded all slovenly examination of facts, all influence of speculative theories; and it hence carries authority as an announcement of facts, which no individual testimony could possess in an equal degree. It is difficult to conceive a correspondence more complete than that which subsists between the facts here recited and the pathological principles which we have endeavoured to illustrate throughout the present article.

It cannot fail to be perceived how intimately these principles are connected, not only with the morbid conditions described, but also with the whole course of medical practice. If such morbid conditions of the frame have any existence, they must more or less affect the progress and influence the treatment of a large proportion of diseases. Wherever they prevail it is obvious that the treatment of specific maladies cannot be wholly independent of them, and even where no plethora exists, the negative can only be ascertained by a familiar acquaintance with the phenomena which denote its presence. Nay, so many specific diseases depend wholly on the depravations of habit noticed in this article, that when the constitutional derangements are corrected, the special diseases spontaneously cease. On every account, then, the doctrines of plethora, its rise, progress, and treatment, must be allowed to constitute an essential part of medical science.

But of all sciences, that of physic is perhaps the least simple. Its principles, individually considered, are clear deductions from well established facts, and, so far, simple in their nature. But it very rarely happens that any one of them, however irrefragable, suffices for our guidance. Morbid actions, however simple in their origin, become so soon combined with others, whether derivative or contingent, that the assemblage manifested in every instance of advanced or specific disease loses all character of simplicity, and requires for its exposition a variety of knowledge, a clearness of conception, and an accuracy of judgment exceeding perhaps what any other earthly pursuit demands.

A most important complication of vascular derangements is that which is derived from coincident disturbance of nervous function; and so continually are these conditions intermixed, that the consideration of plethora would be incomplete if this source of complication were unnoticed. As a matter of fact, it is familiarly known that inflammatory diseases of the same general character and denomination present in different individuals different phenomena according to the degree of nervous irritability respectively attendant. The predominance of this latter may proceed from peculiarity of temperament, or from the influence of stimulants particularly exciting the nervous system, in operation antecedently to the special disease, and independent of it; or it may result from cerebral congestion or irritation incident to the febrile state which plethora is seen to induce. It is further known that nervous irritability, when in excess, is capable of producing derangements which so much resemble those of pure inflammation as frequently to mislead practitioners into employing active depletory treatment where this is unsuitable, if not absolutely injurious. It is time that these several conditions and their combinations should be more fully investigated and better understood, were it only for guarding against an error to which recent enquiries on this subject seem to tend,—namely, that of regarding the inflammatory and irritative states as opposite and contradictory; so that where one state is proved to exist, the other must, by implication, be considered as negatived. The truth of such a position we would not admit; and we are anxious to display the grounds of our persuasion in this respect, entertaining as we do considerable apprehension lest the views of nervous excitability which some able and discriminating writers have of late years presented, (or rather the practical evidences which they have adduced of this being preponderant in certain maladies which had been very generally regarded as purely inflammatory,) should withdraw attention from inflammatory action beyond what the writers alluded to contemplated or would have approved.

The morbid irritability which, simulating inflammatory excitement, gives rise to local disturbances liable to be confounded with pure phlegmasiæ, and which, however it may be temporarily alleviated by bloodletting, is eventually aggravated by it, while it is relievable by opium and ammonia, has been ably illustrated by the late Dr. Gooch in his valuable "Account of the Peritoneal Fevers of Lying-in Women," and also by Dr. Marshall Hall in an "Essay on some Effects of Intestinal Irritation," as in several other of his works. In all that these judicious and eminently practical writers have adduced respecting this condition, and the treatment

required for its relief, we entirely concur; but in admitting fully the truth of their statements, we are anxious at the same time to impress that though the higher degrees of irritability may exist independently of plethora or of inflammation,—nay, may have their origin in actual inanition or in excessive loss of blood, the same nervous depravation is continually found combined in every proportion with plethora, inflammation, and congestion; and that when it is so combined, the treatment, to be safe and effectual, must have relation to both sources of disease. In proportion as plethora and inflammatory action prevail, must depletory treatment take the lead; and according as irritability is excessive, will opium and stimulants be needed. To discriminate these respective conditions, then, so as to assign to each its appropriate treatment, is the point to which practical observation would be most beneficially directed. And in this scrutiny much advantage will result from founding diagnosis not on one or two prominent symptoms, but on the whole assemblage; among which, as was remarked in a former part of this essay, such harmony should subsist that no individual symptom should be contradictory of what the others proclaim. When such contradictions present, then instead of leaning exclusively to that side to which the balance inclines, each class of symptoms should receive its appropriate consideration, and be referred to the principles in which it originates. In the morbid conditions under discussion, it is not difficult to distinguish the purely inflammatory cases from those in which excess of irritability is combined. In the latter, while the disproportionate degree of irritability should itself excite suspicion, a scrutiny of symptoms will shew that these do not all in equal degree denote such activity of inflammation as the prevailing irritability would imply. The pulse, temperature, and tongue do not present that correspondence of derangement which is usually attendant on purely inflammatory action. The pulse, however accelerated, (and in such cases it is often inordinately so,) wants the firmness which belongs to inflammation. The temperature is not always in accordance with the high sensibility evinced by particular parts of the frame; and the tongue, instead of being dry or furred, is oftentimes moist and preternaturally red. So endless, however, are the varieties induced by the combinations which occur, that it would be impossible to render a distinct account of them by any description, or to do more than to point out the sources of disease to which the practitioner's own observation should be directed.

For plethora and inflammation the appropriate remedies, as we have often stated, are bleeding, purging, and antiphlogistic treatment; while morbid irritability yields but to opium and other sedatives, combined, as occasion requires, with cordials and tonics. In proportion as either condition prevails, must its appropriate remedies be combined in the treatment; and on the accuracy with which these remedies are severally adapted does much of the success of medical practice depend.

The subject is much too copious to be discussed fully in this place, where our chief object for introducing it is to impress a warning against hastily inferring, that because irritability predominates, inflammation or congestion is not co-existent. Even where morbid irritability results from exhaustion or inanition, congestions continually occur which call for topical bleeding, however unsuited depletion may be to the constitutional state existing, and even though to sustain strength by tonics and nutritive diet may be at the same time required. This is well exemplified in a state of disease of frequent occurrence, and with which most practitioners must be familiar.

Females under too protracted lactation fall into ill health, marked by exhaustion, and attended with various nervous derangements. This state is common among the poor, who, for various reasons, are accustomed to suckle their children for long periods,—even for two or three years. Pallid aspect, disordered digestion, irregular bowels, and acute pains of head, with prostration of strength and great nervous irritability, are the prominent features; but the whole condition thus induced is so peculiar and characteristic that they who are familiar with it are at once led to a knowledge of the cause by inquiries which they might otherwise not think of making. Taught by experience, we have oftentimes, among the out-patients of the hospital, discovered the fact by direct inquiry where there was nothing save the general character of the disease to induce suspicion of the woman being engaged in suckling; there being either no child produced, or one able to walk by its mother's side. Weaning the child is here the indispensable requisite; and its effects are quickly displayed. They are assisted by mild aperients combined with sedatives, cordial remedies, and sustenance. No state would appear on principle less suited for evacuant treatment than this; and under this impression we were for a long time averse to relieving the head by any direct depletion. The inveteracy of the headach, however, forced us to the application of leeches; and the prompt relief which they afforded soon removed all scruples on this score. A few suffice; six or eight applied to the temples give in general all the relief required; but nothing can be more decisive, or more strongly marked than the benefit which they thus afford.

We do not say that all such cases require leeching, but the attendant headach yields readily to this remedy when all others fail to subdue it. The only inference which we can draw is, that notwithstanding the general debility, and perhaps by reason of it, the vessels of the brain become congested and unable to unload themselves; that the topical bleeding, by lessening their contents, enables them to contract and recover their natural diameter,

and with it the power of carrying on the circulation so tranquilly as no longer to disturb the cerebral functions.

The above state only displays congestion as coinciding with irritability and exhaustion; but the instances are of daily occurrence in which morbid irritability is complicated in every variety with relative plethora; and when these states are so combined, it is quite as necessary to correct the plethora as to allay the irritation, the most effectual way of restoring health in such case being, not to pursue any exclusive system, but, guided by experience, to give to each derangement the consideration which it specially claims, and to combine the respective remedies as the prominent derangements may severally demand. A knowledge of the principles on which each class of remedies should be employed furnishes the best guidance for regulating those combinations which such complex states of disease must ever require. One of those conditions, at least, we have endeavoured to illustrate in the foregoing pages; and however we may have failed to do justice to the subject, it is hoped that sufficient ground has been shewn for pursuing the inquiry, and a motive furnished for other observers to complete what we must necessarily leave imperfect.

Before concluding this article, it is necessary to offer a few remarks on the vitiation of blood which arises from redundancy of excrementitious matter, regarding this in its simple state, unconnected with the various degrees of plethora with which it is so continually combined. In doing so the motive is not so much to designate the morbid condition as likely on its own account to become an express object of medical discipline, as to establish the principles which should govern its treatment, when, as continually happens, it is found combined with other derangements. The general phenomena which denote this condition are, a sallow aspect and dusky skin; the pulse low, soft, and compressible; the surface of the body for the most part harsh, dry, and obviously deficient in natural transpiration; the tongue moist, clear, red; the appetite capricious, often craving and voracious, with an endless train of dyspeptic ailments; the alvine discharges inveterately foul, dark, slimy, pitch-like, and exhibiting no trace of healthy fæces; the urine high-coloured, depositing more or less of dark, often fetid sediment: these, with decline of flesh and strength, are the general characteristics of this state. The condition itself we believe to arise from the accumulation in the blood of excrementitious matter imperfectly discharged, and the depraved state of the several secretions we regard as resulting from the laboured though ineffectual efforts of the constitution to accomplish, through their agency, its own purification. It may give a clearer conception of this condition to contrast its phenomena with those which characterize nutritive plethora. In the latter the general aspect is more full and florid; the surface is hot and dry, or inclining to moisture; the pulse hard and frequent, or full, strong, and bounding; the tongue white and furred; the stomach inclining to nausea, with thirst; the stools feculent, though foul, and charged with mucus.

In specifying the symptoms of excrementitious accumulations, it may be imagined that we have included several which belong to the different forms of hepatic disease. That they are frequently regarded as evidences of diseased liver, and treated accordingly, we are well aware; but that they are certainly to be met with where there is no organic lesion of this viscera, nor any particular functional disturbance of it, we are fully convinced. It is true that the functions of the liver are, in common with those of the whole alimentary canal, greatly depraved, but they are so not from any primary defect or derangement of their own powers, but from being required to act inordinately on a vitiated mass which nature is sedulous to purify.

According as nutritive plethora becomes more or less combined with this state, the constitutional efforts increase, and various degrees of febrile and inflammatory excitement ensue. In proportion as this excitement is energetic, and as measures of suitable activity are employed for its relief, the vitiated state of the blood becomes corrected, the secretions and excretions improve, and the general health and strength amend. The increased secretions from the bowels seem to be the discharge by which nature aims at getting rid of such impurities. To promote them, therefore, by suitable purgatives, at the same time supporting the strength by moderately nutritive diet, is the first indication.

When relief, to a certain extent, is thus afforded, the powers of the constitution rally, and a febrile effort is made to assist in the work of purification. According as this advances, depletion should be more active and the diet less stimulating. When sufficient excitement exists to warrant the employment of bloodletting, we may then consider the curative process as in the most favourable train. Perhaps the powers of the constitution are hardly adequate to rectify any high degree of this derangement without the extraordinary effects which a state of febrile excitement supplies, and hence we see experienced practitioners often hail the appearance of febrile symptoms in chronic maladies as announcing a more remediable form of disease.

In every view that can be taken of this condition, it must be considered as intimately connected with the state of cuticular excretion, from defect of which it is more likely to arise than from any other cause. When we reflect on the large amount discharged by this excretory under a healthy state of the system, and that, according to accurate experiments, more than one half the ingesta is carried off by transpiration, it will be readily conceived that great excrementitious accumulation must result from impeded cuticular excretion. This matter being in consequence thrown in inordinate quantity on the other excretories, it can excite little surprise that their ordinary functions should

be thence disturbed, or that their several secretions should present a morbid character.

A constitution naturally feeble, especially if exercise be inadequately taken, sends the blood to the surface too languidly for the exhalent arteries to act with full power, whence excrementitious accumulation commences; the effect of this being directly debilitating, it serves to aggravate the cause, and thus the foundation is laid for a broken constitution and many inveterate chronic diseases. The best preventive of this diseased condition is, unquestionably, exercise, and in slighter degrees of it this would also be the most effectual cure; but when great depravation of habit has already taken place, there is neither the capability of taking adequate exercise, nor would it alone, under such circumstances, succeed. To be effectual it should be carried to the extent of producing some moisture on the skin, as the only sure evidence of the blood being impelled with sufficient force into the capillary vessels. The various forms of warm-bathing are of great value, especially those which combine frictions and other means of softening and detaching hardened cuticle. That of the Russian vapour-bath, noticed by northern travellers, and so accurately described by the late Dr. Clarke, would appear eminently calculated for establishing a healthy state of skin, and an adequate activity of cuticular excretion.

(E. Barlow.)

PLEURISY, PLEURITIS. *Gr.* πλευρῖτις, from πλευρὰ, *the side*, also the membrane that lines the ribs, *the pleura*. Pleurisy signifies inflammation of the serous membrane which lines the cavity of the chest, and invests the organs of respiration therein contained. Modern pathology has narrowed the application of this term, which, in the earlier ages of medicine, was employed to express pain of the side, no matter what tissue was the seat of the uneasy sensation, provided it was acute in its character and accompanied with fever. The frequency of the complication of pleurisy and pneumonia led many to suppose that the former was so essentially connected with the latter as to be incapable of an independent existence. It is, however, now clearly established that, although the parenchyma of the lung and its enveloping membrane are often involved in the same inflammation, still there is no necessary connexion between the affection of the one and that of the other.

If adhesions between opposite surfaces of serous membranes are to be looked upon as evidence of pre-existing inflammation, the frequency with which we meet with this morbid phenomenon between the pleural surfaces warrants us in asserting that no organ or tissue in the body is more subject to inflammation than the pleura.

Pleurisy presents itself under so many varied forms, that we shall find it difficult to exhibit it in one general description. It may be acute or chronic; it may affect one side of the chest or both sides; it may be general, involving the whole of one side, or partial, only involving part of one side; it may be simple or complicated; the complication may be either accidental or essential, and in the latter case the pleurisy and its complication stand to each other in the relation of effect and cause.

I. Acute Pleurisy.—The anatomical characters which the pleura affected with acute inflammation presents, consist of change of texture and change of secretion. We have also to consider the changes which the lung, compressed by the effused fluid, undergoes both in form, volume, situation, and other relations.

The inflamed pleura exhibits numberless minute capillary vessels carrying red blood; these vessels anastomose freely among themselves, and present injected patches of various forms. Sometimes the injection is so general as to appear like an ecchymosis. Careful anatomical examination proves these injected vessels to be situated in the subserous cellular tissue; and that what was considered an actual thickening of the serous membrane in the first stage of inflammation, is due to a serous infiltration into this cellular tissue, as well as to a loosening of the connexion between the serous membrane and the subjacent tissue by the increased caliber of the capillaries, now carrying red blood. In some cases we can peel off the serous membrane, and thus prove the pretended thickening to be nothing more than what we have just stated.

Inflammation of the pleura induces changes both in the quantity and in the character of the ordinary serous exhalation. The first effect of inflammation upon the exhalation of a serous surface is, if not completely to suppress it, at least to diminish it very considerably; so that the dry surfaces have no longer that easy gliding motion which it is the physiological object of this lubrefying fluid to maintain. After an interval varying from an hour to two or three days from the commencement of inflammation, the serous exhalation is much increased in quantity, or, to adopt the language of pathology, the inflammation terminates in effusion. Laennec objects to this mode of expression, as calculated to convey an erroneous idea as to the time when the effusion begins to take place, as he is of opinion that in serous membranes the inflammation and effusion commence at the same moment, and proceed *pari passu*. With this, we must confess, our experience does not agree; and although in the larger cavities, viz. the abdomen, heart, and chest, our examination may not be capable of that degree of precision which would enable us to pronounce with certainty upon the point, still there are other cavities in which the train of morbid phenomena takes place more immediately under the cognizance of our senses, and where we have an opportunity of recognising a determinate interval between the supervention of the inflammation and the effusion; for instance the joints and the tunica vaginalis testis. In iritis, we have ocular demonstration that it is some time after the pain has announced the inflammation, that the increased

secretion of the aqueous humour takes place, causing an unusual prominency of the cornea.

The fluid effused into the cavity of the chest in acute pleurisy varies considerably in quantity; sometimes not exceeding an ounce, at other times amounting to several pints. When it is considerable, and has exercised a pressure upon the yielding parenchyma of the lung, reduced it to its smallest possible dimensions, and pushed down the diaphragm so as to cause the viscera placed below it to be felt lower than their normal situation, viz. the liver on the right side, and the spleen upon the left, it seems to be next directed against the walls of the chest, and produces a change in the form of the side, to which we shall have occasion to advert when we come to enumerate the physical signs of acute pleurisy.

The effused fluid presents itself under very various appearances. It may be colourless, transparent serum; or we may find flocculi of lymph floating in the serum without affecting its transparency; or, again, some of the lymph may be as it were dissolved in the serum, and, rendering it turbid, may impart to it an appearance resembling unclarified whey. Again, it may be a greenish fluid made up of serum and pus in various proportions, and approaching to each of these fluids in colour and consistence, according to the proportions in which they enter into its composition. Or it may be unmixed pus, resembling in its sensible qualities the matter of a phlegmonous abscess; and in this case the disease is ushered in with a strong rigor, the ordinary announcement of suppuration. Lastly, it may be either pure blood, or the ordinary serous effusion more or less deeply tinged with this fluid; the blood in this instance may be forced out either from the capillary vessels of the pleura in a high state of orgasm, or from the vessels developed in the organised false membrane.

In a case of acute pleurisy which we have had recently under our care, and in which the urgency of the symptoms required the immediate performance of the operation of *paracentesis thoracis*, the fluid drawn off was of a yellowish colour and oily consistence, very much resembling in appearance copal varnish. On remaining a short time in the vessel in which it was drawn, it was converted into a tremulous jelly, and after some hours resolved itself into two distinct parts, a thickish crassamentum floating in a thin serum; it in fact very much resembled the blood without its colouring matter. The fluid having collected again, it became necessary, in the course of a fortnight, to repeat the operation, when we found the effusion to present very different sensible properties from those of the original fluid; it was of a greenish colour, and though apparently of a homogeneous consistence, on standing a short time it separated into a thick purulent sediment and a thin greenish supernatant fluid. This operation afforded a very temporary relief; the individual died in four days, and on examination we found not less than eight pints of thick purulent matter (such as is met with in a phlegmonous abscess) in the left side, and both pleura pulmonalis and costalis densely coated with lymph. The difference presented by the effusion on three different occasions constitutes the interesting feature of this case. Andral, in the second volume of his *Clinique Médicale (Sur les Maladies du Poitrine,)* mentions a case in which the fluid effused into the pleura resembled the jelly of meat.

A portion of the fluid effused in pleurisy has a natural tendency to pass to the solid state; from thence we have the false membranes, which present so much variety in their organization, form, extent, consistence, and thickness. The coagulable lymph is scarcely deposited upon the free surface of the pleura when it becomes solid. In the first instance it is a soft, whitish mass, exhibiting no appearance of organization or vitality; but soon red points make their appearance in it, which, elongating themselves into red lines, present unequivocal characters of vascular canals, and, passing beyond the lymph, the matrix of their development, proceed to inosculate with the vessels of the pleura, and thus establish a communication between the circulation of the false membrane and the general circulation. It is impossible to fix the time when organization takes place in these false membranes; nor is it easy to determine to what special influences this process is subject, evidences of such organization being found in false membranes, the result of pleurisy of a few days standing, and being wanting in others of as many months' duration; thus, at least, proving that time is not the sole regulating circumstance.

The form assumed by the lymph deposited on the pleura is very various; sometimes it is deposited in isolated drops, having either the appearance of transparent vesicles or of miliary granules; at other times they closely resemble tubercles. In the differences presented by the lymph deposited in this form, we recognize the grounds of the opinion that hydatids are the form under which tubercles first present themselves, the transparency of these globular concretions countenancing such a belief. In a case of cancer of the lung, in which the cancerous matter presented itself in all the intermediate stages of development between hardened scirrhous structure and soft dissolved encephaloid matter, we found lymph deposited in the form of these isolated drops upon the pleura of the opposite lung, while the lung itself was quite free from disease. We suspect that lymph is the rudiment or matrix of all these morbid growths, which derive their special character from the peculiar cachexy of the individual.

Sometimes the lymph covers a greater or less extent of the pleura in the form of concretions of variable density. The surface of these concretions is sometimes smooth and polished, sometimes it is rough and unequal, and sometimes it has an areolated honeycomb appearance. In many cases these concretions are converted into cellular bands, of variable length, connecting the two pleura, and are

often found traversing the effused fluid. These bands acquire all the characters, both anatomical and pathological, of cellular tissue; they are subject to dropsical infiltration, and in jaundice present a yellow hue; they are often the matrix of morbid developments. That these bands do not fetter the motion, or in any way interfere with the function of the lung, is abundantly demonstrated by the fact of the frequency with which we meet them in our necroscopic examinations where we had no reason to suspect them during life.

The false membrane varies in thickness in different instances; sometimes it can be removed from the subjacent pleura in the form of a thin pellicle, not exceeding the thickness of the pleura itself. Most commonly the thickness of the false membrane greatly exceeds the natural thickness of the pleura, and it seems to be made up of several distinct laminæ superposed. We have seen this membrane an inch thick, and the laminæ of which it was composed admitted of separation like the different laminæ composing the coagulum of an aneurismal sac.

As the false membrane resembles cellular tissue in its properties, it is subject to all the transformations of structure of which this latter texture is susceptible; thus it may be converted into cartilage, fibro-cartilage, or even into bone. It is this membrane, converted either into cartilage or fibro-cartilage, which, in phthisis pulmonalis, establishes such an intimate union between the pleuræ pulmonalis and costalis as to defy our utmost efforts to separate them.

The false membrane may be the matrix of different accidental developments, of which tubercle is by much the most frequent. We often find the surface of the membrane studded with small miliary tubercles: at other times we find these bodies in the substance of the membrane in their different stages of softening. We have no precise data whereupon to average the time when tubercles begin to form in the false membrane; and though we believe they may develope themselves within a very short period, we conceive the work of tuberculization in general to be a slow, insidious process, even in organs most essential to life.

The lung of the side, when the effusion exists, deserves our attention, both in reference to the position which it occupies, and the changes which it undergoes in its proper structure. In general the effused fluid tends to press the lung into the space beside the vertebral column, and when it is in considerable quantity, the organ is reduced to a thin lamina, so that sometimes it is not easy to find it, and thence we have heard of its having entirely disappeared. Adhesions will of course modify the position of the lung, and protect a portion of it from pressure. Sometimes the lung is applied against the ribs by being pressed backwards and outwards; at other times it is completely suspended in the fluid. In general the only change induced in the lung, pressed upon by the effused fluid, is a diminution of size, the mechanical effect of the peculiar circumstances in which it is placed. The air is squeezed out of it. The organ becomes more dense and less crepitating than natural; it assumes very much the anatomical characters of a fœtal lung; it has a smooth, uniform appearance, and does not tear as a portion of hepatized lung will do; its vesicular structure has quite disappeared, and even the bloodvessels are flattened and exanguious: the bronchial tubes become contracted in their caliber. Its resemblance to a portion of muscular tissue which has been submitted to maceration has procured for it the expressive term of carnification.

Tubercles may form in the compressed lung, and there undergoing their ordinary changes, will modify the symptoms of the disease; still it more frequently happens that the tubercles already existing in the lung, in softening, perforate the pleura, and give rise to that modification of pleurisy which might with propriety be termed *puopneumothorax*.*

General symptoms of acute pleurisy.— Acute pleurisy is well entitled to a place among the Pyrexiæ, from the symptoms of high febrile excitement with which it is in general announced; to these symptoms are superadded pain in the side, difficulty of breathing, a hard dry cough, and, usually, decubitus upon the unaffected side: upon these follow, sooner or later, a dulness of sound or absence of the ordinary resonance of the affected side when percussed, a peculiar modification of the voice designated ægophony, and bronchial respiration; then the complete absence of the respiratory murmur, and a palpable dilatation of the affected side.

The febrile symptoms of acute pleurisy are not marked by a uniform intensity. When the disease prevails as an epidemic, these symptoms partake more of a low typhoid type, and considerable derangement of the digestive apparatus holds a prominent place amongst them. The pain is unequivocally the most constant symptom of acute pleurisy; it is the one which especially attracts the patient's attention, and which, from the expression of anxiety and suffering which it imparts to the countenance, is seldom overlooked by the physician: it is described as a sharp, lancinating pain, increased by coughing, by inspiration, by pressure in the intercostal spaces, or by lying on the affected side; its situation is generally referred to near the mamma, and is felt in a very circumscribed space, no matter what may be the extent of the inflammation. It is not easy to explain why this should be the usual situation of the pain. Morgagni attempted to account for it by the greater mobility which this point of the chest presents, as being equally distant from the apex and base of the thorax, and from the sternum and spine. Though the point mentioned be the most usual seat of the pain, still it may be felt in any part of the side, or even in the opposite side, without this side participating in the inflammation.

When pleurisy depends upon tubercles in

* Πύον, pus, πνεῦμα, air, θώραξ, chest.

the pulmonary tissue, the pain is felt in parts of the chest corresponding to the situations of the formation of these foreign bodies; hence in the early or nascent stage of phthisis pulmonalis we hear the frequent complaint of pain under and above the clavicle, in the hollow of the axilla, or between the shoulders, this pain indicating the existence of tubercles in the apex of the lung, the usual seat of their earliest development. This symptom of early phthisis is of much practical value, as it assists our diagnosis at a stage of the disease when the stethoscopic signs are equivocal, and when treatment interferes with most prospect of success.

When the pain is confined to the margin of the ribs, it is not always easy to determine whether it depend upon inflammation of the thoracic or of the abdominal serous membrane, and the difficulty is increased by the fact that jaundice has followed upon unequivocal pleurisy by an extension of inflammation of the pleura lining the diaphragm. Morgagni mentions a case in which Valsalva mistook the complication of jaundice for the primary disease, and overlooked the less palpable signs of a pre-existing pleurisy, proving how difficult it is to establish a certain diagnosis when the situation of the disease is a point where many organs are as it were placed in the same parallel of latitude, and when the disease itself is not marked by any striking functional derangement. The pain is seldom constant, but is brought on by every thing calculated to impress the slightest motion upon the affected side; it sometimes assumes an intermittent character, and returns with a regular periodicity.

In the first moments of acute pleurisy, the respiration is marked by a peculiar nervous hurry. Nature is instinctively aware of the pain produced by a full inspiration, and therefore avoids it; she compensates for the smallness of the volume of air admitted at each inspiration by the frequent repetition of the act, and hence the respiration is short, hurried, and jerky *(saccadée)*. When effusion has taken place, the dyspnœa depends upon a different cause, viz. the mechanical obstruction to the expansion of the lung, and is in proportion to the extent of the effusion and suddenness with which it has taken place. This latter circumstance has much more effect in embarrassing the respiration than the former, as we have known cases where individuals were quite unconscious of any thing affecting their chest, while at the same time there existed unequivocal evidence of extensive pleuritic effusion; and this arose from the organs having had time to accommodate themselves to the encroachment upon their functions. Should the opposite lung be affected either with bronchitis or emphysema, the dyspnœa will be more distressing.

The characteristic cough of acute pleurisy is a short cough, either dry, or accompanied with a thin mucous expectoration: should the sputa be more abundant or deviate from this character, we may suspect a complication either of pneumonia or bronchitis. The cough is often wanting altogether, or is so slight as to attract the attention of neither the patient nor physician.

The difference of opinion which obtains among systematic writers upon the subject of the *decubitus*, or position of the patient in pleurisy, proves at least that it is not constant, and therefore cannot be exclusively relied upon as a diagnostic sign; still we may say that, as long as the acute lancinating pain of the side continues, the aggravation of it, caused by the pressure when lying upon this side, makes the individual seek the more easy position either upon the opposite side or upon the back. When the pain has ceased and extensive effusion taken place, the position, before avoided, is now adopted; because the effusion, interrupting the function of one lung, and placing it as it were *hors de combat*, a necessity for greatly augmented action devolves upon the other, and in order to favour this, nature instinctively points to the position which allows the easiest and most unembarrassed play to those muscles whose province it is to dilate the unaffected side of the chest, and this position is upon the affected side. It is only when the effusion has been sudden and considerable, when the respiration has (if we may be allowed the expression) been taken by surprise, that nature seeks to relieve herself by particular posture. It may happen that a fresh attack of inflammation in the side originally affected, or the lung hitherto free becoming involved, will produce the necessity for a certain position, to which nature in the first instance seemed to be indifferent.

Physical signs.—In the earliest stage of acute pleurisy there is no physical sign to mark its existence. When effusion takes place into the cavity of the chest, its extent is marked by percussion of the side yielding a dull dead sound instead of its ordinary clear tympanitic resonance. This dull sound, it is true, may arise from other causes than from fluid effused into the cavity of the pleura; it may be owing to solidification of the pulmonary tissue, the effect of pneumonia; or to some morbid growth formed in the lung: still we can take such advantage of this sign as will enable us to determine upon what it depends; for although Laennec denies that fluid effused into the cavity of the chest can change its place, and states that it arranges itself between the lung and the walls of the chest, the experiments and examinations of Piorry on this subject, concurring with our own experience both during life, and confirmed by examination after death, enable us to assert that this fluid, being specifically heavier than the lung in its natural state, will displace it, and gravitate towards the most dependent part, and thus by change of position of our patient shall we be enabled to change the results both of percussion and auscultation. We believe the only internal limitation to the displacement of the lung to be the root of the organ; and when the effusion is considerable, and we examine the patient in the sitting posture, the weakness if not the complete absence

f respiration and dulness of sound are owing o the fluid having pushed up and now occupied the place of the lung; but as the root of he organ is its fixed point, when the fluid rises bove its level, it is now that it presses upon it n all sides, and when it has filled the cavity, he lung is as it were suspended in it, and, eing retained here, undergoes different degrees f compression according to the extent of the ffusion. The analogy of the fluid in ascites, isplacing the intestines, confirms the view that ve have just taken of the displacement of the ung by the pleuritic effusion. Adhesions beween the pleuræ pulmonalis and costalis will revent the fluid displacing the lung; and if we id not keep this fact constantly in view in our examinations, we should often be misled. We well remember the embarrassment which the unusual phenomenon of distinct bronchial respiration produced in a case of unequivocal pleuritic effusion, related by Dr. Graves in the fifth volume of the Dublin Hospital Reports, and which an adhesion between the pleuræ pulmonalis and costalis afterwards accounted for. It is only when the dulness of sound and absence of respiration present themselves when we see the patient for the first time, that we can ever be at a loss to determine whether they depend upon pleuritic effusion or solidification of the lung; for the short time in which the whole side or even its inferior half will yield a dull sound, (sometimes occurring within a few hours,) is conclusive of its being due to effusion and not to hepatization, which is a very gradual result, and is always preceded by the crepitant râle. We may state generally that the sudden, equal, and uniform absence of respiration and dulness of sound are peculiar to pleuritic effusion.

When the effusion is very abundant from the first moments of its formation, the respiratory murmur ceases to be heard in any part of the chest, except along the vertebral column, where it is still perceptible for the space of about three fingers' breadth, although more feeble than in the opposite side. When, on the contrary, the effusion is gradual, the respiratory murmur begins by being a degree fainter, and continues to diminish its intensity until it is entirely lost. The respiratory murmur will survive the dulness of sound sometimes for days. When it has ceased in all other parts except beside the spine, it will often continue to be heard under the clavicle, in consequence of the frequent adhesions between the pleuræ pulmonalis and costalis in this situation in phthisis. To the cessation of the respiratory murmur or vesicular respiration succeeds a peculiar modification of respiration, which, from its apparent dependence upon the air not penetrating beyond the larger bronchial tubes, has been termed *bronchial respiration*. As this same character of respiration exists in solidification of the lung in pneumonia, we may presume that it depends upon the same cause in both cases,—namely, the peculiar condition to which the pulmonary parenchyma has been reduced, in one by the compression of the fluid, and in the other by a deposition of foreign matter into its proper structure; so that the phenomenon would seem to depend upon the air entering the bronchial tubes, placed not in the midst of their ordinary spongy medium, but of a dense solid structure, and therefore better calculated to convey every modification of sound, whether of voice or of the entrance of air; furnishing us in the former instance with *broncophony*, and in the latter with *bronchial respiration*.

The voice, as heard by the stethoscope, is observed to acquire a particular character in pleuritic effusion, which led Laennec to regard it as one of its most characteristic signs. From its resemblance to the shrill, jerky, tremulous sound of the goat, he has termed it *ægophony*. (See Auscultation.) This phenomenon is most perceptible about the inferior angle of the scapula, and in the space comprised between the posterior margin of this bone and the spine, and is found to exist only when the effusion has attained to a certain extent, and to cease when it either goes beyond or falls short of this: hence it is not met with either in the very early or advanced stage of pleurisy; and when it has been present and disappeared, its return is hailed as indicative of progressive absorption of the effused fluid. Laennec ascribes it to the transmission of the voice through the compressed lung and the fluid interposed between the lung and the side of the chest. As we before stated that our own experience, confirmed by Piorry's experiments, made us question Laennec's opinion of the stratum of fluid interposed between the lung and side of the chest, of course we cannot admit his *rationale* of the phenomenon, as far as relates to the transmission of the voice through this hypothetical interposed fluid. As the most experienced stethoscopists allow that they can with difficulty distinguish between ægophony and broncophony, we believe the former to be a mere modification of the latter, and to differ only in the structure of the lung not having undergone an equal degree of compression: hence we see the reason why, in the earliest stage of pleuritic effusion, the compression has not been sufficient to produce the phenomenon; as the effusion increases, the compression is greater, and the phenomenon appears, the effusion increases still more, and ægophony gives place to broncophony; as absorption takes place, the compression becomes less, and ægophony appears again; hence we have equal reason to hail the return of this phenomenon as an indirect expression of the diminution of the fluid, but an immediate result of the diminished compression of the lung, and not of the diminished interposed fluid through which the voice is transmitted.

When the effusion is considerable and has formed within a short space of time, the respiration in the opposite lung becomes puerile. The increased action which has devolved upon this lung strongly predisposes it to disease, differing, however, from the original affection; that is to say, the lung is more likely to become consecutively affected either with bronchitis or pneumonia than with pleurisy. When

pleurisy is double, the two sides have become simultaneously affected, and their respective affections proceed *pari passu*.

When the effusion has proceeded to a considerable extent, it produces a change in the side, consisting in an actual increase of its size and form. It is remarkable how small a difference between the two sides, as ascertained by actual measurement, will strike the eye; an increase of six lines will have this effect. The change of form of the side consists in its becoming more rounded, and in the intercostal spaces being either effaced, or rising beyond the level of the ribs. In these spaces fluctuation can sometimes be detected. Change in the form and dimensions of the side has been recognized as a diagnostic sign of pleuritic effusion since the dawn of pathology.

When the effusion is on the left side, it will have the effect of displacing the heart, and of causing its pulsations to be heard either on the right side or in the epigastrium; hence, if we miss the heart in its normal position, and perceive its action in either of these situations, we have very strong grounds to suspect, if not conclusive evidence of, this lesion.

M. Reynaud has suggested a mode of ascertaining the existence of fluid effused into the chest, which consists in the application of the hand to the side where the effusion is suspected, and then making the individual speak, when the effused fluid will be found to interrupt the vibrations which the voice communicates to the walls of the chest when the lungs are sound.

Varieties of acute pleurisy.—Acute pleurisy may be double, that is, it may involve both sides of the chest at the same moment. This is by no means a common occurrence, and when it does take place, and is speedily followed by extensive effusion into both sides, the sudden and extensive mechanical interference with the function of respiration soon extinguishes life. Percussion affords us no assistance in forming our diagnosis in this case; for as we have no absolute standard of the degree of resonance which it should yield, it is by comparison of the two sides that we can alone judge; but the effusion, producing a dull sound in both sides, deprives us of the value of this physical sign. However, if we keep in mind the observations we before made upon the differences between pleurisy and pneumonia, and apply them to the subject under consideration, we shall have little difficulty in identifying this affection, and distinguishing it from the only modification of disease with which it could by possibility be confounded. Double pleurisy, but of inconsiderable extent, often takes place in the agony of acute diseases.

Partial or circumscribed inflammations of the pleura are very common. They in general produce no fever or constitutional disturbance, and are only announced by a pain more or less acute in some point of the walls of the thorax: the pain too is not a constant symptom. A slight exudation of lymph takes place, and this, in the course of time, is transformed into a cellular band. This is the history of those cellular adhesions which unite the pleuræ pulmonalis and costalis more or less intimately. These adhesions have often been found in persons who, during life, never gave reason to suspect any affection of the chest. Although these partial pleurisies may exist alone, they more frequently occur in cases of affection of the pulmonary parenchyma. Phthisis pulmonalis is their most fertile source, and hence arise the frequent pains in different points of the side, of which the subjects of this disease so often complain. These painful points bespeak inflammation of the corresponding portions of the pleura, and in our subsequent examinations we find adhesive cellular bands in these situations. The number of these adhesive bands is, in general, in the direct ratio of the number of tubercles, and they exist particularly in points corresponding to those where the tubercles are most abundant: hence their most constant situation is between the apex of the lung and the summit of the cavity of the chest; the adhesion here is sometimes so firm as to defy our utmost efforts to break it.

Some partial pleurisies demand peculiar attention in consequence of the particular symptoms to which they give rise. Inflammation of that portion of the pleura which lines the diaphragm claims our especial consideration upon this score. Its characteristic features are, in addition to the ordinary constitutional symptoms of acute pleurisy, pain more or less acute of the cartilaginous border of the false ribs, extending into the hypochondria, and even to the flanks; complete immobility of the diaphragm in inspiration, which is performed by the elevation of the ribs; orthopnœa, with an inclination of the body forwards; an inexpressible anxiety of countenance, marked by a sudden change of features; the respiration more hurried and jerky than in ordinary pleurisy; the voice low and interrupted, (entrecoupée); a frequent desire to cough, but an obvious dread of it from the pain which it causes. The intellect is free at first, but when the case is aggravated, and the constitutional symptoms run high, delirium comes on. In addition to the symptoms enumerated, we have the ordinary physical signs of pleurisy; viz. in the first moments of the disease, if the pain will allow us to employ percussion, we find a disproportion between the sound it yields in the inferior part of the chest, and the distinctness with which respiration is heard in this situation, the latter being feeble while the former is clear; in the course of a short time the sound here becomes dull, and the respiratory murmur ceases to be heard, and these two phenomena extend upwards in proportion to the extent of the disease. When the effusion takes place into the right cavity of the pleura, it presses down the liver, and causes it to be felt below the margin of the ribs; when it takes place into the left cavity, it produces a similar change in the position of the spleen. The signs which we have just enumerated may be regarded as the most constant and unequivocal of diaphragmatic pleurisy; others are occasionally present, viz. hiccough, nausea,

vomiting, jaundice, &c. It was the presence of jaundice that led Valsalva to regard the accidental complication as the original disease; a mistake which might naturally occur if, as happens in many cases, the features of the preceding pleurisy had not been strongly marked. The risus sardonicus, to which the ancients attributed so much importance as characteristic of this modification of disease, has not been found constant by modern observers.

There is a partial pleurisy which claims our attention, in order to guard against a pathological error into which we might fall did we not conduct our investigation with care. We allude to interlobular pleurisy, in which the cellular membrane, the result of the present or of a former inflammation, connecting the lobes of the lung, may become the nidus of an abscess, which a superficial observer might easily mistake for an abscess in the substance of the organ.

It is almost superfluous to observe that partial pleurisies owe their importance to the extent of surface which they occupy: the more extensive they are, the more serious are the consequences. Preceding pleurisies, in which adhesions have been formed, limit the extent of future attacks; these adhesions, as it were, divide the cavity of the pleura into smaller cavities, and thus circumscribe future pleurisies.

Inflammation may affect either the costal pleura alone, or the pulmonary pleura, or both at the same moment. In the first case, it is not always easy to determine whether the affection be rheumatism of the intercostal muscles, or inflammation of the costal pleura; we have in each the same pain produced by the same causes, and the same modification of respiration, in the performance of which the ribs seem to take no share. When the pulmonary pleura alone is affected, the pain is produced by the air inspired stretching this membrane, and it is the effort to avoid this that gives the short hurried character to the respiration.

There is a neuralgic pain of the side which is sometimes mistaken for inflammation of the pleura, but which differs from it in being unaccompanied with fever, and in the character of the pain, which is represented as a burning or scalding sensation, and not as a sharp lancinating pain. The neuralgic pain differs from the pleuritic in being relieved by pressure.

Causes of acute pleurisy.—These may be divided into the predisposing causes and the occasional or exciting causes. Among the first may be enumerated congenital malformation, consisting in narrowness of the chest; a sanguine temperament; irritability of the system; weakened health from previous disease; convalescence from fever; the puerperal state. The exciting causes embrace all mechanical injuries directly applied to the pleura; such as contusions, penetrating wounds caused either by cutting instruments,* or by sharp spiculæ of fractured ribs; extension of ulceration from a softened tubercle in the substance of the lung perforating the pleura, and giving rise to a complication to which we shall have occasion to advert; cold applied to the surface when the cutaneous capillaries are in a state of excited action, &c. The mode of operation of the cause last mentioned is supposed to be by directing the fluids from the circumference to the centre, and thus determining their afflux to the serous membrane; and as this cause has also the effect of producing a congestion of the parenchyma of the lung, and, in consequence, a tension and stretching of the investing pleura, it was supposed that in this way it contributed to produce pleurisy. The frequent complication of intermittent fever with pleurisy further countenanced this idea. However, we cannot but consider the rationale of this cause as too mechanical, and would rather connect it with some physiological sympathy existing between the skin and serous membrane of the chest. Pleurisy is often found to depend upon a certain *intemperies* of the atmosphere, which causes an epidemic spread of the disease; and like all epidemics, it then assumes a less sthenic type than isolated sporadic cases do; in this modification of the disease, the digestive apparatus is much deranged, and hence it has been designated *bilious pleurisy*. Metastasis of gout or rheumatism, or a repressed cutaneous eruption, may be the exciting causes of acute pleurisy. Pneumonia, by an extension of inflammation, so often induces pleurisy, that, as we before observed, it was long thought that they could not exist independent of each other. While pathology has controverted this error, it has shown us that pneumonia more frequently produces pleurisy than pleurisy produces pneumonia.

Pleurisy is said to be *latent* when it exists unannounced by the ordinary symptoms which usually accompany it, such as pain of the side, hurried respiration, dry cough, &c. We have observed pleurisy supervene in this insidious way in the convalescence from fever: the patient, after having made some advance towards recovery, is observed to fall back again; he makes no complaint of his chest; still on careful examination we observe a slight hurry of the respiration, and hear an occasional dry cough; these direct our attention to the chest, where we find unequivocal evidence of pleurisy with effusion.

Complications of acute pleurisy with other diseases.—We may premise that acute pleurisy is much oftener simple and uncomplicated than chronic pleurisy. The frequency of the coincidence of acute pleurisy and pneumonia *(pleuropneumonia)* claims the first place in the enumeration of the complications of acute pleurisy. The pneumonia may be either the cause of the pleurisy, or it may be the consequence of it; or these two diseases may commence at the same moment, being the independent effects of the same morbid impression. In general, in pneumonia, when the inflammation reaches the surface of the lung, the contiguous portion of the pleura becomes inflamed, and is coated

* We have seen a fatal case of pleurisy produced by perforation of the pleura in passing the needle round the subclavian artery for the cure of aneurism of this artery.

with a layer of lymph, usually thin, and often an exact measure of the extent of the inflammation of the lung. When the entire lung becomes hepatized, we have often observed the whole investing serous membrane covered with a more or less dense false membrane, marked with parallel lines produced by the impression of the ribs upon it. This complication exhibits the most common case of what has been termed *dry pleurisy*. We need hardly observe that the pleurisy here is of very subordinate importance: it is that, however, of which the diagnosis would embarrass us most, had we not seen the case at its commencement. The pressure of the effused fluid may have the effect of exciting inflammation in the lung: the ordinary stethoscopic phenomena will disclose this complication. The inflammation seldom goes beyond the first stage of pneumonia; and from the repeated opportunities we have had of examining the bodies of those who died with pleuritic effusion, and the few specimens we have seen of pneumonia in the compressed lung, we believe this complication to be very rare, and suspect that the carnified condition of the lung has been not unfrequently mistaken for the first stage of pneumonia. Laennec remarks that the pressure of the fluid has rather the effect of placing the lung out of the pale of inflammation. The third complication, or pleuropneumonia properly so called, in which the proper tissue of the lung and its investing membrane are simultaneously affected, is recognised by its exhibiting the stethoscopic phenomena peculiar to each lesion. The case is not very much aggravated by the complication; Laennec even considers the danger less than if either existed alone in a more considerable degree; for he is of opinion, as we above stated, that the pressure of the fluid controls the pneumonia, and that, in return, the absorption of the effused fluid is promoted by its being compressed between the unyielding solidified lung and the sides of the chest. This is a case in which the fluid is interposed between the lung and the side of the chest, in consequence of the lung, from its increased density, not admitting of displacement.

We have before adverted to the frequency of the complication of pleurisy and tubercles in the lungs, in which case there generally existed adhesions between the pleuræ pulmonalis and costalis. However, it will happen that, in some instances, nature will seem as it were to neglect the precaution of establishing an adhesion between the opposite serous surfaces; and softened tubercles situated near the surface of the lung will, in obedience to the pathological principle of purulent matter seeking the easiest and shortest outlet, perforate the pleura, and immediately give rise to a most intense pleurisy, marked by a very acute pain of the side, most distressing difficulty of breathing, and extreme anxiety. When we come to examine the chest, we find all the physical signs which characterize pneumothorax with effusion, (vide PNEUMOTHORAX,) in which case we know the lesion to consist of pleurisy and a tubercular cavity into which a bronchial tube opens. It may happen that the softened tubercle perforating the pleura will only give rise to simple pleurisy, in consequence of its not communicating with a bronchial tube.

Gangrenous ulceration of the lung and pleura will cause either pneumothorax or pleurisy; in addition to their respective signs, the sputa and breath have an insupportable fœtor.

Pleurisy of one side is not unfrequently complicated with some disease of the opposite lung, arising out of the increased duty that has devolved upon it. This lung may either become emphysematous, or the subject of bronchitis or pneumonia. It is frequently attacked with sudden congestion, which produces most urgent sense of suffocation, and renders the patient's situation truly pitiable. We have before alluded to the fact that when pleurisy of one side exists, it seldom involves the pleura of the opposite side, but leads either to pneumonia or bronchitis; and when pleurisy is double, there is a fair start between both sides, and their affections proceed *pari passu*.

Prognosis of acute pleurisy.— Pleurisy is ever a serious disease; in many cases, however, it terminates favourably. The danger is proportionate, 1st, to the cause upon which the disease depends: when it depends upon ulceration of a tubercle, or upon superficial gangrene of the lung, it is always fatal: 2d, to the extent of the inflammation: double pleurisy is attended with more danger than when the disease is confined to one side; and when the whole cavity of the pleura is inflamed, the prognosis is more unfavourable than when only part of it is affected: 3d, to the quantity and nature of the effusion: 4th, to the time during which the effusion has existed: 5th, to the diseases which complicate the inflammation of the pleura, or which exist along with it.

Previously to noticing the treatment of acute pleurisy, we shall give the history of the disease in a chronic state.

II. CHRONIC PLEURISY.—There are two distinct kinds of chronic pleurisy: one, the continuation, as it were, of the disease in its acute form; the other, to use the usual but paradoxical expression, chronic from its commencement; that is to say, at no period exhibiting either the intense fever, the acute pain, or energy of reaction which characterize an acute disease. When the diagnosis of diseases of the chest was less certain than it has been since the acquisition of the stethoscope, the first form of chronic pleurisy was much more common than it is at present, for this reason,—that formerly being without the means of appreciating the physical signs of the disease, when the pain, the most prominent symptom, had yielded to antiphlogistic means, it was then conceived that the inflammation was subdued and the cure complete; the patient then returning to his former diet and resuming his usual occupations, was often surprised by an attack more violent than the former. Our improved mode of examination teaches us that

every symptom of inflammation may have disappeared, every function apparently be restored to its natural condition, and still there may be considerable effusion into the cavity of the chest: until this be entirely removed, we never can feel secure about our patient. Pleurisy, in its essentially chronic form, creeps on very insidiously, without much acceleration of pulse or heat of skin; and when there is any *unusual* sensation in the side, it does not amount to more than a mere soreness: the difficulty or hurry of breathing is sometimes so inconsiderable as not to attract the individual's attention. An observer is struck with the patient's unhealthy pallid appearance; there is a loss of appetite and a languid look, which emphatically tells us of some mischief going on; on close examination we find that the absence of fever is not constant, but that towards evening there is a febrile movement. A dry cough, or one attended with scanty mucous expectoration, and which has existed a considerable time without any apparent dependence either upon crude tubercles in the lungs or upon gastro-intestinal irritation, should lead us to suspect the possibility of chronic pleurisy.

The anatomical characters of chronic pleurisy do not differ very widely from those of the acute form, especially when it has been a mere transition of one form of the disease into the other. In this latter case, no matter to how distant a period the disease may be protracted, the fluid effused retains to the last its primitive character. As in acute pleurisy, it is a straw-coloured serum, but more consistent, apparently owing to its holding in suspension a considerable portion of the fragments of the false membrane, which, on the fluid settling, sink to the bottom. These condensed fragments, which, on opening the chest, are found in its most dependent parts, constitute, according to Laennec, a connecting link between the sero-purulent effusion and the false membrane. In essentially chronic pleurisy the effusion partakes more of a purulent character: in this case the disease closely resembles an abscess, the false membrane investing the pleura corresponding to the cyst, and endowed with the physiological properties of absorption and secretion. If the constitution be imbued with a scrofulous taint, (which is the habit in which we most frequently meet with this morbid condition,) the effusion will exhibit the ordinary characters of scrofulous pus, viz. a thin, whey-coloured matter, with flocculi of lymph floating in it. When the effusion is mainly purulent matter, mixed with a small proportion of serum, it is of a greenish colour, and very much resembles an infusion of tea to which a small proportion of milk has been added. The effusion in chronic pleurisy is not as exempt from smell as that in the acute disease.

The false membrane in chronic pleurisy is not essentially different from that in acute pleurisy; it is only firmer and more condensed, owing, perhaps, to the longer time it has been under the pressure of the effused fluid. It is capable of all the transformations of which we stated it to be susceptible in acute pleurisy; and to its conversion into fibro-cartilage Laennec ascribes a particular change in the configuration of the chest, to which we shall presently have occasion to advert. It is more prone than in acute pleurisy to become the matrix of morbid developments, especially tubercle.

The lung is more compressed than in acute pleurisy; it is often reduced to a thin lamina, not exceeding six lines in thickness, lying down along the spine. There is also a more complete annihilation of its vesicular structure. It was this condition of the organ that led less careful examiners to pronounce upon its entire removal. Tubercles or other morbid growths may develope themselves in it, and, undergoing their proper changes, modify the symptoms of the original disorder.

Diagnosis of chronic pleurisy.—The physical signs of chronic pleurisy differ little from those of acute, except in being more prominently expressed; and apparently for this reason,—that the disease, from its insidious character, has excited little constitutional alarm, and therefore the individual labouring under it has unconsciously permitted it to go on without seeking medical relief. In general, then, when it presents itself to the physician, it has existed for a considerable time. The affected side is more rounded; the intercostal spaces are more dilated, and raised above their natural level, in some cases admitting of fluctuation being felt; the integuments of the side often become œdematous. When the disease has existed for a long time, the spine is observed to deviate from its natural direction, and to form a curve with its concavity looking towards the affected side. If the left side be the seat of the effusion, the heart undergoes the same displacement as in acute pleurisy.

The œdematous state of the integuments lessens, at least, the value of percussion as a means of assisting our diagnosis. There is not only a more complete absence of respiratory murmur, but not even ægophony or bronchial respiration are present. Double chronic pleurisy is a very rare form of disease.

Partial or circumscribed chronic pleurisy is more frequently met with than the same modification of acute pleurisy; and although there are many circumstances connected with it calculated to embarrass the diagnosis between it and pneumonia, especially our seldom having an opportunity of observing it *ab initio*, still the marked expression of the physical signs seldom leaves us at fault. It sometimes happens that the circumscribed nature of the affection shews itself to the eye by a distinct line of demarcation intersecting the side of the chest. If it happens that the pleurisy occupies the inferior part of the side, (which is most frequently the case,) below this line will be found the physical signs of pleurisy, with dulness of sound and absence of respiration; while above it, the only deviation from the ordinary state of things is puerile respiration.

Pleurisy assuming a chronic character from its commencement generally occurs in a cachectic habit of body, or where the health has been broken down by previous illness. We

have met with it more than once after fever, and usually either in scrofulous habits, or in persons much addicted to intemperance.

Prognosis of chronic pleurisy.—The prognosis of chronic pleurisy is, generally speaking, very unpromising; however, if it exist as an isolated affection, apart from any complication, it may go on for months, nay, for years. If, as is often the case, tubercles form and go through their changes either in the compressed or in the opposite lung, the complication will have the effect of precipitating the fatal termination. In the ordinary course of the disease, a slow wasting fever sets in; there is a gradual emaciation; the appetite fails; the pulse is languid, although not much quickened; the legs swell, and the face becomes puffed; the expectoration often has a disagreeable alliaceous smell. Upon these symptoms well-defined hectic fever soon supervenes, and rapidly wears down the patient.

Nature often takes the cure of pleurisy into her own hands, and seeks to relieve herself of the fluid effused into the chest in one of the following ways: 1. by absorption: or, 2, when the fluid is purulent, by making a passage for it through the pulmonary tissue into a bronchial tube, from whence it is expectorated; or through the walls of the chest, from whence it flows immediately out; or in some cases she adopts these two last ways at the same moment.

When the disease has existed a long time, and nature at length takes upon herself a slow, gradual process of absorption, which she takes a considerable time to complete, we observe that remarkable change in the form of the side to which we before made allusion: this side, which was before perceptibly longer than the opposite one, now becomes less; it is diminished in all its diameters, its circumference sometimes measuring less by an inch than that of the opposite side. Its length is not less encroached upon; the ribs are approximated, the shoulder becomes lower, and even the spine in some cases assumes a lateral inclination from the habitually bent position of the patient. The muscles of the chest, especially the great pectoral, seem to have lost half their volume. We shall easily comprehend the nature of this change when we reflect upon the cause upon which it depends. Laennec, who was the first to notice it, charged it upon the fibro-cartilaginous nature of the false membrane, which continued to oppose itself to the lung's being restored to its original condition: it interfered with its vesicular texture so as to render it impervious to the air: the organ had, in fact, virtually undergone a change of dimensions, in consequence of which the relation between it and its containing cavity was lost. The atmospheric pressure acting upon the side, and not counterpoised from within, causes it as it were to fall in and accommodate itself to the altered condition of the lung. We cease to wonder that the unyielding bony case should have its form influenced by this condition of the lung, when we reflect how speedily an opposite state, or dilatation, will succeed to an emphysematous condition of the contained organ. A cause mainly instrumental in the contraction of the side is the atrophy of the muscles from disease, respiration being exclusively carried on by the opposite side.

When nature relieves herself of the accumulated fluid by a passage through the pulmonary tissue into a bronchial tube, the individual, who has been for some time labouring under either a dry cough or one attended with scanty discharge, is suddenly seized with an abundant expectoration of greenish purulent matter, which comes forth with such a gush as to appear to be vomited rather than expectorated. This discharge from the lungs continues from day to day, the quantity gradually diminishing till it ceases altogether. In proportion as the matter is discharged, we perceive the fulness of the side to give way, and to come down to its normal dimensions. In this case a considerable time will elapse before percussion and auscultation yield their natural results, the sound continuing dull, and respiration feeble; still the function of the lung will ultimately be restored, differing from the case of contraction of the side, in which the dull sound and feeble respiration are permanent.

The third expedient which nature adopts for the discharge of the purulent fluid in the chest is to give the pleurisy the character of an abscess, making its way through the walls of the chest, and pointing externally. When the apparently small abscess on the side of the chest either opens spontaneously, or is opened by art, it discharges a quantity of matter quite disproportionate to its size, and this matter is pumped out at each expiration and cough. Sometimes the matter gets vent both through a bronchial tube and through the side of the chest at the same time. It is a singular fact that when the fluid in the chest is discharged through the lung, and consequently through a communication established between a bronchial tube and the cavity of the pleura, pneumothorax does not ensue, although it is previously the same lesion that gives rise to this morbid phenomenon, the difference being only in the mode in which this lesion takes place.

Treatment of pleurisy.—If the energy and activity of our practice in the phlegmasiæ should be in proportion to the importance of the part inflamed, there is scarcely any part in the whole animal machine of which the inflammation demands a more decided and uncompromising plan of treatment than the pleura. If we temporize in the treatment of pleurisy, the least evil we can anticipate is a protracted convalescence; whereas if we meet it, *in limine*, with vigour, we often as it were strangle it in the birth.

I. *Treatment of acute pleurisy.*—The treatment of acute pleurisy comprises all the means usually employed to reduce constitutional fever and local inflammation.

Bloodletting.—In the first stage of the disease, when febrile excitement runs high, and is accompanied with much local distress, we should bleed with an unsparing hand from a large orifice, and in the manner most calculated to make the speediest impression upon the system.

Should a single bleeding conducted in this way fail to afford very decided relief, we should resort to the operation again within a few hours, and repeat it at more or less distant intervals, according to the urgency of the symptoms and the capability of our patient to bear further loss of blood. Some have attempted to fix the precise quantity of blood to be drawn in the cure of a pleurisy; a generalization to which nature will not submit, the effects of bleeding differing in different individuals. It would be to trust to a very fallible guide indeed were we to depend upon the indications of *the pulse*. In this, as well as in the inflammations of all other serous membranes, the pulse, so to speak, as often underrates as exaggerates the extent of the mischief, being rather a measure of the constitutional irritability of the individual than of the actual amount of disease. The usually accompanying *pain* is a symptom upon which we can place more reliance, and the effects produced upon it serve in some measure to guide us as to the extent of depletion; but even it, so far from being proportionate to the extent or intensity of the inflammation, is often absent when the inflammation occupies a considerable extent of surface; and even when both sides are affected at the same moment, if it be present, it is often found not to amount to more than a mere soreness. The *dyspnœa*, or rather the nervous dread of drawing in a full breath, in many cases lasts for so short a time, that we must see the patient in the first moments of the attack to have the value of this symptom. Were we to lay down any general rule, deduced from the common symptoms, as to the limit to which we would carry sanguineous depletion, we should be most disposed to regulate this by the strength of the patient, and the relief of the pain and consequent power of taking in a full inspiration.

While we distrust the indications of the pulse, which, in some cases, from its composure, is calculated to mislead us as to the expediency or necessity of bleeding, so we should be equally on our guard not to be betrayed into the opposite error of considering an accelerated pulse, which may be produced by the depletion we have employed, as the index of continuing inflammation, and be thus led to push depletion still farther, and thereby originate functional disorder ultimately terminating in organic disease of the heart. We have seen this mistake so often committed, that we deem it necessary to subjoin this caution.

While we employ general bleeding, we may at the same time seek to relieve the local congestion by cupping and leeching. In the necessarily protracted operation of topical bleeding, we should manage it with caution, so as not to run the risk of exposing our patient to cold. Venesection does not seem to be equally applicable to every modification of pleurisy. Thus, when it prevails as an epidemic, or developes itself in the progress of fever, or occurs as a puerperal disease,—in all these instances it assumes an asthenic type, when it becomes very questionable if general bleeding be at all admissible, or if we should not rather confine ourselves to local bleeding, with such other resources as art affords. This at least is certain, that in these cases bleeding should be employed with extreme caution. In circumscribed pleurisy, with which the constitution does not seem to sympathise, the application of a few leeches to the seat of the pain will often remove all uneasiness. If, as in phthisis, in which partial pleurisy is so common, the exhausted state of our patient will not bear even so small an abstraction of blood, the temporary application of a hot turpentine stupe will often answer our wishes.

Purgatives.—The saline purgatives are especially suited to this first stage of pleurisy, as they diminish the mass of the circulating fluid by greatly increasing the secretion of the intestinal mucous surface. We follow up this antiphlogistic treatment by other means calculated to reduce fever, by producing diaphoresis, or otherwise, viz. the different preparations of antimony, tartar emetic in very minute doses, James's powder, Dover's powder, &c.

Sedatives.—These are often very useful in quieting the irritation of the cough, and thus procuring the repose of the organ affected. With such a view we derive much benefit from the use of hyoscyamus, conium, lactucarium, &c. Some recommend the use of opium in larger doses after bleeding, by which we continue, as it were, the sedative impression of the bleeding, as well as allay the irritation produced by the pain, and soothe the cough.

Mercury.—The combination of calomel and opium enjoys an established celebrity in the inflammations of serous membranes; and after the use of venesection, and where there exists much pain, the remedy is invaluable. In such cases, our object is to bring the system as speedily as possible under the influence of mercury, by which we as it were supersede the morbid action which is going forward.

The treatment which we have just laid down applies to the earliest stage of pleurisy. However, it often happens that the patient does not present himself till the disease has existed at least for some days, and the intensity of the symptoms has in some degree abated, when the inflammation has assumed rather a subacute character, and has partly terminated in effusion. It is now that we have most reason to complain of the pulse not intimating to us the extent of the mischief. We now come to the long agitated question,—how late in the progress of pleurisy are we warranted in using the lancet? Without attempting to lay down a general rule upon the point, we would say that even now, notwithstanding the tranquillity of the pulse which often exists, we expect decided advantage from bleeding, inasmuch as we thereby, 1. check the further effusion of fluid; 2. promote the removal of the fluid already effused, by increasing the powers of the absorbing system at the expense of the circulation; 3. render the system more susceptible of the influence of the medicines we employ.

When the inflammation has nearly subsided, and the acute pain given way to a mere sensa-

tion of soreness, and we have the physical evidences of effusion, the indications of cure now are different, our main object being to promote the removal of the effused fluid. The means we employ for this purpose are either internal or external; the former comprising those medicines which, acting by way of derivation either upon the kidneys or bowels, thus indirectly affect the effusion; the latter comprehending the different modifications of counter-irritation, which, by stimulating the absorbents, tend to produce the same effect more directly.

Diuretics.—The popular combination of squill, digitalis, and calomel, produces as speedy a diuretic effect as any we can employ. Laennec speaks highly of the infusion of digitalis from experience of its value in the particular case under consideration. It recommends itself to our notice upon the double grounds of its diuretic property and the control it exercises over the circulation; an important recommendation, when we consider the proximity of the organ affected to the source of the circulation, and the advantage from the blood being driven into it with diminished impetus. We may also employ, separately or in conjunction with the above, the saline diuretics, viz. the nitrate, acetate, and bitartrate of potash.

Purgatives.—If the strength of the patient will permit, we may make use of the hydragogue cathartics, viz. elaterium, jalap, scammony, camboge, &c.; but the operation of these medicines is attended with so much exhaustion, that we can only employ them occasionally.

Diaphoretic medicines afford us such very feeble assistance at this stage of the disease, that they scarcely deserve a place among our remedial agents. We have not found tartar emetic to sustain its character of an active antiphlogistic agent in uncomplicated acute pleurisy; but when the lung is involved in the same inflammation, we then find the advantage of associating it with our remedies.

When we are endeavouring to affect the system with mercury administered internally, we may at the same time employ mercurial friction on the side, by which we assist the internal exhibition of the mineral, while we stimulate the absorbents.

Stimulating liniments carry with them the advantages that we can regulate their irritating property *ad libitum*, and that they do not unfit the surface to which they are applied for any future application.

When the milder counter-irritants, as auxiliaries to the internal means employed, have failed to make any impression upon the fluid, we resort to blisters. Andral's work* abounds in cases in which the removal of the fluid seemed to date itself from the application of a blister. A succession of blisters acts more effectively than a single one of which the discharge is continued by an irritating application.

As long as fever and inflammation are present, we of course insist upon rigid abstinence. But when these have subsided, and have left their effects alone behind them, the reasons for continuing the same strict system are scarcely less cogent; for in this way we lower the circulation, and thus establish a physiological ratio between its powers and those of the absorbing system, whereby the latter are much increased, and act with much more avidity upon the fluid in the chest. We find it extremely difficult to carry this part of our treatment into effect; for our patient will regain a degree of health, and feel very little if any inconvenience from the fluid in the chest, and not being able to reconcile our severe restrictions with his sensible amendment, will become impatient of restraint, and, yielding to his improved appetite, will in all probability bring on fresh inflammation.

Sometimes a considerable time will elapse before any impression is made on the fluid, the system seeming as it were to stand out against the operation of our remedial agents up to a certain point, and then suddenly yielding, its removal rapidly ensues. At other times our medicines begin to take effect quickly, and remove the fluid gradually. We recognise the effects of our remedies by the side losing its fulness, by the reappearance of ægophony,* by the return of the respiratory murmur and clear sound to situations where we before sought them in vain. Percussion will continue to yield a dull sound for a considerable time after the return of the respiratory murmur.

It seldom happens that in acute pleurisy we have to resort to the operation of *paracentesis thoracis;* nor should we ever think of it as long as we have any prospect of removing the fluid otherwise; still it may happen, from the other lung becoming affected either with bronchitis or pneumonia, or from having been already emphysematous, that to relieve the urgent sense of suffocation we have no alternative. In almost all these cases we find the operation to be attended with no more than a mere temporary relief, the fluid soon collecting again. It is an ascertained fact that the operation is, in general, less successful in acute than in chronic pleurisy, the reasons for which we shall endeavour to explain when we come to speak of the treatment applicable to the latter form of the disease.

1. *Treatment of chronic pleurisy.*—The treatment of chronic pleurisy, or of that modification of the disease which from its commencement exhibits some of the characteristics of an acute inflammation, is as different from that of acute pleurisy as the respective natures of the two forms of the disease. Antiphlogistic means, whose activity is measured by the intensity of the febrile symptoms and the strength of the individual, constitute the treatment of acute pleurisy; and amongst these means, bleeding, as we have seen, occupies a most prominent place. In essentially chronic pleurisy,

* Sur les Maladies du Poitrine.

* This effect was ascribed by Laennec to the transmission of the voice through a diminished stratum of fluid; but we consider it to be rather due to a less compressed state of the lung from the diminution of the compressing fluid.

we seldom, if ever, have occasion to resort to constitutional bleeding. The weakened, if not the vitiated habit of body in which it generally takes place, will not admit of the exhaustion which this operation would produce; even local bleeding must be employed with considerable caution. The indications of cure are, to remove the fluid from the cavity of the chest, and to improve the dilapidated state of the system. The means by which we try to promote the removal of the fluid may be divided into constitutional and local; the former comprising those agents whose action is directed to some organ or set of organs at a distance from the seat of disease, and which effect the object we contemplate by establishing a counter-irritation and increased secretion at the expense of the diseased secretion, which continues to take place into the chest until it is as it were superseded.

Most of the means which we adverted to as applicable to the stage of acute pleurisy when effusion has taken place, may be seasonably employed in chronic pleurisy, qualified alone by the consideration that in the latter form of the disease the habit of body in general is not such as will bear the operation of active medical agents. When we employ mercury, we must manage its exhibition with caution, and beware lest, in pushing its use too far, we give rise to an irritative fever, which would soon exhaust the weakened constitution in which this modification of pleurisy usually presents itself: we should content ourselves with slightly affecting the gums. When hectic symptoms show themselves, we should cautiously abstain from the use of mercury altogether. We employ the same diuretics as in the second stage of acute pleurisy. We cannot, without incurring the risk of weakening our patient too much, resort to active purgation; we must, therefore, be satisfied with the mildest medicines of this class, and those whose operation draws least upon the stamina, viz. castor oil, manna, &c. Diaphoretic medicines lend us more aid in this than in the second stage of acute pleurisy; for instance, Dover's powder, James's powder, &c.

Constitutional means or internal medicines, we must in candour admit, do not assist very much in the removal of the fluid.

The external applications, and upon which we place our principal reliance, comprehend the different modifications of counter-irritation, viz. blisters, setons, issues, stimulating liniments, &c. Blisters are unequivocally the means most calculated to promote the absorption of the fluid secreted into the chest, as well as to interfere with its further secretion. We employ a blister commensurate with the extent of surface involved in the inflammation, and repeat its application in preference to keeping the blistered surface open by means of irritating substances, each repetition having as it were the effect of renewing the counter-irritation.

The next part of the treatment of chronic pleurisy regards the improvement of the habit of body and relief of the constitutional symptoms which most commonly accompany this form of the disease. We are not obliged to prescribe the same restricted diet as in acute pleurisy, but would admit a certain latitude, always taking care to avoid such substances as are calculated to produce febrile excitement, and consequent acceleration of the circulation; for, as we before observed, the powers of absorption and circulation observe an inverse ratio, and as we require the efforts of the former to remove the fluid, we should defeat our object did we not observe this caution. It is, besides, an object of importance that as little blood as possible should be transmitted through the lung lying under the pressure of the fluid. In many cases chronic pleurisy is attended with such slight constitutional symptoms as scarcely to deserve to be considered more than a local disease; still in most instances hectic fever sooner or later sets in. At this stage of the disease, change of air is productive of the most decided benefit, often effecting an almost instantaneous amelioration in the symptoms: the night perspirations cease, the appetite improves, and sleep becomes refreshing. In the exhibition of tonics we have had reason to prefer the infusion or decoction of bark, combined with sulphuric acid, to the more concentrated sulphate of quinine. We have found much advantage, in these and similar cases, from the mineral acids in decoction of Iceland moss. When our curative means take effect, we recognize their success by the physical signs of the disease gradually disappearing; by the side losing its fulness; by the intercostal spaces sinking down to their ordinary level, and being less dilated; and by the return of a feeble respiratory murmur, and a less dull sound on percussion; and, in case of the left side having been the seat of the disease, by the heart's pulsations being felt in their normal situation; and by the liver ceasing to be felt below the margin of the right false ribs when the disease has occupied this side. But when, instead of these evidences of the efficacy of our means, we find the fluid to increase, and all the sensible signs of the disease more marked, and in consequence the dyspnœa more distressing, the operation of tapping the chest is our last and only resource. We must confess that the results that have usually attended this operation are far from being calculated to inspire us with encouraging anticipations, (see Empyema;) still even the few cases in which either complete recovery or relief for a considerable time has followed it, prevent us from despairing. It is impossible to judge what might be the event were the operation undertaken earlier; this must be a matter of conjecture, as we must ever look upon an operation, the unavoidable consequence of which is the admission of air into the inflamed cavity of the chest, as a serious matter, and only warranted by the failure of other means to produce the object we desire. We have similar effects produced in chronic abscesses when opened. As long as they had no communication with the air, so long they produced no constitutional disturbance; but no sooner is the air admitted than hectic symptoms

quickly supervene. The cavity of the chest affected with chronic inflammation resembles a chronic abscess, both in its physiological and pathological conditions. The failure of success of the operation for empyema may be ascribed to the following causes;—to the irritative fever which often follows immediately upon the operation; or to the condition of the lung, occupied by tubercles in different stages, and giving rise to constitutional symptoms; or to the lung having been so long pressed upon by the fluid as to render its natural elasticity quite irrecoverable. We have before observed that the operation, undertaken under the most auspicious circumstances, is not exempt from a certain share of danger.

We now come to consider if there be any case so hopeless and desperate that we can promise ourselves no advantage from the operation: if such case there be, it is when there is extensive tubercular development in the compressed lung; but even here Laennec does not hesitate to recommend the operation, from his conviction of the curability of phthisis even when there exists unequivocal evidence of a cavity in the lung.

Mr. Crompton has had considerable experience of the operation for empyema and its results; and of ten cases upon which he has operated, three have been attended with complete success. After operation, his practice is to inject a weak solution of chloride of lime, which he finds to have the effect of diminishing the discharge and of correcting its character. (See Empyema.)

We have remarked that the operation of tapping the chest is more likely to be successful in chronic than in acute pleurisy; that is to say, if an untoward combination of circumstances demands operation in the early stage of acute pleurisy, such operation is more uncertain in its result than the same operation undertaken in chronic pleurisy at a period equally distant from its commencement. This fact, established by experience, we would account for in one of two ways; either that the constitution sympathises less, or suffers less irritation from the admission of air into the cavity of the chest, covered with a dense coating of lymph, as is the case in chronic pleurisy, than from letting in the same fluid upon the naked pleura unprovided with any such protection; or perhaps it may depend upon inferior susceptibility of inflammation in one case than in the other. In chronic pleurisy, the older the disease is the less likely is the operation to be successful, because the more chance is there that the lung is disorganised; and the longer the lung has remained under pressure of the fluid, the less likely is it to recover its natural elasticity. The more circumscribed the pleurisy is, the more promising is the prospect of a successful operation.

For further information on the subject of the present article, we refer the reader to Empyema, Perforation, Pneumonia, and Pneumothorax.

(Robert Law.)

PLICA POLONICA, from *plico*, to knit together. This disease derives its name from the manner in which the hair is plaited or matted together, and, as its name also implies, is of most frequent occurrence in Poland. It has, however, been also observed in Tartary, among the Cossacks of Russia, in Hungary, and in a few instances in Switzerland and France. The people of Poland believe that it was carried into their country by the Tartars in the twelfth or thirteenth century. Schlegel, a physician practising in Moscow, who published a work on plica in 1806, gives a singular account of its origin. The Poles on the death of one of their kings, Miceslas II. in 1034, petitioned Pope Benedict the Ninth to release from his vows Casimir the son of Miceslas, who had entered into a convent of Benedictines in France; the request was granted on certain conditions, and one of the conditions required was, that from that time forward the men of Poland should keep their heads shaved. Casimir on his accession enforced the tonsure through all his dominions, and to the present day a part of the ceremony observed in assuming the national costume of Poland consists of shaving the head, a single tuft of hair being left to grow from the top of the scalp after the manner of the Tartar and some Indian tribes. The poorer inhabitants of Poland being wretchedly lodged and clothed, and exposed to the combined injurious influence of a marshy soil and a damp variable climate, the general cutaneous exhalation is at all times below the healthy standard, and the secretion from the scalp being still farther diminished by the custom of keeping the head shaved, there is, according to Schlegel, an increased compensating action thrown upon the bulbs of the hair which has been allowed to remain; and hence arises the greatly increased growth of this portion of the hair, and the unnatural quantity of viscid secretion which is at the same time thrown out.

The hair grows to a very unusual length, and being not only plaited but matted together by a viscid fatty secretion of an abominably fetid odour, resembling the stench of rancid fat, and in most instances crowded with vermin, presents an extremely disgusting picture of filth and disease. The hair of the scalp is that generally affected, but the disease is also seen in the axillæ, on the breast, and the pubes. In a few rare instances the nails are altered in their appearance, become livid or yellowish, long, and crooked, so as to resemble the talons of a bird of prey: this change is generally in the nails of the toes. The length which the hair sometimes attains is almost incredible. Cases are narrated of its reaching to the heels, of its being in such quantity and of such a length as to fall on the floor over all sides of the bed on which the patient lay. In the museum of Dresden there is a specimen preserved nine feet long. Not the least singular circumstance in the history of plica is the extraordinary attachment the Poles entertain for this dirty appendage. If the hair do not become spontaneously matted and filthy, the Poles spare no pains to make t so: the men

put on dirty fur bonnets which have become coated with viscid secretion from being worn by others who laboured under the disease, or they interlace with their own hair masses of old plica steeped in beer! The women wear their hair very long, and, to encourage the growth of plica, refrain from combing it, and fasten it in knots, and make it adhere by glue or rosin. They will for years willingly suffer the greatest torture in carrying or dragging after them a mass of this matted hair, and beggars who are fortunate enough to possess a good plica cherish it with the greatest care as the most certain means of obtaining alms. In some parts of Poland the lower classes look upon plica as a special favour from Providence, which will preserve them from harm and sickness; in other parts it is viewed as an infliction coming from a malignant spirit, but not the less cherished, as it is then considered a protection from all other misfortunes. Lafontaine, a physician resident in Warsaw, who published a work on plica in 1792, relates the case of a pregnant woman who had plica of four months growth on the pubes: during that period the urine was allowed to filter through the matted hair, and after labour commenced she could not be persuaded to permit the plica, which firmly resisted the protrusion of the child's head, to be incised, until her life was in the most imminent danger.

The prejudice in favour of plica is extended even to inferior animals. Horses presenting an appearance of the disease are valued beyond others, and hence the jockeys of Poland have learned to add another to the many arts practised by their brethren of other countries. It is said that in Poland, and in some parts of Russia, plica is occasionally observed in sheep, dogs, wolves, and foxes.

The physicians of Poland have not escaped the contagion of prejudice. Kerckhoff,* whose observations were made during the stay of the French army in Poland, relates a case illustrative of this. The patient, a boy of about fifteen years of age, complained of severe pains of his head. He lay in a most filthy state, and his black hair, knotted long and matted together, gave out an intolerable stench. The Polish physician in attendance strongly opposed Kerckhoff's suggestion of cutting off the hair, on the ground that the humour exuded on the hair might turn in on the brain and cause apoplexy. Kerckhoff entered into a compromise with the Polish doctor; and the hair was cut off in portions of two fingers' breadth at intervals of two and four days. In twenty days the whole scalp was cleared, and then, by simply keeping the head combed and washed, all the bad symptoms vanished.

Stories are related by some writers of the disease appearing very suddenly, and the hair preserving for years the particular form of dressing it possessed at the time of the seizure. These stories are, however, treated as fables by the best informed authors; and a statement generally made and believed in Poland, that the long hairs of plica are acutely sensible, and are the seat of great pain when touched, is equally void of foundation. In some instances the bulbs of the hair and the scalp are very sensible, owing to irritation, and pulling the hair ever so slightly gives acute pain; but Larrey and all modern observers positively assert that the hair may be cut at any part without causing the slightest pain, provided it be done without dragging the bulbs.

Pathology.—On the nature of plica the most opposite opinions are entertained. By some it is pronounced as a disease "sui generis," having its seat essentially in the bulbs of the hair, and requiring very cautious treatment. Others as stoutly assert that plica is merely the product of neglect and dirt, and that it requires for cure nothing but the shears and cleanliness. This difference of opinion is not alone between foreign observers and the physicians of Poland, but the latter themselves are divided on the question. Among those who hold the first opinion are Lafontaine, who asserts that he saw the disease in a new-born infant, and Robin, surgeon to Frederick the Great, who relates the following experiment. He shaved the heads of two boys on whom the disease was just beginning to appear, and then paid particular attention to the hair during its growth. His attention was in vain, for the disease re-appeared. Schlegel agrees with Lafontaine and Robin; and more lately among foreign physicians, Chaumeton and Mouton, who were attached to the French army when in Poland during the late war, hold the same opinion. It is further argued in support of their view, that if plica owed its origin merely to want of cleanliness, it would not be confined to Poland, but should be equally found among the Russian, Prussian, and Spanish peasants, who are as dirty in their habits as the lower classes of Poland; that its appearance frequently constitutes the marked crisis of some other disease; that it is accompanied with a peculiar secretion; that the nails, which are known to be merely a variety of the same tissue as the hair, are in bad cases engaged by a similar diseased action; and that the bulbs of the hair exude a peculiar viscid secretion, and are found swollen and acutely sensible. In conclusion, it is asserted that plica cannot be suddenly removed without great danger to the patient. On the other hand, Davidson, a Scotchman, who was physician to one of the kings of Poland, published a work in 1668, in which he pithily observes of the disease, "Nullus habet, nisi qui non velit carere," and declares that he treated and cured more than 10,000 cases; that he always, without hesitation, cut off the plicæ, and that no injurious consequences supervened. Larrey, Chamsern, Gasc, Kerckhoff, &c. who had opportunities during the late war of investigating the disease in Poland, support the opinion promulgated so many years since by Davidson, and assert with him that the fear entertained of cutting off

* Observations Médicales par Jos. Rom. Louis Kerckhoff, Docteur en Médecine—Médecin de l'Armée des Pays Bas, &c. Published in vol. vi. of Medical Transactions of College of Physicians in London.

plica is a mere chimera. In support of their opinion they point to the facts, that Polish recruits are always cured by their hair being cut and their habits changed after their entrance into the army; that the disease is almost invariably confined to the lowest classes, and principally to the Jews, who form an immense proportion of the population of Poland, and are universally acknowledged to be the filthiest people on the face of the earth. They further state that strangers residing in Poland never contract the disease unless they sink so low as to approximate to the natives in manners and dirt, and that the disease is disappearing just in proportion as improved habits and comforts are extending; moreover, that in cutting off a plica, as in the case related by Kerckhoff, and which we have already noticed, the agglutinated hair is found distinct and round at the roots. To the last argument it is replied, and with justice, that the diseased action which produced the plica having ceased, the hair which has continued to grow will after a little time have pushed out from the scalp the agglutinated mass of hair, and hence that the soundness of the hair at the roots is no proof that diseased action had not previously existed. Larrey is further of opinion that the urgent symptoms, as pains in the bones, joints, &c., which occasionally precede or accompany plica, owe their origin to a complication of syphilis. Jourdan, the translator of Schlegel and Lafontaine's works, and the writer of the article "Plique" in the Dictionnaire des Sciences Médicales, suggests that there should be a distinction made of plica into true and false; true plica being that form of the disease described by Schlegel, in which the bulbs of the hair are inflamed, become enlarged and acutely sensible, produce a rapid growth of hair, and at the same time glue it together by a peculiar secretion which is poured out from the skin and the hairy bulbs, and even forces its way through the substance of the hair near the skin. False plica Jourdan considers as a mere accidental matting of the hair dependent altogether on external causes. This view would probably reconcile many of the conflicting statements, but even in our investigation of the nature of what, according to this classification, we may call true plica, we meet with great difficulties. We have not information before us sufficiently accurate to enable us to say what is the precise source of the fetid secretion which glues the hairs together,—whether it is poured out by the bulbs of the hair, the sebaceous follicles, or the general surface of the skin. The surface of the skin where the hair is affected is described as being in a state of ulceration in some cases, but this may be an effect of the state of the hair rather than a cause of it; and finally, the state of the scalp may, for aught that we yet know, arise from the presence of some ordinary eruption, the matting of the hair and the viscid fetid secretion being complications added by the influence of extraneous circumstances. Lafontaine asserts that hair presenting shades of red is more liable to plica than hair of other colours, but Schlegel states that he never observed any difference of liability arising from colour.

Alibert makes three subdivisions of plica according to the form it may chance to assume. He calls his first species "plique multiforme," where the hairs form a great number of ropes hanging round the patient's face like serpents round the Gorgon's head; his second species "plique à queue, ou solitaire," in which the whole hair is united into one long plica or tail, principally met with among females, and on those wearing their hair after the national Polish fashion. He calls his third species, "plique en masse, ou larvée," in which the hair is all melted into one cake, covering the head like a helmet. These subdivisions are, however, useless; for the varied forms which the hair assumes appear to be merely the result of external accidental circumstances.

The people of Poland believe that plica is contagious, but there does not appear to be satisfactory ground for this belief. Kerckhoff inoculated children and himself with the viscid secretion, and failed to propagate the disease; and Davidson, who had ample experience, is also a disbeliever in its contagion. Alibert, on Robin's authority, states that a Polish nobleman who kept a seraglio, of which four of the inmates had plica, never contracted the disease. On the other side, Lafontaine and some of the French observers of plica believe that it is a contagious disease.

Symptoms.—The premonitory symptoms of an attack of plica, according to those who look upon it as a peculiar disease, are pains in the back and limbs, vertigo, lachrymation, with violent itching, sensation of pricking, and increased sensibility of the hairy scalp, followed by a copious secretion of a peculiar viscid sweat, of the consistence of honey, which speedily glues the hairs together. On the appearance of this secretion the previous symptoms disappear. It is said in Poland that one of the most usual forerunners of an attack of the disease is a perverted appetite, and hence there is a saying, "Sæpe sub pica, latet seu fœtus seu plica." Of all the symptoms, however, none give a certainty of the approach of the disease except the breaking out of the viscid sweat. Cases are given by Alibert, Lafontaine, Schlegel, &c. of plica appearing as a crisis of or alternating with internal diseases; according to their accounts, the internal affection was alleviated when the plica secretion was abundant, and *vice versa*. When the hair is cut very close, in what we may call true plica, a brownish fluid frequently exudes from the bulbs of the hair, and the appearance of this fluid has given rise to the belief that the hair poured out blood.

Treatment.—The directions for treatment, of course, vary as much as the opinions on the nature of the disease; those who look upon the disease as the product of dirt, directing us to cut off at once without dread the matted mass, and afterwards trust for a cure to soap and combing; and on the other hand, those who see in the cutaneous affection the elimination from the system of a poison, which they call

'virus trichomaticus," warn us in the strongest language not to meddle, lest we turn the poison back on the brain or lungs, &c. Lafontaine extends the supposition of the existence of a peculiar virus so far as to direct us, when any symptoms appear which we suspect are premonitory of the approach of plica, to hasten its appearance by warm cataplasms, sinapisms, &c. to the scalp. Under whatever view we regard the disease, the supposition of the existence of a virus is a mere assumption, and the advice to force the eruption is only an illustration of the prevalence of the same bad principle which of old so erroneously directed us to force out the virus of other eruptive diseases, as small-pox or measles. Mouton, to whose opinions we have already alluded, says we may without fear cut off plica if it be dry, and if it be united to the scalp by hair sound near the roots, which he says indicates that the diseased action which had produced the plica has ceased; but that we ought not to interfere as long as the bulbs of the hair are inflamed and sensible, and continue to pour out a viscid secretion, keeping the hair matted at its roots. Various remedies are recommended in Poland. Lycopodium is much used by the people, who use it both as an external application and an internal medicine; but there does not seem to be any settled rule or principle of treatment. Preparations of mercury, antimony, sulphur, zinc, baths, emetics, diaphoretics, and narcotics, have all in turn been recommended. Among these, the golden sulphuret of antimony is probably the remedy on which most reliance is placed. Patients who are debilitated or advanced in life require, it is said, the administration of tonics; and it is scarcely requisite to observe that an occasional application of strong mercurial ointment to the hair is requisite to destroy the vermin, which breed in it with immense rapidity. It is unnecessary to say any thing on the management of false plica, in which the matting of the hair, arising from neglect, is present without any disease of the bulbs.

(D. J. Corrigan.)

PNEUMONIA, (πνευμονία); *peripneumonia*, or *peripneumony*, (περιπνευμονία); *pneumonitis*, *pulmonitis*, *peripneumonia vera*, (from πνεύμων, -ονος, *pulmo*, *a lung*, or *the lungs*;) are names given to an inflammation of the parenchyma of the lung, which is the most common of all the dangerous inflammations.

Peripneumony and pneumonia are the names applied by Hippocrates, Aretæus, Celsus, and other ancient writers on medicine, to most of the acute diseases of the chest without severe pain; those connected with this symptom being termed pleurisies. Many succeeding authors have not admitted this distinction; and inflammations of the lung have been as often described under the name of pleurisy as under that of pneumonia. The earlier cultivators of morbid anatomy, Valsalva and Morgagni, were the first to prove the distinct existence of the two diseases, but they gave no means of distinguishing them before death. Hence Cullen, although he makes pleurisy a species of the genus pneumonia, expresses his belief that the term pleurisy might with propriety be applied to every case of the disease. It is only through the aid of auscultation that pneumonia and pleurisy have been recognized as distinct diseases, and it is therefore only in the writings of those who have employed this method of diagnosis that the truly distinctive characters of pneumonia can be found.

Cullen's generic definition of pneumonia more frequently holds good than his specific distinctions, on the correctness of which, as we have just remarked, he does not insist. *Fever, pain in some part of the chest, difficult breathing, and cough*, which he ascribes to the genus pneumonia, are in the greater number of instances present in both pleural and pulmonary inflammation; but there are cases of both kinds in which each of these symptoms is absent. The specific definitions of pleurisy and pneumonia are still more frequently at fault; thus the *softer pulse, duller pain, constant dyspnœa, and livid face*, are as much the characters of severe bronchitis as of pneumonia, to which he ascribes them; and the *hard pulse, acute pain increased on inspiration, painful decubitus on the affected side, painful cough, first dry and afterwards with expectoration, often bloody*, the assigned characters of pleurisy, indicate pleuropneumonia as much as pleurisy, and are sometimes presented by bronchitis or peripneumony joined with pleurodyne.

The following is the character which we would give as most generally applicable to pneumonia:—*Fever, with more or less pain in some part of the chest; accelerated and sometimes oppressed breathing; cough with viscid and rusty-coloured expectoration; at first the crepitant rhonchus, afterwards bronchial respiration and bronchophony, with dulness of sound on percussion in some part of the thorax.* In this, however, as in many other diseases, pathology is the only sure basis of definition: pathologically, therefore, pneumonia consists essentially of an inflammation of the parenchyma of the lungs, occasionally but not necessarily extending to the pleura investing them; which inflammation, although it usually occasions a certain combination of general symptoms, is not so essentially connected with these symptoms as to receive from them an infallibly pathognomonic character.

The pathological and anatomical characters of pneumonia, as well as its relation to general symptoms, have been industriously and successfully investigated by the French pathologists, particularly by Laennec and Andral; and it is to them we owe the most important matter of the following history. Andral calls the disease pleuro-pneumonia, from the circumstance of some part of the pleural covering of the lung being involved in the inflammation: we do not deem it necessary to deviate from the example of Laennec, who confines this term to that form of the disease in which the pleura is affected in a sufficient degree to modify the pulmonary inflammation. This will be noticed among the complications of the disease.

I. GENERAL HISTORY OF PNEUMONIA.

Symptoms.—Like other severe inflammations, pneumonia is accompanied by a pyrexia, which often commences in a rigor, prior to any other symptom. Sometimes this shivering fit does not occur until after the establishment of pain, dyspnœa, and other symptoms; and in some cases, especially where the pneumonia succeeds to a bronchitis, or when the first attack is felt in bed, it is not observed at all. Frequently a feeling of great depression and languor, with pains in the back and limbs, and a disordered state of the stomach and bowels, precede the attack; then a shivering fit comes on, followed by a violent reaction, with great heat of the skin, and during this hot stage the local symptoms of heat, pain and oppression in the chest, with more or less cough, are developed. The pyrexia is generally very intense, and in plethoric individuals is accompanied by great flushing of the cheeks, injection of the conjunctivæ, headach, and other signs of local determination of blood. This general fever may precede by a day or two the local symptoms, sometimes diminishing in intensity when they appear, and sometimes continuing and masking them. The pain in the chest, which when present is generally an early symptom, varies greatly in degree, being sometimes very intense, sometimes diffused and dull; frequently it is a deep-seated feeling of heat and weight rather than of pain. Most commonly it is deep-seated in the anterior parts of the chest, below the sternum or below the mamma, sometimes under the scapula; acute pains are more common in either of the sides. Andral says that there is never any pain without an extension of the inflammation to the pleura;* Laennec asserts, on the contrary, that there is frequently pain, and sometimes a point of sharp pain when no pleurisy is present;† this is more in accordance with our own observation, and it is remarkable that in several of the cases described by Andral, where there were various degrees of pain, no mention is made of any inflammatory appearances on the pleura on examination after death.‡ There is commonly a cough at this time, which aggravates the accompanying pain, or causes a feeling of pain when none is otherwise present. It is generally at first either dry or accompanied with simple catarrhal expectoration, and short, not occurring in paroxysms, and is by no means proportionate to the intensity of the inflammation; it is sometimes so slight as scarcely to be noticed by either patient or attendants. The shortness of breathing or dyspnœa, which is commonly an early symptom, is a better measure of the extent and severity of the disease; but we should be mistaken if we always trusted to the feelings of our patients as to its presence or degree. In its slighter degrees they are not sensible of it, a supplementary quickness of breathing removing the sensation of dyspnœa; but an attentive observer readily discovers this quicker and shorter respiration, and the more perceptible elevation of the ribs and depression of the diaphragm that attend it. The number of respirations in a minute, which is in health about twenty in the adult, may now be counted at thirty and upwards, and in severe cases it occasionally exceeds sixty. In some examples, especially where the attack has been sudden, the dyspnœa is greater and more obvious, causing the patient to assume one particular posture, on his side, or on his back with his shoulders elevated; and from their sensibly increasing his oppression, he avoids all exertions of movement and speech; this difficulty of breathing continues to increase as the disease advances. The pulse is quick, and in most instances sharp. With respect to its hardness, it is subject to great diversity, but in many cases it is (notwithstanding Cullen's definition) both hard and full at the commencement of the disease. This character, however, rarely continues long, and often the pulse is weak and small from the beginning. Under the febrile excitement the urine is more highly coloured than in most other symptomatic fevers; and there is more or less of the thirst, white or brown fur on the tongue, loss of appetite, pain in the head and limbs, depression of the strength, &c., that usually characterize them, and blood drawn generally exhibits a buffed and concave crassamentum. This fever may affect particular organs especially, with the production of other symptoms; as the brain with delirium, the stomach with sickness, &c.; but these complications will be better considered hereafter.

The symptoms usually continue in this state from twenty-four to forty-eight hours. At a period varying within that space, the cough, which was hitherto dry or with the expectoration of common bronchitis, becomes accompanied by the expectoration of a very characteristic kind of sputa. They are of a yellow-reddish or rusty tinge of various shades, semi-transparent, tenacious, and running together into one mass. At first this expectoration scarcely exceeds the tenacity of the white of an egg, resembling in all but its colour the sputa of acute bronchitis, and, when poured out, falls in glutinous strings; but it often becomes so viscid that inverting the vessel and even shaking it in that position will not detach it. The same tenacity sometimes imprisons in the mass a multitude of little air-bubbles, which may produce a spumous appearance. The colour may vary in numberless gradations from a light reddish or greenish yellow to a deep orange red or rusty hue. All these tints proceed from various proportions of blood intimately combined with the secretion of the bronchial membrane. This new feature added to the other symptoms is quite characteristic of the disease. The dyspnœa is frequently increased at this period, the inspirations being obviously short and quick; and if the disease is extensive, the oppression becomes very urgent. The pain, on the other hand, is commonly diminished; sometimes it remains and prevents the patient from lying on the affected side. The most common posture is therefore on the back, as lying on the same

* Clinique Médicale, tom. ii. p. 327.
† De l'Auscultation Méd. tom. i. p. 432.
‡ Op. cit. obs. 29, 38, 43, 46.

side would restrain the supplementary expansion which is required there. Often, connected with this posture, one of the cheeks is flushed, but there is no constant correspondence, as Dr. Stack has observed, between this and the side affected.

The disease may go on in favourable cases to the third or fourth day, and then decline in consequence of the resolution of the inflammation, which is indicated by a general alleviation of the symptoms. The pain and dyspnœa are considerably relieved; the cough becomes looser and less distressing; the expectoration less viscid and rusty-coloured, more abundant, and resembling the sputa of bronchitis. The pulse loses its sharpness, and more gradually its frequency; the skin becomes cooler, and sometimes moistened with perspiration; the urine is increased in quantity, and deposits a sediment. Sometimes this amelioration is a speedy process, and restores the patient to a state of convalescence in six or eight days; but it is sometimes more protracted, slight exacerbations recurring every evening, and some of the symptoms remaining stationary, and extending the duration of the disease to a fortnight or three weeks. The quickness of the pulse, and dyspnœa, sometimes with cough, are the symptoms most apt to linger, with a temporary recurrence of the sanguinolent tinge of the sputa; and although there is a great improvement in other respects, they are to be regarded as signs of a lurking disease which a slight cause may be sufficient to aggravate into a severe relapse.

The increase of the disease in more formidable cases manifests itself on the third or fourth day by an augmentation of the dyspnœa, which becomes so urgent as to oblige the patient to have his head and shoulders raised; and the inspirations, short, forced, and amounting to from forty to sixty in a minute, are effected by sudden elevations of the ribs and depressions of the diaphragm; in some cases the side not affected obviously partaking disproportionately in the respiratory effort. The cough is sometimes more frequent, but this is not constantly present in aggravated cases. The viscidity and colour of the expectoration more exactly correspond with the increase of the disease; the tenacity reaches its acmé, so as to adhere strongly when the vessel is inverted, and even shaken in that position; and the colour is more deeply tinged with blood. The pulse becomes quicker, and often weaker and smaller. There is great depression of the bodily powers; and the patient's attention is engrossed by efforts to breathe under the weight and oppression which he feels at the chest. The tongue is often loaded and dry: the skin sometimes continues harsh and hot; in other instances there are partial perspirations and coldness of the surface. Occasionally the features are livid; but this is less common in pneumonia than in severe bronchitis. Sometimes there is delirium or coma; these are dangerous symptoms, especially in old persons; and when present, they frequently disguise the character of the disease. We have known a case of delirium occurring in a supposed idiopathic fever, and another of delirium tremens, which proved fatal through an inflammation of the lung, which was only discovered after death. Hippocrates noticed the danger implied by this symptom; and succeeding authors have confirmed his remark. Laennec describes comatose affections, the result of sanguineous congestions in the head, as of much more unfavourable import than fierce delirium.

When the disease terminates favourably, the amendment is generally marked by some critical evacuation, such as perspiration, diarrhœa, expectoration, or a lateritious deposit in the urine. Of these Laennec considered the last to be the most common: Frank and Andral describe perspiration as more frequent; from our own observation we should say that these two are commonly conjoined; and there seldom occurs in pneumonia a perspiration that can be called critical, without at the same time a deposit in the urine. The latter, however, sometimes takes place when there is no manifest increase of the cutaneous perspiration. A copious expectoration does not occur so frequently as it is described by Sydenham and Cullen to have done; and it is probable that the character of the disease has in some measure changed since their time; for, as Laennec remarks, there are some epidemic forms of pneumonia which very commonly terminate by free expectoration, and which generally go on favourably after this is once established. Other critical phenomena happen more rarely; as epistaxis, hematuria or some other hemorrhage, the menstrual discharge, &c. The commencement of the amendment is generally pretty obvious, and usually occurs in the morning. The observations of Andral have in some measure confirmed the opinions of Hippocrates and other authors ancient and modern, that there are certain days in the duration of the disease in which there is a greater tendency to amelioration. Of ninety-three cases, he found twenty-three give way on the seventh, thirteen on the eleventh, eleven on the fourteenth, and nine on the twentieth days. The recoveries in the remaining cases commenced on twelve out of forty-two non-critical days, as many as eleven being ascribed to the tenth day.* Thus the recoveries on critical days averaged as high as fourteen, while those on non-critical scarcely exceeded three.

In cases of favourable issue, after continuing with greater or less intensity for the various periods just mentioned, and generally on the occurrence of some of the critical phenomena before named, the symptoms become mitigated, and a notable amendment takes place. The dyspnœa becomes less oppressive; the cough less constant; the expectoration less viscid and sanguinolent, and more free; and the pulse less frequent, often with an increase of fulness. The fever generally diminishes with the inflammation; if a critical perspiration have not already appeared, the skin soon becomes soft and moist; the tongue gets cleaner, and the thirst

* Clin. Méd. t. ii. p. 365.

abates. Generally the patient is fully sensible of his real improvement; he feels each day a great accession of strength, and advances rapidly to convalescence. Some dyspnœa and quickness of pulse generally linger after the other symptoms; and there is sometimes a cough with an expectoration of bronchitic mucus, which in some cases remains for some time, but more commonly is carried off with those changes in the sputa which are observed in acute bronchitis. The breathing and pulse in some instances do not assume their natural slowness until after the patient has entered on a tonic and restorative method of treatment.

Relapses are by no means uncommon in recovery from pneumonia; and they are marked by a recurrence of the characteristic symptoms, —pain, shortness of breath, cough, and viscid sanguinolent expectoration. The fever has seldom so sthenic a character as at the first attack, and frequently it is decidedly adynamic, the strength having been reduced by the previous disease and treatment. Hence a relapse, if a serious one, is often more dangerous than the first attack.

The progress of fatal cases of pneumonia is marked by a continued aggravation of the dyspnœa, with increasing failure of the strength. The cough becomes less capable of expectorating the sputa, which sometimes retain their viscidity and sanguinolent hue as long as any are voided. In the greater number of instances there is a total suppression of the expectoration for some hours before death; but in others it is still excreted, but of a different character. Sometimes it is merely pituitous, transparent, or of a dirty tinge; sometimes it is a semi-opaque dirty mucus; occasionally purulent specks of a yellowish white colour are visible in it; more rarely it is purulent, with streaks of blood, or in opaque nummulary forms of a yellowish white colour, consisting of pus and a little mucus. Not unfrequently various mixtures of these different kinds are seen together; but the whole sputa in the latter stages of the disease are generally scanty. Andral describes sputa of a very remarkable kind as occasionally occurring in the last stage of pneumonia: they consist of a slightly glutinous liquid of a reddish brown colour, resembling liquorice-water or thin syrup of prunes. Rarely, sputa of a mixed greenish and dirty red or grey colour, and putrid fetor, are the last observed. With any of these changes in the expectoration the state of the patient puts on a worse aspect; the pulse becomes thready and intermittent; the countenance pallid, cadaverous, and bedewed with a cold sweat; the lips livid, the breathing gasping and convulsive, with a rattle in the throat; the sensorial functions, if entire before, now give way, and the patient dies asphyxiated.

Such is the general type of pneumonia as it presents itself to the semeiological observer. This appears to be the proper place to enumerate historically the causes which have been observed to excite the disease, or favour its production; and we shall afterwards proceed to scrutinize more closely the various changes which constitute its pathological history. Unfortunately the principal part of our knowledge of these changes has been derived from a study of their effects in the dead body. It will, therefore, give better ground to our pathology, if, after enumerating the causes, we describe the anatomical characters of pneumonia.

Causes.—The previous occurrence of the disease seems more than any other circumstance to predispose to pneumonia. Rush describes the case of a German living in Philadelphia, who had the disease twenty-eight times. Andral gives a case in which it recurred the sixteenth time within eleven years.* Dezoteux treated seven times a pneumonia in a subject who had suffered from it fifteen times;† and Chomel alludes to its recurrence the tenth time in the same individual.‡ Perhaps the only other circumstance that can be fairly viewed as a predisposing cause, is the presence of tubercles in the lungs. It has been said that the adult age, the male sex, a sanguine temperament, and certain occupations, as those of singers, street-criers, public speakers, &c. predispose to the disease; but if it occurs more frequently in persons under such circumstances, this is to be referred to their being more exposed to the exciting causes, rather than to any constitutional predisposition. With regard to age, it has not been found, since the disease has been accurately distinguished, that any age is particularly exempt from it. The symptoms are generally more prominent in middle life, and it is therefore more readily distinguished; but infancy and old age appear to be equally liable to it. M. Guersent reports the disease to be very common and fatal among children; and that of the deaths among those in the hospital of sick children at Paris, before the completion of the first dentition, three-fifths occur from pneumonia, chiefly latent.§ From our own observation we are inclined to consider young children as more frequently the subjects of pneumonia than adults. Of fifty-five cases attended by Mr. Byam and the writer during one year, at a dispensary in the parish of St. Marylebone, thirty-two were of the age of six years or under. Neither Laennec nor Chomel concurs with Stoll and Auenbrugger in considering persons of sedentary modes of life, such as tailors, the most liable to pneumonia. Masons, porters, out-door labourers, and carpenters, present the greatest number of examples; which is plainly to be ascribed to their being more exposed to the exciting causes. The same circumstance is, as M. Chomel observes, the reason why men suffer more frequently than women. Out of ninety-seven cases which occurred in the wards of La Charité, under his care, seventy-three were men, although the number of patients of either sex was nearly the same.‖

Cold, excessive exertion of the lungs by vio-

lent exercise or by the voice, the inhalation of irritating vapours and asphyxiating gases, wounds of the lungs and blows on the chest, the bite of the rattlesnake, and the action of some other poisons, as fungi, may be named as exciting causes of pneumonia. To these may be added several diseases on which this inflammation occasionally becomes engrafted; such are bronchitis, hooping-cough, pulmonary apoplexy, phthisis, the exanthematous, continued, and sometimes traumatic fevers, particularly those supervening on extensive injuries or operations. It is so frequently complicated with hooping-cough, small-pox, and measles in children, that we consider the danger of these affections in a great measure to arise from this complication. In common with other inflammations, it may be occasioned by the suppression of habitual discharges, as the catamenia, hemorrhoids, and other hemorrhages, and issues or ulcers of long standing. The inflammations of gout, rheumatism, and cutaneous diseases, are sometimes transferred to the lungs by metastasis.

The influence of cold in producing inflammation of the lungs is sufficiently apparent in the much greater prevalence of the disease in cold seasons and cold climates. Of ninety-seven cases recorded by Louis in Chomel's wards at La Charité during five years, eighty-one occurred between February and August, and only sixteen in the remaining five months of these years. Of the cases described by Andral, the number occurring in March and April amounted to a third of the whole; the fewest took place in May, October and November, and the remaining months had an equal share. Of two hundred and forty-three cases which were treated at the Edinburgh New Town Dispensary during three years, ending September 1, 1824, sixty-seven occurred from 1st September to 1st December; one hundred and four from 1st December to 1st March; ninety-four from 1st March to 1st June; and sixty-eight from 1st June to 1st September. We have observed in London nearly an equal prevalence of the disease from the beginning of December to the end of April, and a considerably smaller proportion in the remaining months; but it appears generally that the latter winter and early spring months are most fertile in producing pneumonia in these climates. Pinel and Bricheteau consider the most frequent cause of pneumonia to be the sudden exposure of the heated body to cold after violent exertion, especially that of the voice.* Laennec remarks on this point that cold long-continued, or applied when the body is only moderately heated and covered with perspiration, is much more powerful as a cause of pneumonia than when cold succeeds to an excessive heat, and is not long continued: "the Russian who rolls himself in the snow after coming out of a hot bath, or the baker who goes from his heated oven, almost naked, into an atmosphere of a temperature below the freezing point, is not liable to attacks of the disease; while the porters, whose occupation leads them to stand for a length of time at the corners of the streets, are frequently affected by it."* It is certain that cold winds or cooling influences long applied, are more sure to produce the disease than mere changes of temperature; and the perspiring body must obviously suffer more as it is exposed to the additional cooling agency of evaporation. Transitions of temperature of short duration are more effectually resisted by the body; and if the reaction from them produce any inflammation, it is generally one of the mucous membrane, a coryza, a cynanche, or a bronchitis: it is when the cold has penetrated deeply that the parenchymatous inflammations more frequently follow. Hence, besides cold winds, any kind of exposure at a low temperature, as on horseback, sleeping in the open air, &c. occasionally excite pneumonia. Rarely it has been produced by drinking cold liquids when the body is in profuse perspiration, and sometimes by intemperate indulgence in alcoholic liquors.

The cause of the greater number of cases is, however, either unknown, or of the obscure character in which epidemic and endemic influences are involved. Of seventy-nine cases investigated by Chomel, fourteen of the individuals had been exposed to cold; five had taken an excess of wine, one had been over-fatigued, one had suffered great mental excitement, one had breathed for some length of time the fumes of charcoal, and the remaining fifty-six could assign no cause for their complaint.† The epidemic occurrence of the disease is clearly proved; and such has been its extent, that a contagious nature has been ascribed to it. Laennec remarks that epidemic pneumonia is probably often owing to deleterious miasms, suspended in the air, entering the circulation and operating particularly on the lungs, as the poison of the rattlesnake and of some fungi is said to do: hence many persons are seized in their very chambers in spite of the utmost care taken of their health.‡ In many epidemics it is difficult to decide the amount of influence which known physical causes, such as changes of temperature and moisture, may have in determining the production of morbific effects on the body; but no meteorological observations have ever discovered in the physical conditions of the air a sufficient cause for the remarkable prevalence of this disease, which occasionally constitutes a third, or even a half of the acute complaints of our hospitals. In one of these epidemics, it was observed by Huxham that the disease showed itself in the form of bronchitis in low and damp situations, while at a short distance, on elevated spots, it prevailed as a peripneumony. Elevated districts are perhaps the more liable to pneumonia because they are more exposed and colder; whereas the humid air of low valleys, whilst it diminishes the intensity of the cold, relaxes more the mucous surfaces, and renders them the weaker points of the circulation. The account of Hippocrates would not seem to coincide

with this statement, as he describes pneumonia as common in marshy districts,* but that he probably includes severe bronchitis also under this name. Hoffmann ascribes to pneumonia an endemic character in some parts of Westphalia, Sweden, Pomerania, Denmark, and Russia; but the physical climate of these countries is a sufficient explanation of its prevalence, and Britain may as fairly be added to the list. Nor are the milder climates free: at Nice, Genoa, Pisa, and Florence, the disease prevails greatly, and cuts off a good many of the inhabitants.† The neighbourhood of Mount Vesuvius is remarkable for the frequency of its occurrence: here it may more properly be called endemic, as it may reasonably be attributed to the noxious exhalations which prevail there.‡

II. ANATOMICAL CHARACTERS OF ACUTE PNEUMONIA.

We owe the most accurate information which we possess on the morbid anatomy of this disease to the researches of the French pathologists, particularly those of Laennec and Andral. There are, however, many doubtful points relating to the essential seat and effects of the inflammation which still remain to be cleared up before our pathology of pneumonia can be considered accurate.

Laennec arranges the general effects of inflammation on the lungs into three stages or degrees, each of which is distinguished by marked characters—the first degree, or *engorgement*; the second degree, or *hepatization*; the third degree, or *purulent* infiltration. These are the common effects which inflammation in its general course produces in the lung. Abscess and gangrene are of uncommon occurrence, and to be viewed as exceptions rather than as regular events.

In the first degree of inflammation, the engorged or obstructed state, the lung is externally of a dark or livid red colour, to which a slight whitish opacity of the pleura sometimes gives a violet hue; it is heavier and more substantial to the touch than a healthy lung: when pressed, it yields less of the crepitating sound and feel, and instead of generally collapsing under the pressure, and partially rising on its removal, it receives and retains the impression of each finger, giving the feeling of a liquid contained in cellular substance, as in an œdematous limb. On examining it closely through the transparent pleura, there are seen numerous little round bubbles of air without the angularity of the natural vesicular structure; and the septa, which are commonly very visible, are scarcely to be discerned. On cutting into the lung in this state, a bloody serum, containing numerous minute air-bubbles, flows from it, sometimes in great abundance and almost clear, sometimes more scanty and sanguinolent or turbid, and with various proportions of the spumous bubbles. The substance thus cut into is of a red colour of various shades, crimson, dark red, brown red, chocolate red, or of a livid puce colour approaching to black. The vesicular texture of the lung can still be discerned, particularly after the serum has drained from it; and by pressing it gently and washing it repeatedly, the natural colour, appearance, and elasticity may in some degree be restored. There are varieties in this state of engorgement, some of which depend on the degree or duration of the inflammation, and others on individual peculiarity. The progress which the inflammation has made is pretty accurately represented by the defect of air in the tissue; in the slightest degree, there being a good deal of air, the lung feels still crepitous, and the serum which flows from it is very frothy. The quantity of serum indicates rather the intensity of the inflammation than its duration; but as far as we have observed, it partly also depends on the coagulability of the blood. In recent severe inflammations, which have proved fatal in the first stage, it is generally very copious; but in those which have endured for several days, it is seldom as abundant even in points where the second stage has not commenced. The progress towards this second stage is marked by a paler colour, a diminished quantity of both liquid and air, and an increasing solidity of the tissue. There is another variety of the inflammatory engorgement, probably depending more on the state of the blood than on the degree of inflammation: the lung presents an extreme lividity, and when cut, instead of yielding serum, exudes slowly a dark grumous blood in greater or less quantity. This appearance is noticed by Chomel,* as occurring particularly in cases of pneumonia complicated with other acute affections, as fevers; and we have repeatedly observed it. The writer, together with Mr. Ryan, recently examined the lungs of a child of eighteen months, affected with chronic hydrocephalus, who was carried off by an attack of pneumonia: both lungs were partly hepatized, and partly of a very dark red colour, appearing of a livid purple through the pleura; some parts of this inflammatory engorgement still contained a good deal of air, and, when pressed, exuded merely a little grumous blood, mixed with bubbles. Other parts of the lung were hepatized. The child had repeated attacks of convulsions during the two days before his death, and between four and five ounces of serum were found between the membranes and in the ventricles of the brain, which was uncommonly voluminous. But what we think most worthy of remark is, that the blood was fluid in all the vessels examined, and this we apprehend to be the cause of the peculiar character of this inflammatory engorgement of the lung. This was probably the case, also, in the complications noticed by M. Chomel, for a fluid state of the blood is very commonly observed in typhoid fevers after death. We consider that these circumstances render it probable that the separation of the serum in the engorged lung is more a cadaveric than a pathological process; and that, as the blood coagulates in

* De Aere, &c.

† Clark on the Influence of Climate, 2d edit. p. 121.

* Dict. de Méd. t. xvii. p. 235.

the distended vessels, its serum transudes into the vesicular structure. Where, on the other hand, the blood does not coagulate, it is too thick a fluid to exude into the cells, or to flow freely as serum does when the lung is cut. We do not maintain that there is no interstitial serous effusion during life; the analogy of other inflamed parts renders it probable that it does take place, but, we suspect, by no means to the extent which is commonly found in the engorged lung after death. We shall revert to this point when speaking of the pathology.

The colour of the lung inflamed to the first degree depends on the blood in it, in some cases deepened or modified by the black pulmonary matter: in the lungs of old people the abundance of this matter gives the inflammatory infarctus a blacker or more dingy hue; whilst in children the colour of the blood entirely prevails. Although very much heavier than was natural, a portion of lung in this state retains enough air to prevent it from sinking in water. Another remarkable change wrought in the lung by the most considerable degrees of inflammatory engorgement, is a diminution in its molecular cohesion, so that the fingers break through or tear its substance much more readily than in a healthy lung. This effect was first described by Andral,* and afterwards by Chomel.† Andral formerly considered this softening of the tissue a test by which inflammatory engorgement might be distinguished from that produced by gravitation, the mechanical hyperæmia; but he has since abandoned this opinion, and, as did Laennec in his clinical lectures, referred the more easily lacerable state of the lung to the physical effect of an unusual proportion of blood in it. "The reason of this fact will be readily understood if we reflect that when the lung contains a much larger proportion of air than of blood, the parietes of the bronchia, when pressed by the finger, press in their turn on the compressible fluid they contain, and in this way, by compressing or expelling the air, retire before the pressure of the finger, and so escape being ruptured. But when the lung contains a larger proportion of blood than of air, the former fluid being almost wholly incompressible, the pulmonary tissue cannot recede from under the finger, and is therefore easily ruptured."‡ Chomel, however, in his article before quoted, published in 1827, still maintains the applicability of this test; he says that the merely congested lung preserves its natural consistence; but the inflamed lung in great measure loses it, insomuch that it requires very little force to make the fingers break through its substance. Our own examinations have led to conclusions somewhat different from those of both these authors. We are convinced that both inflammatory and mechanical engorgements tend to diminish the cohesion of the parenchyma more than the mere increase of liquid in it can explain, and for the following reasons: 1. if a portion of the healthy tissue adjoining an engorged portion be pulled gently, a laceration takes place in the latter before the healthy portion is stretched to the utmost, and with a much smaller degree of force than is required to tear this healthy portion: 2. the fragility of the tissue is not always in proportion to the quantity of liquid in it: 3. an engorged portion of lung does not lose its greater friability when the blood has been gently pressed and washed out of it. We have never been able to discover any physical difference between the first stage of marked inflammation and that engorgement supposed to be a mechanical congestion in the most dependent part of the lung occurring shortly before and after death; and it would appear, from the observations of Laennec, that the resemblance between the latter state and pneumonia is not confined to the anatomical appearances; for where the agony, or moribund state is prolonged, points of hepatization are formed in the most congested portions of the lungs; so that this author was led to class them as the results of real inflammation, which he called *pneumonia agonizantium*.* In these remarks he is confirmed by Louis.† Whilst, therefore, we are led to recognise softening of the parenchyma as the pathological result of hyperæmia or sanguineous congestion, we find in it no distinction between active idiopathic inflammation and that congested state of lung which supervenes, in some measure mechanically, on an obstructed state of the pulmonary circulation.

The second stage, *hepatization*, (the red softening of Andral,) has very distinctive characters. A lung in this state is solid and inelastic to the touch, of the consistence and weight of liver, and portions of it sink in water: it is no longer crepitous, neither does it, when cut, yield bubbles of air, but when pressed, a bloody fluid exudes sparingly from it. Its friability is generally greater than in the first stage, the fingers readily breaking through its substance; and if a portion be pressed between the fingers, it is reduced to a red homogeneous pulp. A hepatized lung appears to be more voluminous than is natural, but this depends on its being solid, and not collapsing, as a healthy lung does, on opening the thorax. Externally its colour is seldom so deep as in the first stage, and when cut into, it is also lighter, presenting shades varying from a blood or livid red to a light pinkish purple, or colour of muscle, and various degrees of these colours are sometimes seen mottling the lungs, so as to resemble some kinds of marble. Scattered through the hepatized portion various lines are visible, of a lighter colour, and specks almost white; a close examination discovers the former to be portions of the interlobular septa, less affected with inflammation, and the latter sections of bronchi or bloodvessels, whose coats have entirely escaped. There is generally in a hepatized lung another character, which becomes apparent on a close inspection, and more

* Clinique Médicale, t. ii. p. 307.

† Recherches sur la Phthisie, p. 30.

plainly with the aid of a lens. On a portion being cut, a number of little points can be distinguished, looking like grains of a somewhat lighter colour than the intervening spaces; and if the surface be wiped or lightly scraped, these grains appear slightly elevated, as if they consist of a more solid material. They may be made still more obvious by tearing the hepatized lung; they are then seen as little ovoid bodies, and may be detached singly from the tissue. In most instances these grains are closely pressed together so as to constitute the chief substance of the diseased part; but sometimes there are interstices of a darker colour, and in some cases the granular appearance is entirely absent. This uniform non-granular solidification of the lung, described by Andral* and Chomel,† is not recognised by Laennec, who considered the granular appearance as an essential character of hepatization; but from having seen the condition observed by the other authors as an indubitable result of inflammation, we do not hesitate to describe it as a variety of hepatization. This state of the lung differs from common hepatization in the absence of the granules, and a consequently darker and more uniform texture: it is sometimes softer, and bears a considerable resemblance to the substance of the spleen, whence it has been called *splenization*. In appearance it resembles that condition of the lung produced in pleuro-pneumonia, called by Laennec *carnification*, which we shall allude to hereafter; it differs, however, from this in being more friable. Andral was, we believe, the first writer who ascribed the granular appearance of a hepatized lung to the individual vesicles; and in this opinion he is followed by Laennec and Louis. In the second volume of his "Clinique Médicale" (p. 312) he describes the inflammation in pneumonia as occupying the air-vesicles, the internal surface of which secretes a viscid mucus, which, accumulating so as to fill their cavities, produces the granular bodies in question. In confirmation of this opinion, Louis asserts that this appearance can be imitated by gently injecting the bronchi.‡ Laennec says that these little bodies "are evidently air-cells converted into solid grains by the thickening of their parietes and the obliteration of their cavities by a concrete fluid."§ Many minute examinations which we have made of hepatized lungs have convinced us that the granulations contain no viscid mucus, nor does their appearance by any means confirm the opinion of Andral. They appear rather to consist simply of the little bunches of vesicles, (in which, according to Reisseissen, each minute bronchus terminates,) whose membranous tunics have become so swelled by the deposition of a soft albuminous matter in them, as well as from the increased size of their blood-vessels, that their cavities are obliterated. Both from the uniformity of their appearance when examined, and from the absence of any such matter in the sputa before death, we have long doubted that there is any effusion into the cavities of the air-cells, as supposed by Laennec; and Andral, in his later work, seems to take a somewhat similar view, which he illustrates by the appearance presented by an inflamed lung when carefully dried. When the lung is in the first stage of inflammation, "the only morbid appearance it presents when dried is a reddish, yellow, or brown tinge in the parietes of its capillary bronchia and air-cells; and in some cases even this shade of colour is wanting, and the lung, which before being dried presented a remarkable degree of congestion, when dried differs in no respect from a healthy lung. When the experiment of drying is tried on a hepatized lung, the parietes of the capillary bronchia and of the air-cells present invariably a red colour, and are, moreover, considerably thickened, so as to cause in some points a remarkable diminution, and in others a total obliteration of their cavities."* The same sagacious pathologist refers the absence of granulations in the variety of hepatization before described to the greater degree of tumefaction which the air-cells undergo, by which they are approximated so closely as to be confounded together. This explanation does not seem to accord well with the darker hue of this variety; and we are inclined to hazard the opinion that the inflammation and swelling are in this case chiefly in the vessels and interstitial tissue between the cells and the bronchi, without involving the membrane which principally constitutes these cells, and which analogy would point out to be of the nature of mucous membrane. We propose this explanation merely as a question, and it is one of some interest; for if it should be confirmed by further observation, it would open a more important inquiry whether such variety in the seat of the inflammation is distinguished by any peculiarity in the pathological history of the disease. The discrimination between the minute elementary tissues of the alimentary canal, in relation to disease, has not been without its practical utility; and there can be little doubt that inflammation of the lungs would exhibit some variation in its signs or course according to the parts of the parenchyma which it affects.

The advance of a hepatized lung towards the third stage is marked by its becoming lighter in colour and less humid. The change in colour seems to be produced by a substitution of more of the yellowish white semi-solid albumen for the red particles in its substance, by which the deep red or dull red of hepatization passes into a salmon-colour or a dingy pink, variously marbled in the degree of its progress, as well as by the mixture of black pulmonary matter. It is at this period that a hepatized lung attains its greatest degree of solidity; when gently pressed, a turbid red liquid exudes scantily from it: very little additional pressure crushes its substance into a thick pulp; for although its compactness is increased

* Path. Anatomy, vol. ii. p. 510.

§ Transl. p. 201.

* Path. Anat. vol. ii. p. 511.

by the effusion into its substance, its molecular cohesion is greatly diminished.* A close inspection will generally discover that the granulations are the lighter points, and sometimes minute yellowish white specks can be discerned in them, which are the first development of pus.

The lung affected with the third degree of inflammation, or rather its third effect, purulent infiltration, presents a still further change of character. It generally changes the red tinge for a yellowish drab or stone colour, which is still varied with red in parts less advanced, and with grey, blue, or blueish green, from the admixture of black pulmonary matter.† At first the lung retains the weight, compactness, and granular texture which characterise hepatization, the change being confined to the colour; whence this state has been called yellow hepatization, *hépatisation grise*, and by Andral *ramollissement gris*,‡ from its increased friability. On cutting into it, no matter exudes in this early stage of suppuration, because the cohesiveness of the texture is still sufficient to retain it; but very slight pressure reduces it to a thick purilage, in which pus obviously constitutes a principal part. In a more advanced degree the colour is of a straw or sulphur yellow, which begins in patches and spreads through the mass: on cutting into the lung, no granular texture can be seen; but a yellowish, opake, purulent matter oozes in greater or less abundance according to the progress which the suppuration has made. The solid matter obviously diminishes as the pus is secreted; for after squeezing this out, what remains in the hand is a mere debris of the pulmonary tissue, with a few granulations in which the suppuration has not advanced. Except in particular cases, the matter thus formed has a much fainter odour than that from an ordinary abscess. The softness of the lung in this state is so great, that even the slight pressure of a finger readily makes a cavity, which immediately fills with pus; and both Laennec and Andral remark that this may be inadvertently produced in the course of examination, and mistaken for an abscess. In the most advanced stage of purulent infiltration, a lens will sometimes enable us to perceive that the only remnant of texture is a coarse irregular network, composed chiefly of vessels, bronchi, and the septa of lobules.

The purulent infiltration just described is the form of suppuration to which pulmonary inflammation tends; the matter is rarely collected in a focus, and still more rarely in an encysted abscess. Laennec and Andral have recorded a few instances where the suppuration had in one part become complete, and contained pure pus, whilst the adjoining parts were in a state of purulent infiltration quite diffluent on the margin of this sort of abscess, but firmer as they receded from it. This event has generally occurred in cases of partial peripneumony; and it appears to be no more than a completion of the process of suppuration, of which ordinary infiltration is only the beginning. The reason assigned by Laennec is probably correct;—that abscess of the lung is rare, because cases of partial peripneumony usually yield early either to nature or art, while an affection of greater extent produces death before the tissue can be removed by absorption. He cites a case in which a cavity lined with a strong false membrane, and capable of containing a pint and a half of fluid, existed in the middle of the right lung; the pulmonary pleura was destroyed to the extent of more than six square inches, and the wall of the cavity on this side was formed by the costal pleura, which adhered closely to the lips of the excavation. Several bronchial tubes opened into this cavity.* As there were no signs of tubercles, Laennec considers the cavity to have been caused by an abscess. A similar case occurred to Dr. Chambers at St. George's Hospital, and the lung is preserved in the museum there. A case of encysted abscess was shown to the Academy of Medicine by Dr. Honoré in 1823. It was filled with pus, as large as a middle-sized apple, and surrounded by a hepatized state of the lung. The general testimony of the latest pathological anatomists is in support of the opinion of Laennec, that the termination of pneumonia in abscess is of rare occurrence. Broussais says that he only met with it once; and in this case the inflammation was produced by a musket-ball lodged in the lung for six years.† Andral considers it extremely rare, and questions the accuracy of Laennec's statement, that in the year 1823 he met with more than twenty cases of partial peripneumony terminating in abscess. If we compare these opinions with the writings of Morgagni, Baillie, or, in fact, any writer on morbid anatomy prior to

* This character led M. Andral to call hepatization *red softening*; but the objectionable nature of this term is sufficiently apparent from the fact that Laennec misunderstood its meaning (op. cit. p. 206, note); and Chomel described the state in question as a hardening of the lung (*endurcissement rouge*, Dict. de Méd. loc. cit.) Andral meant *friability*.

† These appearances are beautifully and faithfully delineated in the first number of Dr. Hope's coloured illustrations of morbid anatomy, the inspection of which will be more instructive to the student than any verbal description; see especially fig. 4. From the blue shades which slight admixtures of the pulmonary matter produce, Dr. Hope supposes that this matter is sometimes blue: we believe, however, that this colour depends on a property which all whitish semitransparent bodies possess of transmitting the yellow and red, and reflecting the blue rays, so that, when the light transmitted through a thin transparent film is absorbed by a dark body under it, the blue rays are reflected from the film. Nothing illustrates this more perfectly than opal glass, through which dark objects appear blue and light ones orange; and an example of the same optical effect more in point may be given in the superficial veins, which through the skin appear blue, although they contain nearly black blood.

‡ This word *gris* is not here to be translated *grey*, a mixture of black and white, but *drab* or stone-coloured, like light brown paper, which in France is called *papier gris*.

* Op. cit. p. 206.

† Hist. des Phlegm. Chron. tom. ii. p. 111.

the last twenty years, or with the notions of the less informed of the present day, we shall be surprised at their discrepancy with the frequent mention of abscess of the lungs by these latter. The common error has been to mistake tubercular vomicæ, which are of very common occurrence, for abscess; and it is not easy always to avoid the mistake, even in the present state of our knowledge. Laennec says that tubercular cavities are to be distinguished by their containing some remains of the tubercular matter, or by the co-existence of tubercles in other parts of the lungs; but these remains may have been eliminated; and where a rounded vomica, containing only pus, is found singly in an inflamed lung, it may readily be mistaken for an abscess. Such examples show how uncertain are the anatomical distinctions between vomica and abscess; and perhaps any absolute boundary between these lesions is not to be met with in nature. We may recur to this subject when speaking of chronic peripneumony.

Abscesses of the lungs have sometimes been met with unattended with any marks of inflammation; the pus being apparently secreted in some other part of the system, is merely deposited in the lungs. We remember to have seen several abscesses of this kind in the lungs of a woman at the hospital of La Charité at Paris, who died with diffuse cellular and venous inflammation and suppuration of the leg and thigh. They were small, round, full of pus, and lined by recent coagulable lymph, the adjacent pulmonary tissue being quite crepitant. The liver, the spleen, and one of the kidneys presented similar abscesses in their parenchyma. Many other examples are on record of both circumscribed deposits and infiltration with pus after great surgical operations;* but as these are not connected with pneumonia, we need not describe them here.

Gangrene of the lung is rarely a consequence of inflammation. That it is so at all is questioned by Laennec, who considered this lesion as idiopathic, like hospital gangrene or anthrax, and as exciting rather than following the inflammation, which he says is by no means of an intense kind. It has, however, been fully proved that gangrene of the lung does occasionally succeed to inflammation of the organ, although, as in the case of abscess, it likewise occurs independently of it. Inflammation may be so intense as to destroy the vitality of a part, as mechanical injuries or chemical decompositions do; and of the occurrence of this event in the lung, there are a few instances on record.† As a consequence of acute inflammation gangrene is commonly diffuse, surrounded by purulent infiltration or hepatization, and bounded by a deposit of lymph. The colour of the gangrenous part is a greenish brown, a dirty olive, or a dark brown, which a certain admixture of purulent and black pulmonary matter in some parts changes into a greenish grey. It is about the consistence of the lung in the third stage, except in some points where the sphacelus is more advanced and diffluent, and a turbid or greenish sanies runs readily from it. It is, however, the putrid fetidity which most distinguishes gangrene, and this test enables us to discover the presence of slight degrees of gangrene where it is not sufficiently extensive to affect the colour. Where the tissue is in the third stage, the colour as well as the odour readily characterizes it, but the hepatized lung bordering on gangrene can only be detected by its odour. We have sometimes found portions of hepatized lung very fetid, and although not materially altered in consistence, and only a little darker in colour than usual, we have been induced to think that the gangrenous process had commenced in them. M. Chomel describes a gangrenous condition of the lung, which is seen in the bodies of those who have died after some days' illness in consequence of being exposed to the effluvia of cess-pools or sewers. The lung is found almost black or greenish, full of a sanious, greenish, and extremely fetid liquid, softened in many places, and in some falling into deliquescence. Chomel thinks this lesion marks the passage of the first stage of inflammation into gangrene. The same pathologist supposes the possibility of a whole lung being destroyed by gangrene in the case of its being compressed and rendered impermeable to air by an extensive pleuritic effusion; and he quotes a case, which he conceives to be of this kind, from the *Opuscula Pathologica* of Haller, in which the left lung had entirely disappeared, and the pleural sac was filled with a quantity of fetid albuminous liquid, in which the large vessels and bronchi terminated as if they had been cut off.*

Circumscribed gangrene, if the result of inflammation at all, follows only the chronic kind; being apparently caused by the obstruction to the circulation which chronic inflammation sometimes produces in the lung. This form of gangrene more frequently occurs independently of inflammation, as the result of various septic influences present in the system, and answers more exactly to Laennec's opinion respecting pulmonary gangrene in general. For an account of the relations of gangrene to these causes and to inflammation, we refer the reader to the article MORTIFICATION.

We have hitherto described the general type of the several consequences of inflammation of the lung as detected by anatomical investigation. It remains for us now to notice the different varieties which individual cases present with regard to combination, extent, and complication of these inflammatory lesions.

Pneumonia is called *lobar*, *lobular*, or *vesicular*, according as it affects whole or continuous parts of lobes, or certain polygonal subdivisions of these, or single bunches of vesicles. Lobar inflammation is the most common, and may be limited to an irregular portion of a lobe, or

* *Andral*, Path. Anat. vol. ii. p. 540. Dr. Hope's Illustrations, &c. part i. fig. 10, 11, 13.

† *Andral*, Clin. Méd. t. ii. p. 295. Dr. Hope's Illustrations, part i. fig. 4.

* Dict. de Méd. t. xvii. p. 240.

t may involve a whole lung, or a great part of oth lungs. When the inflammation is extensive, it is commonly found in different degrees of advancement. The most frequent of hese combinations is the engorgement or first tage, with the second, hepatization; and the radual transition of one into the other may here e very distinctly seen. The greatest advancement is commonly at the lower parts and margins of the lobes, (which are, according to Laennec, the most usual seats of peripneunony,) where we have the solid, airless, liver-ike state of the second stage. In receding rom this towards the less inflamed portions, he lung is more livid, softer, and moister, but till does not crepitate on pressure, and, except n some spots, does not pit, but breaks under he finger. Further still, there is some crepiation, but the lung feels heavy and yielding to he touch, and is of a dark red colour. In the lighter degrees of inflammatory engorgement, he colour is brighter and the crepitation more listinct, and the serum that flows on incision is very frothy. There is frequently around the nflamed part an œdematous state of the tissue, he colour of which is natural, but a yellowish rothy serum flows from it on incision. The hird stage can also generally be traced in progressive degrees from the hepatized portions, ightening them by marbled shades of a paler or yellower hue, which sometimes take the shape of the polygonal lobules, and sometimes pass continuously over the interlobular partitions without distinction. Where these transitions of colour are abrupt, and mottled with black pulmonary matter, there is produced that appearance which Laennec compares to some kinds of granite, with its red and yellow felspar, grey quartz, and black mica. Combinations of these three degrees may affect the whole of both lungs; and this to the extent that the whole of one lung, and more than half of the other, are solidified; but it is obvious that they cannot be so far involved in the second or third degrees, as life must be destroyed long before they could be rendered so totally impervious to air.

The anatomical evidence as to the parts of the lung most frequently affected by pneumonia is not entirely in accordance with that furnished by clinical observation. Hence we find Morgagni, Frank, and Broussais, who draw their conclusions from dissections, assign the upper lobes as the most frequent seat of inflammation; while Laennec and Andral, who included cases of recovery in the calculation, found the lower lobes to be most commonly inflamed. The reason of this discrepancy is, that inflammation of the upper lobes is the most frequently fatal; hence Chomel, although out of fifty-nine dissections he found the inflammation occupying the apex in thirteen, the base in eleven, and the whole or central parts in the other cases, does not withhold his assent from the decision of Laennec. That the right lung is more frequently inflamed than the left is agreed on by all writers, and is proved equally by examination of the physical signs and by dissection.

Inflammation not unfrequently attacks single or a few isolated lobules, being abruptly limited by the interlobular cellular tissue, so that lozenge-shaped or polygonal patches of red engorged or hepatized tissue are found in the midst of healthy structure. The same distinction is sometimes exhibited in the degree to which the inflammation has advaneed, some lobules of light purulent infiltration appearing in a livid engorgement. The inflammation in lobular pneumonia seems to originate in several points at once, and not to be sufficiently intense to traverse the barrier of the interlobular membrane. It is this form that supervenes frequently to great surgical operations or severe accidents, and it is common in children.

Andral has distinguished another variety of acute peripneumony, which, as he supposes it to affeet individual air-cells or vesicles, he calls vesicular. This presents itself to the anatomist in the form of little red spots, varying in size from that of a pin's head to that of a hempseed, and in colour from blood red to livid red: they are often more fragile than the rest of the tissue, which is sometimes quite healthy, but in many instances contains the miliary granulations of Bayle. This form of inflammation is not common, and requires a light colour of the lung to make it distinct; but we have observed it sufficiently to enable us to follow M. Andral in recognizing it as a variety.

A considerable variety in the anatomical character of pneumonia is produced by the age of the subject. The lungs of young children are naturally more membranous and vascular than those of adults; and from this circumstance, and because the bronchi and vesicles are smaller, the texture is less light and crepitating to the feel. These characters are to be borne in mind when it is examined in an inflamed state, for they render the absence of crepitation and lightness, produced by this lesion, less apparent than in the adult. On the other hand the colour, naturally light, of a pink buff hue, makes the red appearance of inflammation more visible at this age. Pneumonia is seldom found so far advanced in children as in the adult. After many days' duration it is often found only in the first stage, and its existence for weeks frequently does not bring it beyond the stage of hepatization. The division of the lungs into lobules is more apparent in children and in the young of all animals than it is afterwards; which fact is an example of the progressive incorporation of elementary parts, which marks increasing perfeetion in the seale of organization. This anatomical difference appears to be the cause of the frequency of the lobular form of pneumonia in early life, and of the greater immunity from the inflammation which the interlobular texture often exhibits. The margins of the lobes are not uncommonly the only portions found hepatized in the lungs of children who have died of pneumonia supervening on hooping-cough. In old people the prevalence of the black pulmonary matter, and the rare, light, and often emphysematous texture of the lung, affect the character of the inflammatory appearanees, the

first two stages being darker and more dingy in colour, and the structure more readily disorganized and infiltrated with pus. Hence, whilst in children we see the suppurative process retarded by the density of the structure and the compactness of the effusion, in old people we sometimes find pus secreted in the second and even in the first stage before the red particles are removed; and this confusion of degrees is the more common where the pneumonia is of the congestive kind, as in typhous fever. Dr. Hope has given a drawing of a portion of lung from an old woman who died of typhous fever, which exhibited all the physical characters of purulent infiltration except the colour, which was a deep opaque chocolate. He says that he has frequently met with this state in the peripneumony of exhausted and cachectic subjects, especially after typhous fever.

Before describing anatomically some remarkable complications of pneumonia, we would stop for a moment on the question—what is the essential seat of pneumonia? Some pathologists, and among them Andral, place it in the air-vesicles and minute bronchi; others consider it to be in the interstitial cellular texture between these; whilst a third opinion supposes it to occupy all these indiscriminately. The writer, some years since, thus expressed his opinion: "Our knowledge of minute anatomy does not permit us to specify with certainty the exact and essential seat of this inflammation; but I am disposed, from a consideration of the signs and of the effects on the tissue, to refer it principally to the plexus of vessels and submucous tissue surrounding and uniting the minute extremities of the bronchi. It may, and usually does, extend to the mucous membrane of these extremites, and of the smaller bronchial tubes; but this is, *strictly* speaking, rather a bronchitis attendant on the parenchymatous inflammation, than a part of the pneumonia."* We have, since writing this, made many minute examinations of the lung in various forms of inflammation, and if they tend at all to modify this opinion, it is to the effect that the plexus of capillary vessels rather than any distinguishable texture, is the essential seat of pulmonary inflammation. On inspecting, by the aid of a simple lens, the margin of a slightly inflamed spot of lung, numerous vessels may be seen, distended with blood, passing across, around, and between the vesicles, with very little regard to their form or disposition; and as the scrutiny is extended to a part more inflamed, these vessels are so multiplied and confounded with each other as to be no longer separately discernible. In this state it is impossible to distinguish whether the tunics of the cells, or the tissues which connect them, are most affected, for they all appear one mass of redness, in which are seen the cells irregularly diminished in size, and containing bloody serum with bubbles of air. The interstitial cellular texture, where it can be separately discerned, namely, between the lobules and around the larger bronchi, is generally less vascular and of a lighter colour than the other parts, and in some instances appears to be nearly free from the inflammation. The lining membrane of the minute bronchi, although generally of a deep red colour, is sometimes blueish red, as if from redness under it rather than in it; and on tracing these tubes higher, the presence of this inflammatory character is very uncertain. These examinations and some pathological considerations induce us to consider the capillary ramifications of the pulmonary artery and veins to be the proper seat of pneumonia, and that these may involve more or less of the tissues through and around which they pass. Thus through them the tunics of the air-cells, particularly the sub-mucous, commonly become the seat of inflammation; whence are formed the granulations of ordinary hepatization. When, again, the inflammation is confined more to the inter-vesicular plexus and tissue, which appears to be the case in the more congestive form of inflammation, where vessels larger than capillaries are involved, the uniform non-granular form of hepatization which we have before described, is produced.* If, as is commonly the case, the inflammation extends to the extremities of the bronchial arteries, which are said by anatomists to anastomose with the pulmonary, the mucous membrane lining the vesicles and minute bronchi partake of the inflammatory action, and exhibit it in the manner peculiar to mucous membranes by the secretion of a viscid mucus, and afterwards of pus. So, likewise, when the inflammation reaches the surface of the lung, it is generally, but not constantly, propagated to that portion of the pleura which invests it and derives its vessels from it; and this extension of the inflammation may add another character to such instances of the disease. But it is its seat in these extensive capillaries of the lungs through which the blood of the whole system is continually passing,—it is this affection of so considerable and important a portion of the circulatory system that causes the severe and intense character of pneumonic inflammation; and the more constantly we hold this in view, the better shall we understand the pathological history of the disease, and its important relation to remedial measures.

We have just mentioned the extension of inflammation to the pleural covering of the lung; this occurs so frequently that some writers have used the terms pneumonia and pleuro-pneumonia as synonymous. But in the ordinary

* A Rational Exposition of the Signs of Diseases of the Lungs and Pleura, by Charles J. B. Williams, M.D. 1828. p. 80.

* An uncommon effect of pneumonia has, since writing the above, been brought under our notice by Dr. Stokes, in a recent number of the Dublin Medical Journal. A part of the lung was in the third stage; and the suppuration, instead of prevailing most in the tunics of the bronchi and vesicles, had scarcely affected them, but had destroyed the interstitial tissues, so that the vesicles presented the appearance of bunches of little grapes or berries. We need not remark how much this fact confirms the view which we take of the occasional diversity in the principal seat of pneumonic inflammation.

ses of pneumonia the pleuritic affection is so ight that it scarcely modifies the disease, and, ce the inflammation of the bronchi, which is usual an accompaniment of pneumonia, is to e viewed as incidental rather than essential in e disease. In these cases the pleuritic in-mmation will shew itself to be modified by e seat and extent of the pulmonary disease. hen this is partial, that portion of the pleura hich covers it has upon it an albuminous de-osit, which is generally thin, and if the disease as been of sufficient duration, shews signs of ganization. The corresponding portion of the stal pleura frequently presents a similar de-osit; an instance of that propagation of in-mmation by contiguity which seems to assi-ilate the proximate cause of inflammation to mething more subtle and mobile than the mmon properties of texture, and to bring it to close analogy with electric agencies. These buminous effusions are the basis of false mem-anes, which form adhesions between the lung d the costal pleura. Underneath them the embrane exhibits points and patches of red, in ordinary pleurisy. When the pulmonary flammation is of small extent, there is com-only a small sero-purulent effusion into the eural sac; but extensive hepatization prevents s from taking place, by filling the pleural ca-y with its own unyielding substance, and the ng is then partially covered with a thin false embrane, which is thicker along the edges, in e interlobular fissure, and occasionally at some ints where the inflammation was first extend-to the pleura.* These circumstances prove e greater intensity of the pulmonary inflam-ation, and constitute the reason given by ennec for not calling such a complication a e pleuro-pneumony.

There is another remarkable combination of eurisy and pneumonia, in which the former with abundant liquid effusion has the predomi-nce, and signally modifies the effect of the in-mmation on the tissue of the lung. The pneu-onia is generally circumscribed, sometimes ular, and is often seen in several distinct spots the lower parts of the lung. Laennec describes e hepatization under these circumstances to be uch more flabby and less solid than in simple eumonia. It is of a red or livid red colour, d destitute of granulations or other trace of air-lls; but the vessels and bronchial tubes are ll conspicuous in it. It contains no air, and t more moisture than muscle; from its re-mblance in compactness and suppleness to is tissue, Laennec distinguishes it by the m *carnification*. In a case of this kind, hich we have recently seen, we could not t recognize in this carnified state of the ng the uniform, non-granular hepatization hich we have described as that in which the terstitial plexus and tissue are the only seat the inflammation; and this variety of con-lidation, which is arrested or restrained by e pressure of the pleuritic effusion, appears be another proof that the essential seat of eumonia is not in the air-cells. It exhibits the essential effects of pneumonic inflammation in colour and solidification, without the granu-lations and humidity which are fortuitous and dependent on effusion extending to the walls of the yielding air-cells. As it might be expected, the progress of this form of pneumonia is slow, and rarely reaches the suppurative stage; but Laennec says that in subjects who had died in from one to three weeks after the sub-sidence of inflammatory symptoms, he has found "the affected portions of the lung flabby, dry, and yellowish, with the vesicular texture discoverable in some places, but the vesicles apparently filled with a half concrete pus." It has been remarked by Dr. Stack that this compressed state of the lung is some-times perpetuated by false membranes, the product of the pleurisy, binding it down.* This we have seen exemplified more than once: in one case illustrative of such an effect of a false membrane, a pneumothorax had supervened on the absorption of the liquid effusion.†

Laennec calls that only true pleuro-pneumo-nia in which both diseases are extensive, there being copious pleuritic effusion, with a con-siderable extent of peripneumonia. Such a combination is of rare occurrence, and as there is only a difference of degrees, it does not ap-pear why this alone should be entitled to the compound name.

The anatomical characters of resolution or cure of peripneumony are worthy of remark; they are particularly described by Laennec. When recovering from the first stage, the pul-monary tissue becomes drier and more filled with air, but for some time retains its red colour, as if dyed. Sometimes the texture con-tinues for a while to be œdematous. A hepa-tized portion in progress towards cure assumes a paler hue, passing through shades of red grey and reddish flax colour, until it becomes a little redder only than natural. The texture at the same time becomes more yielding and moister, containing a frothy serum, which abounds more and more in air as the resolution advances, the granulations giving place to the developement of the air-filled vesicles. These changes begin at several points, and, when ad-vanced, often leave others still hepatized. When the tissue resumes its natural dryness and colour, it remains firmer, more elastic, and heavier for some time after. The first signs of restoration from the third stage are the yellow tinge becoming lighter, and the pus more liquid by the intermixture of serum; air-bub-bles afterwards appear and continue to increase, while the pus is reduced to small specks. As the vesicular texture returns, it resembles the first stage of engorgement in all respects but colour, which appears on incision to be dirty yellow or greenish, and this continues even after the complete re-absorption of the serum. The anatomical history of the process of cure of gangrene of the lungs will be found in the article MORTIFICATION.

III. PATHOLOGICAL HISTORY OF PNEUMONIA.

Operation of causes.—Pneumonia is the

* Transl. of Laennec, p. 487.

* Dublin Hospital Reports, vol. iv. p. 90.

† Rational Expos. &c. p. 143.

most frequent of all the parenchymatous inflammations. This in part proceeds from the very vascular structure of the lungs, which renders them very susceptible of inflammation; but we also see a reason in the nature of their function, which peculiarly exposes them to suffer from the various influences that injure the balance of the circulation. Whatever view is taken respecting the generation of heat, it is sufficiently established by experiment that the function of the lungs is intimately connected with it, and that the application of any cooling influence to the body makes a demand on an increased activity of this function. As, under such influence, the blood returns freely to the lungs in a state more highly venous than usual, there is a greater necessity for respiration, and both this increased flux and the consequent augmented activity bring this organ into a condition peculiarly favourable to the development of inflammation. If the application of cold be not long continued, the pulmonary congestion may soon be removed by the due oxygenation of the blood, and consequent restoration of the balance of the circulation before the tonicity of the pulmonary vessels has materially suffered; some minor part of the circulation, as that of the bronchial membrane, occasionally alone being the seat of inflammatory reaction. But if the cold be severe and long continued, if a large portion of the body, especially the chest, be exposed to it, the pulmonary vessels suffer not only from their increased task and the congestion consequent on its imperfect completion, but likewise from the sedative influence of the cold directly affecting them; hence, whenever reaction is established, they are the parts most likely to suffer from its effects. The manner in which excessive exertion and the inhalation of asphyxiating gases and vapours excite the disease is obviously likewise by the congested state which they occasion in the vessels, which, if sufficiently continued, only requires the addition of a subsequent reactive excitement to convert it into inflammation. Alcohol and its various compounds also act as occasional exciting causes of pneumonia by their narcotic influence on the nervous system, by which the sensation of want of breath that excites the respiratory act is blunted, and a congestion of blood takes place in the lungs in consequence of their insufficient action. How far in these several instances the stasis of highly venous blood in the pulmonary vessels may contribute to injure the tonicity of their coats, and thus to render them peculiarly obnoxious to the consequent reaction, is only a matter of conjecture, not unsupported by analogy.

The presence in the body of various poisons, as that of the rattle-snake and deleterious fungi, may lead to the production of pneumonia partly in the same way, but probably also from a specifically injurious influence on the pulmonary vessels. There is no organ in the body so intimately exposed to the influence of the blood as are the lungs; the whole circulating mass passes rapidly through their fine vascular filter, and if there be a noxious ingredient in the blood, it may be reasonably expected here to shew its effects. Hence the origin of pneumonia, not only from the poisonous influences just named, but probably also, as Laennec has surmised, from the more subtle ones of an epidemic nature. The inflammations arising in the course of various febrile and exanthematous diseases may owe their existence in some degree to a similar mode of influence; but the tendency of the phlogistic reaction to localize itself in parts predisposed to inflammation in many of these disorders, is likewise a link in the chain of causes, which must not be withheld from our recollection. In eruptive fevers particularly, it is common, as Andral has remarked,* to see a great degree of dyspnœa precede the appearance of the eruption, and generally cease, as if by magic, when this fully takes place. In some cases, however, and especially where the eruption recedes or is not fully thrown out, the dyspnœa continues, and assumes the character of a more permanent disease. This is obviously a congestion persisting and becoming converted by general vascular excitement into an inflammation. The deficient resonance of the chest, remarked by Avenbrugger and Corvisart at the commencement of eruptive fevers, is a physical indication of this pulmonary congestion.

The intercurrence of pneumonia with other inflammatory diseases of the lungs and neighbouring parts will admit of a more direct explanation: it is an extension of inflammation by contiguity, and arises from some additional external cause, as when bronchitis or pertussis becomes a pneumonia in consequence of exposure to cold; or from an additional internal movement, as when, in consequence of a checked excretion or a too well nourished mass of blood, such slight or membranous inflammations spread and infest the more considerable circulation of the parenchyma. The remarkable tendency which is exhibited among children to such a propagation of inflammation is dependent on the greater proportion of membrane and vascularity of the lungs, as well as on the higher activity of their function at that early age; facts pointed out by Majendie and Laennec, and strictly corresponding with the rapid progress of diseases of these organs at that period. The frequent intercurrence of pneumonia with hooping-cough appears to depend not merely on a propagation of inflammation; the congested state of the lungs induced by the cough and imperfect oxygenation of the blood has likewise its share in favouring the development of inflammation.

The metastasis of the inflammation of gout and rheumatism occasionally falls on the lungs, but seldom without some predisposition to disease in the organ, from previous attacks of inflammation; and there is nothing in these instances which tends to throw new light on this obscure point of pathology. Whether these, and likewise the cases of pneumonia supervening after severe accidents and surgical operations, noticed by Guthrie, Bell, Dupuytren,

* Clin. Méd. tom. ii. p. 287.

and others, are connected with an altered condition of the circulating fluids, is a question which cannot at present be placed on any other than the ground of conjecture.

Tubercles and apoplectic engorgements in the lungs may excite inflammation both by their irritating influence, and likewise, if they are numerous or extensive, by the obstruction which they occasion in the circulation, and which leads to the congested state which we have so frequently observed to favour the development of inflammation. The points adjoining tubercular excavations are likewise occasionally attacked with inflammation. It is to be remarked of these and other inflammations which originate chiefly from mere local irritation, that they are much less severe and permanent than those in which the system at large is more concerned, and the inflammation is as it were the focus of a general derangement. Accordingly it is observed that such intercurrent peripneumonies are commonly slight, and, if recognized, yield readily to treatment. But their latent character constitutes their worst feature, their symptoms being merely a slight exacerbation of those of the pre-existent disease; and unless detected through the aid of their physical signs, they may speedily prove fatal.

In reviewing the pathological relations of the causes of pneumonia, we cannot avoid noticing the important link which congestion of blood in the lungs forms in the development of the inflammation. In by far the majority of cases this congestion is immediately determined by the operation of the exciting cause, and precedes what may be termed the irritative stage of the inflammation. Such we have seen to be the effect of cold extensively applied, of violent and long-continued exertion, of certain poisonous influences, (which, by diminishing the sensibility of the nervous system, impair that sensation of want of breath which excites the respiratory act,) and of the congestive stages of various febrile diseases. The connexion of congestion with inflammation is still more forcibly illustrated in the pneumonia of the moribund, in which the blood, imperfectly oxygenated through the failure of the respiratory forces, accumulates in the pulmonary vessels, which even then become the seat of inflammatory action, and if the agony or change of death be of long duration, produce those changes which are recognized as the results of ordinary pneumonia. This point has been fully established by Laennec and Louis. The latter found signs of partial inflammation in 22 out of 112 cases which died of various chronic diseases, and in which the inflammation could have existed only a few days before death.* Laennec not only found proofs in the dead body, but likewise repeatedly discovered signs of this inflammation supervening during the failure of the powers before dissolution in various diseases. Seeing, then, the close relation which simple congestion, or passive hyperæmia, (as Andral terms it,) of the lungs bears to inflammation, so close that their anatomical distinctions cannot be discerned, it remains for inquiry what is the additional pathological movement which gives to inflammation its character and permanency, and renders it more than simple hyperæmia. In answering this question by asserting that it is a reaction of the neighbouring arteries and of the heart, we only describe a phenomenon which does succeed, and which is the next of a series of actions constituting the disease in question. This is the irritative stage, and is in most examples posterior to the formation of a congested state of the vessels. In some instances, however, as where inflammation succeeds to a wound or other mechanical injury of the lung or other irritation in its substance, the afflux of blood is posterior to the irritation, which is then the starting point of the pathological changes. In the article IRRITATION we have already described an afflux of blood as generally following an excitement of a part, and it does so the more certainly and fully in proportion as the organ is vascular and freely supplied with blood; hence the lungs are peculiarly liable to the congestion of irritation, and if the cause be applied for a sufficient length of time, this congestion may become inflammation. We do not here stop to trace the progressive changes and reactions which accompany the development of inflammation in general; these are sufficiently dwelt upon in the article on that subject; but in considering the lungs as an object of inflammatory action, it cannot escape our observation that their vicinity to the heart, their great congeries of vessels through which the whole blood of the body passes, their spongy and yielding texture,—all tend greatly to increase the delicacy of the balance of their circulation, and render any disorder of this balance peculiarly liable to those reactive processes of the principal circulation which form a part of inflammation and fever.

Physical signs of pneumonia.—Through the aid of auscultation and percussion we obtain a better knowledge of the pathological process of pneumonia than can be obtained in any other way, for through their means we in a measure apply our senses to the very seat of the disease. But there is still some degree of doubt about the precise mechanism of certain of these signs, and this obscurity leaves us uncertain as to some minute points of the pathological progress of the disease, which we have already found not clearly determined by their anatomical history. We shall, however, describe the signs as they have been accurately observed, and afterwards state the view of the pathology to which they, together with the anatomical characters of the disease, appear most rationally to lead.

On the first invasion of inflammation of the lungs, contemporaneously with the earliest of the general symptoms before described, the ear unaided, or through the stethoscope, will perceive in some part of the chest a peculiar sound accompanying the usual respiratory murmur: it is a fine crackling or crepitating sound, like

* Rech. sur la Phthisie, p. 39.

that produced when kitchen salt is thrown on a heated iron; or like the crepitation which occurs when a healthy lung is pressed between the fingers. A pretty correct idea of the sound may also be obtained in a readier manner by rubbing between the finger and thumb a lock of one's own hair close to the ear. This is the *crepitant rhonchus*, and was considered by Laennec to be pathognomonic of the first stage of pneumonia. The space where it can be heard is often at first very limited, sometimes not extending more than an inch or two; but when more advanced, it may occupy nearly a whole lung. The parts where it is most commonly first heard are, below the inferior margin of the scapula, below the axilla, or about the lower margin of the pectoral muscle, —points corresponding with the lower lobes of the lungs, which, as we have before noticed, are the most frequent seat of inflammation; but it is occasionally met with in other parts of the chest. At the commencement of inflammation, the crepitation is merely an *addition* to the ordinary respiratory sound, which is still distinct; but as the disease proceeds, the crepitant rhonchus prevails more and more, until it is the only sound heard in that spot during the respiratory movements.

At this period the part begins to sound a little duller on percussion than the corresponding opposite point, particularly if this be practised mediately, with M. Piorry's plate, or even on one of the fingers of the left hand pressed closely on the chest. The progress of the inflammation is marked by the minute crepitations constituting the rhonchus becoming less continuous and regular, and being confined principally to the end of each inspiration; and as the lung begins to pass into the state of hepatization, they are heard only on coughing or on deep inspiration, and at last cease entirely. If the disease is extensive, in proportion as the crepitant rhonchus diminishes, the respiration in the sound parts of the lungs becomes louder than usual, and like that of children, whence it is called by Laennec *puerile respiration*. In the second stage of pneumonia, if the disease is extensive, the sound emitted on the percussion of the part of the chest corresponding with the hepatized portion, is quite dull, and yields no more resonance than the region of the liver. On applying the ear, neither the ordinary respiratory murmur, nor the crepitant rhonchus of the first stage is heard; but sometimes another kind of sound is substituted for them, and this occurs most commonly in proportion as the hepatization approaches the middle parts and root of the lobes, and extends to the surface. This is a whiffing sound, resembling that produced by blowing through a crow's quill, and it is occasionally so loud as almost to amount to a whistle. This is the *bronchial respiration* of Andral and Laennec, and in its acute and defined character forms a remarkable contrast with the dull diffused murmur of natural respiration. It is often heard most distinctly during the forcible respiration of coughing. A peculiar resonance of the voice, called by Laennec *bronchophony*, is less commonly observed at the same points. The voice resounds at the end of the stethoscope in a modified tone, as if it came through little tubes. It does not, as in perfect pectoriloquy, appear to originate in the stethoscope, and it is not heard in distinct words, but in notes of various continuance, not always synchronous with the words uttered by the mouth, and at intervals is alternated with what may be called whiffs of the bronchial respiration. With these several sounds there is often mixed a mucous rhonchus or fine gurgling, but this seems circumscribed and does not obscure the others. The puffing or blowing sound of bronchial respiration sometimes gives the auditory sensation of a person blowing into the ear through a narrow tube; and as this sound is sometimes interrupted, and occurs in irregular puffs or whiffs, it gives the impression of a moveable veil or loose curtain fluctuating under the impulse of the air.

In the third or suppurative stage, in addition to the dulness on percussion observed in the second stage, there is sometimes a coarse mucous rhonchus, heard especially at the root of the lungs or about the lower axillary or mammary regions: this is the only physical sign of the termination of the inflammation in this stage; and when it is observed to commence in a part where bronchial respiration and resonance have been previously heard, it may be taken as a pretty certain proof of the supervention of this change. Sometimes, however, the bronchial respiration and resonance continue without this sign, and there is then no physical indication of the occurrence of the third stage.

If the suppuration becomes complete, by the formation of an abscess in any portion of the lung, no physical indication of this event presents itself until the purulent matter has been partly expectorated. In that case a gurgling or cavernous rhonchus will be heard in the corresponding point; and when the evacuation of the liquid contents of the abscess has been further completed, this rhonchus will give place to the *hollow cavernous respiration* or *pectoriloquy*, indicating a cavity communicating with the bronchi. If, however, the abscess is very large, it may leave a cavity in which the *metallic tinkling* or *amphoric resonance* is produced, precisely as these phenomena are developed in phthisis after the evacuation of the contents of tubercular vomicæ. The gangrenous termination of peripneumony will announce itself by the putrid fœtor of the breath and of the matter expectorated; and in case the gangrenous portion is detached, whether in a circumscribed slough, or in a diffused deliquium, the same signs of a cavity may be produced as in abscess of the lungs.

Such are the physical signs which the most accurate observers have concurred in attributing to peripneumony and its consequences in their simpler forms. We shall better understand their nature as well as the varieties to which they are subject, if we examine them more rationally, in relation to the other symptoms, and to the effects of the inflammation anatomically discovered in the tissue. With respect to the crepitant rhonchus, there can be no doubt

that its seat is in the minutest order of bronchi and air-cells of the lungs, since it is only diseases which affect these parts that present this or any sound resembling it. But the precise manner in which they are affected in order to produce this sound is not quite so certain, and different opinions upon it have been entertained. M. Andral considers the crepitant rhonchus to be nothing more than a finer modification of the mucous rhonchus; the latter becoming crepitant when its seat is in the minutest bronchi and air-cells, the narrow dimensions of which render the bubbles which compose it finer and more equal. Hence he asserts that the crepitant rhonchus is produced by the intermixture of air and liquid in the air-cells and smallest bronchi in other diseases as well as in pneumonia, and that it occurs in acute bronchitis whenever the inflammation and excessive secretion extend to these parts. Although he absolutely denies the accuracy of this statement, Laennec does not appear to have clearly made up his mind as to the physical cause of the crepitant rhonchus of peripneumony. Speaking of this sound in one place, he says: "Besides the sound of crepitation, a sensation of humidity in the part is clearly conveyed. We feel that the pulmonary cells contain a watery fluid as well as air, and that the intermixture of the two fluids produces bubbles of extreme minuteness."—"The consistence of the fluid appears always greater in the mucous than in the crepitous rattle."—"In respect of the size of the bubbles in the different rattles, they may be estimated as *very large*, *large*, *middling*, *small*. The last term is especially applicable to the crepitous rattle of peripneumony, in which it seems as if an infinity of minute equal-sized bubbles, formed at once, were thrilling or vibrating rather than boiling on the surface of a fluid."* In another place, however, he says that at the invasion of the inflammation, the crepitation "conveys the notion of very small equal-sized bubbles, and seems hardly to possess the character of humidity."† These opinions are equally inconsistent with each other, and with his observation on the certitude with which he strenuously insisted that simple acute bronchitis never presented this sign; for truly, if the intermixture of air and liquid in the minute bronchi were the only elements of the crepitant rhonchus, this disease as well as pituitary catarrh, which certainly present this condition, ought in an equal degree to produce this sound. Such, however, was the fine accuracy of Laennec's observation, (as, during the last year of his life, when he was most perfect in his art, we had personally ample opportunities of proving,) that we do not hesitate to receive his testimony on this point as the most exact, whatever inconsistency may appear in his reasonings upon it; and therefore, although we cannot pretend to such a perceptive acumen as to be able always to distinguish the crepitant from the mucous rhonchus in all their modifications and gradations, we assume the authority of the great auscultator as a proof in addition to others, that these two sounds are essentially different in their nature, and owe their characters to peculiarities in the mechanism which produces them.

It is agreed on by all auscultators, that œdema of the lungs and the margins of hæmoptoic engorgements may produce a rhonchus of the crepitant kind, and it naturally occurs to us that these lesions resemble pneumonic engorgement in the pressure to which they subject the vesicular parenchyma. If we compare with these instances the very close representation of the crepitant rhonchus which the simple pressure of a healthy lung will produce, we are led at once to an explanation of the mechanism of this sign. By this pressure the air is expressed from the tissue, whilst the tubes and cells are so narrowed by the pressure that it can only pass out of them in successive bubbles, the escape of each of which produces a minute crepitation: this sound Laennec tells us differs from the crepitant rhonchus only in being not so strong; here no preternatural fluid is present in the air-cells. In œdema, or in effusion of blood into the substance of the lungs, we have the interstitial effusion and narrowing of the minute air-tubes and cells, and from the nature of the expectoration we may conclude that there is also an increase of liquid within them; the rhonchus that accompanies them is accordingly described by Laennec to consist of moister and somewhat larger bubbles than that of peripneumony, and he terms it subcrepitous. Lastly, we have the peripneumonic engorgement, in which anatomy assures us that there is the same narrowing of the air-tubes and cells by the swelling of the interstitial bloodvessels, whilst the observation of the sputa leads us to conclude that the interior of these tubes and cells is lined with a viscid secretion; this produces the drier and stronger sound of the genuine pneumonic crepitation. This is in principle the same explanation which we advanced some years since in the following passage; "The distended vessels, and the serous effusion in the interstices, press on the minutest bronchial ramifications, and partially obstruct the ingress of air into the cells to which they lead; whilst the viscid secretion of the mucous membrane simultaneously inflamed, filling the caliber of the tubes thus narrowed, only yields to the air in respiration forcing its way through it in successive bubbles. This bubbling passage of air through a viscid liquid contained in an infinity of tubes of equally diminished caliber, causes that regular and equable crepitation which constitutes the true *rhonchus crepitans*."* We were led to doubt the accuracy of the explanation of Andral and Laennec, from the circumstance that the character of the expectoration in pneumonia does not countenance the supposition that there is during life any other secretion into the air-cells than the characteristic viscid secretion of the mucous membrane which

* Dr. Forbes's Translation, p. 52.
† Op. cit. p. 212.

* Rational Exposition, &c. p. 81.

lines them. In a former article we have pointed out the tendency which the natural respiratory movements have to throw all superfluous secretion from the smallest bronchi into the larger, until they are brought under the influence of the act of expectoration. (See EXPECTORATION.) Now if, as those who found their opinions solely on morbid anatomy maintain, there were a serous effusion into the air-cells in the first stage of pneumonia, there ought to be more or less of this serum mixed with the sputa, as in some cases of pulmonary œdema: this is not the case, for the expectoration is a glutinous mucus from the onset of the inflammation, and instead of becoming more serous, increases in viscidity as the inflammation becomes more vehement. Moreover, we venture to follow the example of Laennec in asserting that there is a mucous or liquid rhonchus of the fine bronchial ramifications, the character of which is sufficiently distinct from the rhonchus of pneumonia to merit its separation in kind as well as in degree from the latter sign. This fine mucous rhonchus, which we have observed in pituitary catarrh, and in the general bronchitis accompanying continued fever, occupying the base of the lungs, the common seat of the crepitant rhonchus, is distinguished from this latter in the greater inequality of the bubbles which compose it; they appear to roll through a liquid without breaking with that regularity which distinguishes the crepitation in pneumonia: there are, besides, little hissing or whistling sounds mixed with them, which convey to the mind the impression of a moveable proportion of air and liquid in the tubes. If this mucous rhonchus is to be distinguished from the subcrepitant of pulmonary œdema and apoplexy, it is by the greater irregularity of the minute sounds which constitute it; but we cannot pretend to assert that this distinction is always possible from the nature of the sound, nor can we deny that there are gradations and combinations of the two rhonchi which entirely baffle our power of discrimination. But we do maintain that the crepitant rhonchus of peripneumony is, with few exceptions, sufficiently characterised by its pure equable crepitation, unmixed with hissing or any sounds of liquid, to render it a valuable and available means of distinguishing this disease in its earlier stages.

In conceiving the mechanism of this rhonchus according to the explanation given above, we must take into account the force with which the air passes through the narrowed tubes, and we shall then perceive why the bubbles crepitate drily, and the liquid is not carried before the air passing to and fro, as it would be were its viscidity less and its quantity greater. It has been asserted that the crepitation of peripneumony may be imitated by the bursting of bubbles on the surface of fluids of the tenacity of serum, and hence it is concluded that the crepitant rhonchus depends on the mixture of air with such a fluid in the lungs; but the cases are by no means analogous: in the one, the bubbles rise and burst merely from their own levity; in the other, an active moving force is constantly driving and breaking them through an infinity of minute tubes. On the whole, then, the more we have examined and reflected on the subject, the more we are convinced that the physical cause of the crepitation of peripneumony is the forcible passage of air through narrowed passages lined with a viscid liquid; and if we modify at all the explanation formerly given, it would be that we have not the ground to confine the crepitation to the minute tubes only, but that it probably occurs in the air-cells likewise.

We can readily perceive how the various degrees of this rhonchus become an accurate measure of the progress of the inflammation. Thus, when this is most moderate, the air enters many tubes still without obstruction or crepitation, and the natural sound of respiration is heard together with the crepitant rhonchus; but when the narrowing of the tubes and cells and the viscid secretion lining them, become more universal in the part, no air enters there without this crepitation being produced, and this rhonchus is then heard pure and unmixed. The next change is the gradual diminution of these crepitations, owing to the increased swelling of the coats of the air-cells, or of the interstitial tissues. Anatomical investigation teaches us that at this period there is a deposition of a semi-solid lymph or albumen; this appears to cause such a successive obliteration of the tubes and cells as to entirely obstruct the entry of air into them. Accordingly, as the lung passes from the first stage of inflammation into the hepatized state the crepitations become fewer, are heard only at the acme of inspiration, or during the forcible efforts of coughing, and at length cease altogether.

The physical cause of the bronchial respiration and resonance is more obvious. The deposition of albuminous matter in the parenchyma of the lung has the effect, as we have just seen, of obliterating the spongy structure and converts it into a solid mass. In the healthy state, the different density of its materials (air, membrane, and liquid) prevents the transmission of sounds from the interior to the surface; but now that this density is rendered uniform, it propagates the sound of the air passing to and fro in the larger bronchial ramifications of the interior; and during the exercise of the voice, its resonance also traverses the hepatized substance in a similar manner. It is obvious, therefore, that the extent and intensity of these sounds must greatly depend on the number and size of the bronchial tubes involved in the hepatized portion; hence they are most distinct when the inflammation occupies the summit, root, or central parts of the lung, and extends to the surface; but when the lower, the central, or the superficial portions are alone affected, they may be altogether wanting. When the principal part of a lung is hepatized, including the central portions, which contain many considerable bronchi, a noisy resonance of the voice, almost amounting to pectoriloquy, is heard in the scapular region, in the central parts of the axilla, or about the lower margin of the pectoral muscle, but it may be generally distinguished from imperfect pectoriloquy

its more diffused character, and from that of the perfect kind by the indistinctness of the words uttered. The puffing or fluctuating sound of bronchial respiration and bronchophony, which we have mentioned as sometimes met with, is referred by Laennec to a thin portion of healthy and crepitant lung immediately on the surface and between the hepatized portion; and if this observation is exact, the cause of this irregular puffing seems to be the air entering or leaving this healthy portion, and thereby changing the degrees in which the sound from the interior is transmitted through it.

We have mentioned the supervention of a liquid mucous or gurgling rhonchus as the only physical indication of the occurrence of the third or suppurative stage. This sign is the proof of that softening and deliquescence of parts which mark the process of suppuration in all its forms, but we do not obtain from it any further light on the intimate nature of this termination of inflammation. The more liquid form of the expectoration generally corresponds with the presence of the mucous rhonchus; sometimes, when there is little or no expectoration, the bronchial respiration and brochophony continue in this stage.

The physical signs of abscess and gangrene sufficiently explain themselves; they apply only to the cases where a cavity has been produced by the more or less perfect evacuation of the gangrenous or suppurated parts; and are, first, the coarse bubbling rhonchus, and afterwards, more rarely, the cavernous respiration and resonance, or pectoriloquy, which are described as the signs of tubercular cavities in phthisis. (See Tubercular Phthisis.) In the uncommon case of a large abscess, there may be the metallic tinkling instead of these signs. In the work formerly quoted will be found the only explanation that has been given of this sign, and this explanation has enabled us to generalize with success on the cases of its production, but it has too little connection with our present subject to require an exposition here.* If the abscess or the sloughy portion of the lung has not been evacuated, auscultation teaches us nothing of the presence of either. Fetidity of the breath, especially in coughing, and of the expectoration, is the only physical sign of gangrene of the lungs. This may occur, however, in simple bronchitis, and it is only where auscultation has detected signs of pneumonia that it can be admitted as a proof of the death of a portion of the pulmonary tissue.

We have hitherto considered the general type of the physical signs of pneumonia in its most simple state, and we need say little on the varieties contingent on the situation or extent that the disease occupies. If it be confined to the central part of the lung, the spongy tissue of the surface may prevent the various sounds generated in the inflamed portion from reaching the ear; and this, we apprehend, happens far more frequently to auscultators in general than it did to Laennec, who states that he only met with one case of pneumonia where the stethoscopic signs were wanting; that he could detect a central spot of inflammation, not exceeding the size of a filbert, by the distant deep-seated crepitation, or bronchial respiration, heard beyond the pure murmur of the surface. It requires a very fine ear and considerable experience in auscultation to discover these signs at all in many cases of central pneumonia; and we believe, with Dr. Forbes, who made a similar comment, that it is expecting too much of auscultation to suppose it infallible in detecting every degree of pulmonary disease.

It has always appeared to us, that the more the student in auscultation holds in view the pathological state on which the signs depend, rather than those signs themselves, and habitually reflects on their physical mechanism, as far as it is known, without empirically dwelling on names or bare descriptions of sound, the more surely will he estimate the value of this method of diagnosis, and the more instruction will he receive from it. He will thus see that central peripneumony may be so situated as to yield sometimes no physical symptom, and at others those to be discovered only by a very careful examination; and hence he will see the impropriety of a partial method of diagnosis, and the great importance of attending to the sputa and other indications. When the inflammation is extensive, all these difficulties vanish, and the more intense and puerile respiration in the sound portions of the lung, depending on the more rapid and forcible passage of air in them, further shows the infringement that has been made on the proper function of the organ.

It is not uncommon, especially in partial peripneumony, to observe the signs of the several stages of inflammation co-existent in different parts of the lung. Generally the base or lower lobe, the part most liable to inflammation, presents its greatest degree, being hepatized, and yielding no sound of respiration or resonance on percussion; a little higher are heard the bronchial respiration and resonance, and above that the crepitant rhonchus, which mixes with and gradually gives place to the puerile respiration which occupies the upper parts of the lung. More rarely this order is reversed, the upper parts being the first and most affected. Bronchial respiration is particularly obvious when the hepatization affects the root or middle portions, without extending to the margins of the lobes; and the obvious reason of this is that there is still a passage of air through them to the sound parts.

The resolution or cure of peripneumony is marked by the re-appearance, in a reversed order, of the signs which attended its progress. If the inflammation has reached only the first stage, engorgement, the resolution announces itself by the return of the respiratory sound mixed with the crepitant rhonchus which before prevailed, and this pure vesicular murmur increases, whilst the crepitation diminishes, as the tissue becomes more free to the passage of the air. If the disease has proceeded to hepatization, the same recurrence of symptoms is observed: thus, in a spot where no sound of

* Rational Exposition, &c. p. 136.

the ingress and egress of air had been heard, or perhaps only a bronchial respiration, a slight crepitation begins to be distinguished at the end of each inspiration, apparently produced by the air once more gaining admission through some of the fine bronchial tubes, whose calibers have been partially restored by the re-absorption of matter effused in and around their parietes. This sign, the *rhonchus crepitans redux* of Laennec, increases in intensity as the resolution proceeds; the bronchophony and bronchial respiration are diminished as the lung re-acquires its spongy texture, and becomes a worse conductor of sound: after a while the natural respiratory murmur is heard mixed with the crepitant rhonchus, and as the texture becomes more permeable to the air, this increases as that diminishes, and the healthy state of the lung is thus gradually restored. It must be remarked, however, that this returning rhonchus differs slightly in character from that of incipient pneumonia, in its being less even in its crepitations; and as it increases in intensity, it gives more the sound of bubbles, resembling the mucous rhonchus, with which at this period it often becomes obviously mixed. The nature of the expectoration in retroceding pneumonia explains this difference, for we see in its diminished tenacity and more bronchitic character the reason why the crepitation ceases to be dry; and after a while, when their proper calibers are restored to the tubes and cells, the continuance of this secretion produces a simple mucous or bubbling rhonchus. We commonly, however, hear some crepitation in a part which has been inflamed, for some time after the resolution has apparently taken place; and this seems to indicate an œdematous state of the part, which we know in other instances to succeed to inflammation. If the inflammation has been of long continuance, especially if hepatization has existed for some time, the returning rhonchus is less regularly crepitant in its character; and if there be bronchial respiration present, this, instead of becoming diminished, is sometimes in a measure increased at first by the resolution. This fact, which has been also remarked by Drs. Graves and Stokes,* seems to depend on the increased passage of air attending the re-opening of the hepatized tissue before this has lost its good conducting power. The progressive change which supervenes, however, soon disguises this sound, not only by the tissue again becoming a bad conductor of sounds, but also by the bubbling or mucous rhonchus which generally occurs in a greater or less degree in the tubes which were before the seat of bronchial respiration. This change, compared with the free expectoration which commonly attends the resolution of pneumonia, exhibits a direct evidence of the interesting manner in which nature clears away effused matter from a tissue by free secretion from the adjacent membranes. When the hepatization has continued stationary for many days, the returning crepitant rhonchus is never so regular in its character as in more recent cases; and whilst in some points this rhonchus has appeared and already given place to one of a mucous kind, in others there is only a faint crepitation, indicating a remarkable inequality in the progress of the resolution; some of these we should be disposed to view as cases of lobular pneumonia, in which the inflammation had commenced at several distinct points simultaneously; but in referring to the anatomical characters of the resolution of peripneumony before described, it will be seen that the restoration of the tissue to the healthy state is there seen to be also irregular and unequal, being probably modified by the degree of inflammatory orgasm in the different periods rather than by its absolute duration.

It is less easy to define whether any peculiar sign marks the restoration from the third stage, since we have no certain mark of the supervention of this stage. The coarse mucous rhonchus, which in fatal cases goes on increasing until it becomes tracheal and terminates the existence of the patient, in favourable cases becomes finer and less bubbling, in consequence of the free expectoration of the matter; and as this is secreted and cleared away, the air finds its entrance into the smaller bronchi and vesicles with a mixture of the mucous and crepitant rhonchi; these, in process of time, again yield to the natural vesicular respiration; but as may be expected from the degree to which the disease has attained, this restoration is very slow, and a subcrepitant rhonchus, depending on an œdematous state of the parts, often lingers for weeks after the other signs seem to indicate a removal of the peripneumony. The process of cure, after the formation of abscess, consists in the evacuation of its contents and its subsequent cicatrization. The signs of a cavity, the gurgling or cavernous rhonchus, or respiration, or pectoriloquy, therefore, gradually diminish until they nearly cease altogether; but there is generally left some dulness of the respiratory sound and of the resonance on percussion in the spot, often accompanied with a bronchial resonance, after the signs of cicatrization have appeared to be complete; and this is a natural consequence of the permanent modification which the disorganization has produced in the texture of the part. Laennec states that in several instances of abscess from partial peripneumony, which he observed in 1823, the cicatrization was completed within a period of from fifteen to forty days. In another patient who had pectoriloquy and cavernous rhonchus, over a space of three square inches on the lower part of the right lung, three months elapsed before these signs completely disappeared; and in another case, where a much smaller abscess existed in the top of the left lung, they did not entirely disappear until after six months; long before this, however, both these patients had recovered their flesh and strength, and considered themselves completely cured. In the few instances in which gangrene of the lungs has terminated favourably, similar symptoms have been observed; in fact, after the removal of the gangrenous portion, a cavity is left, which must

* Dublin Hosp. Rep. vol. v.

be cicatrized precisely as that produced by an abscess.

Physical signs of pleuro-pneumonia.—The extension of the inflammation of the lung to the pleura, (an event, as we have seen by the anatomical history, very common in pneumonia,) sometimes adds to the physical signs of the latter disease others of a novel character, which it is of importance to record. They depend exclusively on the presence of a liquid effusion, for as far as we have observed, we have been unable to recognize the affection of the pleura by physical signs, unless where this effusion has taken place. Some recent writers have indeed asserted that a creaking sound of friction is produced when the pleuræ are coated with freshly effused lymph, but this statement we have been unable to verify. The liquid effusion of a pleuro-pneumonia may declare its presence by producing of itself new physical signs, and by modifying those of the inflammation of the lung. Where the pleuritic effusion is not extensive, which is the common case, there may be so little liquid effusion that its presence can scarcely be detected, or it is discovered only by the greater deficiency of sound on percussion in the most dependent parts of the thorax, which parts regain a portion of their natural resonance when a change of posture raises them higher in relative position. Together with such a degree of effusion all the ordinary signs of pneumonia may present themselves without perceptible modification. But if the liquid effusion be greater, and sufficient to cover a considerable portion of the lung, it will disguise these signs, by rendering the crepitant rhonchus less distinct, while the sound on percussion is quite dull wherever the liquid reaches. If the pneumonia have attained the state of hepatization with bronchophony, and the point presenting this phenomenon be covered with liquid, the tone of the local resonance will become changed,—it will assume a cracked or bleating character, or rather a sound of this description will accompany the bronchophonic resonance. This combination of ægophony and bronchophony Laennec compared to the squeaking voice of punchinello; but besides the buzzing and squeaking combination of noises which this comparison represents, there is a tremulous or vibratory character in this morbid sound which seems alternately to approach and recede from the ear in sudden jerks. We have heard the voice otherwise modified by this combination of disease, as if it came through little cracked brazen trumpets; but, as far as we have observed, it is the undulatory or tremulous character which most constantly depends on the presence of the liquid, and is therefore the surest indication of the existence of a pleurisy. The most common seat of this phenomenon is the same as that of bronchophony, in the interscapular regions, but it may extend, especially when the effusion is abundant, through the whole of the ægophonic region, that is, in a band about three inches broad running from below the inferior margins of the scapula, in the direction of the ribs, to the sternum. It is most purely ægophonic in the anterior regions, there being commonly a noisy bronchophony behind. (See Pleurisy.) We have yet supposed the effusion only extensive enough to push aside slightly the lung from its apposition to the walls of the chest, and the sounds of pulmonary respiration are still heard pretty distinctly, modified by the inflammation, in the first stage into the crepitant rhonchus, and afterwards into the bronchial respiration and resonance; but there are some cases which we have described anatomically, and in which a copious pleuritic effusion has suddenly increased during a pneumonia, and has compressed and pushed aside the lung in such a manner that the sound of respiration can only be heard in the form of a crepitant rhonchus towards the root of the lungs, that is, in the scapulary, axillary, and infra-clavicular regions. This is the form of disease which produces the state before described anatomically under the name of *carnification*, and the pneumonia may in most of these cases rather be considered as secondary in existence as well as importance, and it is sometimes confined to a few lobules; but Dr. Stack inclines to the opinion that even in these instances the pneumonia is primary.* The pathological as well as the anatomical characters of pleuro-pneumonia lead to the belief that where one inflammation has greatly the predominance, the other is of trifling import, and that where both exist to a considerable extent, the complication, instead of presenting a more aggravated case, rather mitigates the severity of both diseases, and this from a cause purely mechanical. The pressure exerted by the pleuritic effusion moderates the inflammatory action of the lung; and again, the lung, in some degree consolidated by the inflammatory process, and not yielding to the encroaching effusion, sets limits to its accumulation. If, however, the intensity of a pneumonia is diminished by a coexistent pleurisy, its duration is probably prolonged; for the process of resolution is always much slower in this than in the simple case. This is because the interstitial effusion is more solid, and less mixed with the serous exhalation produced by common inflammation, and which cannot but assist in the discussion of the denser products. On the other hand, a pleurisy coinciding with a pneumonia will be of easier and speedier cure, inasmuch as the effusion is less abundant. The dry state of the carnified lung, taken together with the still constant production of the crepitant rhonchus in the course of the inflammation thus modified, affords an additional proof that this sign owes its existence to interstitial pressure *on*, rather than to any liquid effusion *within*, the air-cells.

Pathology of the general symptoms of pneumonia.—Having made ourselves acquainted with the essential pathology of this disease, we may with advantage review the general symptoms in relation to it; we shall thus complete

* Dublin Hosp. Reports, vol. iv.

the circle of its history, and appreciate only the value and importance of the various signs and symptoms.

In idiopathic pneumonia, arising directly from the application of an exciting cause, the inflammation commences before the febrile process begins; hence, during the period of general uneasiness, langnor, or depression, which are sometimes felt before an attack of pneumonia, the auscultator will generally discover a crepitant rhonchus in some part of the chest; sometimes there is a sense of fulness, soreness, or oppression about this part, or a stitch in the side; but these are often wanting until the supervention of fever, which first disguises, then developes the various general symptoms. At this time the pulse is commonly small, occasionally not altered in frequency, but generally accelerated. This is the latent stage of the inflammation, in which we cannot but point out its resemblance to the first effects of various mechanical injuries on a part of the body, which we have already shewn to be produced according to a general law in the system. (See Irritation.) A cause has here been applied which has destroyed the balance of the circulation, and so affected the vessels of the lungs that their tonic power has suffered, and they become the seat of a congestive load of blood. This is the local injury, and first exerts its noxious or depressing influence on the system precisely as a crushed limb or a severe contusion would do, the local symptoms being more apparent in these latter instances because the animal sensibility of these parts is greater than that of the lungs. Hence the first symptoms of this, as well as of other inflammations, may be those of prostration or irregular reaction; and accordingly we find syncope, pallidity of the surface, vomiting, hiccup, &c., occasionally to precede the febrile stage of pneumonia. Rigor is, however, the more common symptom of commencing reaction, and it is the harbinger of that series of vascular movements which constitute the general and local character of phlegmasial pyrexia. After the rigor, which is accompanied by its usual smallness and frequency of the pulse, contracted coldness of the surface, and general depression of the powers, soon succeeds an increased action of the heart and arteries, indicated by a pulse of greater force and fulness, with more or less of the hard and sharp character of sthenic irritation; the surface becomes flushed and hot; and all the internal organs, the mucous surfaces, and secreting glands suffer from the febrile reaction in the interruption or perversion of their various offices. Under this influence the tendency of particular constitutions, or the morbid disposition of individual organs, is discovered. In some the gastro-enteric mucous membrane especially feels the effects of this vascular excitement, and we have great thirst, scanty and high-coloured urine, tenderness of the epigastrium, irritability of the stomach, with a reddened tongue and fauces, and the various sympathetic signs of gastric fever. In another the fever assumes more of the bilious character, with bilious vomiting, turbid, saffron-coloured, and ammoniacal urine, and occasionally a jaundiced tinge of the skin. It is a rarer case for the head to suffer, but cases are not wanting in which great intolerance of light and sound, with delirium, have accompanied the symptomatic fever of pneumonia. In others, especially those of a plethoric habit, the fever is congestive; and besides the accumulation of blood in the focus of inflammation, there are other local determinations caused by the general vascular excitement; hence the head, the liver, the stomach, and the bowels may suffer, at once or singly, from the irritation extending its influence to a whole system of loaded vessels. It is during the development of this general reaction, which may thus vary in kind as well as in degree in different subjects, that the local symptoms declare themselves in the most prominent manner. Thus the same point of inflammatory congestion, with its crepitant rhonchus, which was perhaps the only local indication of disease, now increased and developed by reaction into active inflammation, becomes the cause of cough, pain, and dyspnœa in the various degrees that accompany the increasing period of pneumonia. It is not easy to define the cause of the variety in these symptoms which different cases exhibit;—why some patients should suffer scarcely any cough, while others are greatly harassed by it; why the breathing may in some be accelerated to a great degree without the patient being sensible of it, while others complain much of oppression when there is but a moderate encroachment on the function; and why some suffer acute and distressing pain, while others are scarcely conscious of any uneasiness. In a general way we must refer these differences to the state of the nervous system, the sensibility of which in these varying instances is sometimes exalted and sometimes depressed, either by individual peculiarity, or by some complication which the accompanying fever may produce. Thus, when there is a congested state of the vessels of the brain, sensibility is blunted, and the patient approaches the verge of suffocation without complaining of either dyspnœa or pain. When, on the other hand, the inflammation is more concentrated within the chest, leaving comparatively free the sensorial functions, the exalted sensibility depending on inflammation is more easily felt, and this more especially when a part liable to tension, as the pleura, is involved in the disease. The urgency of the cough may also in a measure depend on the degree in which the bronchial lining membrane is inflamed; for if it is not affected, its sensibility will probably, through derivation, become lower than usual. Cough is occasioned by affections of the larger order of bronchial ramifications more powerfully than by those of the vesicular structure; and there is often, therefore, little of this symptom until the inflammation is extended to the lining of these tubes. From the absence also of the bronchial inflammation, there is often no expectoration at this early period; and cases occasionally present themselves in which it does not occur throughout

the disease. The pathology of the secretion of the bronchial membrane, those viscid rusty sputa that so signally characterise peripneumony, is interesting. As in simple acute bronchitis this secretion becomes more tenacious in proportion to the intensity of the inflammation, so in this secondary bronchitis, when the vascular action of the membrane is augmented to its greatest degree, being as it were backed by the inflammation of the adjoining important and extensive vascular plexus, the secretion acquires still greater viscidity, and, in addition to this, becomes tinged by colouring matter from the mass of surrounding blood. When it is considered that this secretion proceeds from the immediate vicinity of the diseased part, it would appear that it must tend to relieve the inflamed vessels, and the inflammation, when very slight, may be terminated through this relief; but in the greater number of instances the relief thus afforded is too trifling to arrest the inflammation, and the viscid secretion, by still further obstructing the tubes and aggravating the dyspnœa, augments the danger of the disease, and this it does the more in proportion as its tenacity is greater.

The obstruction which the inflammation thus causes to the functions of pulmonary circulation and oxygenation of the blood now reacts in a new way on the circulating powers; the pulse, which at the commencement of the pyrexia had shown the heart to be vigorously contributing to the reaction, now falls in strength and hardness, whilst it commonly increases in frequency; and the stethoscope often discovers that there is a spasmodic briskness in the heart's contraction which seems to struggle vainly against the obstacle. Frequently this irritable contraction of the heart amounts to palpitation; and when we consider how its compartments must suffer from the injured balance of the circulation, this irregular action is readily explained. Owing to the obstruction in the lungs, the right side of the heart is unduly charged with blood, and subjected to the stimulus of over-distention; while the same obstruction prevents the left side from receiving its proper supply, and that blood which it does receive is but imperfectly arterialized. This pathological view, which is nothing more than a statement of observed phenomena, explains equally the violence and intensity of the inflammation in the pulmonary vessels, which are under the immediate influence of an over-stimulated right ventricle, and the weakness and failure of the general circulation, which depends for its support on the left ventricle. The depression thus occasioned by the failure of the general circulation, and by the imperfect oxygenation of the blood, is sometimes so great as to resemble typhous fever, whence such forms of the disease have obtained the name of *pneumonia typhodes*. Dr. Mackintosh has stated his opinion, in which we partly concur, that these varieties depend on the extent of the inflammation and obstruction to the pulmonary function, or on a complication with local congestions, and not on any thing specific in the pneumonia itself. The same writer thus expresses himself: "There is undoubtedly such a form of pneumonia, but I object to the adjunct *typhodes*, as expressing erroneous ideas of the pathological condition of the body. This form of pneumonia was very prevalent during the war, among troops stationed in exposed situations along the coast, and in large garrisons where the duty was severe. The soldiers were often seized with it when exposed at night as sentinels; instead of walking about they frequently stand shivering in their sentry boxes, the surface continues long chilled, and, with a view to fortify themselves and to produce warmth, they are in the habit of drinking ardent spirits in considerable quantity. In the strongest subjects I have seen the disease under such circumstances run its course to a fatal termination in from forty-eight to sixty hours."* This sketch is well worthy of notice, as it illustrates the powerful effect in aggravating the disease, of two causes already noticed, long-continued cold and intoxicating liquors.

There is another complication of pneumonia which is very apt to give it an uncommonly depressed or typhoid type; this is, with severe bronchial affections, whether of the acute inflammatory character or of the asthenic kind, which goes under the name of peripneumonia notha. We have elsewhere described the peculiar prostration accompanying advanced states of these diseases, and have there referred this feature to the circulation of an imperfectly arterialized blood in the system, (see Bronchitis); and we can readily conceive how serious such a complication must be in pneumonia. In persons advanced in life, and in frames debilitated by excesses or by a cachectic habit, the pneumonic inflammation is often accompanied by an early sinking of the powers; such individuals, after a few hours only of pain, cough, or acute symptoms, become lethargic or insensible, with a weak intermitting thready pulse, pallid skin, partial sweats, cold extremities, and, after lying in that state for some days, sink often without any of the prominent general symptoms of diseases of the lungs. This is a latent form of pneumonia which is far from uncommon; and although after death a large portion of the lung may be found in the second or third stages, none but a very attentive examination could have detected from the general symptoms the real situation of the fatal disease. Auscultation would have indeed furnished a much readier means of discovering such an extensive organic lesion; but we have known cases to have deceived practitioners, competent and versed in the use of this method of exploration, from the circumstance that their attention had not been drawn to the thoracic viscera, all prominent symptoms having ceased before they had an opportunity of seeing the patient. In these and other latent forms of peripneumony, to which we shall presently revert, although no obvious dyspnœa be present, the frequency of the respirations may be detected on a close inspection, and the hand placed on

* Elements of Pathology, &c. 2d edit. vol. i. p. 420.

the chest will often perceive the vibration of a liquid gurgling in the bronchi; these circumstances may lead to a suspicion of the existence of the disease, but it can be recognised with certainty only by auscultation and percussion: it is unnecessary here to detail this class of signs, as their distinctive characters will again come before us under the head of *diagnosis*.

In its simpler forms, when the disease is extensive and has reached the second and third stages, the whole symptoms commonly show an abatement of the pain, fever, and other indications of exalted organic and animal sensibility, whilst there is an increasing injury and embarrassment of the function of the affected organ. The orgasm of the inflammation has in a measure expended itself in the effusion, and the general pyrexia sinks under the depressing influences of an injured function, with which the whole frame sympathises. This change in the character of the symptoms is of the highest practical importance, as it is a signal to modify the treatment in a material degree. The discontinuance of the more intense degree of inflammatory action is moreover evinced by the expectoration, which, losing its extreme viscidity and sanguinolent tinge, now bears more the character of a serous exhalation, or of a disordered mucous profluvium. The purulent and albuminous matter and bloody streaks that are sometimes seen in the advanced stages of pneumonia, are rather to be ascribed to the accompanying bronchitis than to the breaking down of the tissue of the lung: when the latter does happen, in the much rarer case of abscess or gangrene, the expectoration is commonly very copious, that from an abscess being distinctly puriform, whilst that from gangrene contains pus, or mucus with a dirty brownish or greenish sanies, occasionally with portions of sloughy tissue, all characterised by an intolerable putrid fetor. The suppression of the expectoration which commonly occurs in fatal cases arises usually from the failure of the respiratory forces to effect its expulsion, and not from a cessation of the secretion. Hence by auscultation we hear a mucous or bubbling rhonchus, which goes on increasing and extending to the larger bronchial tubes, until it becomes tracheal, when it is audible to the bystanders, and constitutes the *death-rattle*, long known as a harbinger of death. Expectoration, as we have elsewhere shown, (see Expectoration,) so far depends on a free exercise of the organs of respiration, that unless air is carried beyond the accumulated matter, the expulsion of this matter can scarcely be effected. The short gasping breath drawn when a large portion of the pulmonary tissue is hepatised cannot accomplish this: the cough, when present, can scarcely reach the obstructing matter, and not unfrequently the sympathetic sensibilities and muscular powers on which this forcible respiratory act depends, are so much reduced that it ceases altogether.

In reviewing the symptoms of a favourable termination of pneumonia, the first class of phenomena which claim our attention are the critical evacuations. These, together with the preference which they shew for particular days, are among the obscure laws which govern the human frame, and which must be the subject of far more extended observation before we can hope to explain them by reference to any of the simpler vital or physical influences. When Broussais ascribes critical evacuations to a predominance of a secondary irritation in a secreting organ over the primary, he only substitutes a new and unsatisfactory form of words for a simple declaration of the fact; for the salutary effect of the evacuation is much more explicable than the cause which determines its presence and its kind. Besides, the word irritation seems not a very appropriate one to apply to the influence which changes the skin from hot, harsh, and dry, to soft and perspiring, the urine from scanty, high coloured, and scalding, to copious and less acrid, and the expectoration from very viscid and sanguinolent to an abundant, simple, and more liquid mucus. For the present we would prefer viewing critical evacuations rather as signs than as causes of improvement; for although in a free expectoration or a hemorrhage we can at once perceive a rational mode of relief, yet the cases of perspiration, diarrhœa, or a lateritious deposit in the urine, may with equal reason be viewed as a *consequence* of the diminution of the disease, which restores to the skin, the bowels, or the kidneys, such functional powers as enable them to carry off from the system matters accumulated during a period when the powers were more or less paralyzed or perverted by the general febrile derangement; and the fact that such evacuations do sometimes take place without proving critical is another reason for leaning to this view. The subject involves more conjecture than would be consistent with the design of a practical work, and we therefore abstain from entertaining it further than to remark, that no close observer of nature can refrain from the conclusion that, in one way or another, primarily or secondarily, a disordered state of the fluids forms an important link in all extensive febrile and inflammatory diseases.

The tendency to evening exacerbation in this and in other diseases is another phenomenon more observed than explained. We remember to have heard M. Andral cite in his lectures the personal experiments of a physician, which illustrated forcibly the effect of periodic habit on the body: for several nights in succession during the winter, at a particular hour, he plunged into a river, returning immediately to his bed. On intermitting the practice on certain days, a shivering fit came on at the customary plunging hour, and was followed by the usual re-action, as if the plunge had not been omitted. Perhaps the evening exacerbations of this and other inflammatory and febrile diseases may be partly referred to the same law of habit, of which this is merely a prominent illustration. The addition of nutrient matter to the blood, together with the accumulated excitements of the day, produce a tendency to a febrile movement in the evening, and these causes are so regularly applied that their effect

becomes a habit, and persists even when they are removed. With a few, the morning is the time of exacerbation, and with such persons this may be determined by a slight habitual disturbance, which is common at that period in dyspeptic individuals.

The rapid general improvement which commonly attends the progress of recoveries from pneumonia indicates rather the restoration of the healthy balance of functions than the entire removal of all local disease; for some dyspnœa and quickness of pulse often remain up to an advanced period of convalescence, and by means of auscultation we discover a cause in the still diseased state of portions of the pulmonary tissue. A bronchial respiration, a resonance of the voice, or a crepitant rhonchus, with some dulness on percussion, remains as a proof that the effects of inflammation are still present, and, amidst other signs of apparent recovery, these require time and care to secure their restoration. Sometimes, as we have seen anatomically, points of hepatization remain for a considerable time, and may become a focus for the rekindling of the acute disease by any error of diet or regimen; or, if left unsubdued, the inflammation may continue there in a chronic form. It is a commoner case that a crepitating or rather subcrepitant rhonchus persists; this, if there is no lingering fever or considerable cough, and if the expectoration has lost its red or yellow tinge and viscidity, is to be considered as the effect of œdema rather than of inflammation of the tissue, and is removed most effectually by a mild tonic combined with expectorants and diuretics.

Pathological varieties and complications of pneumonia.—We have already noticed the complication of pneumonia with bronchitis, and the effect that it commonly has of increasing the depression attendant on the disease, and thereby disguising its inflammatory nature. Drs. Graves and Stokes* have judiciously remarked that in the treatment of this combination the first remedies and a single bleeding produce such relief to the bronchitis, that a practitioner may be led to suppose that the whole disease is overcome; whereas auscultation discovers, by a remaining crepitant rhonchus, that the most formidable affection still remains to be subdued. There are, however, a few instances in which this combination puzzles even the auscultator. The pneumonic crepitation is sometimes so masked by a loud and general mucous rhonchus that even an attentive examination may fail to detect it: this happens especially when the pneumonia is central and towards the root of the lungs, and does not extend to the surface. Laennec indeed asserts that a deep-seated crepitant rhonchus can always be distinguished, by those practised in the stethoscope, from any mixture of sounds produced nearer to the surface; but we now think that to insist, as we once did, on the possibility of this distinction, would be to reckon too much on the infallibility of auscultation. The presence of a rusty tinge in portions of the expectoration will more frequently declare a latent peripneumony; and in the progress of the disease the extension of the inflammation to the surface will make it more easy of recognition. Pneumonia may arise in the course of either acute or chronic bronchitis, and such an event is of great importance in both cases. Acute bronchitis is most liable to pass into peripneumony in young subjects; and the habitual chronic catarrh of old people sometimes takes a similar course. Andral remarks that this accident is not an unfrequent cause of the kindling up of fever and increase of dyspnœa in aged asthmatic subjects; and these symptoms may erroneously be ascribed to an aggravation of the habitual senile disease; this increases the danger of the complication, and for causes that we have just explained, the diagnosis must often rest on uncertain general symptoms.

There are two modifications of bronchial inflammation which occasionally exhibit a strong tendency to pass into pneumonia, pertussis and the influenza or epidemic catarrh. The violent fits of coughing frequently co-existing in these complaints with considerable fever, appear to us to have a great share in extending the inflammation to the great pulmonary plexus of vessels. These paroxysms of cough determine a great degree of congestion in the lung, and we have already seen how easily such a congestion may become inflammation. Of such a termination of hooping-cough we have witnessed numerous instances, proved in some by anatomical inspection, and in many by the addition of a crepitant rhonchus to the physical signs of pertussis. In many of the latter cases the fever had been so gradually increased, and the general peripneumonic symptoms had been so mixed up with those of the aggravated pertussis, that but for auscultation the more serious disease might have escaped detection. This complication is most common in very young and delicate children, and during winter and spring, the usual peripneumonic season. Of the supervention of pneumonia on influenza we have seen several instances during the epidemic that has lately prevailed to so great an extent, and from the effects of which the country is still suffering (May, 1833). It was at the time of its greatest prevalence, when the weather was cold and changeable, that the disease in occasional examples put on this decidedly inflammatory type. In two instances we resorted to free bloodletting with immediate relief; and it is worthy of remark, that the patients suffered less from weakness than many others where no depletory measures were adopted.

We have before described the combination of pleurisy with pneumonia. Next to bronchitis, it may be said to be the most natural concomitant of the parenchymatous inflammation, for its contiguity exposes it to be involved in an extension of the disease. As we have said before, it may considerably modify its course, but instead of, as bronchitis, disguising the seat of the complaint, it often declares it more openly by adding the prominent symptoms of pain or stitch in the side, and a catch

* Dublin Hosp. Rep. vol. v.

in the breathing. These obvious symptoms are not, however, the constant concomitants of pleuro-pneumonia; and cases sometimes present themselves in which this and every other variety of the disease require the fullest investigation of both physical and general signs to ascertain their nature with precision. As far as we have observed, a pleurisy supervening on pneumonia aggravates the case most when it is attended with a sharp pain and catch in the breathing; for it then keeps the patient in a distressing struggle between pain and suffocation, and unless the pain yield soon, it may in this way prove fatal. Generally it soon subsides, the active orgasm being derived to the pulmonary tissue, which on account of its greater vascularity is more obnoxious than the pleura to the inflammation. For this reason it is not common for the pleurisy to gain on the pneumonia, and it is usually limited to the points where the latter reaches the surface.

Peripneumony frequently attacks phthisical subjects in both the early and the advanced stages of tubercular disease. Miliary tubercles in the lungs may be viewed as causes both predisposing and exciting; they render persons more liable to inflammation on exposure to cold or any other exciting cause; and during a febrile state of the system, their presence and mechanical irritation may localise in this organ a general inflammatory diathesis. In several instances of subjects who have died of continued fever with pneumonia, we have seen numerous tubercles in the inflamed lung, and similar cases are recorded by Andral and others. The liability of phthisical subjects to intercurrent peripneumony has been noticed by Laennec, Louis, and Andral. It is not generally severe, and is often spontaneously cured; which illustrates a remark which we have before made, that pneumonia excited by a local cause is never so severe as that which arises from an extensive impression on the circulation. Nevertheless, the similarity of its symptoms to those of the phthisical disease often screens it from notice, with the effect that its treatment is neglected, and if it does not at present endanger life, it accelerates the progress of the other fatal disorder. Hence, as Laennec recommends, it is important to examine from time to time the chests of consumptive patients, particularly when there is any sudden feverish attack or decrease of the strength. Andral asserts that intercurrent peripneumony, from being overlooked, frequently occasions the death of phthisical subjects.

We have had occasion to speak of the occurrence of pneumonia in the course of various febrile disorders, and it is the more important, as the inflammation here commonly takes a latent form. This is especially the case in severe small-pox and erysipelas, and in fevers of the congestive kind. In a considerable proportion of the fatal cases of these diseases, this inflammation seems to be the cause of death. During the prevalence of a peripneumonic epidemic, and in the winter season, Laennec remarks that in patients suffering under these disorders, any marked increase of fever in the young and robust, and any sudden prostration of strength and loss of consciousness in the aged and debilitated, are generally the result of a pneumonia supervening, and it is frequently accompanied with neither dyspnœa, cough, expectoration, nor any of its usual symptoms. The frequent occurrence of a latent pneumonia in continued fever is a fact too well known to morbid anatomists; it has already been noticed in the article FEVER CONTINUED. A harsh state of the skin, fetid excretions, and sordes on the teeth and tongue coming on in subjects worn out by cancer or other severe chronic diseases, according to Laennec, frequently indicate pneumonia, which soon ends with coma, tracheal rattle, and death. The bronchial affection of measles sometimes passes into pneumonia, especially if the eruption is repressed or disappears suddenly; but in this case the symptoms are commonly urgent, and sufficiently characteristic. Endemic fevers sometimes determine an inflammation of the lungs, which is frequently latent. Broussais records this of the intermittent fevers which attacked the military in the hospitals of Bruges.* The same has been remarked of malaria fevers of other kinds, and of the pestilential cholera. The latter disease sometimes shows a remarkable tendency to pneumonia in the stage of re-action, and this event seems to be favoured by the great congestion which occurs in the pulmonary vessels during the period of collapse. The re-action of intermittent febrile diseases has been sometimes observed to be so regularly accompanied by pneumonic symptoms that some authors have given the name of intermittent peripneumony to these affections. Thus Broussais has noticed the quotidian returns of inflammation both of the lungs and of the pleura at the time of the febrile paroxysm. But it must be remarked that in these cases either the pulmonary affection must have been exceedingly slight, or it must have continued during the apyrectic period, and merely have been more fully developed by the excitement of the paroxysm.

Pneumonia is sometimes produced in gouty and rheumatic subjects, and this may occur either vicariously, so that the limbs are relieved, or conjointly with the affections of these. In the first case, the pulmonary affection is generally apparent; in the latter, it is sometimes latent. P. Frank has remarked that in rheumatic subjects pneumonia sometimes terminates without any expectoration, with a copious discharge of clear urine, amounting to twelve pounds and upwards. This curious fact is another sign of the connexion which subsists between rheumatic and gouty affections, and a diseased state of the fluids of the body.

Hypertrophy of the heart modifies the pulse in pneumonia in a manner that deserves notice. Instead of falling in strength as it generally does, and becoming small and frequent, from the causes that we have before explained, the pulse in some degree retains the hard vibrating character peculiar to hypertrophy. This is the

* Hist. des Phlegmasies Chron. t. 1.

case, however, only when the left ventricle is affected. Hypertrophy of the right ventricle predisposes to pneumonia, and generally aggravates its form. In pneumonia complicated with any disease of the heart, the pulse becomes more fallacious than ever; and neither its frequency nor its strength bears any relation to the extent of the inflammation.

Inflammation of the mucous membrane of the stomach and bowels is by no means an uncommon accompaniment of pneumonia. It generally gives a more adynamic type to the disease, and manifests itself by the peculiar state of the tongue, which is at first very red, and afterwards parched and brown, with great thirst, vitiated excretions, and frequently tenderness at the epigastrium. Various other diseases may combine themselves with pneumonia, and although they may manifest themselves by their peculiar groups of symptoms, yet the complication generally increases the obscurity of the case, and the difficulty of its treatment.

Several surgical writers have noticed the occurrence of pneumonia after amputation and other great surgical operations, and likewise after extensive wounds; and it has been supposed that this disease is frequently the cause of death in these cases. This is a very interesting subject, and one that requires further investigation. The disease of the lungs in these instances appears to be quite of the latent kind, and sometimes it only declares itself by the dyspnœa and rattle a short time before death. We cannot speak from personal observation on this subject; but from the description given, it would seem that these cases of pneumonia may be ranged in two classes; those which partake of the character of the pneumonia of the moribund, which has been often alluded to in this article, and which seems to be a concomitant rather than a cause of the changes of death; and those which supervene during a febrile reaction, and are disguised by other local and general symptoms. The latter class occurs most commonly in the subjects of amputation, or where a great change has been wrought in some part of the circulation, leaving the heart vigorous and disposed to sthenic re-action. The former comprises cases of bad wounds or unfavourable operations, where the powers fail under the local injury, and as a part of this failure, a congestion takes place in the lungs, which is, by a partial re-action, converted into inflammation.

It will be perceived that, in describing these various complications, we have comprehended nearly all the varieties of pneumonia which have been described by authors; and we apprehend that the pathological views of these varieties with which modern researches have so fully furnished us, so clearly expose the real nature of the greater number, that it is unnecessary to consider them further in a separate form. The false or bastard peripneumony, *peripneumonia notha* of Sydenham, does not require notice here, for it has been already described under its proper head, Bronchitis. The bilious peripneumonies described by Stoll and other writers of his time, do not appear to constitute a real pathological variety of the disease; for they were either cases of bronchitis in which the sputa were tinged with bile from a simultaneous affection of the liver; or, what is more probable, they were ordinary cases of pneumonia attended with the characteristic expectoration, which is often yellow or greenish, from the admixture of various proportions of the colouring matter of the blood, and which these writers hypothetically ascribed to an intermixture of bile. Laennec says that he has frequently met with these greenish sputa where there existed no bilious complication: he admits that he has sometimes seen them disappear after bilious evacuations; but this circumstance can be viewed in no other light than that these evacuations were critical, and coincided with a resolution of the inflammation.

Diagnosis of pneumonia.—We have devoted so much space to the consideration of the signs of this disease, that we have now only to recal the most characteristic, and compare with them the distinctive signs of a few other maladies with which they may be confounded.

The manner of attack, the dyspnœa, the pulse, the pain, the cough, and the side of the decubitus, although in the manner in which we have described them, they contribute to form the general character of the disease, yet are quite incompetent to distinguish it with certainty from other acute inflammations of the chest, particularly bronchitis and pleurisy. Still these symptoms are not to be disregarded, for taken in conjunction with the physical signs, they often assist us much in the diagnosis. Of all the diagnostic signs of pneumonia, the characteristic form of the expectoration is the most infallible; and when it does occur, there can be no doubt of the existence of parenchymatous inflammation; but it is sometimes entirely absent; frequently it does not appear until after the disease has existed for two or three days, and it generally ceases as the inflammation reaches the second and third stages. It may moreover pass by such insensible gradations into the colourless form of bronchitic sputa, that it is not always easy to determine whether it partakes of the pneumonic character or not. The crepitant rhonchus, when it occurs distinctly or unmixed, and in conjunction with the general signs of pneumonia, may be considered as quite pathognomonic; and as its presence is much more constant than that of the expectoration, it may be considered as the more available diagnostic sign. Laennec considered it the most important of all physical signs, "inasmuch as it is invariably present, and from the very invasion of the disease; and exists in no other case, except in œdema of the lungs and pulmonary apoplexy, two diseases which are easily distinguished from this by their own peculiar signs and symptoms. M. Andral is mistaken in saying that the crepitous rattle sometimes exists in acute bronchitis, (Clin. Méd. tom. 2. p. 333.) and I think this is evident from his own cases. From its constant presence in this disease, I regard it as the most practically useful of all the stethoscopic signs, inasmuch as it points out, in

its very earliest stage, one of the most severe and most common diseases, and thereby enables the physician to apply his means with much more chance of success than he could have done even a few hours later."* M. Piorry has lately questioned the pathognomonic relation of the crepitant rhonchus to pneumonia, not from observation of disease, but from the circumstance that a crepitation like it may be produced on applying the stethoscope to a lung out of the body.† Such an hypothetical objection cannot, however, be entertained, in opposition to the mass of evidence in corroboration of Laennec's opinion, and we have already explained how the artificial crepitation in question is produced. (See page 419.)

The preceding characters will be quite sufficient to distinguish recent pneumonia from pleurisy. In the latter the sound of respiration is unaccompanied with a rhonchus, and is only rendered weaker, first by the pain restraining the respiratory movements, and afterwards by the liquid effusion pushing aside the lung. There is sometimes dulness on percussion in the early stages of both diseases; but in pneumonia this dulness will be found to be fixed in the spot where the crepitant rhonchus is heard; in pleurisy, on the other hand, it generally occupies the most dependent part, and changes with a change of posture. This last criterion, which is very easily applied, is sufficient to discover moderate pleuritic effusions in every case except in that of the effusion being limited by adhesions of the lung to the ribs. The ægophonic resonance of the voice, when perfect, is another sign equally distinctive of pleurisy; but as for its production there must be only a certain thickness of the layer of fluid, its presence is often of short duration, and it may thus escape detection. The diagnosis between these diseases is much more difficult in their advanced stages, particularly when they are extensive. Thus it may happen that we are called to see a patient who has been ill for a considerable number of days, and who has had more or fewer of the equivocal general symptoms which are applicable to either pleurisy or pneumonia; by auscultation we find no sound of respiration in one side of the chest, which is also quite dull on percussion. The question then presents itself—is the case one of pneumonia, with the whole lung in a state of hepatization, or is it a case of pleurisy, acute or chronic, with a very extensive effusion? These difficulties have been sagaciously pointed out by Dr. Stack,‡ and we admit them to be sufficient to mislead any but a very careful observer. But an attentive consideration of the previous history, and a minute examination of the physical and some general signs, will, we believe, always furnish us with a correct diagnosis. We have in two instances been mistaken, but we refer our error rather to the insufficiency of our examination than to an absence of diagnostic signs; and these cases, which occurred in dispensary practice, presented a rare combination of deceptive circumstances. The most obvious distinction between a hepatized lung and copious pleuritic effusion is the constant occurrence, in the former case, of a loud and almost pectoriloquous bronchophony under the scapula, along the spine, and below the clavicle, and the general absence of this sign in the latter. This test would have been sufficient to distinguish the case cited by Dr. Stack as one of peculiar difficulty; the absence of this resonance clearly proving it to be pleurisy and not pneumonia. The *presence* of this bronchophony is not, however, an equally sure proof that the lung is hepatized. In one of the instances before alluded to, with a perfect deadness of sound on percussion over the whole of the right side of the chest, a bronchophony and bronchial respiration were heard between the scapula and spine and below the clavicle on this side, from which we too hastily concluded the disease to be pneumonia; on dissection it proved to be pleurisy, the right thorax being full of serum and lined with a dense false membrane; the lung was compressed by the effusion into a mass which adhered by solid pillars to the upper part of the cavity under the clavicle, and to the posterior part exactly in the points where the bronchophony had been heard. These adhesions were obviously the cause of the sign which misled us; and as the possibility of their occurrence in other cases must detract from the certainty of its indications, we must seek for further means of distinction. In copious pleuritic effusion there are commonly several signs of displacement, which are absent in hepatization of the lung. Thus the affected side is commonly enlarged, as can be ascertained both by inspection and measurement. By viewing or feeling both sides of the chest at the same time, if there is no obvious enlargement, it may be perceived that the affected side does not partake, equally with the sound side, of the respiratory movements; it remains stationary in a fixed state of distention, and this in a more remarkable degree than occurs with a hepatized lung. The intercostal spaces are also more prominent on the affected side, which gives it a more rounded appearance; this character readily distinguishes pleuritic effusion from hepatization in thin subjects, but it fails where the integuments are fat or œdematous. Dr. Stokes has pointed out some other means of distinction, founded on the same circumstance of displacement, which occurs exclusively in pleurisy.* If the disease occupy the left side, a copious pleuritic effusion will generally displace the heart, which will be heard and felt pulsating, not in its usual place, but to the right of the sternum; in pneumonia the pulsations are not displaced, but they are uncommonly audible throughout the affected side. If the disease be on the right side, an effusion will push down the liver, and make it perceptible below the false ribs; it will also press aside the sternal medias-

* Dr. Forbes's Transl. p. 213.
† Gazette des Hôpitaux, t. 6. No. 116.
‡ Dublin Hosp. Rep. vol. iv.

* Dublin Med. Journal, March 1833.

imum, so that the whole sternum would sound dull on percussion; in hepatization of the whole right lung there is neither displacement of the liver nor of the mediastinum; and as the resonance of the sternum on percussion depends on portions of both lungs beneath, its right half would yield a dull and the left a clear sound. By some or other of these distinctive marks we may venture to assert that a pretty certain diagnosis between pneumonia and pleurisy may always be obtained. For further particulars on this point we refer to the articles Pleurisy and Empyema. The distinction of slight degrees of pleurisy accompanying pneumonic inflammation will depend on the circumstances that change of posture modifies the sound on percussion, rendering the dependent parts the least sonorous, and that the bronchophony is rendered bleating or vibratory whenever a thin stratum of liquid is interposed between the pleuræ. Pleurisies circumscribed by adhesions are scarcely to be recognized unless when sufficiently extensive to cause a fulness of the intercostal spaces. But as we have before remarked, the pleurisies supervening on pneumonia generally are of secondary importance, and their detection is not an object of great interest.

Bronchitis in its severer forms is frequently confounded with pneumonia; it is often by the physical signs only that they can be distinguished with certainty, and even these sometimes fail to detect a latent pneumonia in combination with bronchitis. In pure bronchitis no crepitant rhonchus occurs, but there may be a variety of mucous, sibilant, and sonorous rhonchi. The distinction of these from the pure crepitation of peripneumony is sufficiently obvious, but it is not so easy to distinguish this crepitation when it is mixed up with the other rhonchi. In these difficult cases we must look more to the expectoration, progress of the symptoms, and state of the countenance. With respect to the latter indication, as a diagnostic mean in bronchitis, pleurisy, and pneumonia, we have received some valuable hints from Dr. Stack,* although we can scarcely accede to his opinion that it is generally more sure than the physical signs. In pleurisy, either the face is flushed and the lips are florid, or their appearance is not changed from that of health. In humid or severe bronchitis, the parts of the face usually coloured and the lips are more or less blue or livid, according to the extent of the bronchial membrane affected, and the quantity of secretion in them, which prevents the oxygenation of the blood. The flush of pneumonia is different from either, being an intermediate shade of purplish red. There is no correspondence between the flush often observed in one cheek and the side affected, and the flush often shifts from side to side. In pleurisy and bronchitis, the colour in the lips and cheeks is commonly circumscribed, the other parts being uncommonly pale; but in pneumonia the redness, when present, is more suffused over the whole countenance. These variations of colour, which seem to depend on the degree in which the functions of arterialization and circulation of the blood are respectively affected, may assist us in doubtful cases in forming a diagnosis, but we have seen them fail too often to place implicit reliance on them. In the advanced stages of pneumonia, bronchial resonance and respiration and the perfect dulness on percussion sufficiently distinguish it from bronchitis, in which the mucous rhonchus and a considerable clearness of sound on percussion persist until the last. Dr. Stack, indeed, cites a case of humid bronchitis, in which, a few hours before death, the chest yielded no resonance, but no such example has been elsewhere described, and the anomaly must be attributed to the moribund state of the patient and the imperfect entrance of air into the lungs at that period.

The physical signs of extensive pulmonary apoplexy sometimes approach closely to those of peripneumony, there being in the spot affected a dulness of sound on percussion and absence of the respiratory murmur, surrounded by a crepitant rhonchus. The absence of fever, however, and the presence of hemoptysis will generally be sufficient to characterize the former disease; and by referring to its history, it may be perceived that there is commonly much difference in the origin and progress of the two complaints. An inflammation of the tissue of the lung is sometimes engrafted on apoplexy of the organ, and it will then be more difficult to distinguish; but the access of feverish heat, the increase of the crepitant rhonchus, and the viscidity of some portion of the sputa, will generally give evidence of the complication.

Combinations of several affections of the chest will sometimes, more closely than simple diseases, simulate pneumonia. Œdema of the lungs combined with pleurisy or even pleurodyne, may produce physical signs resembling the first stage of peripneumony, and a similarity in many of the general symptoms increases the difficulty of the diagnosis: the different character of the expectoration, and the history and progress of the case, are the means of distinction most to be relied on, and an attentive examination of these will seldom fail to lead to a correct decision. It is sometimes more difficult to distinguish between chronic induration of the lung, whether from chronic peripneumony, agglomerated tubercles, or melanose formations, and the hepatization of local acute inflammation supervening on phthisical disease. If the case has been watched, the attack of the latter affection must have been marked by some augmentation of the fever and dyspnœa, and the physical signs of the first stage would have further characterized it; but if the hepatization is complete before the first time of examination, we must remain for a time in doubt. These local hepatizations are sometimes formed and reabsorbed without much aid from treatment, and it is therefore less important to distinguish them than the inflammatory stage which precedes them, and which is, as we have just observed, cognizable by its peculiar signs.

* Dublin Hosp. Rep. vol. iv. p. 90 et seq.

In fine, we would recommend the student to found his diagnosis as much as possible on a knowledge of the true characters of disease, rather than on any detailed distinctions which can be comprised in a treatise. The varieties and complications of diseases are too numerous to be capable of adaptation to any fixed rules of diagnosis; but when the mind of the observer is fully imbued with the principles of a true pathology, his judgment will find in any combination of phenomena some means of distinction less fallible than the memory can ever furnish from the most minute exposition of possible cases.

Prognosis.—The remark which we have just made on the subject of diagnosis may with nearly equal force be applied to the prognosis, or estimate of the severity and probable issue of the disease. Our study of the pathology will lead us to form a correct opinion more surely than any enumeration of good or bad signs. The prognosis of this disease is always serious, and even in favourable cases must be spoken of with caution, for cases, which are slight at first, sometimes take an unfavourable turn; and in progress towards recovery, as long as the disease lasts, there is a chance of a relapse, which may throw the patient into new and peculiar danger. The circumstances of the pathology of a case which affect the prognosis, are the degree of the inflammation, its extent, its seat, its complication with other affections, and the condition of the various functions of the body.

As is the case with other inflammations of important organs, the continuance of the disease increases its mischief and danger as it injures the organization of the part; hence the prognosis is more serious if hepatization has taken place, and still more so if the signs seem to indicate the supervention of the third stage. The duration of these stages varies very considerably according to the effect of the treatment and the age of the subject. Laennec states the average proportion to be as follows: "The obstruction, or first stage, usually lasts from twelve hours to three days before passing to the state of complete hepatization; this lasts from one to three days before spots of purulent infiltration make their appearance; and the period of suppuration (from the time when the concrete purulent infiltration is distinctly perceptible until this is completely softened into a viscid fluid) varies from two to six days. Bloodletting, derivatives, and resolvents or stimulants of the absorbent system, obviously retard the progress of the disease, and consequently prolong the period of the first two stages. Convalescence is rapid in proportion as the inflammation is of small extent and has been early checked."*

We have already had occasion to remark that in children the inflammation continues for a much longer period in the first stage; after some weeks' duration, presenting only some hepatized points at the margin of the lung or in isolated lobules. Laennec has observed the same peculiarity in certain epidemics, as in the *grippe* of 1803, when he noticed the first stage to continue for seven or eight days, sometimes affecting the whole of one lung and part of the other, and proving fatal before any distinct hepatization occurred. We have before mentioned, on the other hand, the remarkable tendency of the inflammation in old and debilitated subjects to pass rapidly to the state of purulent infiltration; the author just named describes this to take place sometimes within thirty-six or even twenty-four hours. Recovery is sometimes effected by resolution and re-absorption from every degree of pneumonia, but the chances of this favourable termination are very small when the signs of hepatization have continued for such a length of time that purulent infiltration has probably occurred. Even simple hepatization requires time and favourable circumstances for its removal; for besides that the deposited matter obstructs the due function of the part, and thereby prevents the restoration of the balance of health, it likewise remains as an irritating cause, giving a proclivity to the recurrence or continuance of inflammatory action. Unless, therefore, the tendency to this be kept in a state of subjection, and the process of absorption be perceptibly gaining ground, the prognosis must continue to be doubtful. The supervention of gangrene will always increase greatly the danger of a case. If the gangrene is extensive, it must inevitably prove fatal; and where small and circumscribed, if the powers of the system are weak, they can scarcely be sufficient to support life until the noxious dead matter is thrown off; if, however, the pulse and muscular system show still considerable strength, this process may be happily effected, and there are recorded instances of recovery even from the gangrenous termination of pulmonary inflammation. An interesting case of this kind recently fell under the observation of the writer in conjunction with Dr. Chambers and Mr. Jay of Sloane-street, and was watched with great interest during a doubtful period of several days; the inflammation in the second state affected the right lung, and signs of excavation (concluded to be gangrenous from the odour of the expectoration) were heard at the inferior angle of the scapula; the case was greatly aggravated by the sudden supervention of a pleurisy on the left side, excited probably by the irritation of gangrenous matter in the circulation. This new attack, and the depletions necessary to subdue it, greatly increased the danger; but the powers of life ultimately prevailed; the expectoration became less fetid, more purulent and abundant, and after some time gradually ceased under the influence of a mineral acid; the cavity progressively diminishing was at length cicatrized, and the patient, in three weeks from his worst state, was quite convalescent.

The extent of the inflammation, as may be anticipated, greatly affects the danger of a case. A double pneumonia affecting both lungs at once is frequently fatal, even in the first stage; and whenever the whole of one lung is

* Op. cit. p. 211.

nvolved, there is much peril of an unfavourable issue. Cases do occur, however, although rarely, in which the gravity of the case does not bear proportion to the extent of the inflammation; and these anomalies in great measure depend on the natural capacity of the function of respiration in the individual, and its power to bear abridgement. Thus we sometimes see a pneumonia of small extent occasion orthopnœa and other symptoms of a severe case; whilst in another example auscultation may indicate that nearly a whole lung is involved, yet the patient is scarcely sensible of dyspnœa, and the other functions are not greatly disordered.

Inflammations attacking the superior lobes and root of the lungs are more fatal than those confined to the base or lower lobes; and this circumstance explains the discrepancy of authors, before noticed, respecting the comparative frequency of inflammation in these different parts. The cause of the difference appears to be, that disease of the upper portions and root of the lungs obstructs the passage of blood and of air in the larger vessels, so that the peripheral parts unaffected with inflammation do not receive their due supply.

The complication of pneumonia with other affections generally increases the danger of a case: thus peripneumonies supervening in the course of fevers and the exanthemata are generally of a serious nature; and the more formidable because they are often latent. Inflammatory affections of the gastro-intestinal canal, coinciding with pneumonia, render it less tractable and more dangerous; and the same may be said of bronchial, pericardial, meningeal, and peritoneal inflammations. Pleurisy, as we have seen, may diminish the intensity of the inflammation, if it is on the same side; but if it attacks the opposite cavity, it must aggravate the functional disorder. Pneumonia occurring in the course of phthisical disease is seldom severe in itself, but it has a tendency to accelerate the development and softening of the tubercles. This inflammation is more than usually fatal during pregnancy and in the puerperal state. It is especially dangerous at the extremes of life, more particularly in weakly infants and in cachectic old people, and those exhausted by habitual excesses; and the fatality is much greater among the lower classes than among those well and regularly fed and clothed. M. Chomel observes that the mortality in hospitals amounts to a fourth of the cases, which is considerably more than what occurs in private practice. The same physician gives the following statement respecting the influence of age in the mortality of pneumonia: in seventy-nine cases, of thirty-three at ages between 18 and 30 years, three died; of nine aged from 30 to 40, two died; of eleven aged from 40 to 50, five died; of fifteen aged from 50 to 60, eight died; of eight aged from 60 to 70, four died; and the three cases which occurred beyond the age of 70 all terminated fatally.*

* Dict. de Méd. t. xvii. p. 233.

The state of the functions in pneumonia, although it is not sufficiently constant to be of much use in determining the diagnosis, is often an important guide to the prognosis of individual cases. Thus a severe degree of dyspnœa, when constant, increasing and unyielding to treatment, may justly excite our serious alarm; and the more so as it is conjoined with a state of the circulation which betokens a continued predominance of irritation, or a failure of functional strength. Thus, when in a case with severe dyspnœa the pulse is very quick, as above 120, without much strength, there may be reason to fear that the system may not bear the treatment necessary to arrest the course of the disease, and our opinion must be in a proportionate degree apprehensive: the knowledge, through the physical signs, that the inflammation in its second stage is the cause of this state of the symptoms, will diminish our hopes, as we know it to be then less within the power of medicine; and when the pulse becomes small, weak, and intermitting, the danger may be considered imminent. There may, however, be extensive and serious disease without exciting this combination of symptoms; and although their presence positively indicates danger, their absence does not always represent safety. An obstinate cough, with scanty or difficult expectoration, is an unfavourable symptom, both because it indicates that there is no vicarious relief from the bronchial mucous membrane, and because the very exertion of coughing never fails to aggravate the disease and wear the strength. The character of the expectoration is one of the most valuable indices which we possess for the estimation of the gravity of a case. In simple pneumonia the viscidity and rusty tinge of the sputa are in exact proportion to the intensity of the inflammation, and their increase in quantity and diminution in tenacity and colour are the common attendants of its resolution. Scantiness or absence of expectoration, when other signs prove the existence of a considerable inflammation, is a bad sign, for the reason before mentioned. Dirty or brown watery sputa, and those containing pus, import great danger, inasmuch as they indicate the probable supervention of the third stage; and a gangrenous odour generally implies a state of great peril. The indications of the expectoration are rendered less certain when bronchitic or catarrhal disease is combined with the pneumonia; and the same remark may be applied to the complication with phthisis. The sudden suppression of expectoration is generally an unfavourable symptom; it is peculiarly so when auscultation discovers a general mucous rhonchus in the chest, because it proves that the muscular powers are inadequate to expel the accumulating matter from the bronchial tubes; and a suppressed secretion of sputa, unless it is the obvious result of a diminution of the inflammation, generally tends to increase it. Pneumonia is frequently resolved without any increase of the expectoration; but when this increase does occur, it always has a favorable influence, and contributes greatly to the cure.

A dry harsh state of the skin often attends bad cases complicated with gastric disease, with a loaded parched tongue, great thirst or sickness, and tenderness of the epigastrium. A moderately perspirable skin is the most favorable state; profuse perspirations sometimes occur in fatal cases. The same has been remarked of diarrhœa; yet, as we have before mentioned, both these discharges occasionally prove critical; it is expedient therefore to hold in view, what we have before suggested, that they are to be considered as critical only when they accompany a manifest improvement in the other symptoms. A copious deposit in the urine may generally be viewed as a favorable sign; and the observation of Hippocrates seems to be commonly true, that if, after having been turbid, the urine becomes clear before the fourth day of the inflammation, a fatal tendency may be apprehended. Delirium is generally considered to be a symptom of great danger, and it is the more so when it is constant, and not merely the temporary effect of the nightly febrile exacerbations; but in hysterical females it is often the effect of the treatment, and portends no evil. A comatose or lethargic state is an equally fearful case, as it shows that the functional disorder has already greatly encroached on that strength which is required to bear the treatment necessary for the reduction of the inflammation. The continuance of the various symptoms of inflammation without abatement, notwithstanding the administration of the proper remedies, is always a just reason for apprehension as to the issue.

IV.—Treatment of Pneumonia.

In our examination of the pathology of this disease we found ample proofs that it is an inflammation largely affecting the system of bloodvessels, and that, whatever share nervous irritation may have in exciting or supporting it, these vessels are its peculiar seat, and through them is produced its peculiar mischief. We have moreover seen that in the greater number of cases a congested state of these vessels is the immediate effect of the application of the exciting cause, and precedes that complication of nervous and vascular motions which constitutes reaction and inflammation: we have likewise had many occasions to perceive the serious relations which the disease when formed bears to the two functions most essential to life, respiration and circulation; and the result of all these investigations is to lead us rationally to the recommendation of that mode of practice which the experience of ages has already sanctioned. Pneumonia in its acute form may be called an exquisite type of inflammation, and it is, more than most other inflammations, the proper object for those measures which are called antiphlogistic, and of which bloodletting is the chief. The treatment of other inflammations may require modifications and qualifications because the vessels which they affect may be related to a secretory function, or they may be small and unimportant, or there may be more of nervous irritation than of vascular orgasm, or there may be a coexisting depressing influence in the system; and thus it is that in inflammations of the mucous membranes, of glands, of cutaneous and muscular tissue, of tendons, fascia and nerves, and, in some cases, of serous membranes, bloodletting is less effectual, and requires more limitation than in the disease which we are now considering. This measure it is true, is not all-powerful in pneumonia, but there are few practitioners who do not admit it to be by far the most important in the early stages: we shall see the limits of its efficacy in rationally examining the subject. Every one who has studied the phenomena of inflammation must be aware that they do not depend entirely on the quantity of blood in the system and although we greatly reduce this, we may still leave unaffected the state of the inflamed vessels, which remains as a present cause of disorder to the function of the part, and the focus of a speedy return of inflammatory reaction. This may be said of pneumonia even in the first stage; but the second is obviously still less under the control of bloodletting which, although it may act favourably in preventing an increase of inflammation and in reducing the mass of fluid to pass through the disabled organ, has little or no effect on the solid effusion which now constitutes the organic mischief. Here, then, we have to seek for other remedies to aid the operation of bloodletting, and to resort to where its beneficial operation ceases; and it is an advantage, which modern medicine has to boast of, that it does possess means which are of considerable efficacy in fulfilling these intentions. We are not sufficiently assured of the mode of operation of some of these remedies to be able to class them with certainty as fulfilling specific therapeutic indications, and we shall therefore act more safely by adopting a more empirical course; first describing them under their respective names, and afterwards considering their combined application in the treatment of individual cases.

Bloodletting.—Almost all medical writers ancient and modern, concur in their testimony as to the advantages of this measure in pneumonia; so that even Laennec, who depended on it much less implicitly than most others said that "its employment had been proscribed only by some few theorists and medical heretics."* But there is a considerable diversity of opinion as to the extent to which it ought to be carried, the period of the disease during which it is beneficial, and the best method of practising it. Many ancient physicians, and Galen among the number, recommended the bleeding in pneumonia to be carried to syncope, whatever be the period of the disease; and this practice has been followed by many of the present day, especially in this country. Cullen advises that blood be drawn either until there be remission of the pain and relief of the respiration, or, if these do not appear, until symptoms of a commencing syncope come on. This, we believe, is the plan most commonly pursued in this country, and at this first bleeding a quantity varying from sixteen

* Dr. Forbes's translation, second edit. p. 244.

o forty ounces of blood may be taken before ither of these effects is produced. By some practitioners a much larger quantity has been aken without indueing syncope, even to the mount of seventy or eighty ounces; but we onsider it doubtful whether it is ever advisable o exceed the highest quantity before stated. Cullen observes that a first bleeding, however arge, will seldom prove a cure of the disease; nd as the pain and other symptoms recur, the neasure must be repeated, even in the course f the same day, to as full an extent as before; nd although its greatest efficacy is in the first hree days, this recurrence will make a repeition of the measure proper at any period of he disease, especially within the first fortnight. Vith this practice may be contrasted that of nany continental physicians, who never take nore than twelve or sixteen ounces daily, and imit the bleeding to the first two or three lays. under the apprehension that larger and ater depletions interfere with the natural crises f the disease. We even find Pinel and Brieheteau strongly deprecating the free use of the ancet, and inculcating the precepts of Hippoerates, Stahl, Boerhaave, and Van Swieten, to reat mild peripneumonies only by diluents, expectorants, fomentations, pediluvia, and abtinence; and declaring that one or two bleedngs at the commencement are all that are enerally useful in the severer cases. It is a atisfactory proof of the superiority of the English method of practice to find that the est authorities in France now advocate free lepletions much more than formerly. Andral nd Chomel recommend bloodletting to sixteen r twenty ounces, practised, if necessary, two r three times a day during the first days of he disease, and more moderately afterwards. Some of their countrymen still more recently ave preseribed two or three pounds to be rawn every twelve hours at the commencenent of the inflammation, and if the dyspnœa ontmues, eight to twelve ounces daily afterwards. We may remark, as a partial excuse or the tardy adoption of these more energetic neasures by continental practitioners, that probably many of the *mild peripneumonies*, deeribed formerly as cured without bleeding, were in reality cases of bronchitis, and that an improved pathology and method of diagnosis have proved to them what pneumonia really requires. We now know fully, and we are indebted principally to our foreign brethren for this knowledge, that pneumonic inflammation tends much more strongly to effusion and disorganization than to resolution; and our study of the pathology has pointed out, in a very striking manner, that the spontaneous relief of an extensive plexus of vessels gorged with blood, and under the immediate influence of an irregularly excited heart, is too improbable an event to be thought of otherwise than as an exception, the general rule being to an increase of the engorgement, and a progressive encroachment on the proper state and office of the organ. Expectant medicine, in such a case, is therefore both irrational and dangerous.

There are, we presume, no practitioners in this country who question the superior utility of free bloodletting, as early as may be after the development of the inflammation; and it is generally admitted that the measure is more effectual when the blood is drawn from as large an orifice and as speedily as possible. The impression on the circulation is thus more readily produced, and at less expense of blood, than where the aperture is small and the detraction more gradual, scantier, and more frequently repeated. With a view to this effect, Aretæus advised that a vein in each arm should be opened simultaneously, and this plan was adopted by Huxham and Husson. There is, however, a limitation to the advantage of this sudden impression on the system; and this limit seems to us to depend on the degree in which the disease has become fixed in the pulmonary vessels. In the first hours of the inflammation such a sudden loss of blood in the semi-erect posture as will make the pulse soft and weak, and induce some feeling of faintness, will often restore the balance of the circulation, and enable the inflamed vessels to recover their wonted caliber; so that, although some general re-action follows the approach to syncope, the seat of the disease does not suffer from its effects. But if the inflammation has subsisted longer, the inflammation is rarely thus cured by a single bleeding; the vessels of the lungs remain distended although syncope be induced, the depressing effect of the depletion is of short continuance, and the returning reaction brings back the inflammation in its former character. On this account, when the inflammation has lasted more than twelve hours, we are distrustful of a syncope induced by a small bleeding, and we have generally found it necessary to repeat the venesection sooner and more frequently than where more blood has been drawn at first, and only a tendency to faintness produced. Cullen has justly remarked that many persons faint even upon a small bleeding, and as this may prevent the drawing as much blood at first as a pneumonic inflammation may require, it is the more necessary in these cases to repeat the measure more largely afterwards. Early fainting should therefore be rather avoided than desired, and if the patient feels it approaching when only a few ounces have been abstracted, and little relief is manifested in the symptoms, it is expedient to stop the orifice, and to let the patient lie down for a few minutes, which, with the aid of a little cold water and a smelling-bottle, will restore the circulation to a state in which it will bear the necessary depletion. The quantity to be drawn may vary in different adult subjects according to the age, constitution, extent of the inflammation, &c. from twenty to forty ounces. If it is known that the patient bears bleeding well, the larger the orifice and the speedier the loss of blood the better; but nervous subjects, and those liable to palpitation and fainting fits, must be coaxed more gradually to bear a full depletion, and guarded from a fictitious syncope by the horizontal posture. If these precautions are neglected, the disease will continue to gain

ground in spite of the apparent impression on the circulation, and each hour lost will diminish the beneficial influence of subsequent depletory measures. Much discretion is required in determining the quantity of blood to be drawn, and this determination can never be satisfactorily made beforehand; within the limits just named, therefore, the immediate effect of the operation is the only sure guide. In the first stage of the inflammation, whilst the crepitant rhonchus prevails, and there is little or no dulness on percussion, bloodletting shews its greatest efficacy, and the more so even when this stage is recent. Hence, as we have already remarked, one full speedy bleeding of thirty ounces or thereabout, instituted within the first few hours, will often prove sufficient to destroy the orgasm, and relieve entirely the dyspnœa and pain; the remaining quickness of pulse and cough yield to subsequent milder treatment; and the knowledge of its superior efficacy at this time may authorize us to carry the depletion beyond the point of producing relief to the symptoms, and even to the verge of syncope. After the first twelve hours have elapsed, and when the stethoscope discovers no remains of respiratory murmur mixed with the crepitant rhonchus of the affected part, there is little chance that a single bleeding will prove sufficient; and although, when well borne, it may be carried to forty ounces, more regard must be paid to avoid syncope than in the first instance. This is the more necessary when the crepitant rhonchus is on the decline and becomes mixed with bronchophony, and the part sounds dull on percussion, signs which prove the transition to the second stage. As this becomes formed, as the disease obtains a physical hold of the part, full and sudden impressions on the circulation lose much of their beneficial influence; and they are to be sought for only when the first stage of inflammation still prevails and spreads in another part of the pulmonary tissue. If we are called to a patient with a lung already hepatized, and on whom bloodletting has not yet been practised, it is generally advisable to bleed, but not with an expectation of complete relief to the symptoms, or with a view to reduce the pulse; the solid effusion constitutes a material cause of the dyspnœa, which no bleeding can remove; and the heart, although sometimes quieted by diminishing the load which it has to propel through an obstructed organ, often becomes more irritable, and rises both in force and in frequency. If the bleeding is carried to syncope at this stage, it is commonly succeeded by a re-action, which aggravates the dyspnœa and adds to the disorder of the hurried circulation. Bloodletting is not the chief remedy in this stage, and even where used for the first time, it should be restricted to the object of aiding other measures, and not pushed to the length of inducing syncope.

All the advocates of bleeding in pneumonia admit the necessity of repeating the measure in case of the continuance or recurrence of the symptoms of inflammation, and it is in the steady and discreet perseverance in this measure, notwithstanding a variety of phenomena which may seem to oppose it, that the scientific and experienced physician shews his skill and proper firmness. The temporary relief afforded by the first bleeding may have given place to an aggravated dyspnœa, and the pulse may have become weak, contracted, and very quick; symptoms of great debility may have shewn themselves; and the patient may express feelings of faintness and exhaustion, which seem to be further evinced by his indisposition to any exertion or movement unconnected with his efforts to breathe. This array of discouraging indications deters the timid practitioner from again resorting to the lancet, and he finds in certain authors a sanction for a supine course in their cautions, that if the bleeding be pushed far, the disease will become typhoid, the expectoration arrested, and the frame thrown into a state of hopeless debility. As long, however, as the physical symptoms indicate the continuance of the first stage of inflammation, except in a few cases to be presently noticed, there should be no hesitation freely to repeat the bloodletting any number of times until the symptoms are relieved; and it has been proved by ample experience that this treatment, instead of giving rise to a typhoid state, and facilitating effusion, prevents these events by arresting their real cause, the inflammation and its extensive injury to the respiratory function. These are far more formidable and deadly than the consequences of even an immoderate loss of blood, and we can add our testimony to that of Dr. Mackintosh when, after cautioning against excess in the use of this measure, he says, "nevertheless I am persuaded from experience in treating the disease, and from examinations after death, that much more mischief is done by bleeding too little than by bleeding too much."* It is the delay or insufficient application of this measure at first, that often throws the disease into that apparently typhoid form which has deceived so many as to its real cause; and nothing but the actual experience that the pulse frequently rises in force and fulness, the breathing becomes easier, the lethargy or sinking and the anxiety of the countenance become diminished, and the strength increased, as the pernicious oppression of the respiration is relieved by repeated bleedings, can impress the mind fully with the safety and expediency of the measure. "How often," says Andral, "have we not seen bloodletting employed with the greatest advantage in individuals in whom the pulse was small and contracted, the face pale, the extremities nearly cold, the general debility apparently very great, but in whom at the same time the respiration was greatly oppressed." †

We do not maintain that there are no cases in which the disease is from the beginning connected with a truly adynamic form of fever, and in which bleeding even to a small extent, and however

* Practice of Physic, vol. ii. p. 424.
† Clin. Méd. t. ii. p. 380.

arefully managed, causes faintness without relief. This occurs sometimes in those whose vascular ystem has been greatly debilitated by excess n ardent liquors, and in those of a strongly corbutic diathesis; it sometimes prevails epiemically at the same time as other typhous liscases, and changes the character of the eripneumonies that may then happen to preail. It may be almost a question whether in hese cases the local disease in the lungs is not ather a congestion of blood in an altered tate than an inflammation, and it is very ommonly the sequel rather than the cause of he fever. At all events, the impropriety of he free use of bloodletting is obvious from its ffects, and our chief reliance must be on ther measures.

With regard to the time in which it will beome proper to repeat the measure, much will epend on the severity of the case and the uccess and extent of the first bleeding. If his was copious, and produced signal relief to he dyspnœa and pain, its full effect will not e apparent for four or five hours, during vhich time further benefit may follow from he use of other remedies; at the end of that ime the patient should be seen again, and if e should be found still to suffer, and esecially if there have been any increase of lyspnœa, the bleeding must be repeated with reedom, either until some relief be manifest, r till an impression be produced on the cirulation. If the first bleeding failed from the peedy supervention of syncope before much lood was drawn, it will be necessary to repeat the visit in an hour or two, and again to nake trial of the measure, when the patient vill often be found to bear a much larger bleeding than at first, and with proportionate nd more permanent relief to the symptoms. The pulse furnishes a much less certain indicaion for the use of the lancet than the state of he breathing, which is the function which we should be most anxious to relieve. In the irst stage it rarely happens that bleeding will ot produce some immediate relief of this kind as well as of the attendant pain, and this effect may generally guide us in the extent to vhich we may carry the measure. If, however, although the breathing seems little afected, during the flow of the blood at this epetition of the practice the pulse becomes ery weak, quick, and running, it is expedient o stop the bleeding and trust to local depleion and other remedies. It cannot be denied hat this intolerance of bleeding shews itself in ome rare instances from the very commencement of the disease, giving to it the real typhoid ype; this character, however, has been ascribed to a greater number of cases than deserve it, and we cannot be too careful in our endeavour to distinguish the real from the false cases of vascular debility: the distinction can seldom be so satisfactorily made as by the cautious trial of venesection itself. Laennec has, it is true, pointed out one test, which is sometimes of great use and certainty, in the state of the action of the heart as investigated by the stethoscope: when, amidst symptoms of general debility, the pulsations of the heart are heard and felt more strongly in proportion than the arterial pulse, which they not unfrequently are, especially under the sternum, there can be no fear of bleeding, however weak the pulse may seem; but if they are both weak, the detraction of blood will almost always occasion complete prostration of strength.* There is an exception to this rule in the complication with hypertrophy of the heart, in which the pulsations continue to be apparently strong when the circulation is really very weak. The palpitation of reaction after loss of blood in nervous subjects may likewise be mistaken for the strong pulsations of Laennec; and this error is the more to be avoided as this reaction often accompanies a state of the circulation which will not bear bloodletting.† A good auscultator may distinguish the palpitation of reaction by its louder sound and more abrupt but less forcible impulse than those attending the really sthenic pulsations of the heart; but some experience in auscultation is required to make this distinction available in practice. Although, therefore, this test is very useful in deterring us from venesection in some cases of real debility, yet where it seems to indicate the use of this measure, it must not make us neglect the careful study of the effects as the blood flows from the vein.

In the second stage of inflammation, when dulness on percussion and the absence or the bronchial character of the sound of respiration indicate hepatization of the lung, bloodletting loses that efficacy which entitles it to the foremost place in the remedies for pneumonia. Some writers, indeed, proscribe its use at this period, as injurious and interfering with the curative process. The ancient physicians generally renounced bleeding after the fifth day if the expectoration was abundant, for fear of checking it, and their caution was followed by most practitioners until the end of the last century. We can readily perceive that the efficacy of bloodletting must be very much abridged by the permanent form which a solid interstitial effusion has now given to the organic disease, and therefore it is no longer to be expected that its repetition, however copious or frequent, can at once remove the dyspnœa or lower the pulse; but in a more moderate degree it is still useful, inasmuch as it reduces the quantity of blood which is to pass through the lungs, and tends to prevent the progress of the inflammation to the third and more hopeless state, purulent infiltration. We find, accordingly, many excellent practical writers, Stoll, Cullen, Frank, De Haen, Andral, Chomel, and even Laennec, recommend the repetition of venesection during the second and even the third stage, whenever the state of the

* Op. cit. p. 249.

† In hysterical females especially, this and other symptoms of nervous excitement, as pain, delirium, and convulsions, often occur and deceive the unwary as to their real cause; they are not dependent on the disease, but on the loss of blood, and, belonging to the class of irritations of re-action, require sedatives rather than further depletory measures. See IRRITATION.

breathing, the pain, or the fever seem to require it. Laennec thought that to bleed to syncope might produce the evil effect of checking the expectoration, apprehended by former writers, and in this opinion our own experience disposes us to coincide. If venesection has been freely practised before, the occasional loss of eight or ten ounces from the arm, conjoined with local depletions, is generally as much as is borne well or proves useful, and the further relief of the disease must be left to other means. In some instances this quantity may be exceeded with advantage, even at this period, when the stethoscope discovers the development of inflammation in a new part. If, likewise, bleeding has been neglected or only sparingly used before, a larger abstraction is often serviceable, even in the second stage, to remove that relative plethora into which the obstructed state of the lungs converts the ordinary fulness of the vascular system, and hence the great relief that even at this period general bloodletting sometimes affords. Here, it may be perceived, there is no reason for a large orifice or a speedy abstraction of blood, and these should be the rather avoided, as the syncope which they may induce is not a desirable event.

We have said nothing respecting the buffy coat of the blood as a criterion of the propriety of venesection, because we have not observed any constant relation between this sign and the intensity or even the existence of inflammation. When the crassamentum is buffed, cupped, and firm, early in the disease, it may confirm us in perseverng in the measure; but in the after stages, the separation of the fibrine from the colouring matter may proceed as much from irritation or the use of mercury as from inflammation, and it is at this time only that its indications are wanted.

Local bloodletting.—It is obvious that, in the greater number of cases, the abstraction of blood from the integuments of the chest can produce but little impression on a disease that occupies so considerable a portion of the vascular system as that extensive tree of vessels which conduets the smaller circulation; and accordingly local depletion is but a subordinate measure in the treatment of pneumonia. Many practitioners, however, often employ leeches or cupping as subsidiary to phlebotomy at the commencement of the disease. Thus Andral tells us that Lerminier often ordered the painful side to be covered with leeches during the flow of blood from the vein. This method, it may be remarked, is better adapted to an hospital, where there are plenty of experienced assistants, than to private practice, where one of these operations is enough at a time: but we have found great advantage in prescribing local bloodletting in the space of an hour after general, especially where a stitch in the side indicated the extension of the inflammation to the pleura. From twenty to forty leeches followed by a large cataplasm, or from ten to sixteen ounces of blood drawn by cupping, often not only have the effect of relieving a pain which greatly aggravates the difficulty of breathing and cough, but also in some degree prolong the depression resulting from the general depletion, and prevent the bad effects of a reaction which sometimes succeeds to the depression. In aged and exhausted subjects and in those cases of real adynamic pneumonia which do not bear venesection, this local bloodletting becomes a principal remedy, and although much inferior in efficacy, and less worthy of our confidence, it must often be our resource when the strength would sink under general depletions. In infants the bleeding from leech-bites is equivalent to a general bloodletting, and below the age of two years is very commonly substituted for it. It may be suggested, however, that about and above this age, when, in the early stage of the inflammation, the symptoms are pressing, it is better to use venesection; and if there should be any difficulty in bleeding from the arm, from four to eight ounces may be taken from the jugular vein with great advantage: but if depletion be again necessary, that by leeches will be generally sufficient. It is sometimes recommended to apply a leech or leeches to the foot or arm of infants suffering under inflammatory diseases, because the bleeding can better be controlled in those parts; but the greater benefit produced by the depletion near the affected organ leads us to apply them in preference close to the sternum, or under the clavicle of the affected side; we have never experienced any difficulty, when it became necessary, in stopping the hemorrhage by a compress and bandage or slips of adhesive plaster. In adults, when leeches are used as local depletories, the intercostal spaces nearest to the point of pain are the best place of application, for contiguity, independently of vascular communication, affects the removal as well as the propagation of inflammation.

In the second and third stages of pneumonia local bloodletting may sometimes be substituted for venesection, on any return of pain or slight increase of dyspnœa which seems to demand more immediate relief than can be obtained from the internal remedies or blisters. In slight limited inflammations, such as those attacking phthisical subjects, it is often the only kind of bloodletting that is necessary.

Tartar emetic.—Next to bloodletting this remedy is perhaps the most powerful that we can employ for the cure of acute pulmonary inflammation. Its utility in emetic and in nauseating doses had long recommended it in pectoral complaints, but its power of subduing acute inflammations independently of its emetic, nauseating, or diaphoretic effects, has been only of late years developed. Rasori of Genoa was the first who established it,* and besides

* Although we yield thus much to a foreigner, we must not pass over a just claim to priority in *practice* in favour of Dr. Marryatt of Bristol, who died in 1793. In the last edition of his "Therapeutics," published in 1790, is the following passage, in which both the febrifuge virtue of tartar-emetic, and the *tolerance* of the system in regard to it, are described. "Any fever may be soon extinguished by the use of the following powders:—Take of tartarized antimony five grains, white sugar (or nitre) a drachm; let them be well rubbed in a glass mor-

the testimony of many of his own countrymen in its favor, it has received the highest and most unqualified praise from the illustrious Laennec, whose sanction, after the great light which his labours have thrown on the pathology of this disease, cannot but command our attention. Although it may fall short of the sanguine hopes held out by the advocates of this practice abroad, the experience of many distinguished physicians in this country tells much in its favour, and we believe justifies the opinion expressed at the beginning of this paragraph. The success which has attended the treatment of peripneumony by repeated emetics, as recommended by Riverius and Stoll, probably in part depended on this peculiar action of tartar emetic; under this practice in the hands of Dr. Hellis of Rouen, and some others in France, the proportion of deaths was considerably less than usual, not exceeding one in nine; while the average mortality of the disease, when treated by bloodletting and derivatives, amounts to one in six or eight;* and in hospital practice, and among the lower ranks, it is often greater. The efficacy of the emetic treatment in croup, advised by Dr. Cheyne, and in ophthalmia and in hernia humoralis, probably partakes of the same principle, and is less dependent on the emetic than on the *contro-stimulant* or *anti-inflammatory* effect of the tartarized antimony. As the subject of large doses of tartar-emetic has been already described in the article INFLAMMATION, we shall here only speak of its application in the treatment of pneumonia.

Rasori, with whom the regular introduction of this practice commenced as long ago as the year 1808, gave the medicine in the following manner. Usually after one or more bleedings, but sometimes without this measure, from twelve to twenty-four grains, or in severe and advanced cases, from a scruple to half a drachm were given during the day, and the same repeated in the night; these doses were daily increased until they amounted to a drachm or several drachms in the twenty-four hours. The result of this extraordinary practice was, that out of 832 cases of pneumonia 173 died. Out of 115 cases treated in the same way by Tommasini of Bologna, only 14 died; and several other equally favourable reports are made by other physicians of Italy. There are, however, counter-statements to oppose to these;* and, as we had occasion to observe when speaking of the neglect of bloodletting, we have no certainty that all the cases here enumerated were in reality pneumonic. At all events, later experience has proved that there is no advantage in the excessive doses here used, and, on the contrary, that greater success has resulted from more moderate quantities. The uncommonly small mortality of only two in fifty-seven, which Laennec asserts to have attended his method of exhibiting tartar-emetic, warrants our quoting his own account of his treatment, which will likewise show how much confidence he placed in the measure.

"As soon as I recognise the existence of the pneumonia, if the patient is in a state to bear venesection, I direct from eight to sixteen ounces of blood to be taken from the arm. I very rarely repeat the bleeding, except in the case of patients affected with disease of the heart, or threatened with apoplexy or some other internal congestion. More than once I have even effected very rapid cures of intense peripneumonies without bleeding at all; but in common, I do not think it right to deprive myself of a means so powerful as venesection except in cachectic or debilitated subjects. In this respect Rasori does the same. I regard bloodletting as a means of allaying for a time the violence of the inflammatory action, and giving time for the emetic tartar to act. Immediately after the bleeding I give one grain of the tartar emetic dissolved in two ounces and a half of cold weak infusion of orange leaf, sweetened with half an ounce of syrup of marsh-mallows or orange-flowers; and this I repeat every second hour for six times, after which I leave the patient quiet for seven or eight hours, if the symptoms are not urgent, or if he experiences any inclination to sleep. But if the pneumonia has already made progress, or if the oppression is great, or the head affected, or if both lungs or one whole lung is attacked, I continue the medicine uninterruptedly, in the same dose, and after the same intervals, until there is an amendment not only in the symptoms, but also indicated by the stethoscopic signs. Sometimes even, particularly when most of the above-mentioned unfavourable symptoms are combined, I increase the dose of the tartar-emetic to a grain and a half, two grains, or even two grains and a half, without increasing the quantity of the vehicle. Many patients bear the medicine without being either vomited or purged. Others, and indeed the greater number, vomit twice or thrice, and have five or six stools the first day;

tar, and divided into six powders; one to be taken every three hours, notwithstanding the nausea the first may possibly occasion. If these are taken (which is commonly the case) without any manifest inconvenience, let there be seven grains in the next six powders; and in the next ten. Here I beg to retract what I said in some former edition of this work, viz. that till sickness and vomiting were excited, this noble medicine was not to be depended upon. For I have since seen many instances wherein a paper has been given every three hours, (of which there have been ten grains in six powders,) without the least sensible operation, either by sickness, stool, sweat, or urine, and though the patients had been unremittedly delirious for more than a week, with subsultus tendinum and all the appearances of hastening death, they have perfectly recovered without any medical aid, a clyster every other day excepted. I have lately seen a great many cases similar to the above, and the tartarized antimony has invariably produced the same effect."—See Medico-Chirurg. Review, No. 31. p. 253.

* *Laennec*, p. 261.

* See an interesting and valuable note by Dr. Forbes in his translation of Laennec, third edit. p. 269. It contains a succinct history of the new mode of exhibiting tartar-emetic, and some very judicious comments upon it.

on the following days they have only slight evacuations, and often, indeed, have none at all. When once the *tolerance* of the medicine (to use the expression of Rasori) is established, it even very frequently happens that the patients are so much constipated as to require clysters to open the body. When the evacuations are continued to the second day, or when there is reason to fear on the first that the medicine will be borne with difficulty, I add to the six doses to be taken in the twenty-four hours, one or two ounces of the syrup of poppies. This combination is in opposition to the theoretical notions of Rasori and Tommasini, but has been proved to me by experience to be very useful. In general, the effect of tartar-emetic is never more rapid or more efficient than when it gives rise to no evacuation; sometimes, however, its salutary operation is accompanied by a general perspiration. Although copious purging and frequent vomiting are by no means desirable on account of the debility and hurtful irritation of the intestinal canal which they may occasion, I have obtained remarkable cures in cases in which such evacuations had been very copious. I have met with very few cases of pneumonia where the patient could not bear the emetic tartar; and the few I have met with occurred in my earliest trials; insomuch that this result now appears to me to be attributable rather to the inexperience and want of confidence of the physician, than to the practice. I now frequently find that a patient who bears only moderately six grains with the syrup of poppies, will bear nine perfectly well on the following day. At the end of twenty-four or forty-eight hours at most, we perceive a marked improvement in all the symptoms. And sometimes even we find patients who seemed doomed to certain death, out of all danger after the lapse of a few hours only, without ever having experienced any crisis, any evacuation, or indeed any other obvious change, but the rapid and progressive amelioration of all the symptoms. In such cases the stethoscope at once accounts for the sudden improvement, by exhibiting to us all the signs of the resolution of the inflammation. These striking results may be obtained at any stage of the disease, even after a great portion of the lung has undergone the purulent infiltration. As soon as we have obtained some amelioration, although but slight, we may be assured that the continuation of the remedy will effect complete resolution of the disease, without any fresh relapse; and it is in regard to this point more particularly, that the greatest practical difference between the emetic tartar and bloodletting consists. By the latter measure we almost always obtain a diminution of the fever, of the oppression and the bloody expectoration, so as to lead both the patient and attendants to believe that recovery is about to take place: after a few hours, however, the unfavourable symptoms return with fresh vigour, and the same scene is renewed, often five or six times, after as many successive venesections. On the other hand, I can state that I have never witnessed these renewed attacks under the use of tartar-emetic. In these cases we observe only in the progress towards convalescence, occasional stoppages. And this is more particularly the case in respect of the stethoscopic signs; as we find that between the period when the patient experiences a return of his appetite and strength, and fancies himself quite cured, and the period at which the stethoscope ceases to give any indication of pulmonary engorgement,—more time frequently elapses than between the invasion of the disease and the beginning of the convalescence. It is necessary to observe, however, that this remark is still more frequently applicable to the disease when treated by bloodletting; and moreover, that the patients subjected to the antimonial method never experience the long and excessive debility which too often accompanies the convalescence of those who had been treated by repeated venesections."*

M. Peschier of Geneva appears to have given tartar-emetic much in the same way as Laennec; and with such success that, according to his report, he speedily cured almost every case without the aid of bloodletting, although he never exceeded fifteen grains in the twenty-four hours.† Of those who have written favourably of the remedy on this side of the channel, we may name Dr. Mackintosh of Edinburgh, and Drs. Graves and Stokes of Dublin; but these physicians differ from its foreign advocates in making tartar-emetic a remedy secondary to bleeding. The experience of the former leads him to conclude that vomiting is more speedily produced by a small dose dissolved in a large quantity of water, than a large dose of the drug mixed with a little sugar; but in the latter case the nausea is more severe and of longer continuance than in the former."‡ Drs. Graves and Stokes begin with a mixture containing six grains for the first twenty-four hours, and add to this two or three grains each day afterwards as the severity of the case may require, until fifteen grains are given daily; beyond this quantity they think it unnecessary to go. They use general and local bleeding freely, and in case of an increase of the symptoms, resort to it without trusting to larger doses of the tartar-emetic. They consider the treatment by this medicine as most eligible in strong constitutions in the early stage of inflammation, during the prevalence of the crepitant rhonchus, and before there is any dulness on percussion; when hepatization has taken place, it loses much of its efficacy. Any symptom of gastritic disease they consider as counter-indicating its use; and they find that the *tolerance* of the remedy is sometimes more readily established by applying leeches to the epigastrium.§

Our own experience in the use of tartar-emetic leads us to agree pretty closely with these observations. In truly sthenic cases of pneumonia, we have generally found that it perpetuates the impression produced by the

* Dr. Forbes's Translation, p. 255.
† Biblioth. Univ. Juin 1822.
‡ Practice of Physic, vol. i. p. 426.
§ Dub. Hosp. Rep. vol. v.

lancet more promptly and decidedly than any other remedy, and in a proportionate degree insures the relief of the patient, at a smaller expense of blood and strength than the ordinary method of treatment even with the aid of mercury. But we cannot assent to the opinion of Rasori, in which Laennec seems to join, that the remedy has no depressing effect except in regard to the inflammation, which it directly reduces; for we have very commonly found that it lowers the strength, and sometimes the frequency, of the pulse, before its beneficial effects on the inflammation are perceptible, and occasionally even when these do not ensue. It may have specific effects on the inflamed vessels, but it likewise sometimes exerts a sedative action on the general circulation. This is not always apparent, and its absence may result sometimes from the local irritation of the medicine counteracting its depressing influence, and in some cases from the system being capable of resisting its effects. Certain it is, that in a few instances, principally in children, its administration has been followed by a more rapid sinking, and seemed to hasten the fatal termination. These were, it is true, cases of advanced disease, in which after death the lungs exhibited extensive marks of unconquered inflammation. We think it more necessary to point out this depressing operation of tartar-emetic, because Laennec takes no account of it, but considers cases of debility as particularly adapted for its use. Nevertheless we have seen aggravated instances of pneumonia advanced to the second, if not the third stage, and accompanied with great apparent exhaustion, recover under the influence of tartar-emetic and blisters, when bloodletting had ceased to bring relief, and was no longer practicable. Unless, however, in case of failure of the action of other remedies, we should not be disposed to give tartar-emetic in any case where the circulation is really weak; and it should likewise be withheld where it appears to depress greatly without improving the state of the respiration.

A very important point in the exhibition of this medicine is to establish the *tolerance*, which means an insusceptibility of the stomach and bowels to its emetic and purgative effects. Rasori supposed that the presence of an inflammation in the system is the cause of the drug having a different operation from usual, and that the stimulus of this inflammation must be neutralized by the directly sedative or *contro-stimulant* property of the medicine before the body can be made sensible of its common emetic effects. But, as Laennec has observed, this is not consistent with the fact, that after the tolerance is once established, ten, twenty, or thirty grains may be taken and continued daily throughout the period of convalescence without any sensible effects. We have seen patients recover their strength, appetite, and power of digestion when they were taking twelve grains daily. The experience which we have, that the most inflammatory and plethoric cases are those in which this medicine is most successful, indicates indeed its peculiar power over excited vascular action, but its occasional utility over more advanced forms of pneumonia and in hernia humoralis proves that it likewise possesses a sorbefacient power.* The directions which we have quoted from Laennec with regard to the best mode of exhibition to ensure the tolerance of the medicine, are those which we have generally found most successful. It is desirable to vary the vehicle according to the taste of the patient, and to choose that which is most grateful to his stomach. We have often found the "king's cup," a weak infusion of fresh lemon-peel sweetened according to the liking of the patient, convey the medicine very comfortably, but it is best not to give more than a wine-glassful with each dose, as in our experience a larger quantity is more apt to produce vomiting. The first dose generally produces this effect however given, and frequently the second more slightly: the third commonly merely nauseates, and the tolerance is then established. This is the common average of the operation of the medicine. If the vomiting continue after the second dose, or be very violent then, it will be expedient to take some measures to diminish the irritability of the stomach and bowels. Where there is diarrhœa as well as vomiting, instead of the syrup of poppies recommended by Laennec, we prefer the addition of three or four drops of the liquor opii sedativus, or of the solution of muriate of morphia, to each dose of the medicine, and this may be advantageously given with an effervescing mixture, as recommended by Dr. Tweedie in the article Fever; but it is necessary that the alkaline carbonate should be accurately neutralized, otherwise it would decompose the tartarized antimony. Where the vomiting becomes obstinate and urgent, we can confidently recommend the addition of a drop or two of hydrocyanic acid to each dose of the medicine, as in the following form:

℞. Antimon. tart. gr. iſs. ad gr. iiſs.
Aquæ distill. ℥i.
Acid. hydrocyan. *mi*.
Aq. cinnamomi, (vel flor. aurant.) ℥iii.
Syrup. tolutan. ℥i. Fiat haustus.

This may be given every second, third, fourth, or sixth hour, according to the severity of the case. The draughts should not be made long before they are used, as they soon become decomposed, and the oxyde of antimony is precipitated. For this reason it may be sometimes useful to prescribe the tartarized antimony in a powder, to be dissolved at the time of exhibition in a wine-glassful of lemon-peel infusion, to which, if necessary, the hydrocyanic acid may be added. We decidedly prefer the exhibition of the medicine in a liquid form to that of a powder, as we consider it to be more safe and efficacious. Where, notwithstanding the combinations just mentioned, the vomiting still continues, a few leeches to the epigastrium, or, what is more efficacious, a mustard poultice applied there for a few minutes, will sometimes effect the tolerance of the remedy. If, notwith-

* See Dr. Mackintosh's Experiments, Lancet, vol. ii. p. 536.

standing all these precautions, the vomiting persists, it must be left to the discretion of the practitioner whether the medicine is to be continued or not; and in deciding this he will have to balance between the beneficial influence already produced by it, and the distress and injury likely to ensue from so violent an operation still continued.

It seldom happens, however, that this intolerance of the medicine does remain where its continued exhibition would be safe; and unless the remedy should be producing a marked improvement in the pulmonary symptoms, we may generally consider obstinate and violent vomiting or diarrhœa as an indication to desist from its continuance. We are further warned from its use in all cases where there is a florid red, or brown and parched state of the tongue, with great thirst, and tenderness and tension in the epigastrium, or over the whole abdomen. We do not find that a moist furred tongue, whether white or brown, gives any contra-indication, and we have often seen this state removed by the first operation of the medicine. In continuing the medicine, we must be guided more by the physical than by the general signs of the disease; and it should not be hastily discontinued, for it does not appear, like mercury, to produce a permanent effect on the system. As long as there is a rusty tinge and viscidity in the sputa, and distinct crepitation or absence of the respiratory sound in the seat of disease, the medicine should be continued, three times a-day at least. It is an advantage of this remedy that it may be combined with others, adapted to the various stages of the disease; and, although such combinations speak equivocally as to its individual powers, in some of the severest cases in which the treatment was most signally successful, we have joined the tartar-emetic with general bloodletting at first, with blistering and mercury afterwards, and lastly with the decoction of senega or some slight tonic.

Mercury and opium.—The exhibition of these drugs as an antiphlogistic remedy, first practised by Dr. Robert Hamilton,* and afterwards revived and warmly recommended by Dr. Armstrong,† is now pretty generally resorted to in this country, and as it has been fully noticed in several preceding articles, need not here long occupy our attention. Like tartar-emetic, it is to be generally considered only as a measure secondary to bloodletting, and the salutary effect is particularly shewn when the latter remedy has reduced the inflammatory orgasm, and can be carried no further. The efficacy of this combination depends in a great measure on its being given to such an extent as to affect the gums; but its beneficial operation is often manifest before this effect is produced, and in some cases, especially in children, without its occurring at all. But there is seldom that obvious improvement from the first doses which is often apparent in the exhibition of tartar-emetic; the operation of mercury is more gradual, and, as may be expected, when once the system is under its influence, the effect is more permanent. It is therefore especially adapted to the advanced stages of the disease, in which the continued operation of a remedy is required to resolve a solidification of the lung; and in effecting this, and in preventing those remains of inflammation which lay the foundation for destructive chronic disease, mercury is pre-eminently serviceable. Some doubt has existed whether the mercury or the opium is the principal agent in subduing inflammation. Dr. Hamilton considered it to be the calomel, and he combined opium with it to relieve pain, and to prevent it from passing off by the bowels. Dr. Armstrong held that the opium was a powerful means of subduing inflammation after bleeding had made a decided impression on the general vascular action. In pneumonic inflammation, however, we cannot but admit that both medicines have their beneficial effects, each by its own influence, and by modifying the action of the other. Thus the opium acts as an anodyne in subduing the pain and cough, and as a sedative in relieving that nervous irritation which often follows both bleeding and the free use of mercury, and which tends to the re-establishment of inflammation; whilst the injurious stimulant and restringent operation of the drug is prevented by the previous bloodletting and the mercury. The latter medicine, again, besides this corrigent effect, more gradually exerts that specific antiphlogistic and sorbefacient action which has established its value in many diseases, and of which the treatment of iritis frequently affords a visible illustration. If we adopt this view as a guide in the application and management of these combinations, we shall find that it leads to the rules which experience has already sanctioned.

Calomel is the form of mercury which is generally preferred in acute inflammations, and as its purgative effect is not an object, there is the greater need to combine it with opium. Dr. Armstrong, indeed, considered the purgative operation of a first full dose of calomel to be salutary, by brushing away the coat of mucus from the intestines, and thus opening the absorbents for the specific action of the medicine: this may with advantage be practised in pneumonia, and especially where a disordered or torpid state of the excretions indicates a purgative. With this view, from five grains to a scruple of calomel may be given immediately after the first bleeding; but as a continued catharsis is seldom desirable, especially where there is free expectoration, the opium should be added to the subsequent doses. With respect to the quantity and frequency of these, some difference must be observed according to the form of the disease. In the most sthenic cases, uncomplicated with idiopathic fever or gastric affection, large doses of calomel, of from six to twelve grains, or even more, may be given three or four times a-day with better effect than smaller doses more frequently repeated. The proportion of opium must likewise be varied according to circumstances. Where after a full

† Practical Illustrations of Typhous Fever, &c. p. 453.

bleeding the pain is considerable, with little fulness in the pulse, and especially if there are signs of nervous irritation, from a grain to a grain and a half of opium may be added to every six grains of calomel; but if the action of the heart is still strong, half or a third of that quantity will generally be sufficient to prevent the mercury from irritating the bowels, which is in that case the principal object of the opium. We have generally preferred Dover's powder, or a simple combination with ipecacuanha to the opium alone; for while the anodyne powers of the drug are not impaired, its stimulant quality is thus considerably diminished. In a few instances the sulphate of morphia has been substituted for the opium, and apparently with good effect, but our experience on this point is too limited to enable us to speak with certainty. In less sthenic cases, and especially where there is much gastric derangement, or a fever which assumes more of the idiopathic character, with a dry loaded tongue, hot skin, and vitiated excretions, the calomel is with greater advantage given in more divided doses, and frequently; as from gr. iß. to gr. iii., with two or three grains of Dover's powder every second or third hour. In some instances, particularly where there is an irritative diarrhœa, the hydrargyrum cum cretâ may be advantageously substituted for the calomel, double the quantity being generally given. The remedy, in whichever of these various ways it is given, should be continued until it either produces a decided impression on the disease, or affects the gums. Generally these effects take place simultaneously, and the improvement is seldom permanent and progressive until the influence of the mercury on the system is manifest in the gums. It is a favourable sign when this takes place readily, for the most obstinate and formidable inflammations counteract the specific influence of mercury; and if, after salivation has been produced, the inflammation becomes rekindled, the gums get well, and the breath loses its mercurial fetor. As soon as the mercury has shewn decided effects, it may be diminished to two or three moderate doses in the day; but when the disease has advanced to hepatization, it is proper to keep up its influence in a minor degree for some days. Mercurial inunction is sometimes practised to accelerate the introduction of the metal into the system, but this is too slow a process to be of material assistance where so much promptitude is required.

Counter-irritants.—It is generally agreed, among medical writers, that blisters are not admissible in the early stage of pneumonia, and not a few deny their utility altogether in the acute disease. There are two objections against their use: one is, that whilst the inflammatory fever lasts, their stimulus adds to it, and thus reacts injuriously on the inflammation; and the other, in our estimation scarcely less important, that they prevent the use of those means of examination of the chest, which, as we have seen, are necessary to inform us accurately of the state of the pulmonary disease, and of the effect of more powerful remedies upon it. The last objection does not apply to blisters on the legs or some distant part, which are recommended by some physicians even in the early stage. M. Lerminier applies two to the legs immediately after the first bleeding; as soon as they are dry, he repeats them on the thighs, and does not use them on the chest until the disease has taken a perfectly chronic character. Unless, however, in case of complications with cerebral disease, in which distant revulsion may prove salutary, the effect of this measure is too trivial to be relied on, and the practitioners of this country seldom trust to counter-irritation on any other part than the parietes of the chest, but reserve its application till the active character of the disease has been subdued by other measures. In slight cases they may often be advantageously applied immediately after the first bleeding; but in the severer disease both the objections which we have just stated would deter us from using them until the pulse is soft, and the heat of the skin moderate. Whilst the disease remains acute, blisters from six to ten inches square are to be preferred to smaller ones, as they scarcely irritate more, and their salutary derivative and evacuant effect is much greater. When the disease, after having reached the stage of hepatization, is proceeding towards cure, smaller blisters, repeated one after another in different parts of the chest, are of considerable utility, and enable the patient to bear a slightly tonic treatment, which is often very salutary at this period. It is at this time only that other means of counter-irritation can well be substituted for blisters. The friction necessary for the application of the tartar-emetic ointment or solution constitutes an objection to its use during the pain, cough, and oppression of the acute stage; but as a safeguard against relapse, and as a means of countervailing the internal irritation and of promoting the sanative process, this method of counter-irritation reaches deeper and is more permanent than repeated blistering. (See Counter-irritation.) Rubefacient plasters, as those containing a small proportion only of cantharides, are sometimes sufficient, and produce considerable benefit on the same principle; but they should be of full size, and renewed with sufficient frequency to insure their continued activity.

Evacuants.—We may comprehend, under this title, emetics, purgatives, diuretics, and diaphoretics, all of which are occasionally useful, but it is generally agreed that they are remedies of minor importance, and require some judgment in their application. From the success which has attended the treatment of pneumonia by emetics, in the hands of some physicians, as Stoll, Riverius, Dumangin, Hellis, and Good, we cannot doubt that these remedies are sometimes decidedly useful; and probably they may be so, in the early stage of the disease, by breaking that chain of morbid action by which the incipient congestion becomes converted into inflammatory fever, as well as by their relaxing and derivative effect. They are, however, generally considered as violent and uncertain remedies, and enough of their pe-

culiar effect may be obtained in the ordinary operation of the large doses of tartar emetic, of which the ulterior action has a higher claim to our confidence.

Much difference of opinion exists as to the employment of purgatives in pneumonia; some practitioners, particularly those of this country, using them freely, not merely to evacuate the bowels, but also as depletories to reduce the action of the heart and arteries. Dr. Pring recommends them with this view, and considers them of equal power with bloodletting in subverting inflammatory action.* The general objection against their use is that they tend to check the expectoration, which is a natural means of relief to the disease; but probably they are likewise injurious in exciting in the mucous membrane of the alimentary canal an inflammatory state, which gives to the disease that typhoid tendency in which we have recognised one of its most dangerous forms. These considerations deter us from exciting any thing like a continued discharge from the intestines, but we consider that their daily evacuation is a safe and expedient measure, and if this is not effected by the medicines given with another object, it must be excited by a colocynth pill or senna draught, or, where there are signs of gastric excitement, by castor oil or a laxative enema.

Diuretics are indicated chiefly where there is a simultaneous effusion into the pleura; but we have likewise found them useful in combination with tonics in the decline of the disease, to remove the œdema which commonly lingers in the lungs and sometimes affects other parts of the body after the active inflammation has subsided. Nitre, in doses of a scruple or half a drachm in the former case, and the same, or the spirit of nitric ether in the latter, generally answer as well as any other medicine, and their effect is commonly increased by the mercury, digitalis, squill, or other medicines given to fulfil other indications. A diaphoretic operation also often results from the use of the tartar emetic or calomel and opium when these are given; when they are not, a great heat of skin often renders it expedient to give James's powder, or antimonial or ipecacuanha wine, with a view to determine to the skin; and in children especially, the warm bath sometimes proves useful in the same way; but these remedies are too uncertain and trivial in such a disease as pneumonia to withdraw our principal trust from other more important measures. In some cases profuse sweats come on, which weaken the patient without relieving the symptoms, and require the exhibition of a mineral acid to restrain them.

Sedatives.—The remedies of this kind which have been held in greatest repute in pneumonia are opium and digitalis. We have already noticed the former in conjunction with calomel, but it is likewise employed alone with a view to quiet vascular action. Dr. Armstrong recommends at least three grains of opium to be given immediately after bleeding to syncope or approaching syncope, and its effect is to preserve the reduction which the loss of blood has already effected in the pulse. This is a point particularly to be observed in the administration of opium. As long as the vascular action is strong, this drug will stimulate and prove injurious; but when reduced by a full depletion, it seems to paralyse those powers of reaction by which, after this temporary reduction, irritation and inflammation are rekindled. We have repeatedly seen the utility of opium in this way; but it has been generally in the first stage of the inflammation; and although we do not hesitate to give it in the full dose recommended, we judge it to be always safer to combine it with calomel and ipecacuanha. Where there is much pain, from twenty to forty minims of the liquor opii sedativus, given immediately after the bleeding, act more speedily and satisfactorily than solid opium. In the after-stages, when the antiphlogistic remedies have reduced, as far as may be, the inflammatory action, opium often proves of the greatest benefit in relieving the cough, which frequently continues troublesome and obstinate even in the decline of the disease. With this view it is generally combined with expectorants, which we shall presently have occasion to notice. Hyoscyamus, conium, extract of lettuce and of belladonna, are sometimes used with the same intention, and, where opium is ill borne, may prove serviceable; but, although they may at all times be given with less risk, they are generally much inferior to it in efficacy. These medicines, besides reducing the excess of irritability on which the act of coughing depends, seem in some degree likewise to relieve the oppressed state of the breathing, which occasionally remains after the active disease is subdued, and this they probably effect by diminishing those changes in the blood by which it is rendered venous, and thereby lightening the task of the function of the lungs. (See Dyspnœa.) The action of digitalis is considerably different, being principally on the vascular system, and it does not possess any anodyne qualities. It has been much extolled as an aid to bloodletting in reducing inflammatory action; but although it occasionally shews considerable efficacy, its operation is far too uncertain to entitle it to our confidence. Its exhibition is moreover not unattended with danger, for when given largely to affect the pulse, it sometimes developes its effects suddenly in syncope and extreme reduction of the heart's action. We trust to it more in the decline of the disease; and in the dose of ten to twenty minims three times a day, combined with an opiate in an expectorant mixture, we have found it of great use in reducing the pulse and easing the respiration. Some practitioners speak highly of larger doses, frequently repeated, until an impression is produced on the circulation; but we have not seen enough advantage in this plan to induce us to recommend it, and unless watched with the closest attention, we cannot consider it a safe practice. Colchicum may be used with the same intention, but it is more apt to pass off by the bowels, and should

* Principles of Pathology, p. 208.

therefore be combined with opium. It is most suited to the pneumonia of rheumatic and arthritic subjects, and may be given in the dose of ʒi of the wine with a few grains of carbonated alkali. Hydrocyanic acid does not appear to deserve the encomiums that have been passed upon it, and except to quiet an irritable state of the stomach, we have not seen it useful in pneumonia.

Expectorants.—During the active stage of the inflammation, whilst the pulse is sharp and the skin hot, the secretion of the bronchial membrane is not within the influence of any of those medicines which are called expectorant. The general measures which reduce the inflammatory orgasm of the great pulmonary vessels are then the best means of relaxing those of the bronchi, and this effect may afterwards be kept up by small doses of antimony or ipecacuanha. In an advanced state of the disease, however, the promotion of expectoration becomes an object of great importance, as on its accomplishment may depend the life of the individual. Where the inflammatory symptoms have entirely given place to those of weakness with a great embarrassment of the breathing, the carbonate of ammonia becomes a most valuable remedy, and we have more than once seen it apparently turn the scale in imminent cases. It may be given in doses of five grains or more every hour or every two hours, or more frequently if the sinking state of the patient seem to require it. The decoction of senega is in these cases a good vehicle for it, and great advantage has sometimes resulted from the addition of the tincture of the *lobelia inflata*, which, although an uncertain remedy, often shews great powers in facilitating expectoration and relieving dyspnœa in several advanced forms of pulmonary disease. The first dose of the medicine should not exceed ten minims; but unless it produce sickness, it may be increased by three or four minims in each successive dose. Different individuals bear it very variously; we have known a drachm taken at a dose, with great relief to the breathing and without inconvenience; in another instance eight minims produced such sickness and giddiness that it became necessary to discontinue its use. When the urgency of the symptoms which indicated the use of ammonia has ceased, it may be of importance to keep up a free secretion from the bronchi, in order to assist in the resolution and dispersion of the solid effusion in the tissue of the lungs, and for this purpose expectorants of less stimulating quality are to be preferred. We have generally found a combination of tincture of squills and ipecacuanha, in the dose of ten minims of each, answer very well; if the cough is troublesome, a few drops of liquor opii sed. or forty or more of the compound camphor tincture should be added. The vehicle for these medicines may be the almond emulsion, with a little liquor ammon. acetat. when the expectoration is thin and scanty; but when it continues viscid, we have found great benefit result from the exhibition of expectorants in an alkaline vehicle, which is the only form in which the alkaline treatment, so much extolled by Sarcone and Mascagni, has appeared to us useful in peripneumony. Ten or twenty minims of liquor potassæ, or the same number of grains of a carbonated alkali, may be given with the above-named expectorants in water, camphor julep, or any simple vehicle, or in the more asthenic cases, with decoction of senega. In the course of recovery from pneumonia we often find it useful, whilst any pulmonary symptoms remain, to join some expectorant with the tonic that is employed.

Tonics and stimulants.—In ordinary pneumonia this class of medicines is out of the question as long as any signs of active inflammation remain. When, however, depletions do no further good, and the pulse is weak, the skin cool, and the expectoration no longer rusty and tenacious, then, although some dyspnœa and cough still remain, considerable benefit is sometimes derived from the exhibition of a mild vegetable tonic, such as the decoction of senega, or a weak infusion of calumba. We have already named the first of these as a vehicle for carbonate of ammonia to promote expectoration, but it seems also to prove useful from its slightly tonic property, and as a stimulant to the absorbent system. In the state which we have just described, we have often seen the symptoms remaining stationary, without tendency to improvement, until this medicine was given, and then in a few hours the pulse has become slower, the breathing more free, the tongue cleaner, and the strength somewhat improved. By auscultation, also, we have found, in a returning crepitant rhonchus or other vesicular sound, a proof of the impulse which this treatment gives to the absorption of the effused matter. When the active stage of the inflammation has been subdued by tartar emetic, it is a good plan to continue to give it three or four times a day in this decoction, as there is nothing inconsistent in the action of the two medicines. After the mercurial treatment it is even more useful, and may generally be given soon after the gums are decidedly affected. The infusion of calumba we have thought better adapted to cases in which there had been much accompanying gastric disorder, and in these it has sometimes cleansed the tongue, which had continued foul in spite of the prevalence of mercurial action in the system. In the exhibition of either of these tonics, however, a close attention must be paid to prevent the rekindling of the inflammatory disease, and they must be discontinued on the appearance of any sign of reaction. They are most safely employed in conjunction with an external counter-irritation on the chest; and it is under these combined measures that the most rapid recoveries take place. In the more typhoid forms of the disease, especially those complicated with adynamic fever from the beginning, tonics and even stimulants are required more frequently, and with less limitation. In some of these cases, where bloodletting is not borne, bark and camphor may be given even in the early stages of the disease, for the pneumonic affection is really more a passive congestion arising from an extremely

atonic state of the vascular system, with probably an altered state of the blood, than a true inflammation. Laennec says that he has, with success, given both bark and wine in certain epidemic peripneumonies, particularly in one which prevailed among the troops in 1814. He also recommends these to be administered towards the termination of the disease in old persons, and in debilitated and cachectic subjects, when, after the suppurative stage, the fever passes off and resolution goes on very slowly. He considers cinchona the best remedy in gangrene of the lungs, even when there is extensive hepatization around the eschar; but to be effectual it must be given to the extent of an ounce of the powder daily, or an equivalent portion of sulphate of quinine. Except in case of complication with intermittent fever, where the specific operation of bark is required, we are disposed to trust at first to opium, camphor, and ammonia, in the typhoid pneumonia, combining them with calomel, and to resort to the bark only if the general strength seems to require it afterwards.

Application of the treatment.—We have only to point out here the manner in which the several remedies which we have described may be combined in the treatment of individual cases. Where the case is at all severe, the treatment with tartar-emetic, or with calomel and opium, should be commenced immediately after the first bleeding, and continued uninterruptedly until an impression shall have been produced on the disease. It is not safe, however, with either of these remedies to lay aside bloodletting; if sensible relief does not ensue in the course of five or six hours after the first full bleeding, this measure must be repeated as before recommended. In the most acute and inflammatory cases, uncomplicated with gastric disease, we have sometimes combined the mercurial with the antimonial treatment, by giving a pill containing from six to ten grains of calomel, with from half a grain to a grain and a half of opium every four or six hours, and the tartar-emetic draught before prescribed, in the middle of that interval; and where the tolerance is established soon, the effect of this treatment is very powerful. If the bowels are too much acted on, the hydrargyrum cum cretâ in double quantity may be substituted for the calomel. When an amelioration takes place in the symptoms, the mercury may be omitted, and the case left to the tartar-emetic and whatever depletion or counter-irritation may be required. If the attack of pneumonia is very recent, and accompanied with a sharp stitch in the side, or catch in the breathing, a full dose of opium immediately after a large bleeding, as recommended by Dr. Armstrong, will sometimes be found sufficient to cut short the disease. This plan can only be adopted where the bleeding has been so copious as to produce a great and real impression on the heart's action, almost, if not quite, amounting to syncope. The dose of opium should be large; three or four grains of the aqueous extract, or if the pain and tendency to reaction are urgent, from 30 to 60 minims of the liquor opii sed. are the preparations to which we give the preference. Even in this case we think it advisable to give from six to twelve grains of calomel, or from ten to twenty grains of blue pill with or soon after the opium; the mercury does not interfere with the sedative operation of the latter, and by preserving the balance of the secretions, it prevents those functional derangements which sometimes follow the use of opium even in this way. If the disease has in any degree passed into the second stage, and even if the first has lasted more than twenty-four hours, there can be little hope of stifling it with opium, and we must then resort to the alterative powers of tartar-emetic or mercury, with whatever bloodletting the case may bear. Blisters can seldom with advantage be resorted to, until all fulness and hardness of the pulse and heat of skin have subsided; and either these symptoms, or even the continuance of a fixed pain, would counter-indicate the use of the decoction of senega or any of the mild tonics which prove useful in the decline of the inflammation.

If from the copious expectoration of pus and the physical signs of a cavity in the lungs, it is probable that an abscess has been formed, it may be necessary to support the strength by a stronger tonic, as the sulphate of quinine or bark with a mineral acid; but the expediency of this must depend on a complete predominance of the symptoms of weakness over those of inflammation. In case of gangrene, some of the medicines of a supposed antiseptic power may be given. Drs Graves and Stokes, in a case of this kind, gave the chloride of lime in the dose of three grains with one of opium three times a day, with the effect of removing the fetor from the expectoration, and for a time improving the symptoms. We have seen the same medicine in solution apparently produce the same result; but we cannot expect much from the operation of such agents. The principal object in case of gangrene is to support the general strength, and counteract the noxious influence of the dead matter, until it can be thrown off from the system.

The great fatality of pneumonia among children renders it necessary that its treatment should be directed with the greatest care and promptitude. This fatality does not arise so much from the course of the inflammation, as we have seen that this is less rapid than in adults; but from the latency of the local symptoms, and the tendency of the disease, under this disguised form, to pass the period in which bloodletting is most effectual. Hence many of the cases of infantile pneumonia which we have to treat, especially in the lower classes, are already in a sinking state: the depressing influence of the injured function of the lungs, which at this age ill bears any abridgement, having already removed the sthenic character of the disease. This circumstance represents to the mind the importance of physical examination of the chest in all the febrile diseases of children, in order that if any crepitant rhonchus be discovered, the fit remedies may be promptly applied. In this early stage bloodletting is highly efficacious, but when used after the dis-

case has lasted for several days, it sometimes produces convulsions and sinking without relieving the respiration. The same observation may in some degree be applied to tartar-emetic, and yet these are the most effectual remedies which we possess for infantile pneumonia, and if used together at the commencement, seldom fail to subdue it. Mercury with difficulty produces its specific action on infants, but it is still of great effect as a purgative; and when bloodletting is no longer borne, calomel, in doses of half a grain up to two grains, according to the age of the child, every hour or second hour, is the remedy on which we have principally to depend. Unless where there is an irritative diarrhœa, opium can seldom be used with advantage; in that excepted case Dover's powder is the best form. Although mucous or bloody stools imply an undue irritation from the calomel, and ought to be checked, yet copious evacuations of green bile are essential to the success of its operation, and seldom produce in the pneumonia of children the bad effects which result from purgation in the adult. It would seem that expectoration, as it is a less natural process in early life, so its importance as a vicarious discharge is of inferior moment, and does not prohibit purgatives and other measures that may arrest it. Counter-irritation with tartar emetic ointment or solution is of great efficacy in the after stages of pulmonary inflammation in children, and should especially be persevered in where there is any sign of a phthisical tendency. This, together with a sedative linctus to quiet the cough, and a light tonic if required, constitute the chief part of the treatment most eligible in the decline of the disease.

In aged persons the disease is often very intractable in consequence of the great debility which accompanies it. The mere circumstance of age should not, however, restrain us from the use of the lancet, where the state of the breathing and pulse, and heat of skin seem to indicate it. Frank bled an octogenarian pneumonic patient nine times with a happy effect. It must be confessed, however, that the period in which bleeding is useful in old people is short, and the frequent complication of a pituitous catarrh with pneumonia still further restricts its utility. Expectoration is in these cases a most important process, and when bleeding weakens so much as to be likely to interfere with the performance of this act, it must be abandoned. In some cases cupping may be substituted, but blisters of ample size are more effectual, and may be employed much earlier than in younger subjects. The internal remedies may be administered as usual, but it is often necessary to resort soon to the tonics and stimulants before described.

We know of no reason why the sex of the subject should materially modify the treatment of pneumonia. The presence of the catamenia ought never, in cases of any severity, to interfere with free depletory measures, for the influence of this relief on the system is trifling compared with the progress of a dangerous inflammation. The case may be different in slight examples and towards the decline of the disease, and stimulating pediluvia may be used, if the circumstances indicate it, to promote a natural crisis of this sort.

The complications of pneumonia with other diseases will require that the treatment should in some measure combine the indications of these various affections. Thus in the complication with bronchitis the power of bloodletting will be more contracted, whilst the antimonial treatment of blistering will claim more confidence. In pleuro-pneumonia, local bleeding, in addition to venesection, becomes a very useful remedy, and if the pleuritic affection be extensive, or accompanied by much pain, calomel and opium will form the most eligible remedy. In the treatment of pneumonia occurring in continued fever, the probable duration of the latter affection must be held in view, and depletions practised in a more cautious manner. The mercurial treatment is generally the best here likewise, especially if the fever partakes much of the gastritic character; and the hydrarg. cum cretâ, with ipecacuanha or Dover's powder, is the preferable preparation. When any of these fevers take on the typhoid or adynamic form, stimulants and tonics will sometimes be required, and must be given notwithstanding the pulmonary disease. It must be confessed that medicine has often very little power in these cases; but as far as our experience goes, stimulants judiciously given when the heart's action is very feeble, and the muscular powers are very low, have appeared to relieve the pulmonary affection, as well as for a time to restore a portion of strength; and it is only by over-stimulating the heart that there is a risk of aggravating the inflammatory disorder. They must, therefore, be carefully watched, and diminished or withdrawn as soon as any sharpness or hardness is perceptible in the pulse. Besides those before enumerated, we may mention musk, which is highly recommended in the typhoid form of pneumonia by M. Recamier, who gives it in doses of from 21 to 30 grains, with an effect which he considers almost specific. It seems to us questionable whether the affections which have been called intermittent peripneumonies, and said to have been cured by bark, are really inflammations: it is more probable that they consist in a simple congestion of the lung determined by the febrile paroxysm, just as simple congestions are more familiarly known to take place in the spleen, liver, &c.; and from the near pathological affinity between the two, it is not surprising that such a congestive state should produce many of the local phenomena of pneumonia. Although there can be no doubt of the power of bark and arsenic over these intermittent diseases, yet even here the oppression of the affected organ during the paroxysm is occasionally such as to require the aid of bloodletting. Neither should this measure be withheld, from fear of suppressing the eruption, in the pulmonic affections coming on at the commencement of the exanthemata; the internal affection is a present and dangerous evil, not to be neglected on account of other imaginary ones.

In the peripneumonies supervening on hoop-

ing-cough and influenza, it is sometimes a chief indication to give sedatives to allay the cough, which appears often to have a considerable share in producing the parenchymatous inflammation. Besides bleeding, therefore, to the extent that the case may require, large doses of the tincture of hyoscyamus (3ij. and upwards), or, in hooping-cough, the extract of belladonna, in doses of half a grain to the adult, and one-sixteenth to children below two years (these being gradually increased), will be found of much efficacy in counteracting the inflammatory tendency of these affections. Local depletions and counter-irritation will generally be sufficient to arrest the inflammations intercurrent on phthisis; and we have found the tincture of digitalis very useful in these cases. Where an inflammatory state of the mucous or serous membranes of the alimentary canal accompanies pneumonia, it is of great moment that the treatment should extend to these complications, for they greatly aggravate the case, and render it less tractable. Free leeching of the abdomen must be included in the depletory measures, and the hydrargyrum cum creta with Dover's powder will be the best antiphlogistic alterative. Purgatives must be at first rigidly proscribed, and the bowels merely evacuated by laxative enemata or suppositories. In the progress of recovery, a teaspoonful of castor oil daily, and infusion of calumba with dilute nitric acid, or some such light tonic, will often contribute greatly to restore the healthy functions of the membrane.

Diet and regimen.—No one can question the propriety of a strictly antiphlogistic regimen in ordinary cases of pneumonia. A total abstinence from all solids must be enjoined during the inflammatory stages of the disease, and the liquids taken should be of the mild mucilaginous kind, such as barley-water, tea, lemon-peel, and other simple vegetable infusions. It is generally recommended to give these beverages warm; but unless large draughts are taken, we see no objection to their being given cold if the patient prefers it. We have heard Professor Hamilton of Edinburgh express his decided belief that liquids are injurious in pneumonia by adding to the mass of blood, and thus counteracting a principal good effect of bleeding; and so far does he carry this opinion, that he considers that even pediluvia may do harm by throwing more liquid into the system through the absorbents. Although a zealous advocate for a dry diet in some other complaints, the writer is not persuaded of its utility in the present disease, except in cases where the dyspnœa is urgent. In such cases we have seen the breathing distinctly become worse after copious draughts of liquid, and with a view to keep the mass of blood which passes through the lungs as rich in quality and as small in quantity as possible, a paucity of drink may here be reasonably recommended. The antimonial treatment generally requires a certain degree of abstinence from liquids; for until the tolerance is completely established, a large draught is almost sure to produce vomiting. M. Chomel has pointed out a very important exception to the utility of an absolutely antiphlogistic regimen, in the case of those addicted to excess in wine or spirits. The great fatality of pneumonia in these subjects when treated in the usual way is well known; and observing that one man accustomed to such excess, who continued to take a pint and a half of wine daily throughout his illness, speedily recovered from the disease after only one bleeding, M. Chomel afterwards prescribed a certain quantity of wine in similar instances, and with a success that encouraged him strongly to recommend the practice. These may probably be included in the class of malignant cases, in which Laennec says that both wine and bark are beneficial. After the active stage of inflammation has been subdued, the moderate return to nourishing food, as the appetite craves it, is desirable. It should, however, be confined at first to farinaceous liquids, light puddings, and the weakest chicken or veal broth; these may be gradually improved in nutriment, and in the course of a few days a little white fish may be allowed; and the return to ordinary animal food made by degrees and with circumspection. In case of gangrene or extensive suppuration, as manifested by fetid or copious purulent expectoration, with great prostration of strength, a more nutritive diet, such as beef tea and animal jellies, will be required; and these are cases in which wine may sometimes be cautiously administered; but too much attention cannot be paid to watch lest this regimen should re-excite an active state of inflammation.

In the progress of convalescence from pneumonia, we may say of nutritious food what we have remarked of tonics, that it must be watched in its effects, and that its tendency to rekindle the local disease may be safely restrained by the simultaneous use of counter-irritation on the chest.

Patients labouring under peripneumony should be kept in an airy room of moderate temperature, (about 60°,) being protected on the one hand from an accumulation of heated or impure air, and on the other from draughts of cold air. These points require the physician's attention, and are too important to be left to the sole discretion of the attendants. Much covering can seldom be borne, and it is therefore the more necessary to guard against the effects of accidental cold; whilst the oppressed state of the breathing still requires that the air should not be close or impure. It is of some importance likewise, in the severer cases of inflammation of the lungs, that the chest should be raised above the level of the lower part of the body. The best method of doing this is by a bed chair, which by means of a notched rack can be raised to different angles with the level of the bed; but the same object may in a measure be attained by propping the back with pillows. This posture, besides that it facilitates the breathing and expectoration, prevents the gravitation of the blood to the lungs; and from the close connection which we have frequently noticed between the mechanical and the active hyperæmia of the lung, the importance of this last point is obvious. The exertion of the lungs required in talking

s injurious, and must be avoided, and the odily efforts should be confined to necessary cts. Muscular movement hurries the cir- ulation, and that which does this in the dis- bled state of the lungs necessarily causes that njurious congestion in the organ which we ave so frequently noticed in its connection vith inflammation.

In enumerating the causes of pneumonia, ve had to remark that nothing so strongly pre- lisposes to the disease as its previous occur- ence in the individual. Hence *prophylactic neasures* become of great importance, and the nore so in proportion as the attack has been requently repeated. The necessity is obvious n such cases, of protection from the various xciting causes, by warm clothing, by avoiding xposure, exertions of the voice, and violent xercise of any kind, by abstaining from excess n diet, and by living on that quantity and uality of food which support the strength vithout inducing repletion, and by such diet nd regulated exercise, or if necessary by pro- er medicines, ensuring the due performance f the secretory functions. Among the most ssential articles of warm clothing, we may nention a flannel waistcoat next the skin, and luring the prevalence of cold weather, a wash- eather vest over it: these will be found more ffectual and less cumbersome than a larger uantity of outer clothing, and should never be eglected by the pulmonary invalid. We can- ot inveigh too strongly against the pernicious ractice of females liable to pulmonary inflam- nations subjecting themselves with their necks nd chests bare to the trying changes of tem- erature inseparably attendant on evening vi- iting. In cases where, in spite of all precau- ions, the complaint recurs repeatedly at every eturn of cold weather, and renders the indi- idual a constant invalid, a change of residence luring the winter and spring months to a more enial climate becomes a desirable measure. Torquay and the Undercliff of the Isle of Vight in our own country, and the south west f France, the coast of Egypt and Barbary, Madeira, and some of the West India Islands nay be named as generally the most eligible places of resort; but the circumstances of the ndividual case must in great measure deter- mine the choice. (See Climate.) The most fficacious remedial measures which we know f to counteract this tendency to the reproduc- ion of pectoral inflammation, is a continued ounter-irritation, by means of tartar-emetic or seton or issue, on the chest. We give the preference to the former; and we have seen atients under its influence regain a degree of obustness and hardiness which they had not nown for months. When this measure seems o be no longer necessary, the mild irritation of pitch plaster may be substituted. Those ersons in whom there is only a proclivity vithout any symptoms of real disease, should abituate the pulmonary circulation to regu- ated impressions of cold and healthy reaction, y sponging the chest with vinegar or salt vater, at first tepid, and afterwards cold, and using vigorous friction with a rough towel af- terwards.

v. chronic peripneumony.

Laennec commences a section under this head, with a question as to the existence of such a disease; and although he adduces a few exam- ples, which he admits to be of chronic inflam- mation, he views it as "hardly probable that an organ so vascular, so mobile, and so essen- tially living as the lungs, can remain long in such a state of slow and inactive inflammation, as we know to be the condition of organs less necessary to life."* But this argument is hardly tenable on a comparison with other organs equally vascular, and is inconsistent with the existence of chronic pneumonia to the extent in which he admits its existence. The form of disease considered by him to be chronic peripneumony is a hard compact kind of hepatization, sometimes found around gan- grenous excavations and hæmoptoic engorge- ments, and very rarely also around tubercular cavities and between tubercles. The lung thus affected creaks when cut, is more livid or grey than ordinary hepatization, and presents a more distinctly granular form, so that it resembles the eggs of certain insects closely pressed toge- ther, without any intervening substance. This may reasonably be considered the chronic form of granular hepatization. But as we have found the acute disease occasion a consolidation of the lung without the appearance of granules, so it may be reasonable to expect that the chronic inflammation may present us with a corresponding uniform kind of induration. Accordingly, we find Andral, Chomel, and Louis, describing other non-granular forms of chronic solidification. It is sometimes found of a bright red or a buff colour, but more frequently it is livid or grey, being variously modified by the quantity of blood and the black pulmonary matter in it. It exudes little or no fluid when pressed, and is quite solid, sometimes approaching to cartilage in density. The red kind is most commonly a sequel of the acute disease imperfectly cured; the grey kind is more frequently found in the lungs of phthisical subjects, with miliary tubercles scat- tered through it, or surrounding tubercular vomicæ. The resemblance between the sub- stance of the miliary tubercle and this grey uniform induration, and the circumstance that yellow tubercular matter is frequently found in the tissue thus indurated, led Laennec to the belief that this induration was only a diffused form of the same accidental tissue which he called a first stage of tubercle. The resem- blance is certainly very strong, and as we often see an indurated hypertrophy of the in- terlobular septa,† so a close inspection will generally detect that the solid state of the lung is owing to the same deposition in the inter- stitial tissue of a matter more or less dense, which we know in other parts to follow chronic inflammation. As far as it is connected with

* De l'Ausculr. Méd. t. i. p. 475.

† See Dr. Hope's coloured illustrations, fig. 3 and 5.

phthisical disease, this matter will be fully treated of under the head Tubercular Phthisis; but we cannot refrain from repeating the opinion (which is nearly that of Andral also,) that the miliary and diffused indurations considered by Laennec as the first stage of tubercle, are the effect of chronic inflammation of the interstitial tissues of the lung. The length to which this article has extended prevents us from entering on the question of the relation of inflammatory to consumptive disease; but we cannot refrain from expressing our belief, that if tubercle is not generally produced by chronic inflammation terminating in an irregular form of suppuration, extended pathological research proves more and more that an absolute line of demarcation cannot be drawn between the indubitable result of inflammation, and the various forms of what is now called tubercle. We have just adverted to the resemblance between the texture of miliary granulations and certain forms of chronic inflammation; and those familiar with pathological anatomy will acknowledge that there is no constant line of distinction between purulent and tubercular matter; and that, although they are generally different, yet cases frequently present themselves in which they so completely pass into each other that no physical characters appropriate them to either kind of lesion. That tubercle may sometimes be developed without any inflammatory process, is sufficiently proved by the examples in which it occurs in various parts of the body at once, apparently as a modification of the ordinary nutritive secretion of the part under the influence of a peculiar diathesis; but the prevalence of this diathesis in a lower degree, although insufficient in itself to produce tubercle, may give a tuberculous character to the products of any inflammation that may arise, and this the more effectually as the inflammation is asthenic and defective in the energy of its orgasm. Although we thus express our conviction of the connection of this subject with that of pulmonary consumption, we must not entrench on the article devoted to that disease, and we will close these remarks by quoting from the little work before noticed the conclusions to which we were then led, as they develope what we consider still to be the full extent of the relations of inflammatory to tubercular disease. "The lungs may become infested with tubercular matter:—1. by the tubercular suppuration of the indurations, whether granular or diffused, which we have been induced to consider chronic inflammations of the pulmonary tissue, this being the natural termination of such inflammation: 2. by tubercular suppuration of other inflammations of the tissue; this effect being determined by the prevalence of the tuberculous diathesis:* 3. by secretion in tissue bearing no marks of other lesion, the tubercular matter being here deposited through excess of the tuberculous diathesis," modifying the common nutritive secretion of the part.*

The symptoms of chronic pneumonia supervening on an acute attack partake of the general character of this modification of inflammation. Thus, although the general fever abates, and the functions are in some degree restored, yet the pulse is still quick, the breathing short, the cough remains, the expectoration often assumes the characters of that of chronic bronchitis, and the patient, although he recovers in some degree his appetite and strength, looks ill, and does not advance beyond a certain degree of amendment. Percussion and auscultation will discover the remaining disease by the dull resonance of the corresponding part of the chest, and the absence or bronchial character of the respiratory sound. The solid state of the lung which causes these signs, if it be not removed by the sanative processes of nature aided by remedies, will gradually induce other disorder: either it may terminate in suppuration, and, if extensive, it will endanger life by the unmanageable decay in which it involves the lung, and which, if not identical with tubercular disease, bears to it a strong resemblance in its symptoms and course; or remaining a solid obstruction to the circulation and respiration, it occasions dropsy and that cachectic state which we find induced by chronic pleurisy, pulmonary emphysema and other local diseases which permanently infringe on these vital functions; and here again a condition is produced which is on all sides admitted to be most favourable for the development of genuine tubercular consumption. In fact, however we study the relations of inflammation and tubercle, whether rationally or from evidence, whether at the bedside or in the dissecting-room, we are continually meeting with proofs of proximity between them, which are far too constant and regular to be ascribed to accident. Were we to describe the symptoms of pneumonia originally chronic, we should only have to state phenomena which are detailed in another article. See Tubercular Phthisis.

Treatment of chronic peripneumony.—If this disease is so exceedingly rare as it is supposed by Laennec to be, we might pass over the subject of the treatment entirely as he does; and if, as we believe, it constitutes a form of consumptive disease, we must refer to the article on Tubercular Phthisis for its fuller consideration. We would, however, make one remark to reconcile views which may otherwise appear conflicting; that because tuberculous disease may be developed and hastened by a form of inflammation, it does not follow that consumption is to be treated by depletions and abstinence. We have often seen that these measures do not restrain the asthenic and chronic forms of inflammation, while they may injure the general power of the constitution, and that the combination of treatment most useful in these cases is a mild tonic and nutritive regimen, with external counter-irritation, and whatever altera-

* See *Dr. Alison*, on the Origin of tuberculous Diseases, Trans. of the Medico-Chir. Soc. Edin. vols. i. and iii.

* Rational Exposition, &c. p. 160.

ive the case may suggest. We believe these o be the most successful measures in the disease n question, which may in addition require expectorant and other remedies for particular symptoms, and the removal of the occasional anses by resorting to another climate. We ave known a case of chronic solidification of he lung, which had already begun to exhibit he commencement of a phthisieal career, cured nder a course of iodine internally, with exernal counter-irritation, and careful protection rom transitions of temperature. The prospect f a cure will be in proportion as the disease s limited in extent, and the constitution strong nd free from that diathesis which we have oticed as the cause of the worst form of conumptive disease.

(C. J. B. Williams.)

PNEUMOTHORAX.—This term, (compounded of πνευμα, ατος—θωρηξ.) signifies a collection of aëriform fluid in the cavity of the pleura. As such a pathological state had not attracted notice till modern times, it remained undistinguished by any proper appellation till the beginning of the present century, when the word pneumothorax, invented by M. Itard, was adopted to designate it. It has been objected at various times to this term that its etymological composition is incorrectly formed, but closer examination into the analogies of Greek derivatives proves this to be unfounded; and, moreover, it appears now to be so well established on the basis of authority and general adoption, that any change would be both improper and impracticable.*

Gaseous collections have been frequently noted as occurring in some of the serous cavities as well as the other tissues of the body. It had been often observed that air escaped on opening the thorax in necroscopic examinations, and the attention of surgeons was occasionally arrested, during the operation for empyema, by a rush of air through the canula preceding the flow of matter. The effusion of air consequent on laceration of the lung by fractured ribs was known, but was classed with emphysema, and called *emphysema thoracis*. Those casual observations had not been reduced to any digested form, nor did they lead to investigation of the true origin of the elastic fluid, as it was universally assumed that the latter was extricated by decomposition from the purulent matter. It was not, therefore, till 1803, when M. Itard published his dissertation, that air in the pleura came to be considered as not a mere accidental complication in some rare cases of empyema, or as only occurring after death, but to constitute in itself an important pathological condition. Although thus much appears to have been established by the researches of this author, the insufficient advances which morbid anatomy had made, and the incorrect notions which prevailed as to the pathology of thoracic diseases, prevented him from going much further. His views corresponded with the old crude idea of the chemical decomposition of pus. He regarded it as always consequent to and depending on a latent phthisis, and ascribed the production of the air to the decay of the lung by means of a chronic suppuration, and the long retention of the pus in a shut cavity, which caused a partial absorption of the stagnant liquid, and its decomposition into an aeriform fluid. This was the state of knowledge on the subject till the time of Laennec, for whose labours it was reserved to investigate its true nature, and to give it its proper place in nosology. His researches have attached to pneumothorax the highest degree of importance, and we do not think that the genius and industry of this great physician have been more signally displayed in any of their achievements for thoracic diseases, than in the comprehensive illustration which he has given of the pathology and diagnosis of this affection.

Two sources are recounted by which air in the cavity of the pleura may originate. It has been said to be generated within that membrane, and it may be introduced from without. The former, we have seen, is the origin to which M. Itard ascribes it in every case, and Laennec assents to this manner of explaining the six cases which he cites. In all these instances the pneumothorax was accompanied by a pleuritic effusion, the consequence, as they relate, of phthisis; and the latter author is of opinion that the gaseous development was caused by a decomposition of part of the albuminous matter suspended in the puriform effusion. This, he adds, is rendered probable by the odour of sulphuretted hydrogen which the air exhaled. Neither this nor any of the other circumstances

* We find that Dr. Elliotson, in his lectures, has reproduced the objection of Piorry to the term pneumothorax (Lancet, 1 Dec. 1832, p. 305). He states that these compounds are always made from the dative singular, and that the word should be *pneumatothorax*. With unfeigned deference we would submit that the majority of these compounds are not formed from the prolonged dative, as αιματι, υδατι, but from the nominative αιμα, υδωρ, by changing its termination into ο,—for example, hemorrhage, hydrothorax, &c. Pneumothorax, formed according to this analogy, is a more perfect hellenism, and (as will be easily conceded) much more euphonious than the other formation. Its true signification also is "air in the thorax," and not "lung in the thorax;" for it will be observed that if this were necessarily its meaning, it would follow, by the same analogy, that hydrothorax, signifies, not "water in the chest," but "hydra in the chest," and to represent the former it should be *hydatothorax*. Professor Elliotson has permitted himself to overlook his own principles in saying that pneumothorax means "lung in the thorax," for even if, as he insists, the formation from the dative were followed (as we acknowledge it has been in a *few* instances), it is immediately apparent that "lung in the thorax" would be *pneumonothorax*, πνευμων, pulmo, ονος, ονι. In arranging the terminations of these compounds the ancient Greeks paid especial regard to the euphony, but this does not seem to have been the case with their successors who lived at the decline of the language, for to these are certainly to be referred the few compounds in *ato*, as hæmatocele, pneumatocele. The last word was even changed from the original pneumocele: vide Laennec, de l'Auscultation, tom. ii. p. 241, note. Edition 1826.

by which they were attended would incline observers at the present day, furnished with precise and more extended information on the subject, to agree to this method of explaining it. On the contrary, the examination of their details exhibits sufficient evidence to authorise us in referring them to a cause (the admission of air from without) which will be hereafter mentioned, as by far the most frequent of all. It has never been satisfactorily proved, and it seems to us an extremely problematical circumstance, that pneumothorax ever occurs by the putrefactive decomposition of a pleuritic effusion. The other processes by which air may be developed within the pleura, as recounted by Laennec, will be afterwards adverted to. It may be here stated that some of them are only conjectural; for the experience of one individual could not supply well ascertained facts sufficient to establish by observation all its causes and their relative frequency, particularly as he had to bring to maturity his own discovery of the method of exploring them.

It may be laid down as proved by the recorded experience of medical men, that where pneumothorax exists the air has been introduced from without; for cases of an opposite description are so rare that they must be considered as exceptions to the rule. This position will not be called in question, we apprehend, by any one who has devoted some attention to this subject. Air, then, may enter the serous membrane and form a lodgement in the sac of the pleura, either from the lung and bronchial tubes, or by the thoracic parietes through the skin and intercostal spaces. An example of the former is afforded by the rupture of the pleura from the bursting of a tubercular cavity communicating with the bronchial tubes, and of the latter by the opening of an anthrax of the intercostal spaces through the costal pleura, or by the pneumothorax consequent on penetrating wounds of the chest, whether accidental or artificial. We proceed now to expose the phenomena of this affection; but as most of these are common to it from whatever source it arises, it will be found advantageous to consider them in a description of it as resulting from one particular cause; namely, the first which we shall mention.

Pneumothorax produced by the bursting of a tubercular abscess into the pleura.—This species of the affection is, beyond all comparison, more frequent than all others. If we were to conclude from the experience of the medical men in Dublin who have given most attention to the subject, it might be asserted that it constitutes fully nine-tenths of the cases of pneumothorax, with the exception of the traumatic variety; and this, or even a greater proportion, is established by the cases found in medical writings since the publication of Laennec's work. This great comparative frequency, together with the importance which it derives from its connexion with the history of phthisis, have concentrated upon this form nearly the whole interest which the malady possesses.

Pathology.—The cavities which the progressive stages of aggregation and softening of tubercles form in phthisis are situated almost invariably in the superior lobe of the lung, and it is at the very summit of this that in general the excavation is largest. While the pulmonary parenchyma disappears before the expanding walls of the abscess, a remarkable circumstance is observed in examining the manner in which this tissue is destroyed, which shews that nature was making at least some struggle against her too powerful enemy. It is found that the bloodvessels are not engaged in the ulceration, but become obliterated, and traverse the empty cavity as solid chords. The bronchial tubes, on the contrary, are involved in the destruction, and their divided ends preserved open, levelled to the surface of the parietes of the sac, and forming a part of them. This double provision has obviously for its ultimate end to prevent sudden hemorrhage, and to allow of the evacuation of the tubercular matter. (See Phthisis.) While the latter is accomplished, it is manifest that the same passage which permits the matter to escape admits the inspired air to fill the space which it occupied. If life be prolonged, the parietes are always enlarging their limits, and thus, although slowly, marching towards the surface of the lung. Those centrally situated do not often arrive at the surface, but others, originally developed more superficially, extend in their progress to the serous membrane, which at length becomes in contact with the membrane forming the wall of the cavity. Here the spreading further is generally restrained by the throwing out of lymph and the formation of adhesions, but not uniformly, for in many instances the pleura is perforated. The immediate consequence of this is that the contents of the tubercular abscess, including softened tubercle, muco-purulent matter, and air, are precipitated into the cavity of the pleura. The reception of these contents into the pleura could not take place if the lung were to remain as in its natural state, in perfect apposition with the costal parietes, but a new condition is induced on the occurrence of perforation which permits it. In the physiological condition the lung is retained in a state of distention beyond its mean capacity by the expansion of the thorax, a condition which its highly elastic structure allows. It is, even at the extremest expiration, we believe, still kept more expanded than its elasticity would allow if left to itself, and not counteracted by the atmospheric pressure. The latter force, however, certainly stretches it during inspiration, when the capacity of the thorax is much enlarged; but when perforation of the pulmonary pleura takes place, the pressure becomes equalized on the external and internal surfaces of the lung, and now the elasticity is permitted to act, which it immediately does by producing the recession of the lung from the costal pleura. By this means a space is left and instantly filled with air from the bronchial tubes, which have now, by the intervention of the phthisical cavity, a free communication

with the sac of the perforated pleura. Such s the mechanism by which the atmospheric ir gets ingress in this variety of pneumothorax.*

To physicians who have opened many subects that have died of phthisis, it would at irst only seem a surprising circumstance that neumothorax is not a more frequent occurence. They are accustomed to find very frequently at the summit of the lung phthisical avities, bounded merely by the pleura itself, r with so thin a plate of lung interposed that t is scarcely any protection to it. Yet it is vell ascertained that perforation rarely or ever akes place at the summit, where we so frequently meet with so slender a barrier to prevent it. The explanation of this is found in he fact that the summit of the lung in which arge cavities exist is always covered by a lense cap of false membrane, which effects its irm adhesion with the opposed costal pleura. t would seem that, as the parietes of the cavity pproach the surface at the summit of the lung, n effort of nature is made to intercept the scape of the contents of the tubercular cavity y the formation of these adhesions. A chronic nflammatory action in the pulmonary tissue lways surrounds the cavity for a lesser or greater xtent, and, as it were, precedes its progress owards the surface. The effect of this is visible n the plates of lung often found to intervene etween the cavity and the surface, which are enerally in a state of dark-grey hepatization. t is by this same inflammation that the false membranes are thrown out which effect the adhesion of the pleural surfaces,—those, we mean, which are met with covering the summit of the ung in phthisical patients. It is found that in he same proportion as the cavity advances to he summit, the cap of false membrane becomes nore strongly organized and thicker, and forms hus an effectual protection against perforation s far as those adhesions extend.

It is important to remark, with respect to those lense membranous cases, that as it is in the ummit of the lung that cavities usually exist, o this part is much more favourably circumtanced for adhesion than any lower part; or the sliding motion of the lung on the costal pleura is greatest at the diaphragm, nd diminishes in proportion as we ascend to the summit, where it is little if at all moved by the respiratory action. A constantly quiescent apposition of the two surfaces is that which most advantageously promotes the formation of adhesions, and, as we have just stated, this is possessed only by the summit, and decreases as we descend from this. These considerations explain the observation, well known to all conversant with phthisical dissections, of the existence of the membranous coverings at the summit of the lung. They moreover shew the reason, that while it is in this place tubercular cavities generally first attain the surface, perforation of the pleura most seldom occurs here, and they also lead us to anticipate the fact that the perforation *does* generally take place just below the line to which the adhesions extend.

The rupture may occur in any of the lobes of the lung, but the inferior part of the upper lobe, and the superior part of that beneath it, is the place where it has been most usually observed. In a great majority of cases it has been found to happen on a line with the third rib, posteriorly about the costal angle, and, as we have said, just under the reflection of the false membrane by which the superior lobe is so generally adherent. But although this is its usual situation, it is obvious that it may happen at any part of the pulmonary surface. It has even been known to happen at the base of the lung lying on the diaphragm; but this must be a very rare situation, both because adhesions are common here from the apposition being little disturbed, and because tubercular cavities are uncommon at the base of the lung.

The existence of a large cavity, or even of numerous tubercles, is by no means necessary to the production of pneumothorax. We have known it to occur where the cavity which caused the perforation was smaller than a nut. Andral and others have met with cases where only five or six tubercles existed in the lung in which it happened, and Dr. Townsend had one remarkable case where it followed on the bursting of one single tubercle, which was unfortunately developed immediately under the pleura, while the whole of the lung beside, as well as the other lung, was perfectly free from them.

The inevitable consequence of the escape of the contents of the cavity and of the air into the pleura is the immediate accession of an acute pleuritis of a more or less intense character. This supervenes when scarcely any thing but atmospheric air is received into it, for this proves as decidedly irritant to the membrane as any other of the foreign substances which enter together with it, a fact which appears demonstrated by viewing the false membrane which follows the pleuritic effusion. The latter is found to be as thick and well organized at the superior and middle parts of the pleural sac (where it could only receive the irritant impression from the air,) as the base of the sac upon which the fluid contents of the cavity are emptied. The lung being separated from the costal pleura at the first moments of the perfo-

* It will be observed that we have adopted Dr. Larson's views with respect to the agency of the elasticity of the lung in respiration. We think that, so far as we have stated them, they are consistent with our experimental knowledge on the subject, but we are not ignorant that many think them contradicted by the phenomena of wounds of the chest, where *hernia* of the lung succeeds. It is almost certain that the latter is caused by a vital irritability, and not by mere elasticity, as we see that the invariable action of the latter in the dead subject is to contract the lung when the internal pressure is removed. The forces which act on the lung are by no means sufficiently investigated: the experiments which have been made on the eighth pair seem quite inconclusive on this subject, and until it be further elucidated, many phenomena connected with asthma, hysteria, protrusion of the lung, and its re-expansion after collapse, must remain unexplained.

ration, (as we have described,) becomes now compressed both by the air and the pleuritic effusion, so that, unless it be retained in points by old adhesions, the compression against the spine and mediastinum leaves a large proportion of the pleural cavity filled with air and fluid, constituting the double lesion of empyema and pneumothorax.* (See Empyema.) If the consequences of the perforation be not speedily mortal, the lymph effused by the pleuritis soon becomes organized, and forms a factitious membrane overlaying the whole surface of the compressed lung and costal pleura where the air has been able to penetrate. This false membrane is not to be described, as some have done, as a thickening of the pleura. Even in its most perfect state of organization it may be perceived to be a deposition *upon* the pleura, which membrane lies under it, (although incorporated with it,) of its natural thickness. The lung itself lies compressed and flattened against the spinal column and mediastinum. In cases which have lasted some time, its diminution of volume proceeds generally till it is reduced to about one-fourth, and then, if its substance be cut into, the bronchial tubes and vessels are so matted up in its condensed tissue as to present the appearance called carnified lung. (See Empyema.)

While the false membrane forms a general lining for the sac of the pleura, the orifice of the perforation is spared, and the communication between the bronchial tubes and this cavity preserved. The perforation becomes converted into a fistulous opening with a smooth round edge. This orifice has a tendency to increase in diameter, and often attains the size of the tubercular cavity which originated it, but it rarely passes the size of a shilling. We lately had an opportunity of examining three fistulæ which afforded exquisite examples of the state of those perforations when they attain to a chronic condition. Their surface extended nearly across the cavity whose bursting formed them, and was covered with a smooth membrane of a serous aspect similar to that forming the general empyematous sac. They had the appearance of a shallow *cul-de-sac* about a line in depth, and the largest of them had the diameter of a shilling. On examining a little closely, a probe passed under the circumferential rim of the apparent cul-de-sac into a bronchial tube which communicated with a larger cavity. The disposition of the fistulæ here described is very common, viz. the perforation formed by the remains of a very small tubercular cavity, and the latter connected with other larger cavities by means of bronchial tubes.

The closer anatomy of these fistulæ presents circumstances which are particularly worthy of attention. The bronchial tube by which communication is maintained between the orifice and larger cavity is almost invariably found to open upon the face of the fistula towards the sac in an oblique manner from above downwards. This disposition is noticed as occurring in some of the cases detailed by Dr. Duncan in the 28th number of the Edinburgh Medical and Surgical Journal, and we have witnessed it very strikingly displayed in cases which lasted for a certain period after the perforation. The effect of this is to convert the orifice of the opening into a valvular structure, and as it were to aid in the accomplishment of this object, the superior rim of the opening is sometimes observed to be prolonged downwards for a short space over it. The method by which this structure is produced it is difficult to explain, but the end which it is intended to accomplish appears more obvious: at least an attentive examination of it in a strongly marked instance satisfied our minds that it results from an attempt at obliteration of the fistula by a process of nature. On the smooth face of the opening in the case alluded to, there were five small depressions which appeared to be stopped-up bronchial tubes, and the fistula which remained at the upper part was far advanced in the valvular structure. It seemed to us that those tubes were obliterated whose smallness and direction afforded the greatest obstacle to the entrance of air, while that which remained pervious was of the largest size; but what we would particularly advert to as explaining its resisting the process of obliteration, is the nearly vertical direction which it had with regard to the lung. According to our view, this position favours remarkably the entrance of air in such a case, as it lies directly in the line of the action of the diaphragm, by the contraction of which, almost solely, the air is drawn into the cavity in pneumothorax. Another circumstance bearing on this subject which was noticed in the same dissection* should not be omitted. The lining of the bronchial tube which formed the fistulous communication, a track of about two inches, was quite changed from the character of mucous membrane; it was no longer pulpy and soft like the latter, but partook more of the serous character, and there were remarked all along it firm granulations of considerable size. The same change was observable in the large excavation from which the fistula led; its lining was more like the lining membrane of the heart than the usual soft membrane which forms the secreting surface of phthisical cavities. (See Phthisis.) These observations go some length in explaining the mechanism of these oblique fistulæ, and we think they furnish also an intelligible and just account of the object which they are intended by nature to subserve, which we are led to conclude is an attempt to obliterate the fistulous orifice.

The general membrane of the sac is a highly organized secreting surface, and appears to be peculiarly susceptible of inflammation and its

* This constant complication of pleuritic effusion with pneumothorax has given occasion to some to denominate it pleuro-pneumothorax.

* For an account of this dissection we refer to the May number of the Dublin Journal of Medical and Chemical Science.

onsequences. It must, indeed, be supposed
be in a continual state of chronic irritation,
om the presence of the atmospheric air to which
is constantly exposed. There are frequently
ound upon it more or less organized albumi-
ous concretions, the result of acute attacks of
nflammation. These exudations are either ge-
eral over the whole sac, or partial. They some-
mes surround the aperture in the lung so as
narrow it, and cases have been observed
here it has been closed altogether by them.
he latter event would be most likely to occur*
here the fistula is small and recent, or, on the
ther hand, where the valvular structure is far
dvanced. Another result of inflammatory
ction which it is not uncommon to find on the
ac, is the existence of small erosions with a
ark and irregular base and circumference,
hich resemble small gangrenous eschars more
an they do common ulceration. These ex-
ale generally a fetid odour which gives them
lso the character of spots of gangrene; and it
s a fact which is confirmed by experience, that
he sac is much more liable to gangrenous in-
lammation in empyema with pneumothorax
han in simple empyema. The erosions just
lescribed sometimes penetrate the sac and
leura, and at other times they are not so deep,
ut go no further than the thickness of the false
nembrane. Their existence cannot but sug-
est the idea that perforation may occur by the
lcerative process originating in the pleura,
nd being propagated to the lung and bronchial
ubes, as well as the contrary way, which we
re considering in this section. The occurrence
f pneumothorax originally in this way is,
owever, extremely rare; but we believe that,
hen it has already for some time existed, ad-
litional fistulæ are occasionally formed in this
ay.

The contents of the sac are in every case
ir and purulent matter. In the early stages
f the affection the latter fluid is the secretion
f the pleura itself, the effect of the acute
leuritis which follows the irruption of the
ir. When it has advanced to a more chronic
duration, the adventitious membrane thrown
ut by the pleuritis becomes itself the secre-
ing surface whence the fluid is derived. Its
haracters vary considerably, (see EMPYEMA, PLEURITIS,) and are influenced by the dura-
ion of the disease, vigour of the patient, and
other circumstances. For the most part it is
found to be a greyish turbid serum, through
which homogeneous pus is mixed, and having
n abundant stratum of soft albuminous coagula
at the bottom.

We have already marked the error which
prevailed long after the discovery of pneumo-
thorax, in supposing that the air was formed by
the putrefactive decomposition of the pus.
Such a decomposition of this fluid does not
take place, but, on the contrary, it is generally
remarked that it is inodorous, and free from
any evidence of such a process. It is true
that in some cases both air and fluid exhale a
fetid odour, but in these we must search for
other causes than the putrefaction of the fluid;
for if this happened in one instance, it should
happen in all, as the laws of chemistry do
not alter or suspend their action, which would
be implied by this hypothesis. In the in-
stances in which we have noted the contents
of the sac to be fetid, there was always a gan-
grenous state of the pleura to which the fetor
was evidently to be ascribed; and as we have
shewn that gangrenous ulcerations of the sac
are not uncommon in pneumothorax, we are
inclined to believe that they will be always
found where the putrid odour is exhaled by
the purulent matter.* The absence of the
chemical decomposition of the pus is a fact
which is now fully proved by experience; but
when we consider the conditions to which it
is subjected, it appears to be nothing won-
derful that the idea was so long entertained,
but rather remarkable that it does not invariably
happen. It is constantly exposed to a warm
temperature and to atmospheric air, which,
together with moisture, are the essential pro-
moters of the decomposition of organic com-
pounds. Yet we have witnessed a case where
these conditions existed for a year and a half,
in which the pus was quite free from odour,
and in all its qualities unchanged by the at-
mospheric contact. We are unable at present
to go any length in discussing the cause of
this curious circumstance, but we would ob-
serve that rest is a condition favouring chemi-
cal decomposition, which is absent in the pre-
sent case. Some have considered that it is
sufficiently explained by the fresh supply of
animalised fluid, which the surface of the sac
is supposed to maintain, by a continual secre-
tion and absorption. The blood, when effused
into the pleura, has been sometimes ob-
served to remain fluid. We are ignorant, as
we have said, of the explanation of these facts,
but they seem to prove that animal fluids have
some power of resisting the laws of chemistry
while preserved in contact with the living
solid.

The air enters the sac through the fistulous
opening during inspiration. When allowed to
escape by a puncture of the thorax, it generally
proves to be an inodorous gas, or possessed of
a slight sharpness, but, generally speaking, it
differs little from the atmospheric air whence it
was originally derived. The same gaseous
elements have been found to make up its che-
mical constitution, which has been examined
by Dr. John Davy† and Dr. Apjohn.‡ The
following was its composition in Dr. Apjohn's
analysis, which is the more recent of the
two.

* We are persuaded that this has been the state of things in many of the cases of pneumothorax on record, where it has been reported that examination failed to discover any fistulous communication.

* The fetidity which the bronchial mucus is often known to possess in phthisical patients may be another cause imparting bad odour to the contents of the sac in pneumothorax, as it has generally free access to it through the fistula.

Carbonic Acid..	8
Oxygen	10
Nitrogen	82
	100

This coincides nearly with the composition of expired air as deduced from the investigations of Allen and Pepys, and it is by no means improbable that the surface of the sac acts on it in a similar manner with the air-vesicles of the lungs. Such an action has been, indeed, proved to have existed in Dr. Davy's case, in which analyses of the air were made at different periods. By a comparison of the latter, an interesting fact was deducible. It was found that the quantity of carbonic acid increased as the strength of the patient decreased, and the air which was collected twelve hours after death contained a double proportion of this gas.

In the great majority of instances the air, although free to enter the cavity, is either partially or totally prevented egress during expiration, owing to the valvular disposition of the fistulæ which we have adverted to above. When expiration takes place, the air of the cavity, compressed by the contracting thorax, forces the sides of the fistula together, and thus closes it, exactly in the same manner as the valve of the bellows prevents the air from going out by the aperture through which it entered. The consequence of this is, that the air exerts a pressure within the sac which is always increasing as long as the communication remains open. This compression is fully sufficient to account for the reduced size and flattened appearance of the lung which has been described above, and for the dilatation of the intercostal spaces, which is equally a phenomenon of pneumothorax. It has been a debated point, what part the air, and how much the fluid, contributed to the production of this internal pressure. To us it seems evident that the compression must be nearly altogether attributed to the air, and that the purulent matter exerts pressure only as it is itself acted on by the elastic fluid. The force with which the latter escapes when a small puncture is made in the parietes of the thorax, even some hours after death, (when a diminution of the pressure certainly takes place,) is well known. A fact which occurred in Dublin illustrated in a decisive manner the pressure which the fluid receives from the air. Paracentesis was performed on a man who laboured under pneumothorax with empyema, and the puncture of the chest was made below the level of the fluid, the evacuation of which was considered the chief object. Immediately on the entrance of the canula, the matter was projected through it with surprising force and to a great distance. Its forcible exit continued until it was nearly all evacuated, diminishing, however, towards the end of its flowing. This projection of the matter was undoubtedly to be ascribed to the great compression under which the elastic fluid existed. With respect to the relative proportions of the air and fluid there is the greatest variety. In the majority of cases the space filled by the air is much greater than that which the fluid occupies. The nearest ratio might be set down as two-thirds air and one fluid. These proportions, however, vary not only in different cases, but also in the same at different periods. We are enabled often to ascertain that the fluid gains on the air, and sometimes, though seldomer, that the air increases at the expense of the fluid. In an interesting case detailed by Mr. Smeal,* the fistula became obliterated from the formation of a coagulum, and speedily afterwards it was observed that the air became absorbed, and the fluid pari passu increased. This fact proves the manner in which the proportion of the elastic fluid is preserved, and moreover shews the power which the adventitious membrane possesses of absorbing air, as Nysten's experiments had already done for the pleura.

History and diagnosis.—As the species of pneumothorax which we now describe is the consequence of phthisis, the history of an individual case, if it be investigated with due precaution and diligence, will almost universally demonstrate that cough, hemoptysis, emaciation, night-sweats, &c. (see Tubercular Phthisis,) have existed before the signs peculiar to pneumothorax betray its presence. It happens generally that phthisis has gone on to a very advanced stage ere this distressing complication is brought under the observation of the physician. This is, however, not entirely owing to its invariably occurring at a late period. Somewhat of it is attributable to the circumstance, that the means of its diagnosis have been hitherto scantily disseminated amongst the mass of practitioners, and to their not being used with sufficient confidence by those whose education has embraced them. Auscultation and percussion are now, indeed, daily becoming more practised and relied on, and as this advances it is accordingly found that many more cases are discovered, and moreover it is occasionally detected in the comparatively earlier stages of phthisis. From what has been related in the foregoing section as to its being known to result from very minute cavities, or even from a single tubercle, it follows that it is an accident which may occur in the earliest periods of the history of phthisis, even when the phenomena of the latter are so transiently marked as to be doubtful and to allow of fallacious hopes of recovery. This, which we should anticipate from acquaintance with its pathology, has been observed in actual practice; its supervention has been witnessed at the very commencement of phthisis as well as at its close, so that what experience teaches is, that while the later stages are more exposed to its occurrence, it may happen at the period at which only the faintest suspicion of phthisis has as yet existed.

The means for the diagnosis of pneumothorax are the rational symptoms and the physical signs. We shall consider these separately, comprehending under the latter the signs derived from succussion, percussion, and auscultation. In the first place it is to be remarked

* Med. Chir. Review, July 1831.

at at the first occurrence of the pneumothorax striking change takes place in the entire class f symptoms and physical signs. Before this vent there have been present, in a more or less erfect state, the phenomena of phthisis, but terwards those which we proceed to describe the characteristics of pneumothorax. This hange, then, we would call attention to as in self an important commencement of the chain f symptoms. The moment of this change is enerally perceptible to the patient himself, and hen this is the case, he dwells much upon it in is description to his physician. He sometimes els, in fact, the air passing into the pleura at ie moment of the rupture, as also the rupture self. This sign did not escape the observaon of our older physicians, although they were nacquainted with the pathological conditions hich gave rise to it. Morgagni recites a case which this sensation was accurately deribed as observed by Willis and Lower: Casum habes in sepulcreto descriptum adoscentis qui se Willisio ac Lowero curandum adidit. Is post immodicas equitationes, aliasue corporis diuturnas exercitationes eum liquandiu in sinistrâ thoracis parte eum sennm habuisset, qui esse sine internâ compresione non poterat, ibi tandem *sensit disrumpi uasi vas quoddum; indeque per scuithoræ spuium in regione istâ ab alto in pectoris fundum ulentis stillicidium non tantum ab eo percipi, d etium ab adstantibus audiri potuit.*"* This ensation has been, if possible, still more appotely depicted since the pathology of pneumonorax has been cleared up. We find the folowing description in Louis's forty-first case: La malade éprouva *tout-a-coup*, du côté gauche e la poitrine, une sensation pareille à celle qui ût été produite par un gaz qui aurait circulé le bas en haut dans toute cette partie du thorax."† This actual perception of the perforation y the patients is an element of the diagnosis hich it is so desirable to possess that the practitioner should never omit to inquire after it, et it is one which he must learn to dispense vith, as many cases occur in which no such ensation has been felt, while in others, in which certain period has elapsed, it escapes the paient's memory.

Empyema being invariably an accompaniment of this variety of pneumothorax, the symptoms of the latter are necessarily mixed up with those of the former. This circumstance lemonstrates the insufficiency of the rational ymptoms in detecting it, and partly accounts or the long ignorance which reigned on the ubject. We find the symptoms of empyema et down as dyspnœa and pain, cough and expectoration, decubitus on one side, dilatation of the side, displacement of the heart and depression of the diaphragm, hectic fever. These are found amply discussed as constituting the disease of empyema under its proper head. (See Empyema.) The same catalogue precisely makes up the rational symptoms in pneumothorax. It now devolves on us to consider them in this regard, and we shall find that accurate observation has been enabled to discover several peculiarities in them as belonging to pneumothorax, which render an account of them quite indispensable to its history, and give them some importance as auxiliaries in its diagnosis.

a. Dyspnœa and pain.—These symptoms are to be considered at two periods. First, as they exist immediately on the occurrence of pneumothorax, and secondly, as present during the whole of the remaining duration of the disease. The dyspnœa and pain which follow immediately on perforation are nearly simultaneous with the sensation which we have above described, but they are still more constantly present, and therefore of more value in its diagnosis. The researches of Louis* have called attention in a particular manner to these circumstances. He regards the sudden supervention of acute pain and overwhelming dyspnœa as a constant attendant on perforation of the lung, and as always indicating the period of its occurrence. They are, indeed, symptoms which are so rationally suggested by a knowledge of the new pathological conditions (viz. the sudden perforation of the lung, its collapse, and the effusion of air, &c. into the pleura) which ensue, that they might have been anticipated by *a priori* reasoning, " et à raison de la similitude qui existe entre les circonstances qui accompagnent la perforation de l'intestin grêle, et celle des poumons, on aurait encore pu, ce nous semble, les soupçonner par voie d'analogie."† Louis relates seven cases, in all of which they were present; and we know that in one of them at least they occurred in the presence of the medical men, who were enabled to pronounce on the supervention of pneumothorax from this single circumstance. Their value has been also confirmed by the reiterated observation of them in the experience of others since his publication. We are, then, to regard a sudden access of violent pain in the chest, and of greatly aggravated dyspnœa, as symptoms of the greatest weight, and wherever they supervene in the course of phthisis, the occurrence of pneumothorax should be suggested to the mind of the attendant physician, who should immediately have recourse to other and less fallible means of exploration. Louis observes that the pain, although generally very acute, yet admits of varieties of intensity, and that it is not always in proportion to the sudden breathlessness which the perforation induces; and we find that in one of his cases he notes that the pain was entirely absent.

But here we must not omit to state that instances are not wanting which prove that neither singly nor collectively can these signs be referred

* De Sed. et Causis Morborum, Epist. xvi.

† Recherches Anatomico-Pathologiques sur la Phthisie, p. 461. The sensation, as related in a case of Dr. Stokes's, strikingly resembled the description of Morgagni; the patient, " while in the act of coughing, had a sensation as of a sudden crack, extending from the shoulder downwards, and felt as if a quantity of liquid was shed out into the left side of the chest." Trans. of Assoc. Dublin College of Physicians, vol. v. p. 337.

* Op. citat. † Ibid. p. 476.

to as decisive tests of perforation. Dr. Townsend records a case of pneumothorax from this cause, the commencement of which was marked by neither violent pain nor sudden dyspnœa.* We have also had a case in which the most careful investigation of its history could not determine the period of perforation from the sudden supervention of these symptoms.† In estimating them, it is moreover to be remembered that the dyspnœa of phthisical patients is not uncommonly increased by other obscure causes; and, also, we should be on our guard against mistaking for such an occurrence pleuritic pains, which are so common in phthisis, and sometimes are of more than ordinary sharpness, without being by any means connected with perforation.

The dyspnœa which exists during the general duration of pneumothorax is deeper and more distressing than that of simple chronic empyema. This is, doubtless, partly occasioned by the coexisting sources of irritation of the pulmonary circulation which phthisical patients possess. A cause of equal efficacy and more uniform existence is found in the resistance which the elasticity of the air affords to the great pressure under which it exists in pneumothorax. This causes such a condensation of its volume before it produces the compressing effect of a liquid effusion, that even the greatest expansion of the thoracic parietes can but partially overcome its reaction, so that the dyspnœa resulting from their compression is but partially mitigated by the deepest inspiration. Such a condition is not present in simple empyema, as it is obvious, from the non-elastic nature of the fluid, that deep inspiratory efforts may expand the thorax beyond the limits of its compressing action, which therefore does not maintain a constant embarrassment of breathing, as it does not react (like the elastic fluid) on the immediate compression being temporarily withdrawn.

This appears to be the rationale of the aggravated character which the dyspnœa of pneumothorax possesses. The slightest exercise produces great oppression if the patient be able to walk, but ascending stairs causes particular distress. Even the motion of turning or raising himself in the bed leaves him often speechless from breathlessness for a short time. In the latter case we might conjecture that the fluid is in large proportion, as its mere weight has great influence on the breathing in changing the posture.‡ If the duration of the disease permits it to assume a chronic character, the dyspnœa rather diminishes than increases, although the internal compression shall not be mitigated. This is attributable to that surprising power of adaptation to circumstances which the animal economy enjoys, and which is possessed in an especial degree by the respiratory and circulatory organs. However, whatever fluctuation it may undergo during the course of the affection, as in all thoracic diseases, it becomes aggravated at its close.

The acute pain which ushers in its commencement generally subsides in a short time, and afterwards it runs its course without marked suffering from this cause. But more usually, if the patient lasts, he is subject to violent recurrences of pain which have been traced in some instances to recent inflammations of the sac, and also to the establishment of new fistulæ. These attacks of pain are in themselves additional sources of the dyspnœa; it follows, however, of course, that no secondary occurrence of inflammation, nor opening of new fistulæ, can produce the same degree of pain or overwhelming dyspnœa which ensues upon the original perforation.

b. Cough and expectoration.—These symptoms, which are more or less present in every pulmonary disease, form no essential accompaniment of pneumothorax. No case indeed is altogether free from them, but they are rather to be classed with the signs of phthisis which has preceded it, or with those of the pleuritis which accompanies it, than to be referred to the affection itself. On more than one occasion we have been enabled to mark their connection with bronchitis supervening in the opposite lung. Even a slight degree of cough is harassing to the patient, and in the rare cases where it remains frequent it causes extreme anguish. It is performed in a very laborious manner, in which an instinctive endeavour to refrain from agitating the contents of the thorax is perceptible to the medical observer. This gives to it a peculiar expression, so that we find sometimes set down, in accurately taken cases, "dry, husky, ringing," as the character of the pneumothorax cough. It has occurred to us, while observing it, that it resembled very closely the cough of a broken-winded horse. The distress which it occasions makes it important to attend to this symptom, and an acquaintance with its peculiar character may assist in distinguishing the affection. It is, however, sometimes nearly entirely absent. In a case of Dr. Stokes's, the dissection of which we attended, a complete cessation of both the cough and expectoration took place simultaneously with the occurrence of pneumothorax, but they returned with severity when tubercles in the other lung began to soften.

The expectoration is for the most part scanty, and possesses no peculiar characteristic, but in some rare cases it happens that the fluid contents of the pleural cavity make way through the bronchial communication. When this occurs, the evacuation of the matter is attended with terrible dyspnœa, threatening, when it is copious, sudden suffocation.

It is known that the patients who are ope-

* Trans. of Assoc. of Dublin College of Physicians, vol. v.

† Dublin Journal of Medical and Chemical Science, No. 3.

‡ This remark as to dyspnœa produced by sudden change of posture, is a valuable diagnostic of fluid effusions of any kind in the chest, particularly where these complicate pneumothorax. The description which Morgagni gives of it in what was anciently called convulsive asthma, must be appropriated to such cases, and particularly to that which we treat of. "*Statim anheli fiebant, ac velut moribundi respirabant*, cum retrorsum caput moverent, aut supini," &c. De Sed. et Causis Morb. Epist. xv.

ed on for empyema sometimes acquire a wer of assisting the expulsion of the matter ich collects posterior to the operation, through wound of the side, by forcible expiratory orts and coughing. We mention this to no- e the case of a porter at the Meath hospital, ected with pneumothorax and empyema con- quent on perforation by a tubercular abscess. is man possessed an analogous power of *ex- lling at will* the fluid of the cavity through e fistula in the lung. He was accustomed to ert this whenever it accumulated to a certain antity, by leaning over the bedside so as to vert the thorax, and thus decant it through e mouth, aiding its escape by some efforts of ughing. Another singular circumstance worth ticing was remarked in Dr. Stokes's case just ferred to. When the irritation of the oppo- e lung caused a return of the expectoration, e patient was sometimes unable to raise it out the trachea, but was sensible of losing com- and over it when it ascended as far as the top the sternum. In fact he felt convinced that used to drop down the bronchus leading by e fistula to the pneumothorax cavity.

c. Decubitus.—If the fluid contents of the eural cavity be very small in quantity, the tient may recline indifferently upon either de or upon the back; but in the majority of curately observed cases he has been found to in preference on the affected side. This is e conclusion that our inquiries have led us ; but different statements are found in an- iors on this subject. It is stated by Schmalz* d other writers that the decubitus is invari- ly on the sound side in pneumothorax, and at this affords a striking mark of distinction etween it and empyema. We cannot help specting that this opinion has been originally ther conceived from theory than deduced om observation, and we the more readily ake this remark from observing the occasion nd the manner in which Dr. Duncan† an- ounces it. "The change of decubitus," says e, describing a case, "*is exactly the reverse f what it ought to have been,* for in empyema ne patients commonly lie on the affected, and pneumothorax on the sound side." The easoning, too, with which this has been ad- anced‡ is only applicable to the infinitely rare ase of simple pneumothorax, and not to that vhich results from perforation, for this is always ccompanied by empyema. It is true that in mpyema the dyspnœa is caused by the pres- ure of fluid alone, and it is chiefly for the urpose of relieving the mediastinum and pposite lung of its weight and pressure that ecubitus takes place on the affected side. (See Empyema.) But in pneumothorax the ompression of the internal organs is as com- plete, if not more so, although caused by air, nd if the *weight* of even an inconsiderable quantity of fluid should be added to them lready suffering under this great compression, it will be an object with the patient instinctively to obviate this by lying on the affected side. As far as our experience goes, this position has been, *cæteris paribus*, always preferred. However, it not unfrequently happens that the violence of the pleuritic pain forces the patients to turn to the sound side in spite of the increased oppression which the change induces. We have witnessed a case in which the struggle between the pain augmented by lying on the affected side, and dyspnœa aggravated by changing to the opposite, was extremely distressing; but here the want of breathing triumphed over the pain, and compelled the poor patient to endure the latter as the lesser evil. When the intensity of the pain has passed, if a change has taken place during its continuance, decubitus on the affected side is usually resumed.

d. Dilatation of the side.—On a comparison of the two sides of the thorax, it is observed that the side in which the pneumothorax exists is faintly or not at all elevated during inspiration, and on being measured it is generally found to be larger than the opposite. These differences may be observed at a very early period after the perforation, but for the most part they are greatest at the advanced periods of the affection. The average amount of the dilatation is from one to two inches, as in empyema. The enlargement of the intercostal spaces and their occasional protrusion beyond the level of the ribs are also observable in both, so that, from the mere contemplation of the phenomena of dilatation, there exists no distinctive mark between them. It is said, however, that where they are very conspicuous in pneumothorax, the side is more what the French denominate "bombé" than in empyema. The œdema of the integuments of the side which sometimes attends the latter is not observed, although Louis and others have remarked an œdematous state of the corresponding arm.*

Many instances of pneumothorax are on record in which no difference whatsoever existed in the dimensions of the two sides of the chest. It may be observed that in cases where the air can pass out during expiration from the non-existence or imperfect formation of the valvular arrangement of the fistula before described, the chief source of dilatation, namely, the accumulating pressure of the air, is absent. This valvular structure has not been hitherto much attended to; it has, however, been remarked that in some of the cases where there was no dilatation, the fistulous orifice was very large, rendering it probable that egress from the cavity as well as ingress remained unobstructed. But it must be acknowledged that this sug-

* Versuch einer Medizinisch-Chirurgischen Diagnostik. Dresden und Leipsig, 1825, p. 99.

† Edin. Med. and Sur. Journal, No. 28, p. 327.

‡ See Med. Chir. Review, July 1830, p. 455.

* It appears, from Morgagni, that this œdema of the arm has been frequently noted by the older physicians in pneumothorax. "Verum præterquam quod brachium alterum, quod dolebat, œdemate habebat tumidum (qualem tumorem in thoracis hydrope Fantonus pater, et Buchnerus, aliique, et in his Valsalva noster interdum adnotarunt) *cum ad thoracis motum diceret fluctuationem in eo sentire,*" &c. Morgagni de Sed. et Causis Morb. Epist. xvi. s. 36.

gestion is by no means sufficient to explain the absence of dilatation of the side in many well authenticated cases, in which the air was proved to have been subjected to very great pressure, evidenced by displacement of the thoracic viscera and other phenomena.*

We had an opportunity of demonstrating that the dilatation of the side varies considerably, and that it may even give place to contraction. At an interval of six months between two measurements of a case, it was found that the pneumothorax side (measuring from the centre of the sternum to the spine of the vertebræ), from being one inch wider, had become half an inch narrower than the other. And further, on measuring five months afterwards, it was found to have returned to its former dilated dimensions. We believed that we were enabled to connect this temporary decrease of dilatation with a partial closure of the fistulous communication, and an attempt at cure, as happens when empyema is removed by absorption. The progress of the case, however, (during which other fistulæ formed,) and its termination, did not allow us to confirm this anticipation; but notwithstanding this, the nearly total departure of the tintement coinciding with the contraction and other phenomena left little doubt that such was really the case.†

Schmalz says,‡ "If both sides be engaged, the chest exhibits nearly a cylindrical form." Of the recurrence of double pneumothorax the only two cases recorded that we know of are those in Laennec's work. In the first of these, observed by M. Recamier, the chest is described as "vaste, bombé," terms which have probably suggested the description of Schmalz. Notwithstanding the extreme rarity of both sides being involved, it may not be useless to retain in memory this symptom of general dilatation, as in such a case many of the other signs must be of no avail, inasmuch as they require the contrast which is afforded by the opposite side remaining sound, and it is of the greatest importance to be able to recognize this terrible affection at once, in order to attempt the relief of the dyspnœa by performing paracentesis, the only means which art suggests to prevent speedy suffocation.

c. Displacement of heart and depression of diaphragm.—It appears that less compression is requisite to effect these conditions than to produce dilatation of the side, for the latter has been absent in cases where the heart has been thrust considerably out of its place, and a sensible fulness produced in the corresponding hypochondrium by the depression of the diaphragm. It is here a proper place to remark the singular fact that perforation of the lung and its consequences, in the great majority of cases happens on the left side. Seven of eight cases, which occurred to Louis, were on this side, and we believe that in the cases which have come to our knowledge nearly an equal preponderance existed. So great a disproportion must have been in some degree accidental, for in eight cases described by Laennec, the number on each side was equal. However this may be, it is certain that it occurs oftener on the left, and this circumstance makes displacement of the heart a very common and striking feature in pneumothorax. In cases of extreme displacement, the heart's action is both felt and seen beyond the cartilages of the opposite side, but the average extent is not further than the opposite half of the sternum, or below the ensiform cartilage; for it is found to move downwards as well as laterally when the displacement occurs from left to right. When the pneumothorax exists in the right side, the heart's displacement, for obvious reasons, will be less, but the depression of the diaphragm will be more easily perceived from the protrusion of the liver which follows it. This prominent state of the liver is as truly an effect of depression of the right side of the diaphragm by an aëriform collection as by an empyema; and, as in the latter, it might at first view lead the observer to conclude that the oppression of the respiratory organs was connected with a visible hepatic enlargement. This has been adverted to in the article Empyema; but in a paper on the diagnosis of the latter* by Dr. Stokes, since published, there are some additional signs furnished, which contribute much to the elucidation of this point of diagnosis. We shall notice here but one of these, which is as applicable in pneumothorax as it is in empyema. It has, moreover, a peculiar propriety in the former, as it is a palpable sign, and addresses the eye at the first examination; because we apprehend that the effects of pneumothorax and enlargement of the liver could be confounded only where a defective exploration had at first produced an erroneous impression, unless the air be very small in quantity and the fluid copious, in which case the difficulties connected with empyema recur. Dr. Stokes, however, has observed, that where the diaphragm, depressed and rendered convex downwards by the contents of the pleural sac, causes the descent of the liver, there is a sulcus evident to the sight and touch in the right hypochondrium. This is produced by the two convex surfaces of the diaphragm and liver, respectively terminated anteriorly by the edge of the latter and by the

* See Dr. Duncan's tenth case, Edin. Med. and Sur. Journal, No. 28.; Dr. Stokes's case, Trans. Assoc. Dublin College of Physicians, vol. v.; and five of Louis's cases, marked "Etat extérieur, rien de remarquable," which amounts to evidence of no dilatation, for this exact observer has noted it particularly in the cases where it was present. In Dr. Duncan's case a method of opening the thorax was practised by Dr. Cullen, which is worth relating. Instead of penetrating the sac at once, which is usually done, he dissected back the ribs and intercostals for a considerable space, so as to expose the external surface of the pleura, which rose up distended and elastic. This way is somewhat more troublesome, but it is very advantageous for estimating and displaying the pressure which the air exerts.

† Dublin Journal of Med. Science, No. 3 and 8.

erior margin of the false ribs. It is manifest
t such a sulcus cannot be present in the
re enlargement of the liver, let it take place
any extent, as it requires the opposed con-
xity of the diaphragm for its formation, and
s condition is only produced by a liquid or
seous effusion.

f. Fever.—Whatever has been the condition
the circulation before the escape of the air
perforation, the fever of pleuritis sets in
eedily after this event takes place. Its cha-
ter is necessarily modified by the previous
te of the patient's system, but it always con-
res to aggravate his sufferings. Much, in-
ed, of the dreadful distress which ensues is
be ascribed to the increased febrile action
hich occurs almost simultaneously with the
cident. This will be conceived when it is re-
llected that while one of the lungs is by rapid
mpression nearly deprived of its function of
spiration, the excitement of the heart's action
creases the demand for aeration, so that this
mbination of circumstances often produces a
gree of dyspnœa under which the patient
pidly expires. Such an effect of the fever is
t more likely to occur in debilitated indivi-
uals than in those of robuster stamina; for in
e former, although the constitution be more
hausted, this seems fully counterbalanced as
gards the effects in question, by the dimi-
shed quantity of blood which circulates in
e system of emaciated phthisical patients.

If the immediate consequences be not fatal,
e fever subsides into the same type which
isted before perforation occurred. This is
e hectic of phthisis, in which the pulse seldom
nks below 110, and is exacerbated in daily
roxysms. We are, however, led to believe,
at if the opposite lung be not already the seat
tubercular deposition, or even if this be not
an advanced or progressive state, the phthi-
cal hectic which attended the disease of the
ng that has suffered perforation, is diminished
the supervention of pneumothorax. We
ve witnessed one case and heard of another
which the hectic pulse and night sweats
uld be traced to have actually ceased from
is period. In both instances, it is true, the
ssation was but temporary, but we had une-
uivocal evidence that their return was cotem-
oraneous with the occurrence of disease in
e opposite lung.

The foregoing is a detailed account of what
re called the *rational* symptoms. Their study
s of great importance in understanding the
isease, and it must be acknowledged that
everal amongst them are valuable diagnostic
igns. We proceed now to describe the *physical*
igns. It would be a needless task, at the
resent day, to use much earnestness in in-
isting on the importance of these in the explo-
ation of any thoracic disease, for it is fully
ecognized. We must remark, however, with
espect to pneumothorax, that just in proportion
s the practitioner has attained to a masterly
acility in their application, will he be enabled
o decide with certainty as to its presence or
bsence. The very existence of this affection
n nosology is so intimately connected with its physical signs, that until these were discovered it lay still unnoticed, and correct notions on the subject advanced as they were developed and improved. Hippocrates laid the foundation for its future diagnosis by the practice of succussion, and had he pushed its application a little further, he must himself have arrived at its real signification, as it appears, from some of his remarks on its use, that he was partially aware of some of the conditions necessary for its production. Corvisart and Bayle, masters of percussion, had glimpses of its nature, and remarked its existence in the dead body. Laennec, whose merit in this instance was as great in perfecting and applying the other two signs as in adding his own famous discovery, was the first who detected it on the living body. He brought its diagnosis to perfection by assigning to the physical signs their value separately and in combination; and if any additional light be thrown on its history or symptoms since his time, even this must be ascribed almost wholly to the greater facility and confidence with which it is now recognized by the employment of these means. These considerations are sufficient to shew the great importance which attaches to these physical signs in pneumothorax: upon them, in fact, rests its diagnosis, and he who is skilled in their application may truly pronounce upon this affection, which has remained for so many ages of medicine in obscurity, in as positive a manner (as Andral speaks of these principles applied to thoracic diseases in general) as the surgeon can "of the least complicated dislocation, or the simplest fracture."*

a. Succussion.—Whenever air and fluid exist together in the sac of the pleura, if the trunk be shaken abruptly, the splash of the liquid against the walls of the thorax is often distinctly heard by the patient, or by any one who places their ear on or near the chest. There is no stronger evidence of pneumothorax than this sound, for it is only produced where both air and fluid are present; if either be absent, no splashing sound is heard.

In the writings of Hippocrates this method of exploration was taught as a means of ascertaining the existence of purulent matter in the pleura. Distinct directions are enjoined as to the manner of performing the succussion, and even observations added from which it is apparent that the author could estimate by this means the quantity of pus contained in the pleura: "Among the patients affected with empyema, those who produce most sound, when shaken by the shoulder, have less pus in the chest than those who yield less sound, and who are more flushed and breathless: in respect of those who do not yield any sound, but who have the nails livid and a great dyspnœa, they are full of pus, and their case is desperate." These remarks contain much truth, and implying as they do considerable acquaintance with the phenomena, it is a most remarkable circumstance that they did not conduct their author, or his admiring commen-

* Clinique Médicale, Avantpropos, p. 6, tome ii.

tators for so many ages afterwards, to the knowledge of the real condition which they indicate. Laennec points out the reason why, while such close approximations as that quoted from Hippocrates appeared as it were to leave only another step to unfold the truth, they remained as far removed from it as ever until a very late period. It consisted in a fundamental error as to the natural state of the lungs and pleura. The early notions were a mass of confusion on this subject, but for the most part it was conceived that a vacuum existed in the thorax. This absurd hypothesis precluded the necessity for the presence of air to cause the sound of fluctuation, and being handed down from age to age prevented the truth from reaching the mind even of such men as Morgagni. It is obviously inferrible, from the quotation which Laennec makes from the latter, that this great pathologist believed that the fluid of an empyema was poured out into an empty space in the pleura, which, after a certain quantity of effusion, became filled. In the quotation which we now insert, this opinion is not left to inference, but alleged in the most explicit terms, and even adduced as the only way of explaining the sound of the fluid in a case of pneumothorax. Referring to the "stillicidium cadentis humoris," which we formerly quoted from him, Morgagni says, "Res non ita facilis explicatu iis *qui inter pulmones, et thoracis parietes negant spatii quidquam intercedere; vera tamen, ut postmodum comprobavit humoris, in eo latere congesti, cum fluctuatio in agitatione corporis ab ipso, ab aliisque evidentissime percepta*," &c.* On such an hypothesis the sound of fluctuation should have been heard in every case of empyema, instead of being, as we now know it to be, confined solely to the case where this is combined with pneumothorax. It is very probable, then, that its abandonment is to be attributed to its having failed to detect simple empyema, which it could never have done. It is moreover certain, from the description, that the cases designated by Hippocrates as "full of pus," and which Morgagni would have embraced under those "qui ad summum pervenerunt," were cases of simple empyema, and it shews that, although these great physicians were prevented from seeing its true cause by a false hypothesis, they observed with accuracy and fidelity; as in such cases no sound of fluctuation is heard, the "*space being filled up*," as Morgagni said.

Thus this invaluable diagnostic fell into neglect; there is no evidence of its having been used after the time of the Aselepiades; and even the commentators appear to have esteemed it as useless, and to have alluded to it, as Laennec remarks, merely out of respect to Hippocrates. It was not revived till the true causes which produce it became fully explained, but since that period it has been ranked as one of the most infallible signs by which any internal disease can be recognized.

The Hippocratic method is still generally used in the employment of succussion. While the physician places his ear to the side of the thorax, an assistant shakes the patient smartly by the shoulders, and thus the dashing of the fluid is heard. It frequently happens that the patient is the first to call attention to it by mentioning that as often as he turns over in the bed he is sensible of this sound himself. It is felt by him on descending a stair, or, as we have known, when he makes a forward step with greater quickness than usual. Besides the little confidence which Morgagni placed in it as an indication, he objected to the Hippocratic method that many patients would not suffer willingly the concussion of the trunk. While this remark cannot have the effect which he intended, yet it is worthy of attention. Laennec denies that it is attended with any inconvenience, but in the cases in which we have seen it employed, a very considerable commotion was caused to the patient before the fluid could be heard. An intelligent man, who was under our care for a very long period, was accustomed to produce the fluctuation himself by making a jerking rotation of the trunk on the spinal column. He was enabled to produce the sound with much facility, and greatly preferred doing so himself in this manner to being succussed in the ordinary way by the hands of another. We can conceive that in certain cases such a method would be as impracticable as the former; we leave them both, therefore, at the option of the practitioner, who will of course choose that which causes least disturbance to the patient.

This fluctuation might be also produced by an enormous phthisical abscess half full of matter and air; but such a cavity as would be sufficient to give rise to it is scarcely ever met with, having occurred but once in the large experience of Laennec. There is also a possibility of being deceived as to the source of the fluctuation, if the stomach contain much flatus, and the patient has recently taken drink. The other physical signs will easily preclude the latter error; but its infinite rarity alone seems to be the only protection from the former.

b. Percussion and auscultation.—Laennec has demonstrated, from a review of the knowledge which Avenbrugger, Corvisart, and Bayle possessed on this subject, that percussion alone was insufficient for the diagnosis of pneumothorax. When the side affected is percussed, an unnaturally clear or tympanitic sound is returned, and if this coincide with dilatation of the same side, the evidence for pneumothorax is very strong. From these data Bayle was enabled to recognize it in the dead body in two or three cases; and doubtless, if its pathology had been understood in his time, he would have detected it from the same evidence on the living. But even in the hands of the most experienced master of percussion these signs might lead to a deep fallacy, for it might be thought that the clear-sounding side was in a healthy condition while the other was the seat of either pulmonary engorgement or a pleuritic effusion, which produced the comparatively dull sound; and as to the dilatation of the

* (Prænot. Coac. ii. 432.) Forbes's translation of Laennec, p. 507.

side, it is liable, when considered only in connection with percussion, to lead to the same error; that is, the dilated side might be mistaken for the sound, and the latter regarded as in the state of contraction which results from chronic pleurisy (see PLEURITIS); and again, the converse of this error is also possible, in which the contracted side should be mistaken for the sound side, and the latter considered as dilated and too resonant. That these difficulties of diagnosis from these means are not imaginary our own experience has convinced us as well as the warnings of Laennec;* they are, however, quite removed by adding to percussion the results of auscultation. On applying the stethoscope to the pneumothorax side, it is found that the respiration is as completely absent as if it was an empyema; but percussion has already proved that, instead of the perfectly dull sound, which a collection of liquid in the chest causes, we have now a preternatural clearness of sound, which two conditions, viz. nullity of respiration and clear sound on percussion, never co-exist except in the case of air in the cavity of the thorax.

Although we have indicated the percussion sound of pneumothorax to be exceedingly clear and tympanitic, occasional deviations to a certain extent from this general rule are met with. It will be recollected that when pneumothorax takes place, the expansion of the air-vesicles of the opposite lung becomes much increased from having to perform the compensatory respiration, and consequently the clearness on percussion of this side is simultaneously increased. This is one cause why the *contrast* on percussion is not so striking as might be anticipated, and it suggests how much more valuable this sign would be were it possible for us to contrast the sound of the *same side* before and after the period when pneumothorax was supposed to occur. Another circumstance which occasionally prevents the drum-like resonance peculiar to this affection from being produced, is the existence of partial adhesions, which sometimes retain the lung in spots still in contact with the costal pleura. In the points corresponding to these the sound on percussion will still be dull, while the clearness will be perceptible in the intervening spaces. It is also to be remarked that, although we have laid down nullity of respiration as the rule, this is seldom absolute. Close attention will almost invariably discover a feeble bronchial sound at the root of the lung along the spinal column, which may sometimes lead the observer to imagine that he hears the puerile respiration of the opposite lung conveyed across the spine. But besides this, if there be any points of adhesion, they may cause a faint murmur to be heard. These adhesions may exist at any part of the lung, but as we have in a preceding part shewn that they are very common at the summit, so we are not unfrequently enabled to discover, immediately under the clavicle or in the supra-spinal region of the scapula, the sound of respiration generally of a cavernous character, and mixed with a single bubble of gargouillement. These latter signs may be considered as marking the remains of a cavity (see TUBERCULAR PHTHISIS), and this is sometimes confirmed by the co-existence of an obscure pectoriloquy.

The fluid which is contained in the cavity is recognized by these signs with the same facility as the air. By the absence of respiration we learn that the lung is now displaced by either fluid or air. This being established by auscultation, the results of percussion enable us to appreciate the space in the thorax which is occupied by the liquid and gaseous fluid respectively. As percussion is performed from above downwards, the tympanitic resonance is perceived to give place at a certain level to a total dulness of sound, and where this change abruptly occurs is the line of demarcation between the air and fluid. By marking from time to time the situation of this line, it is manifest that we can ascertain whether the proportion of the air and fluid remains stationary, or if either of them increase at the expense of the other. Finally, it may be instructive to examine their relations under changes of posture, to observe how the liquid obeys the law of gravity, and the tympanitic sound shifts as the air moves to occupy the space vacated by the heavier fluid. Such investigations furnish data from which an acute observer may form a conjecture as to the existence of adhesions, the size of the cavity, and even the amount of the compression sustained by the viscera; upon which points it may be of the highest importance to obtain any additional light, particularly if the idea of paracentesis be entertained.

The signs of pneumothorax derived from auscultation and percussion, so far described, are almost purely of a negative character; but even were the diagnosis necessarily confined to them, there is but one disease for which it could possibly be mistaken; this is emphysema of the lung, or dilatation of the air-cells, many of the characters of which are, however, so clearly distinguished from it, that it could only be confounded with it by a very inattentive examination. They resemble each other in the clear resonance which percussion gives out, and also in the negative results of auscultation. But the respiration is never totally absent in emphysema of the lung, as in pneumothorax; it is only much weakened, and is moreover accompanied by its peculiar râle, which strikingly opposes them. The history and general phenomena are quite distinct; the emphysema is always a chronic malady, and the patient is able to go about; although complaining much of difficulty of breathing, it is more because it interferes with his occupations than from the deadly anguish which overwhelms the patient in most cases of pneumothorax. If these considerations be not sufficiently convincing, the presence of pneumothorax (from perforation at least) may be decisively determined by succussion and the metallic tinkling.

The inventive genius of Laennec was not

* Forbes's Translation, p. 497.

content with these negative results of auscultation. Apparently not long after he had laid the foundation of its diagnosis in these, his perseverance was enabled to add to them a positive sign, the *tintement metallique*. This is a metallic tinkling or ringing sound, heard in the pneumothorax cavity at intervals. It is discerned equally well by the naked ear or by means of the stethoscope, but to examine it accurately and to mark its limits, the latter instrument must be employed. It is so accurately represented by the dropping of a pin into a large wine-glass, or touching gently a sonorous porcelain vase with a quill, that it may be recognized without the observer having previously heard it; by keeping this comparison in mind, having been once heard, it is always remembered.

The metallic tinkling is audible during coughing, speaking, and sometimes during respiration, or it might be more correct to say after these actions. Besides this, it is often heard independently of these, observing a certain periodicity, and finer in its tone. That the finer tone which we have just alluded to is the echo caused by the occasional fall of a single drop of fluid from the summit of the cavity on the surface of the liquid, we only require to imitate it by letting fall into a large wide-mouthed bottle, one-third full of water, one drop of any liquid, to be fully convinced. This variety of the tinkling is explained in this manner by Laennec, who has also proved demonstratively that the sort which results from speaking, coughing, and inspiration, is produced by the air entering through a fistula into the pneumothorax cavity. He did not announce more particularly its proximate cause, and where this master did not speak it might become us to be silent. We may state, however, without presumption, that we never had any hesitation in explaining this variety of the tintement on the same principles as the other. It appears to us to be manifestly the echo of the air forced into the cavity reverberating against its hollow parietes, and that the sound is more particularly caused by the bursting of minute air-bubbles at the orifice of the fistula, formed as the air traverses the latter, by its entanglement with mucus. It is more clearly audible in proportion as the cavity is empty of fluid; but its distinctness and loudness are chiefly dependent on the size of the fistulous communication. We have been enabled to follow the gradual narrowing of the latter by the diminution of the tinkling in one remarkable case. It became so minute that it was by the greatest stretch of attention scarcely perceptible on respiration, and at length became inaudible, but it still persisted on speaking and coughing. At an after period the whole train of symptoms became exacerbated, and the tinkling was again manifest on respiration; and by degrees, as the malady grew worse, it increased to a louder and graver pitch than ever. This is indeed the ordinary change which it undergoes; in most cases the fistulous orifice rapidly enlarging in size, the tintement is heard more and more plainly on respiration, and at length it becomes so deepened in tone as to assume quite a different character.

To the metallic tinkling altered thus by the deepening of its sound, the name of *bourdonnement amphorique** has been given. It is so called because it exactly resembles the sound produced by blowing into a decanter or large bottle. When this sound becomes evident, it is a sure indication that the fistula is growing larger, and consequently that the case is more hopeless.

In exploring for the metallic tinkling, there is a source of fallacy which the physician should be aware of. When the stomach is flatulent, it lies high under the false ribs, and if in this state the patient has lately taken drink, the tinkling may be produced in the stomach, and lead the observer to think he hears it in the chest. On the other hand an incident occurred to the writer of this article, which shews that this source of deception may be held too strongly in view. In examining a case which at first view he had imagined was empyema, the tinkling was evidently perceived; but finding the epigastrium tympanitic, it was disregarded, from the conception that it was produced in the stomach. On the second or third examination the sound was again heard, and now recognized to be the true metallic tinkling.

The only other conditions besides pneumothorax which can give rise to this sign, is the existence of a vast phthisical abscess, such as also produces the sound of fluctuation. Laennec relates its occurrence in a phthisical abscess of such a size that the whole lung was nearly involved in it; but such instances are so infinitely rare that they will never embarrass the diagnosis.

The production of the metallic tinkling in a phthisical cavity, we would remark, is a circumstance quite inconsistent with the views on the subject which Mr. Guthrie has lately published. This gentleman states that Laennec and all who hold with him that it "depends entirely on the passage of air through a hole in the lung into the cavity of the thorax," were mistaken; and in opposition to this he maintains that for its production the air of the cavity must necessarily be compressed. "I do not," says Mr. Guthrie,† "deny the facts of the air, the hole in the lung, or the fluid; but I believe that, to produce the sound of the Jew's harp (the metallic tinkling), the air in the cavity must be greatly compressed, and that it essentially depends upon it." That this latter opinion is un-

* We would gladly use English words, but cannot devise any that would justly anglicise the above; we have, therefore, thought it better to leave the expression which the discoverer applied. Nothing can be better than metallic tinkling, but it appears to us that "utricular buzzing," which is used in the valuable translation of Dr. Forbes, although a correct synonym, is scarcely less foreign than the original.

† London Med. and Surg. Journ. for Jan. 12, 1833, p. 747.

founded, its occurrence in large tubercular cavities, which has been observed by most who are much conversant with phthisical auscultation, sufficiently proves. In such the air can suffer no compression. It is besides well known to exist after the operation for empyema; and we have never heard it more audible than in a case of pneumothorax caused by the bursting of an anthrax of the intercostal spaces into the pleura, in which the external fistula remained open.

We have now concluded the account of the diagnosis, but as we have been necessarily diffuse on some of the points, we think it may not be superfluous here to recapitulate, so as to give at a glance the principal diagnostic signs. By subjoining to each a word of valuation, the reader will be able to calculate the amount of evidence implied by the presence of any one of them.

1. The sensation of something giving way in the chest, and of air entering the pleural cavity.—Very valuable, but often absent or unnoticed.
2. In a phthisical individual the sudden supervention of overwhelming dyspnœa and pain.—Rarely absent, therefore very valuable; still more so if succeeding last sign.
3. Comparison of auscultation and percussion. Nullity of respiration over one side, together with tympanitic clearness of sound, which below terminates abruptly in complete dulness.—If accurately established, amounting to positive certainty, but sometimes not easy to establish. Ægophony rare.
4. Fluctuation on succussion.—Positive certainty, but should be unquestionably verified.
5. Metallic tinkling.—Positive certainty, but should be unquestionably verified.

Prognosis and treatment.—On casting our regards back on the pathology of this affection, we cannot be astonished at any thing which experience can teach us, as to the rapidity and certainty with which it is followed by a fatal result. When we consider the prognosis of phthisis, and add to this the aggravating circumstances of perforation and acute inflammation of the pleura, together with the simultaneous privation of the function of one lung, the consequences will appear to be so inevitable and immediate, that our review of its pathology and symptoms may seem to be a dissertation on a nice point of morbid anatomy and diagnosis, or only useful so far as an acquaintance with it may prevent the physician from being taken by surprise by the supervention of its fearful indications in a case of phthisis. And, indeed, if all knowledge were useless that did not immediately lead to practical benefit, this would be in a measure true; for it must be confessed that at present it does little more than unfold to us how soon we may expect a period to be put to the patient's sufferings. The result of Laennec's experience of it is more fairly drawn from the statement which he makes for the purpose of contrasting it with emphysema of the lungs, than where he specially speaks of its prognosis. "The effusion of air," he says, "comes on suddenly, and cannot exist for any length of time without giving rise to severe symptoms, and even death. I have never seen pneumothorax in any person who was not confined to bed."* Louis only speaks of the result with a view of calculating the time which elapses between the period of perforation and death.† Dr. Stokes relates his case, which lasted five months, as the longest at that time on record;‡ and in upwards of twenty cases witnessed by Dr. Townsend, none, we believe, lasted so long a period. In Louis's seven cases the fatal termination took place at intervals of from sixteen hours to thirty-six days after the perforation occurred; and this author adds, "it is difficult to give an account of the circumstances which produce this difference, and it is in vain to seek for the explanation in the greater or less strength of the patients at the time that the accident took place."§

The only question, then, which the prognosis admits of is, whether recovery in pneumothorax from perforation by tubercle is barely possible. Laennec, arguing from his observation of the cicatrisation of tubercular cavities, is of opinion that it must not be regarded as impossible even in the severest cases. This opinion is shared by some others, but it is to be regretted that the few facts which are produced in its favour are drawn from the older writers, who were ignorant of its production in this manner. Some of them were evidently, at first, cases of empyema, which, by opening into the lung, gave rise to the pneumothorax: and we believe that most pathologists consider even the case related by Laennec, in which the pneumothorax existed for six years, was of this nature. But the progress of a case detailed in the third number of the Dublin Journal of Medical and Chemical Science (which has been more than once adverted to in this article) has induced us to believe that this case of Laennec and some others may probably have resulted from tubercular perforation, and to adopt his opinion as to the possibility of recovery. In this case the individual lived a year and a half after the establishment of the fistula, during which period the dilated side became contracted, but ultimately resumed its former dilatation. The patient's general health and strength became so much improved as to permit him to work as a bricklayer for some months of this period, but this labour exhausted him very much. His own imprudent perseverance in working under exposure produced an attack of severe and general pleuropneumony in the opposite side, which his extraordinary vigour enabled him to outlive, but he ultimately sank under the effects of repeated acute inflammation of the other lung as well as of the pneumothorax sac. The other medical men who saw it with the author agreed with him in thinking that this case might have lasted for a very long time; in fact that the

* Forbes's Trans. p. 499.
† Recherches sur la Phthisie, p. 487.
‡ Trans. Association, &c.
§ *Louis*, op. cit.

contraction of the side, the improvement of health, and the disappearance of the tintement metallique indicated a spontaneous attempt at cure which was counteracted by the reckless neglect of proper caution on the part of the patient. The contemplation of this case, with some observations suggested by it, has, as we have said, induced us to admit the possibility of recovery, which, however, we by no means wish to inculcate in a positive manner: before this can be done by any one a more enlarged experience must be possessed, and the observer who is desirous of deciding the question by facts, has to set out with the melancholy knowledge that not one case proved by auscultation to have been of this nature is on record in which ultimate recovery took place.*

The resources of the healing art, it will be anticipated, can contribute little of a positive nature, if anything, to promote a cure in this calamitous affection. Yet, as in all such extremities the aid of the medical man will be eagerly sought, he should be prepared to do something, although he may regard it as ultimately certain to triumph over human efforts. Few cases will present themselves where some symptoms which aggravate the patient's sufferings may not be removed or alleviated by appropriate means. Proud science may draw back from what seems to be beyond her realm, but the physician has higher instincts to obey and duties to perform here as in other hopeless diseases, in attempting even the mitigation of the pain and anguish which science informs him he cannot altogether remove; and this reflection may be added, that where such motives actuate him to exertion, he is seldom left entirely without means, and never without the satisfaction which obedience to them brings.

We would consider, then, whether any thing can be done to allay the urgency of the symptoms by which the patient is so usually oppressed immediately on the occurrence of this species of pneumothorax; the dreadful dyspnœa, sinking, and pain. We find on this subject no assistance from books, for as the affection itself has been but recently clearly understood, its detection at this early period has been extremely rare; and this, we think, should suggest to all practitioners having the care of phthisical individuals, the utility of keeping in mind their liability to this event, in order to be able to afford assistance with promptitude should it occur. The indications for practice appear to be sufficiently clear. If it has supervened in the last stage of phthisis, when the patient is much emaciated, and already nearly spent by hectic, the treatment must be little energetic. Leeches should be applied in small number to the part where the pleuritic pain is most acute. Afterwards a fomentation of strong decoction of poppy heads, or an anodyne poultice should be used, and in twelve hours another application of leeches might be had recourse to with advantage. The exhibition of a strong narcotic internally will also tend to relieve the dyspnœa as well as the pain, for this class of medicines has the power of diminishing the sensation of want of respiration as well as of lulling the general sensibility of the brain. The use of anodynes may have probably been habitual with the patient before this occurrence, and in this case the usual dose should be increased. We need not specify the particular preparation, but may mention that the "acetum opii" and the "black drop" are often preferred by phthisical patients, and that it is prudent to vary by times from one preparation to another, by which means narcotics do not lose their effect so soon, when the dose is not augmented. If the individual be yet in the very early stages before the perforation, then it would appear to be a very rational proceeding to bleed him copiously, and to treat him with an especial regard to the pleuritis, which speedily ensues. A large bleeding seems to be a very proper measure in such a case for the purpose of diminishing the mass of blood in the circulation; by this means the opposite lung will be less oppressed by the additional influx which takes place from the compressed side;* and this might be confidently expected to alleviate the aggravated dyspnœa of which the latter condition is a principal cause. The leeches can be used here in large number, and the anodyne will follow the bleeding with great propriety, co-operating to the same effect. An assiduous application of these remedies, and watching their effects, might do much to relieve the urgency of these symptoms, which, if they be not by some means arrested, grow hourly worse.

But cases will occur where these means will be insufficient to prevent the dyspnœa from in-

* For our opinion, as above stated, we have not adduced arguments where facts are wanting; but a consideration which weighed with us much, suggested by the above case, may be mentioned here. If the first effects of the perforation be outlived, (which is rare,) it does not appear that a worse condition exists in pneumothorax than in empyema, *provided the opposite lung remains free from tubercles.* It may be objected that there remains the tubercular state of the compressed lung. It is true; but we believe that the conditions which make tubercles so fatally progressive in the lung are absent in the latter; we allude to its constant motion and its great supply of blood. The motion and consequent friction which the action of respiration constantly maintains around a tubercle, appear to us to be a principal cause of the irritation which it produces, and consequently of the increase of its own bulk. Developed in organs whose function does not submit them to motion or friction, their progress is incomparably slower than in the lung. Moreover, the great quantity of blood which circulates in this organ, probably contributes to its rapid progression. We would now observe, that in the lung compressed by pneumothorax the influence of these causes is absent, as it lies against the spine in a state of nearly perfect quiescence, and of comparative anæmia. We would remark, also, that in the above case the hectic sweats ceased almost entirely from the time of the perforation, and we refer to its dissection for some particulars of the compressed lung.

* We find this argument used by Andral in recommending copious bleedings in the case of pleuritic effusion. "Lorsque l'epanchement existe, on doit encore avoir recours hardiment aux saignées, dans le double but de s'opposer aux progrès ulterieurs de l'inflammation, et de diminuer la quantité du sang, qui dans un temps donné doit traverser le poumon comprimé." Clin. Méd. t. ii. p. 582.

creasing to such a pitch as to threaten imminent suffocation, and then the operation of paracentesis is the only resource by which a longer space may be added to the life of the patient. The escape of the air effected by this means is almost always followed by great relief of the symptoms, abatement of the dyspnœa, and lowering of the pulse. This is only temporary. After a period, which is seldom long, although different in each case, the patient sinks, being only saved from suffocation to die of the consequences of the operation. It is, however, justified in such extreme cases by the prolongation of life which it effects, and the alleviation of that most distressing of all suffering which results from extreme dyspnœa.

In such a case, where the only question is whether life shall be allowed to be extinguished, the medical man has no alternative to balance; but if the urgent dyspnœa and pleuritic symptoms have already passed over without destroying the patient, and the case has attained a certain degree of chronicity, is paracentesis advisable? This question is at once set at rest if the existence of tubercles be proved in the other lung, as in such a case not a shadow of hope could be entertained of its success. Since Monro and Hewson advised the operation, it has been occasionally advocated without discriminating between the varieties of pneumothorax; but although the latter of these writers made a sharp conjecture on the subject, it is evident that neither of them had any adequate notions as to that species of which we treat. The chief, if not the only authority by which its performance in pneumothorax from such an internal cause can be supported, is a passage in Riolan, and the case in which Monro advised it. On referring to the former it is impossible to form an idea of what species of it his observations include; but it is very plain that he speaks only of the present relief which paracentesis procured, and not of the ultimate consequences. The following are his words: "Interdum flatus tam violenter distendit pulmones, ut præfocationem adferat, ni succurratur aperto thorace per ipsam paracentesim, quod sæpius factitatum *Parisiis*, magno ægrorum emolumento, et thoracis levatione, etiamsi aquæ nullæ effluxerunt, sed flatus cum violentiâ displosus."* Monro's case, in which the operation was successful, is recorded with considerable accuracy; and we think that any one conversant with those matters, who examines it, will at once deny that it belongs to this class: it seemed, in fact, very probable that the air escaped into the chest by the rupture of some of these distended subpleural vesicles, which are not uncommon in emphysema of the lung, under which apparently the patient laboured for many years.† Universal experience of its failure, as well as the great weight of authority, is against the operation; for no case has recovered after it, of this variety of pneumothorax, since it has been possible to recognise it by auscultation. Its failure appears to have for its cause the readiness to take on a bad inflammation, which the false membrane and pleura possess in this species, in consequence of which it is very common to find a gangrenous state of these membranes occurring after the wound, propagated originally from its edges. Notwithstanding its not having succeeded hitherto, there is still a decided leaning to perform the operation whenever a case occurs. This in some measure is caused by the fact, that the old ideas which connected fluctuation and simple empyema are not yet perfectly exploded, and partly from the too generally applied notion, "melius est anceps experiri quam nullum,"—an adage which is sometimes erroneous, and founded on a forgetfulness of the part which nature takes in the removal of morbid action. The writer confesses it to be his own opinion that the possibility of cure which he has above professed to believe in, lies not in the appliances of art, but in the operations of nature.*

This terminates the subject of pneumothorax from perforation of the lung by a tubercular abscess. We have purposely devoted the bulk of this article to the consideration of this one species for the convenience of arrangement, as well as because it is incomparably more frequent than the whole of the other varieties. To have discussed the latter separately would have involved us in a mass of tedious repetitions; and it seems certain that he who is acquainted with the species which we have chosen for its description, can be at no loss fully to comprehend its pathology and diagnosis, should he meet with it arising from other sources; or at least we trust that the foregoing account of it will place him in such a position that he will be enabled to investigate them for himself. In conclusion, we shall now briefly mention the other methods by which authors have described it to arise.

Pneumothorax from gaseous secretion of the pleura.—The pleura, according to Laennec, in very rare cases takes on the secretion of air like the other serous membranes. This may take place singly, or the elastic fluid may accompany an aqueous or puriform effusion. This variety has not been decidedly established by the observation of other pathologists since the time of Laennec, and we record its existence merely on his authority, and on that of Andral, who relates a case of it, in which, however, this origin was not unquestionably proved.†

Pneumothorax from the opening of an empyema into the lung.—The bursting of an empyema into the lung is not a very unfrequent occurrence; and yet this is an extremely rare source of pneumothorax. When it takes its origin in this way, the empyema has generally been circumscribed. This variety of pneumo-

* Riolan, Encheiridion Anatomicum. Lib. iii. cap. 2. (Med. Obs. & Enq. p. 394.)

† See Halliday on Emphysema, p. 49.

* If ever the perfecting of diagnosis shall arrive at distinguishing the cases where pneumothorax is caused by the bursting of a single tubercle, or of a small mass, we conceive that in such a case the operation may be yet practised with success.

† Clinique Méd. t. ii. p. 512.

thorax is that in which the operation is fairly entertained (see Empyema); and we believe that the cases which recovered after it, where it was proved by the fluctuation to have existed, must be referred to it. We allude to the remarkable cases of Dr. Archer* and Dr. Hawthorne,† &c.

Pneumothorax from gangrenous perforation, and from rupture of the pleura in emphysema of the lung.—The first of these cases has been occasionally remarked, but the latter is extremely rare. Monro's case of successful operation was, as we have before stated, very probably of this nature. In it the rupture took place during a fit of coughing, and it was succeeded by general emphysema of the cellular tissue as well as pneumothorax. Laennec thought that he observed its origin from this cause in one case.

Pneumothorax from lesions of the thoracic parietes.—We should mention under this head, 1st, that consequent on penetrating wounds and lacerations of the lung by fractured ribs, called hitherto by surgeons emphysema thoracis. Dr. Hennen remarks that the fears which exist as to its arising from these causes are greatly exaggerated, as it is in fact a very rare occurrence in military surgery.‡ 2nd. Where it is consequent on the opening of an anthrax or abscess through the intercostal spaces. Of the former we witnessed an interesting case in the Meath Hospital, in which all the phenomena were remarkably perfect. To the latter belongs the singular case described by Dr. Duncan, in which a diffuse abscess spread from the arm to the chest, and penetrated the costal pleura and lung, upon which a circumscribed pneumothorax formed, communicating with the external abscess, and producing elastic tumours on the side.§ 3rd. The species which succeeds to the evacuation of the purulent matter after the operation of empyema. This is an invariable consequence, but we believe that its prejudicial effects are too much insisted upon, as patients sometimes live many years with a fistulous opening in the side, and enjoy a tolerable state of health. The case of longest duration which we are aware of is that related by Dr. Otto, in which the individual daily discharged a small quantity of purulent matter through the aperture formed by the operation for seventeen years, and was enabled for nearly that period to take part in social life.‖

PREGNANCY AND DELIVERY, SIGNS OF.—Few questions in legal medicine, whether considered in a merely professional point of view, or in reference to their relations with criminal or civil law, impose on the medical examiner a more delicate duty, or a more trying responsibility, than the determination of the existence or absence of pregnancy; placed before him, as the question generally is, under circumstances by which all its natural difficulties are increased an hundred fold. It usually happens in such cases that he cannot rely on a single statement made by the individual who may be the subject of examination; but, on the contrary, he must be prepared for every species of falsehood and misrepresentation. And yet on the correctness of his opinion frequently depend the claim to fair fame, virtue, and honour;—the succession to property, and the rights of legitimacy;—the judicious treatment of disease;—and, in criminal cases, the preservation or destruction of the unborn innocent.

The instances which present themselves are unfortunately but too frequent, in which the unmarried female, either yielding to the influence of passion, or made the reluctant victim of the unprincipled seducer, and becoming pregnant, an investigation as to her real state is sought for, in the hope of inducing marriage, or perhaps for the purpose of influencing a jury in the assessment of damages.

An attempt may be made to *conceal* pregnancy by the unmarried, or even by the married under certain circumstances; as in the case of a wife's separation from her husband or his casual absence, in order to avoid disgrace in society, or to enable her with impunity to destroy her offspring. On the other hand, pregnancy may be *feigned* in order to gratify the wishes of a husband or relatives, to extort money, to compel marriage, to deprive the lawful heir of his just rights of succession, or to delay the execution of the sentence of death.

By the law of this country, a woman condemned to death may plead pregnancy in bar of execution, and medical men are appointed to determine the question whether the culprit is really with child or not; and if she is, whether she be *quick with child*, for pregnancy alone will not save her. This rule, we may observe in passing, is one of the most monstrous and barbarous features of our penal code.* Infinitely superior both in morals and in mercy is the law of France, which ordains that if a woman be pregnant at all, she shall not be executed until after her delivery; and

* Pregnant women have always been objects of much regard and reverence. The Roman laws allowed them the same privilege as those of France. The ancients even spared the life of the murderer who took refuge under the roof of a woman with child. The kings of Persia used to present two pieces of gold to each pregnant woman. The Jews, who observed so rigorously the Mosaic law, allowed them the use of forbidden meats, lest the child might suffer from their longings.

formerly the privilege allowed under such circumstances was even greater: in 1795 a law was passed which ordained that no woman accused of a capital crime should be *brought to trial* until it was properly ascertained *that she was not pregnant*,* and in conformity with this, several decisions were reversed where it appeared that the female had not been properly examined; and in more than one instance the sentence of death was annulled, because after the trial it was discovered that the woman was pregnant at the time of being put upon her trial.†

Connected with such investigations, some very melancholy mistakes have occurred, by which the lives of unborn infants have been sacrificed. Riolan relates the history of a woman named Genevieve Supplice, who, after being hanged for robbery, was publicly dissected by him at the school of medicine, and was found pregnant of a child of five months, contrary to the opinion of the surgeons and midwives who had examined her.‡ Mauriceau also mentions having seen at Paris in 1666 a miserable example of this kind in a woman who was hanged and afterwards publicly dissected: she was found to be pregnant four months, notwithstanding the report of the persons who had visited and examined her by order of the judge before her execution, and pronounced that she was not pregnant, being deceived by the fact of her continuing to menstruate. This matter caused a great sensation of disgust and horror, and was reported to the king and his court, and in consequence a severe censure was passed on the persons who, by their ignorance, had caused the untimely execution of the unfortunate woman, with whom had perished also her infant, innocent of its mother's crime.§

A proceeding may also take place at common law, "where a widow is suspected to feign herself with child in order to produce a supposititious heir to the estate, and defraud the lawful heir. In such case the heir presumptive may have a writ *de ventre inspiciendo*, to examine if she be with child or not, and if she be, to keep her under proper restraint until she is delivered. But if the widow be, upon due examination, found not pregnant, the presumptive heir shall be admitted to the inheritance, though liable to lose it again on the birth of a child within forty weeks from the death of the husband."‖

A celebrated case of this kind, which attracted great attention, occurred in the family of Sir Francis Willoughby, who died seized of a large inheritance. He left five daughters, (one of whom was married to Percival Willoughby,) but not any son. His widow at the time of his death stated that she was with child by him. This declaration was evidently one of great moment to the daughters, since if a son should be born, all the five sisters would thereby lose the inheritance descended to them. Percival Willoughby prayed for a writ *de ventre inspiciendo*, to have the widow examined, and the sheriff of London was accordingly directed to have her examined. He returned that she was twenty weeks gone with child, and that within twenty weeks *fuit paritura*. "Whereupon another writ issued out of the Common Pleas, commanding the sheriff safely to keep her in such an house, and that the door should be well guarded; and that every day he should cause her to be viewed by some of the women named in the writ, (wherein ten were named,) and when she should be delivered, that some of them should be with her to view her birth, whether it be male or female, to the intent there should not be any falsity. And upon this writ the sheriff returned, that accordingly he had caused her to be so kept, and that on such a day she was delivered of a daughter."*

There is another case where the court has interfered on proof of the existence of pregnancy being brought before it, and that is, where a female in this situation is imprisoned. Thus in the case of Elizabeth Slymbridge,† "upon suggestion that she had been imprisoned for divers weeks and was with child, and would be in danger of death if she should not be enlarged," Sir Edward Coke, the Chief Justice, admitted her to bail to prevent the peril of death to her and her infant, and in giving his opinion he quotes a similar case which happened in the 40th of Edward III. The editor remarks that these cases are cited as extraordinary instances. The last case is mentioned in Coke upon Littleton, 289 *a*. The record states, "Quia eadem Elena pregnans fuit, et in periculo mortis, ipsa dimittitur per manucaptionem ad habendum corpus," &c.

When proceeding to an investigation of this kind, we must recollect that the signs or proofs of pregnancy are to be collected from various and very different sources, and, moreover, that of some of them we can have no evidence except from the report made to us, while of others we can judge by the changes existing before us, and cognizable by our senses. The following are the chief of these signs:—

1. Certain affections of the constitution induced by pregnancy, which are the result of the new action which has commenced in the uterus; such as suppression of the menses, generally increased irritability of the nervous system, evinced in capriciousness of temper, or perhaps in the production of erratic pains, as in the face and teeth, greater activity in the circulating system, and especially in the exhalents, giving rise to œdema and other forms of

dropsical effusions; alterations in the countenance from absorption of the fat, &c.

2. In consequence of the irritation induced in the uterus, there are a train of sympathies excited in other organs, affecting either their physical constitution or their peculiar functions: such, for instance, are the changes produced in the breasts by which their size is increased, with tingling pains, the areola formed, and milk secreted; the stomach is irritable; vomiting ensues; the appetite becomes variable and capricious, and sometimes the salivary apparatus participates so decidedly in the irritation that complete salivation takes place.

3. The altered condition of the uterus itself, which, increasing in size, ceases to be a pelvic organ, and rises into the abdomen, which in consequence becomes enlarged and prominent, and a corresponding change is effected in the state of the umbilicus; while at the same time certain alterations take place in the os and cervix uteri, affecting their form, texture, &c. which we can recognize by touch.

4. The contents of the uterus so enlarged; the presence of a fœtus therein, and its motions, which we endeavour to ascertain by manual examination, both *externally* through the abdominal parietes, and *internally* per vaginam; and also by the adoption of auscultation to discover the pulsations of the fœtal heart and the placentary sound.

5. Certain organized substances may, under suspicious circumstances, be discharged from the uterus, by a proper examination of which we may be enabled to determine whether they are the product of conception, and of course proofs of pregnancy.

6. After death we may be called on to make an investigation for a like purpose, and, by examination of the uterus and its appendages, to determine the question of actual pregnancy, or of previous impregnation. We shall notice the principal of these signs in detail.

Suppression of the menses.—This is one of the symptoms of pregnancy our investigation of which must almost always be encumbered with this difficulty,—that our knowledge must be derived from the statement of the female herself, nor can we have in general any certain means of disproving or confirming her assertion. It is moreover a circumstance which, notwithstanding its general subjection to a fixed law, has been fully proved by experience to be liable to very many exceptions and deviations.

We are indeed quite justified in adopting as a general rule that in healthy women, whose menstruation has been established and continued regular, and who are not nursing, conception is followed by a suppression of the menstrual discharge at the next return of its period; but then this suppression may not so occur, and on the other hand it may happen from a variety of other causes altogether unconnected with pregnancy: for these reasons we ought, whenever we come to consider this sign, to weigh very fully all the possible circumstances of the individual case before us, and view it in relation to the various exceptions which experience has from time to time shewn to exist. Thus we must recollect that cases have occurred in which conception took place previous to menstruation. One instance of this happened under our own observation, and a very remarkable one is mentioned by Morgagni in these words: "I was acquainted with a maiden of a noble family who married before menstruation took place, though the menses had been expected for some years; nevertheless she became exceedingly fruitful. We were the less surprised at this circumstance because the same thing had happened to her mother."* Frank had a patient who gave birth to three children without ever having menstruated or had lochial discharge, and he saw three others who never had the catamenia, but were not deficient in lochia after delivery.† A woman, 55 years of age, very lately resided in Cornwall, who had borne several children and always enjoyed good health, but had never menstruated or had vicarious discharge of any kind.‡ Capuron quotes several cases of fecundity without menstruation,§ and Foderé assures us of the fact.‖

Some women are very irregular in the returns of their menstrual periods, having them prolonged much beyond the usual interval. The writer lately attended an unmarried woman of 40 affected with polypus uteri, who assured him that the returns of the catamenial discharge with her had been frequently deferred for more than six months without any accompanying circumstance of ill health: instances of habitual suppression for shorter periods are frequently met with. Zacchias mentions that he attended a patient who used to menstruate regularly, but who never conceived until the discharge had been suppressed for three or four months previously. A case somewhat similar is related by Mauriceau,¶ who very justly remarks that such cases not unfrequently give rise to the supposition of protracted gestation.

At the period which is usually denominated *the change of life*, it is very usual to have the menses suppressed for two or three months and then return profusely, giving rise to the idea of pregnancy and abortion, both suppositions being equally unfounded.

On the other hand cases occasionally occur in which women have conceived after menstruation had apparently ceased.

In married women, and others who have

‖ "J'ai eu occasion de m'assurer complétement de ce fait." tom. i. p. 395.

¶ Observation 556, tom. ii. p. 461.

been incurring the risk of pregnancy, suppression may arise from a variety of causes altogether independent of conception, such as different forms of disease, exposure to cold and hardship, mental emotions, particularly that of fear, the effects of which latter we have had an opportunity of observing in very numerous instances in some of our prisons, where young women constantly apply to the physician in consequence of their menses being suppressed, which they very often, and apparently with great reason, ascribe to the alarm and terror which they suffered when arrested and carried to prison.

A woman may conceive while she is nursing, without any previous return of the catamenia, which, however, very usually happens in such cases, as observed by Denman.

Here, then, we have a variety of cases in which the absence of the menstrual discharge could not be made a means of diagnosis, or, if assumed as affirmative of pregnancy, would lead us into absolute error.

It now remains to view the matter in another light, and inquire how far the presence of the catamenia can be considered as evidence that the woman is not with child.

We have met with several instances of menstruation occurring *once* after conception, and at this moment we are in attendance on two ladies to both of whom it happened; and one of them, who has borne three children and is now a fourth time pregnant, assured us that she always knew when she had become with child by the unusual profuseness of the next period. This is distinctly taken notice of by Johnson, who says, "some have the menstrua copiously at the first period."* A diminution in the quantity under similar circumstances has, however, been more frequently observed. "I have seen," says Desormeaux, "some cases in which the appearance of the menses in small quantity and at an unusual time, was almost a certain sign of conception."† A similar remark is made by Puzos, Stein, and Gardien.‡ An interesting case, which confirms this remark, is detailed by Dr. Dewees.§ A gentleman, who had been obliged to absent himself from his family for many months, returned secretly and spent one night at home with his wife, in consequence of which she conceived, as the event proved, although the regular return of her catamenia a week afterwards, in their usual quantity, had led her to expect that she had escaped with impunity.

Again, there are individuals who menstruate with regularity *for more than one period* after conception. "It is well known," says Burton,‖ "by experience, that the menstrual discharge sometimes continues in its usual regularity for two or three months after conception without any dangerous consequences." Instances of this are not at all unfrequent, and are quoted by all who have written at large upon this subject.* It has been asserted as an objection, that these discharges are not truly menstruation; but the discussion of that question does not concern us here. We have only to consider whether there does not frequently, during pregnancy, take place a coloured discharge from the vagina, so closely resembling menstruation in its periods, quantity, and duration, that neither the woman herself nor the medical inquirer shall be able to detect any difference between them; and of this we must declare with Dewees and Gooch, "there can be no doubt."

In still more rare instances, of which we have ourselves never met one, but which are recorded by writers of credit, women have continued to have these discharges through nearly the whole period of pregnancy.† Dewees mentions an instance in which this happened to both mother and daughter,‡ who were in the habit of menstruating up to the seventh month. "On a vu," says Gardien, "chez des femmes jeunes et plethoriques l'evacuation menstruelle continuer pendant les trois ou quatre premiers mois, quelquefois même pendant tout le cours de la grossesse."§

The last, and perhaps most remarkable exceptions to the general rule, to which it appears necessary to allude, are those very singular cases in which menstruation has either appeared for the first time after conception, or in which it continued only during pregnancy. Perfect's eightieth case‖ affords a very satisfactory instance of the former; and Daventer, Dewees, and Baudelocque¶ furnish us with examples of women whose habit it was to menstruate *only* during pregnancy, and who did so through the whole period of that condition, though never at any other time.

There is a source of deception against which we can hardly guard, and which we know to have been resorted to by a young woman in one instance. She apprehended that she was pregnant, but deceived those about her by staining her linen at the usual periods of menstruation: this completely lulled the suspicion of her friends for two months, but in the third a circumstance was discovered which proved that she had incurred the risk of pregnancy, and the writer was requested to see her. On looking at her breasts the areolæ were so

distinct, and exhibited their proper characters so perfectly, that he felt persuaded she was pregnant; and perceiving that her breasts were marked with the silvery lines observable on parts formerly much distended, he told her his opinion that she was then with child, and moreover that she certainly had been so before. This completely took her by surprise, and she acknowledged that she had given birth to a child about two years before, and had suffered much from the distension of her breasts during pregnancy. The event also proved that we were correct in supposing her pregnant then, as she was afterwards in proper time delivered of a full-grown child.

Belloc, p. 65, takes notice of this kind of imposition, which he informs us was attempted on himself by a girl three months advanced. "Il faut alors exiger que les parties soient lavées avec de l'eau tiède; si le sang ne reparait pas, le cas est suspect."*

We should not forget that there are cases occasionally met with, in which suspicions arise in connexion with a non-appearance of the menses, the elimination of the discharge being prevented by some adventitious structure or imperforate state of some of the natural parts, especially of the hymen. In such a case the secretion takes place, but being prevented from leaving the body, accumulates within, distending the vagina and the uterus, and so giving rise to several of the sympathies usually accompanying pregnancy. We had very lately an instance of this under our care in a girl of 17, who between the age of 15 and 16 began to exhibit the signs of puberty. When we saw her, suspicions had been excited of her being pregnant. The abdomen was enlarged, and the uterus could be felt as high as the umbilicus, the breasts were painful, and she had occasional vomiting, and pain in the back and along the thighs. Complete inability to pass water was the cause of our being requested to see her, and on hearing the above detail of symptoms we confess we had our suspicions too, but did not express them: on attempting to pass the catheter we encountered a soft elastic tumour protruding from the external parts, displacing the urethra, and concealing its orifice. This rendered a closer examination necessary, which detected the hymen attached completely all around, and distended by fluid from within: having relieved the bladder, we punctured the opposing membrane and gave exit to about three pints of a dark chocolate-coloured fluid, without smell and uncoagulated.

Frank† mentions two such cases, in one of which the abdomen was as much enlarged as at the sixth month of pregnancy, and the girl herself thought that she felt a foreign body in the uterus, which, however, was found to contain five pounds of a dark and thick blood, without any offensive odour: in the other case the girl was believed to be with child, and in consequence suffered temporary loss of reputation, but the hymen was found imperforate, and, when punctured, gave passage to several pints of blood.

Madame Boivin‡ has collected the details of ten such cases, among which are two much in point. In one from Denman the girl was submitted to examination from a belief that she was with child; the uterus was as high as the navel, and contained no less than four pounds of blood of the colour and consistence of tar.† The other case occurred to Dr. Macaulay, in a young woman of 19, whom he supposed to be not only pregnant, but in labour, as she had pains, and he felt what he thought was "the membranes with the water pushing low down."‡ On puncturing the hymen there came away two quarts of thick black blood. In a case of obstruction related by Dr. Dewees, he mentions that he was fully impressed with the belief that pregnancy existed, as he could distinctly feel the enlarged uterus, and even thought he felt the motion of a fœtus.§

Such exceptions should always be taken into account to guard us against error, but on the other hand absence of the menstrual discharge in an otherwise healthy woman is always a circumstance of great importance, concerning which the remark of Belloc is deserving of great attention. "When a female," says he, "experiences suppression along with other symptoms of pregnancy, we may consider her situation as yet uncertain, because these signs are common to amenorrhœa and pregnancy. But if towards the third month, while the suppression continues, she recovers her health, and if her appetite and colour return, we need no better proof of pregnancy. Under other circumstances her health would remain impaired, and even become worse."‖

Nausea and vomiting.—In general, when pregnancy has occurred, the stomach becomes irritable, in consequence of which the woman is distressed with nausea and vomiting, especially in the early part of the day: in some this commences almost immediately after conception. We had once a lady under our care, in whom there was reason to believe it began the day after marriage, and the date of her labour corresponded to such a belief: most frequently it occurs for the first time between two and three weeks after conception, in others not for as many months, and in some not at all: of this we have now seen several instances.

On the other hand, irritability of the stomach may occur from a variety of causes totally independent of pregnancy, and connected with disease or disordered function, such as suppressed menstruation, so that we must be slow to draw an inference merely from the presence of such a symptom: at the same time a proper degree of inquiry will generally enable us to distinguish between the two kinds. The vomiting of

‖ Cours de Méd. Légale, p. 60.

pregnancy is not accompanied by any other symptom of ill health; on the contrary, the patient feels perhaps as well as ever in other respects, and may even take her meals with as much appetite and relish as at other times, but while doing so, or immediately after, she feels suddenly sick, and has hardly time to retire when she rejects the whole contents of the stomach, and presently feels quite well again: in some instances, however, the woman is distressed by a perpetual nausea, and in a few rare cases vomiting has been so excessive as to endanger the life of the woman from inanition.*

Salivation.—By an extension of the sympathetic irritation which in the stomach causes nausea and vomiting, the salivary apparatus is in some persons excited to such a degree as to produce complete and copious salivation. This fact was expressly noticed by Hippocrates as one among the symptoms of pregnancy,† and has been observed by many others since.‡ Dr. Dewees records a well-marked instance of the kind,§ and the writer of this article was consulted about another in which it occurred profusely in two successive pregnancies, but ceased immediately on delivery.

Affections of the mammæ.—When conception has taken place, and the menses have been suppressed for one or two periods, the woman generally becomes sensible of an alteration in the state of the breasts, in which she feels an uneasy sensation of throbbing, or of stretching fulness accompanied by tingling pains felt about the centre of them and in the nipple. The breasts themselves grow sensibly larger and more firm; a circle around the nipple becomes altered in colour and structure, constituting the areola; and as gestation advances, milk is secreted. But there is considerable variety in the period of gestation at which these changes may occur, as well as in the degree of their development; for while in some instances they may be recognized very soon after conception, in others they are hardly perceptible until gestation is far advanced, or even drawing towards its termination. In general, however, we may expect to find these sympathies (except the secretion of milk) established when two months of pregnancy have been completed; but any opinion deduced from their existence must be modified by several considerations. We must recollect that these changes of form and size may be the result of causes unconnected with conception. In many women the breasts enlarge merely in consequence of marriage and the habits thence arising; in others it may happen from the person becoming fat; it may be caused by accidental suppression of the menses, or their retention by an imperforate hymen,‖ or by any cause capable of distending the uterus. The enlargement from pregnancy may, however, in general be distinguished from that produced merely by fat, by the greater firmness of the breast, which also feels knotty and uneven when pressed by the hand. With some women of an irritable habit, swelling and pain of the breasts accompany each return of the catamenia, especially if they are the subjects of dysmenorrhœa; but under such circumstances the tension and uneasiness subside in two or three days, whereas that caused by pregnancy continues to increase, except when the ovum happens to be blighted, in which case the breasts become flaccid, and lose the characters which they had previously assumed. On the other hand it not unfrequently happens that in women of weakly and delicate constitution very little change can be observed in the breasts till pregnancy is far advanced. Gardien* asserts that the swelling of the breasts is not observable in women who menstruate during the early months of pregnancy; and Mahon† makes the same observation. It should also be recollected that such a condition of fulness of the breasts may be natural to the individual, or it may take place at the turn of life, when the menses becoming naturally suppressed, the person grows at the same time fatter, and the breasts under such circumstances become full, and are not unfrequently painful,—which circumstances concurring are often improperly considered in the light of cause and effect, and irritability of the stomach being at the same time experienced, the woman believes herself pregnant. There is, however, one of those changes which, if carefully observed, is of the utmost value as an evidence of pregnancy, which, according to our experience, can alone produce it,—we allude to the altered condition of the areola.

The areola.—The alteration which takes place in that part of the breast which immediately surrounds the nipple, and is called the areola, appears to us not to have received that degree of notice which its importance merits, as being one of the most certain external indications of pregnancy, arising from the operation of sympathy. On this, however, as on almost all other points connected with this investigation, a very marked difference of opinion exists; for while some suppose, with Denman, that the alteration in the areola "may be produced by any cause capable of giving to the breasts a state resembling that which they are in at the time of pregnancy," many others of equal authority maintain the opinion of Smellie and William Hunter, who regarded it as the result of pregnancy only; an opinion in which we entirely concur, and think we shall be able to shew that much of the discrepancy of opinion on this subject has arisen from want of sufficient care in observing and accuracy in describing the essential characters of the true areola.

Most of those who have noticed this change

† Médecine Légale, tom. i. p. 151.

appear, from their observations on it, to have attended to one only of its characters,—namely, its colour, which is, in our opinion, the one of all others most liable to uncertainty. We should here perhaps except the description by Rœderer, which is by far the most accurate we have met with: "Menstruorum suppressionem mammarum tumor insequitur; quocirca mammæ crescunt, replentur, dolent interdum, indurescunt: venæ earum cœruleo colore conspicuæ redduntur, *crassescit papilla, inflata videtur, color ejusdem fit obscurior, simili colore distinguitur discus ambiens qui in latitudinem majorem expanditur, parvisque eminentiis, quasi totidem papillulis, tegitur.**

The several circumstances here enumerated at least ought in all cases to form distinct subjects of consideration, when we propose to avail ourselves of the condition of this part as an indication of the existence or absence of pregnancy. One other we shall add as equally constant, which is a soft and moist state of the integument, which, together with its altered colour, gives us the idea of a part in which there is going forward a greater degree of vital action than is in operation around it; and we not unfrequently find that the little glandular follicles are bedewed with a secretion sufficient to damp and colour the woman's inner dress. We must recollect also that these changes do not take place immediately after conception, but occur in different persons after uncertain intervals: we must therefore consider, in the first place, the period of pregnancy at which we may expect to gain any useful information from the condition of the areola.

We cannot speak very positively as to what may be the earliest period at which this change can be observed, but we have certainly been satisfied of its existence at the end of the second month, at which period the change of colour is by no means the most distinct character to be observed, but the turgescence of the nipple and the development of the little glandular follicles are the objects which should principally engage our attention; the colour at this period being in general little more than a deeper shade of rose or flesh colour slightly tinged with a yellowish or brownish hue. During the progress of the next two months the changes in the areola are in general perfected or nearly so, and it then presents the following characters: a circle around the nipple, whose colour varies in intensity according to the peculiar complexion of the individual, being generally much darker in persons with black hair, dark eyes, and sallow skins, than in those of fair hair, light-coloured eyes, and delicate complexions. The extent of this circle varies from a diameter of an inch to an inch and a half, and increases in some as pregnancy advances, as does also the depth of colour.†

In the centre of this circle the nipple is observed partaking of the altered colour of the part, and appearing turgid*and prominent; and the part of the areola more immediately around the base of the nipple has its surface rendered unequal by the prominence of the glandular follicles, which, varying in number from twelve to twenty, project from the sixteenth to the eighth of an inch;† and, lastly, the integument covering the part is observed to be softer and more moist than that which surrounds it, and the breasts themselves are at the same time observed to be full and firm, at least more so than was natural to the person previously. Such we believe to be the essential characters of the true areola, the result of pregnancy, and that, when found possessing these distinctive marks, it ought to be looked on as the result of that condition alone, no other cause being capable of producing it.

But we cannot stop here and rest satisfied with the knowledge of the distinctly affirmative part of the question only, without also looking to certain circumstances which will most materially modify the certainty of our conclusions.

In the first place, then, pregnancy may exist and the areola remain deficient in at least one of its usually essential characters, and that, the one too generally supposed to be its most important distinctive mark,—namely, the colour. Within the last few months the writer saw two well-marked instances of this; one in a lady of very fair skin, blue eyes, and light hair; the other in a lady of fair skin, but with black hair and very dark-brown eyes: in both, the colour of the areola was so slight as hardly to differ from that of the surrounding skin, and certainly was less distinct than we have frequently seen it in the virgin, but all the other changes which we have enumerated were well developed in both.

Again, we must recollect that a woman may be presented to us for an opinion, who having perhaps very recently miscarried, her breasts may exhibit all the true characters of the areola, combined with several other circumstances really indicating a state of pregnancy; but if we do not use great caution in giving our opinion, it will in such a case appear falsified by the event, although really correct. In nurses, also, the characters of the areola are kept up and continue in a state of considerable perfection.

Now, as to the colour alone, we may adopt this belief—that where we find it of a deep and dark brownish shade, forming a circle round the nipple, even though unaccompanied with the other changes natural to the part, it affords very strong presumptive evidence of a former state of pregnancy; but when so accompanied, it is a mark of great value, and in our experience has never yet deceived us: and we certainly never saw any other condition of the part produced by disease which could possibly be mistaken for it. At the same time it

* Elem. Artis Obstet. pp. 46, 47.

† We lately saw the areolæ on the breasts of a young woman, of dark complexion, at the time of labour; they were of a very deep shade, and exceeded three inches in diameter. In negro women the areola is almost jet black.

* Crassescit papilla, inflata videtur. *Rœderer.*

† For a very full account of the structure of this part of the breast, see Meckel's Anatomy, vol. iii. p. 652.

ld be observed that the areola does not ays, in pregnant women, present all the acters we have described as belonging to We have seen it at the time of labour pre- ing the dark circle alone without the pro- ence of the glandular follicles, but we r saw an instance of their development, as dy described, without the concurrence of nancy: their absence, therefore, ought not ecide our opinion against the existence of condition, though their presence would be us a very convincing proof of previous ception: we should also be cautious in g influenced by the condition of this part, re the period at which its characters are in ral developed and perfected, as already ribed.

case which occurred recently, while the er was lecturing on this subject, afforded a satisfactory illustration of the value to be ched to this evidence of pregnancy. A young man came a considerable distance from the ntry to be admitted into Sir P. Dunn's spital, the medical men in the country not ing succeeded in affording her relief or re- ing her health. A very prominent sym- m of complaint was amenorrhœa of four nths' duration, accompanied by uterine n, want of appetite, &c. A very intelligent il suggested to the writer, after lecture, he thought we must be mistaken in our ount of the subject, as there was then in house an unmarried patient, labouring only ler amenorrhœa, whose breasts presented areola with all the characters we had de- bed. We immediately saw her, and on mining her breasts we pronounced at once t there was the true areola of pregnancy— announcement which she heard with the st fiery indignation, declaring that she would mit to any thing rather than lie under so unnious an aspersion, and even consenting permit an examination per vaginam, when posed to her as the only thing which could e her character. On making the examina- n we were distinctly able to feel the fœtus *ballottement*. She afterwards acknowledged t she had been "walking by moonlight h a young man who had a great regard for her." If a woman has been pregnant before, and ticularly if she suckled or is nursing, it y greatly embarrass our investigation. The our of the areola depends on the deposition an actual pigment between the cuticle and jacent skin. Of this we have satisfied our- ves by making preparations of the part, one which, shewing this very distinctly, is pre- ved in the writer's museum. In some per- ns of fair complexion especially, this co- ring matter is removed in some time after livery, and the breast resumes its virgin ap- arance; in others the colour remains perma- nt, and there is even a slight prominence of little glands to be observed sufficient to ceive an inexperienced eye. It is also to be collected that it is peculiar to some young fe- ales to have the areola assume a shade of co- ur resembling that which we so frequently serve around or under the eyes.

The conclusion which Gooch came to on this subject was, that "darkness of the areola rarely depends on other causes (than pregnancy), and that, when it exists, it may generally be looked upon as a sign either that the patient is pregnant or has been so formerly."* It seems remarkable that so accurate a writer as Gooch should have confined his description to the colour alone. Smellie's account is more accurate, and he considers it as the result of pregnancy only.† William Hunter has not, as far as we are aware, left us any description of what he considered the true areola, but he professed such faith in this sign as to assert that he could always judge by it whether a woman was pregnant or not, and on one occasion gave a remarkable proof of his accuracy. Happening to examine the breast of a subject brought to him for dissection, he immediately pronounced from the appearance of the areola, that the woman had died pregnant: however, on examining the genitals, the hymen was found entire, but Hunter persisted in his opinion, declaring that the areola was more convincing than the presence of the hymen. The body was opened, and an impregnated uterus confirmed the justice of his assertion.

Since writing the above, a case has come under the writer's observation which greatly strengthens his reliance on this sign. We were requested to see a patient affected with menorrhagia, arising, as was supposed by her medical attendant, from disease of the uterus. The history of the case was briefly this:—the patient was near forty years of age, and had borne five children; in the May preceding she had miscarried in the fifth month, and the placenta was retained eight weeks. In July she returned to her husband's bed, but her health continued feeble, and she had at irregular intervals of one, two, or three weeks, profuse and foul uterine discharges, but had none of the usual symptoms which used to accompany her pregnancy in former instances, so that she utterly disbelieved in the possibility of being then with child. For two months previous to our seeing her, her fears had been much augmented by the presence of a tumour in the centre and lower part of the abdomen, which was almost constantly the seat of severe pain; and she had still the foul uterine discharges. Under such circumstances we entertained little idea of the existence of pregnancy, but on seeing her breasts we were rejoiced to find them full, and exhibiting a very perfect example of the true areola, with all its characters so well marked that we did not hesitate to declare our belief that she was pregnant, though every other circumstance conspired to render it more than improbable. The uterine tumour felt as hard as cartilage, and knotty all over its surface, was very painful, and exquisitely tender to the touch; but the condition of pregnancy was put beyond a doubt in less than a week afterwards by her expelling a fœtus of five months, and along with it its placenta quite

* Account of Female Diseases, p. 205.
† Treatise on Midwifery, vol. i. p. 191.

perfect, and afterwards several pieces or fragments of a substance resembling decidua, mixed up with what appeared to be portions of placenta and membrane, but altered in their texture and consistence so as to possess the toughness of leather.

Could these have remained in utero from the time of the former miscarriage? They certainly were totally different from any of the parts of undoubtedly recent formations. The expulsion of them went on for fully half-an-hour after the rest of the process was completed, and portions continued to be discharged for some days; after which the patient recovered well, and at the end of a month there was not a trace of uterine irritation or discharge, and she considered herself in better health than she had been for a year before.

Milk in the breasts.—The secretion of milk in the breasts is popularly esteemed as an infallible proof of pregnancy, but nothing can be more erroneous than such a presumption, which is contradicted by facts, recorded on the best authority, proving the possibility of its formation under circumstances totally independent not only of pregnancy but even of intercourse, and at ages antecedent to puberty, and after the cessation of the generative faculty.

Perhaps the most remarkable case on record is that of the little girl of Alençon, who was produced by Baudeloeque* before the Royal Academy of Surgery on the 16th Oct. 1783, where she milked her breasts in presence of the members. This girl was only eight years old, and the secretion was caused by the repeated application of an infant which her mother was suckling at the time.

Belloc† mentions a servant girl, who, being obliged to have sleeping in her chamber an infant which was being weaned, and which by its crying disturbed her rest, bethought her of giving it her breast to appease its clamour; and the result was that in a short time she had milk enough to satisfy the child. Foderé mentions having seen a lady, who, in order to escape being imprisoned, pretended that she was a nurse when she was not, and she succeeded in producing milk from her breasts.‡

The same phenomenon has occasionally occurred in women advanced in years. The following case is related by Mr. George Semple.§ "Mrs. B. wife of John Breward, Simpson Green, near Idle, aged forty-nine, the mother of nine children, the youngest of whom is twelve years old, lost a daughter-in-law about a year ago, who died in about a fortnight after giving birth to her first child. On her death, Mrs. B. took charge of the infant, a little puny, sickly baby. The child was so fretful and uneasy, that Mrs. B. after several sleepless nights was induced to permit the child to t her nipple into its mouth. In the course from thirty to thirty-six hours she felt very well, her breasts became extremely pain considerably increased in size, and soon af to her utter astonishment, milk was secre and poured forth in the same abundance as former occasions after the birth of her o children. The child, now a year old, is a fi thriving, healthy girl, and only a few days I saw her eagerly engaged in obtaining an parently abundant supply of healthy nourment from the same fountain which nea twenty years ago poured forth its resources the support of her father." Several otl instances still more remarkable are on cord.*

Another source of deception might arise fr the fact that women sometimes after nursing ret milk in their breasts for a great length of ti The writer is at present in attendance on lady, who, after weaning her last child, whi she nursed for fifteen months, retained *nearly three years* so much milk in her brea that she was obliged to adopt precautions prevent her dress being wet by it. The chi is now five years old, and she can still expre a little milk from the nipples; she has not co ceived since the birth of that child, but h always menstruated regularly. Dr. Franc in his edition of Denman,† mentions, on t authority of Professor Port, that "a lady this city (New York) was almost fourteen yea ago delivered of a healthy child; since th time her breasts have regularly secreted mil in great abundance, so that, to use her ow language, she could at all times easily perfor the office of a nurse. She has uniformly e joyed good health, is now about thirty-fiv years of age, and has never proved pregna a second time, nor had any return of he menses."‡

"We see," says Foderé, "women who hav milk in their breasts from one pregnancy t another, and even for whole years togethe although they have not nursed." And he add that he has had repeated opportunities of ob serving the secretion of milk take place o the cessation of the catamenia at the turn of life, of which fact he quotes two strikin instances.§

It has been already remarked that morbi causes capable of distending the cavity of th uterus may excite the sympathetic changes i the breasts, and it appears that even the se cretion of milk may be thus induced, as hap pened in two cases mentioned by Frank, wh it occurred in one in consequence of physo-

‡ The last mentioned particular in this case is in accordance with the aphorism derived from Hippocrates: "Si mulier, quæ nec pregnans nec puerpera est, lac habet, ei menstrua defecerunt," which is, however, shewn to be incorrect by the perfect regularity of the catamenia in the case under the writer's observation.

§ Médecine Légale, tom. i. p. 440-1 and note.

a,* and in the other from hydrometra.† withstanding, however, the exceptions esta- ied by such facts as the foregoing, we ild attach great consequence to the pre- e of milk in the breasts, and if found in nexion with others of the rational sym- ns of pregnancy, it ought to go a great way confirming our belief in the existence of condition, especially if occurring in a an who had never borne a child or been nant before.

Quickening, and motions of the fœtus.—By kening is generally understood the first ation experienced by the mother, of the of the child within her womb; and a no- is very generally entertained in society it is on the occurrence of this phenemenon the child becomes for the first time en- ed with life.

t appears very unaccountable that such an rdity should have received not merely the tion of popular belief, but that it should the grounds of law in most civilized tries, our own not excepted; for the lish law adopts the distinction, and con- rs the fœtus before quickening as inanimate, merely as *portio viscerum matris*, but as rwards endowed with life; and on this ciple acts in the award of punishment for ne. Thus in a law enacted in 1803, called Ellenborough Act, it is ordained that if any on shall wilfully or maliciously use means ause or procure abortion in a woman *not k with child*, he shall be declared guilty of uy, and may be fined, imprisoned, set in pillory, publicly whipped, or transported my term not exceeding fourteen years; but ne offence be committed *after quickening*, all be punishable with death.‡ In like ner, when a woman pleads pregnancy in or stay of execution, the court orders an stigation as to whether she is *quick with d* or not, for being merely pregnant will be sufficient;§ and if she be pronounced *k with child*, execution shall be stayed l either she is delivered, or proves by the of nature not to have been with child at all. In France the law is at once more mer- ciful and more consistent with the laws of nature and with common sense, when it pro- vides that "if a woman condemned to die states that she is pregnant, and if it be proved that she is so, she shall not suffer punishment until after her delivery."*

It is perfectly monstrous and absurd to sup- pose for a moment that the fœtus does not en- joy vitality from the first moment of its ex- istence, and of course long before the sensa- tion of quickening is felt by the mother; and if it be asked why no indications of life are given before the time at which quickening ge- nerally takes place, the obvious answer is, that the absence of any consciousness on the part of the mother relative to the motions of the child is no proof whatever that such motions do not exist.† Of this fact the writer can speak with certainty. A married lady, who menstruated for the last time on the 10th of November, came to Dublin in March, on the 21st of which month a consultation was held to determine whether she was labouring under a disease of the womb or not, as she had been previously assured by her medical attendant that she could not be pregnant because she had not sick stomach, nor felt the child. On ex- amination the writer distinctly felt through the abdominal parietes the limbs of the fœtus in motion, as did also Mr. Cusack and Dr. Marsh, and yet the lady herself had no consciousness whatever of any such sensation, nor did she *quicken* till the second week of the following month, April, and was delivered of a healthy boy on the 9th of August.‡

In attempting to make a knowledge of this phenomenon available in any inquiry as to the existence of pregnancy, even where there can- not be supposed any intention or motive on the part of the woman to deceive, we obviously labour under this disadvantage, that except we are at the time able to feel the motions of the child, we can have no evidence except her state- ment as to the fact of quickening or otherwise; and nothing is more certain than that she may be completely mistaken on both sides of the question. We have just mentioned a case in which motion of the child perceptible to the hand of another was not felt by the mother; and a second instance of the same kind has occurred to us lately in the wife of a medical friend. On the other hand, the examples of women who have supposed and firmly believed that they had quickened when no such thing had occurred, are numerous even to notoriety. We remember being some years ago called in great haste to see a lady, the mother of seven

Vol. iv. p. 50. French translation.

P. 182, ibid.

This law has been, and I think justly, designa- as immoral, unjust, and irrational; as tempting ne perpetration of the same crime at one time ch at another it punishes with death; while, he words of the admirable Perceval, "To ex- uish the first spark of life is a crime of the same ire both against our Maker and society, as to roy an infant, a child, or a man; these regular successive stages of existence being the ordi- ces of God, subject alone to his divine will, and ointed by sovereign wisdom and goodness as exclusive means of preserving the race and tiplying the enjoyments of mankind."—Perci- s Works, vol. ii. p. 430, 1.

"Here again the law of the land is at variance i what we conceive to be the law of nature; and at variance with itself, for it is a strange ano- y that by the law of real property, an infant *entre sa mère* may take an estate from the mo- nt of its conception, and yet be hanged four nths afterwards for the crime of its mother." is and Fonblanque, vol. iii. p. 141, note.

† Vide Beck's Medical Jurisprudence, p. 137. Gardien, Traité des Accouchemens, tom. i. p. 508.

‡ It may be observed here that the facts of this case are completely in opposition to the explanation of quickening given by Dr. Royston and others, who suppose it to be coincident with, and resulting from, the sudden ascent of the uterus out of the pelvic cavity.

children, who was said to be in premature labour at seven months and a half, accompanied with hemorrhage. On our arrival, her husband, who was a physician, mentioned among other things that she had quickened at four months and a half, and had from that time continued to feel the child as distinctly as in any of her former pregnancies, adding *that he had himself repeatedly recognised its movements also*; on examination, however, we could discover no child in utero, and the case terminated in the expulsion of a few coagula from the uterus without any fœtus whatever. We do not, however, mean to have it inferred that we should not pay attention to the statements of married women on this subject: on the contrary, we should attach great value to the assertion of a person who has already, and perhaps repeatedly, experienced the sensation, and has at the same time no conceivable reason for wishing to deceive; but for the reasons already stated, we cannot yield implicit credence to such representations; they may be mistaken, or they may have strong and powerful motives to misrepresent, known only to themselves. In cases of criminal, or even ordinary legal investigations, there is always a motive to influence the representations made by the woman, and we can only give credence in proportion as the account may appear to us to correspond to other circumstances or conditions of the case, of which we are satisfied. Should we be able to feel the movements of the fœtus, of course we could have no doubt on the subject; but it must not be forgotten that such an examination is liable to be unsatisfactory, or even lead us into error if great caution be not observed. It may be unsatisfactory, because it not unfrequently happens that even in women who have really quickened, and have been for several weeks conscious of the motions of the fœtus, we are unable either to feel the child or recognise its movements. The writer is at this moment in attendance on a lady who quickened more than six weeks ago, and is now in the sixth month of pregnancy, and after repeated examinations neither we nor her attendant physician have been able to feel the fœtus. In another case, in which ascites was combined with pregnancy, which had advanced to the seventh month, it was found impossible to feel the child by any mode of examination that could be adopted, though it was made with great care, both internally and externally, by the writer, and by one of the most experienced practitioners in Dublin. This case gave rise to great embarrassment, and recourse was repeatedly had to the application of the stethoscope in the most skilful hands; but neither the pulsation of the fœtal heart nor the placentary murmur could be heard, though it happened that several times during our examinations the woman assured us that she was at that moment sensible of active movements of the child. Desormeaux tells us of a patient of his who felt her child at the ordinary period, and its movements continued remarkably strong for three weeks, after which they ceased for a whole month, and nothing could excite them: the child was born alive and healthy.* On the other hand we may fall into the error of supposing we have felt these movements, when in reality the woman is not pregnant at all. One such instance we have already detailed, and more recently we met with another. Dewees relates a very marked instance of such an error occurring to himself. A young lady had her menses suppressed for several months, her belly swelled very much, her breasts became enlarged, she had nausea and vomiting in the mornings; in short she had all the usual symptoms of pregnancy. "Examining the abdomen carefully," says Dr. Dewees, "I found it considerably distended; there was a circumscribed tumour within it, which I was very certain was an enlarged uterus. While conducting this examination, *I thought I distinctly perceived the motion of a fœtus.*"† Another source of error would of course be found in a power which it is asserted some women possess of simulating the motions of the child by certain actions of the abdominal muscles. We never met with any such case; but Dr. Blundell, who mentions the fact, tells us of "a woman who was seen by the late Dr. Lowe and other eminent accoucheurs, who simulated these movements so exactly, that, had they judged from this sign alone, they would have pronounced her pregnant."‡

We must now turn our attention to the period of pregnancy at which we may in general expect that this phenomenon shall have occurred. Experience has shewn that it happens from the tenth to the twenty-fifth week; but according to the writer's experience, the greatest number of instances will be found to occur between the end of the twelfth and sixteenth weeks, or, adopting another mode of calculation, between the fourteenth and eighteenth week after the last menstruation. And under ordinary circumstances, when quickening does occur, but especially if it happens in conjunction with the sudden ascent of the uterus out of the pelvis, the woman is apt to feel an unusual degree of nervous agitation, which not unfrequently ends in faintness or even complete syncope, after which she is sensible of a slight fluttering sensation, which from day to day becomes more distinct, until she fully recognizes the motions of the child. The earliest instance of which we were certain was in the case of a lady, who must have conceived on the 10th of November, and she quickened on the 28th of January, the interval being eleven weeks and two days; delivery occurred on the 17th of August. A very general impression prevails in society, that quickening takes place exactly at the end of four calendar months and a half, whereas in fact the greater number of instances occur two or three weeks before that time has arrived, and many also not till long after. We have already mentioned one such case, and have by us notes of several others. At this moment

‡ Lectures on Midwifery, p. 251.

e are in attendance on a lady who has in seven uccessive pregnancies felt the child for the rst time in the sixth month, and once in the eventh. Baudelocque mentions that some of is patients did not quicken until after the ixth or seventh month, and, "in one of these omen," he adds, "whatever we could do, nd notwithstanding the very obvious ballottenent of the child in utero, which we could erform by a finger introduced into the vagina, s motions could not be ascertained either y the mother or the accoucheur who exained her, till the end of the seventh month."*

"There are some cases," says Johnson, where the motions are not felt till near the nd of the reckoning."†

A fact much more remarkable than the ocasional postponement of this change is its otal absence during the whole period of gesation, notwithstanding the subsequent birth of iving and healthy children. Two instances of his came under our own observation, and the act is mentioned by several writers of authoity. Levret speaks of a woman who felt no notion of her child in two successive pregnanies. "I was several times consulted," says Baudelocque, "about a woman whose pregnancy appeared doubtful to her till the last moment, as well as to the physician, because the notions of the child could not in any way be perceived; and nothing that we could do even t eight months and a half could excite them: he child, however, was born healthy, and as strong as usual." Gardien met with two such nstances;‡ and Gooch says on this subject, 'there are cases, though rare, in which the child has not moved during the whole of pregnancy, although it has been born alive and vigorous: of this I have known one instance, nd read of others."§

When we wish to feel or excite the motions of the child in utero, we may expect to succeed by adopting either such a manual examination of the abdomen as we are accustomed to make when examining for a tumour in that cavity, pressing with the fingers backwards towards the spine, or from each side towards the centre; or applying one hand firmly against the side of the uterine tumour, we impress the opposite side quickly with the fingers of the other hand.

Sometimes the simple application of the spread hand over the front of the abdomen is sufficient for our purpose; at other times we shall best succeed by the sudden application of the hand previously rendered very cold by immersion in water, or contact with a marble chimney-piece: this frequently has the effect of making the fœtus as it were start, and communicate a very distinct sensation of its movements.

It is obvious that there are two species of movements of the fœtus which may thus be recognised, one of which depends on the exertion of its muscular power, and of course implies life; the other, the result of mere change of place or situation, effected by some external agency, and capable of being recognized equally in the dead and the living fœtus: this latter, which is more properly mobility than motion of the fœtus, may be most effectually ascertained by a manœuvre, which has been named by the French ballottement, and which we shall describe fully under the section which treats of the state of the uterus.

Size of the abdomen and state of the umbilicus.—An increase in the size of the abdomen being the necessary result of the development of the uterus from pregnancy, a careful examination of that part will be essentially required in every instance of an investigation as to the existence of that condition.

When conception occurs, and the ovum is received into the cavity of the uterus, the organ increases considerably in weight; and its fundus becoming at the same time developed, and so presenting a broader surface for pressure from the superincumbent viscera, it descends lower into the cavity of the pelvis, and so will not, for the first two months, or sometimes more, produce any enlargement of the abdomen by its increased bulk. Such an enlargement, however, is frequently observed at this early period, but it will be found on examination to arise from an inflated state of the bowels, which very generally takes place soon after the commencement of gestation, and continuing for some weeks will cause the patient to look as large or even larger in the second month, than she will afterwards appear in the third or fourth. This inflated state of the bowels generally subsides after a month or six weeks, and then the patient will not appear enlarged at all, but, on the contrary, the abdomen may be found flatter than is natural to the patient, and the umbilicus under such circumstances will sometimes be found more depressed,* and as if drawn inwards and downwards, in which condition it is occasionally the seat of an unpleasant and rather painful sensation of dragging, the part being also at the time somewhat tender on pressure.

This state, however, soon begins to alter, and before the end of the third month the enlargement of the abdomen becomes obvious to the eye, and from this period continues to increase gradually from month to month in the same proportion as the development of the uterus proceeds. In the fifth month the depressed condition of the umbilicus begins to diminish, and by the end of the sixth month it is generally raised to a level with the surrounding integument, and afterwards it in many persons projects above the surface.

Such is the history of this change in the perfectly natural and healthy condition of the pregnant woman; but as there is, on the one

* Art d'Accouchement, ed. 1822, pp. 205-6.

† New System of Midwifery, p. 102.

‡ Traité des Accouchemens, tom. i. p. 509.

§ Account of Diseases of Women, p. 203. Dr. Dewees also relates a similar case, "where the motions of the child were never perceived during the whole period of utero-gestation." Compendium of Midwifery, p. 105.

* This change is noticed by Velpeau, vol. i. pp. 175-6, and also by others. The French have a proverb which says, "en ventre plat enfant il y a."

hand, a host of causes which may produce enlargement of the abdomen, and be accompanied also by several others of the symptoms of pregnancy when it does not exist; so also, on the other hand, a woman may be with child, and yet the development of the abdomen not correspond to the period which has elapsed since conception.

When the enlargement proceeds from a gravid uterus, and four months of pregnancy have elapsed, if the patient be placed lying on her back, with the shoulders a little raised, and the limbs at the same time drawn upwards, so that the thighs shall be in a state of semiflexion on the trunk, and the abdominal muscles thereby relaxed, if the woman be not very fat we shall be able to feel and trace the outline of the gravid uterus, at a height in the abdomen proportioned to the period of pregnancy, as stated in the preceding section; and even though we should not be able, from the fatness of the woman, the tension of the abdominal parietes, or any other cause, to feel distinctly the uterine tumour and define its circumference, we shall at least ascertain that the cause of the enlargement is something which renders the abdomen much more solid to the touch than is natural to that part, and an examination per vaginam detects the co-existence of the changes in the uterus, already described as necessarily accompanying gestation; while at the same time the general health of the woman is found unimpaired or unaffected by any symptom of disease.

When the increased volume of the abdomen is the result of morbid conditions, not affecting the uterus, as disease of the liver, spleen, &c., an ovarian tumour, or ascites, we shall, in general, without much difficulty form our diagnosis from the history of the case, the length of time the enlargement has existed, which may have greatly exceeded the whole term of gestation, the general diseased condition of the system, the total want of correspondence in the symptoms and conditions of the case if it were pregnancy; and, lastly, a vaginal inquiry assures us that the uterus is not enlarged.

When the abdomen is distended by the accumulation of fat in the omentum or in the integuments, or by the inflated state of the bowels, the very soft and yielding condition of the part under the hand when pressed backwards towards the spine, and the total absence of any solid tumour, together with the non-existence of the ordinary symptoms of pregnancy, will form a sufficient basis for an opinion. Should there exist ascites, that condition can hardly be overlooked or mistaken; but it must not be forgotten that pregnancy and dropsy may exist together, and, when they do, they may present a combination of circumstances of the most embarrassing description.*

Again, we must remember that there are women who, from their height or some peculiarity of form, exhibit their increase of size much less than others, so that the abdomen will appear less at seven months than it generally does in the fifth month.* And it is still more important to recollect, that although pregnancy should exist, if the child die the development of the uterus will be arrested, and the enlargement of the abdomen will not continue to increase, but, on the contrary, will sometimes diminish, the dead fœtus being retained in utero for several months, and the patient, although really many months pregnant, may not exhibit any increase of size beyond what is natural to her; or being near the end of her nine months, may not be larger than she was at four or five. The writer lately saw a case of this kind, which gave rise to great doubt. In the month of May he was requested to see a lady who considered herself in the eighth month of pregnancy, and was rendered miserably solicitous about her condition because she had irregular discharges from the uterus, and felt no motion of the child. On examination, her abdomen was found perfectly flat and even depressed, and no tumour of any kind could be detected in its cavity; but the uterus felt per vaginam was evidently enlarged and soft, and the os and cervix uteri had undergone the changes which accompany early pregnancy. The lady had begun to experience the symptoms of that condition in October, which continued till the beginning of January, when they suddenly ceased, and she became liable to vaginal discharges. All doubt about the case was solved shortly after the writer's visit by the expulsion of an ovum with a blighted fœtus, which had evidently not arrived at three months' growth, and during its long stay in the uterine cavity as an extraneous body had become encrusted with a reddish calcareous deposit.

With regard to the changes which take place in the state of the umbilicus, it is to be observed that any solid tumour enlarging the abdomen will also be capable of effecting the elevation of the umbilicus, which circumstance, therefore, of itself can afford us no certain information that the distending agent is a gravid uterus; but if, in a case in which pregnancy is supposed to be advanced to the seventh or eighth month, we find the umbilicus depressed and the belly flat, it will prove certainly that gestation has not advanced to such a period, although it will not be, as asserted by Dr. Gooch, decisive evidence against the existence of pregnancy, which may be present, but not sufficiently advanced to effect the change, or the uterine development may have been arrested by the death of the fœtus.

State of the uterus.—Having thus carefully investigated the circumstances of the case as far as we can discover them either by the report made to us, or infer them by the presence or otherwise of the sympathies already enumerated,

* See case related in the section on *Quickening and motion of the fœtus* in the present article.

* The writer was once called on to attend a young unmarried female of respectability, whom he found in labour, and he was assured by her mother that up to the hour of her labour she never suspected that her daughter was pregnant, not having perceived any alteration in her size; and the young lady had danced all night at a ball about a week before her delivery: she had completed seven months.

we proceed in the next place to an examination of the uterus itself, having for our object to ascertain the following points:—the state of the os uteri and cervix; the condition of the organ with regard to development, and the degree to which it may be enlarged; the correspondence of such degree of enlargement with the other circumstances of the case; the cause of its increase, and the nature of its contents.

1. *State of the os and cervix uteri.*—In the unimpregnated condition of the uterus, its mouth and the lower section of the neck, when examined by the finger introduced into the vagina, can be felt projecting into that cavity from a quarter to half an inch. The part so projecting feels remarkably firm, and about as large as the end of a man's thumb, having in its termination in the vagina a transverse opening, whose lips or margins feel firm and well defined. This may be so far open as to allow the extremity of the finger to be insinuated between them to the depth of an eighth of an inch, sometimes a little more, sometimes not so much; or it may merely communicate a sensation of a slight depression almost without a cavity, such as is felt when the tip of the finger is pressed between the lateral cartilages at the extremity of the nose. Sometimes the os uteri differs very considerably from this description, being almost imperceptible from its diminutive size, and perfectly circular.

When conception has taken place, all these characters begin to alter; the change from the natural condition above described being distinct in proportion to the period of gestation at which the examination is made. In order to fit the uterus for the reception of the ovum and its support, there is, very soon after impregnation, a greater supply of fluids directed towards it; its vessels, which before crept almost imperceptibly through its dense structure, and with their calibre completely constringed, become distended and carry blood; the cellular texture is loosened out, and its interstices are infiltrated with a greater quantity of fluid, and in consequence the organ becomes not only altered in texture, but increased in size and weight. At this time, when the finger is applied to its vaginal extremity, the cervix is felt fuller, rounder, and softer or more springy and elastic under the point of the finger; and the same alterations having taken place in the labia of the os uteri, this part communicates a corresponding difference in the sensation received by the finger of the examiner: the margins of the orifice feel tumid, but softer and much less distinct, having lost the well-defined edge which in the unimpregnated organ is natural to them; while the orifice itself, instead of seeming transverse, feels as if it were circular, and admits the tip of the finger more readily and to a greater depth than in its former state. As pregnancy advances, other changes in these parts may be appreciated. During the sixth month, for instance, we ascertain that the cervix has not only undergone the changes of structure already detailed, but that it has lost somewhat of its length, owing to a portion of its upper section, or that which unites it to the body of the organ, becoming dilated, and taken up as it were to form a part of the distended cavity containing the child; and this obliteration of the cervix from above downwards continuing to be gradually effected, we find, if we examine towards the close of gestation, that the projecting cervix is no longer to be felt, but in its place there is detected, at the upper extremity of the vagina, a globular tumour, which is the enlarged uterus, with the head of the child to be distinctly recognized through its parietes. In like manner also the os uteri undergoes great changes of form, structure, and position, as pregnancy advances.

During the greater part of the first three months, besides the alteration already mentioned, it is felt lower in the vagina, and not unfrequently projecting a little forwards; but as soon as the uterus begins to rise into the abdomen, and leaves the pelvic cavity, as it does by the fifth month at farthest, sometimes a month earlier, its fundus leans forwards, and in consequence the os uteri is directed backwards; its margins are now felt very soft and relaxed, and we distinguish very generally within the circle of its orifice the cervical glandulæ slightly projecting, and feeling like little firm smooth vesicles rolling under the point of the finger. We can now also introduce the finger with great ease to a considerable depth into the cavity of the cervix, owing to the very yielding condition of the labia of the os uteri. From this period, in consequence of the rapid development of the uterus, and the shortening of the cervix, the os uteri rises in the pelvis, and is of course removed farther and farther from the external parts, while, at the same time, the anterior projection of the uterus increasing, its mouth is in the same degree directed backwards, so that, if we examine in the eighth or ninth month, we reach it with difficulty, and must expect to find it in the direction of the upper part of the sacrum. If gestation be drawing to a close, the orifice will often be hardly distinguishable, and when felt gives only the impression of an opening in a nearly flat surface, without any elevated margin, or at most very little, and feeling as a mere rugous opening in the mucous membrane of the upper part of the vagina.

But we must recollect, when we come to form an opinion from the existence of such changes in the os uteri, that there are other conditions of the uterus besides pregnancy by which they may be produced so as to assume almost exactly the characters of those that accompany the earlier periods of gestation. Thus, for instance, the near approach of menstruation and the accompanying irritation of the uterus may (and we have had repeated proofs from examination that it does) effect such a change in the form and texture of the os uteri. The same thing will happen in a more marked degree, when the organ becomes from any cause enlarged, either by an increase of its substance, or, still more remarkably, when its cavity becomes distended by an accumulation of fluid within it, as of blood or water, or the presence of a diseased growth, such as a poly-

pus or hydatids.* Moreover, in some women, especially those who have borne several children, the condition of the os uteri is at all times such as may but too easily impose on us. On the other hand, however, there is one fact on the subject on which we may rely,—viz. that inasmuch as pregnancy must always be accompanied with the physical changes of structure in the uterus already mentioned, should we find in a suspected or doubtful case, especially if supposed to be of some months' duration, the os uteri retaining distinctly the characters which belong to it in its unimpregnated state, that is, its transverse orifice with well defined and firm margins, we may conclude with certainty that the woman is not with child.

2. *Size of the uterus, &c.*—When conception has taken place, the uterus almost immediately begins to increase in size, generally in every part, in consequence of the new action already described, but especially at the fundus. Here the cavity begins to increase its capacity, to enable it to receive and accommodate the ovum, which being accomplished, the upper part of the organ continues to increase in size in proportion to the growth of its contents. The fundus is first developed, then the body, and lastly the cervix; the latter part not being affected by the process of expansion until about the sixth month, as already stated. During the earlier months, therefore, the finger introduced per vaginam cannot reach sufficiently far to arrive at and detect the development which has taken place in the upper part of the uterus; and as the increase of size in the organ is not as yet such as to prevent its being still accommodated within the pelvis, it cannot be detected by examining through the parietes of the abdomen; wherefore, during this period, which extends through at least the first three months, the development of the organ or its degree will be difficult to ascertain, but will become gradually more easy of detection as pregnancy proceeds and the uterus enlarges. In general, by the end of the fourth month, the fundus of the uterus may be felt, especially in a thin person, overtopping the anterior wall of the pelvis. During the fifth it rises to half way between the symphisis pubis and the umbilicus; and if an examination be made per vaginam, we can detect the enlarged uterus, which we encounter when we attempt to pass the finger between the anterior part of the cervix and the inside of the symphisis pubis,—a situation in which, when a woman is not pregnant, and even during the earlier periods of pregnancy, we are not able to feel any thing. At this period, also, we may at the same moment feel the fœtus by ballottement, as described in another section. In the sixth month the uterus rises as high as the umbilicus, which is now for the first time sensibly affected, and begins to rise to a level with the surrounding integuments. In the seventh month the fundus uteri may be felt halfway between the umbilicus and the end of the sternum; and if an examination be made per vaginam, the finger readily detects the globular tumour of the uterus resting on the symphisis pubis, and within it the child's head; but the os uteri is now reached with greater difficulty, both because it is raised absolutely higher in the pelvis, and also because it is removed farther from the external parts by being projected more towards the promontory of the sacrum.

By the end of the eighth month the uterus has risen as high as the ensiform cartilage, and fills the whole abdomen, which is now very prominent and tense, and the umbilicus is in general not merely on a level with the integuments, but projects a little beyond them.

In the ninth month the uterus continues to enlarge, but the degree of its increase is not very observable by an increased elevation of its fundus, which on the contrary very generally falls lower towards the close of the month, so that for a week, or even two, before labour, the woman will appear and feel smaller than she was previously. If at this period we examine internally, the os uteri will in most cases be touched with great difficulty from its situation towards the upper and back part of the pelvis; there are in general no remains of the cervix; and the margins of the os uteri are felt thin, soft, and so relaxed that the orifice would receive with perfect ease the end of one's thumb, and within its circle we may feel the membranes.

Now it is important to notice the different degrees of distinctness with which these changes in the uterus may be recognized in different individuals, or in the same individual at different times, and to speak of the best method of conducting the examination.

In some women there is a natural stiffness and tension of the muscles of the abdomen, which is a great obstacle to an examination; and this they can produce or increase at pleasure, if they wish to baffle us in our investigation. In this, however, we may defeat them, by engaging them at the instant in conversation on some subject connected with their case which will be likely to set them talking. In other cases a similar difficulty will arise from inflation of the intestines or their distention by an accumulation of fœces; or a still more formidable bar may be found in a general condition of *embonpoint*, when the omentum and abdominal integuments may be so loaded and thickened with fat, that we can no more feel any thing through them than if we had a folded blanket between our hand and the patient's abdomen. This is so remarkable in some fat women, that we have found it impossible immediately after delivery to ascertain by external examination the degree of uterine contraction, although there were other satisfactory proofs of its perfection. We should not forget that this is a state of the abdomen very apt to occur at the turn of life, when, from the cessation of the catamenia, women very often fancy or affect to think themselves with

* In introducing hydatids here, we do not mean to be understood as considering them distinct from pregnancy, from which we believe they always arise, but as distinct from the natural conditions of that state, and from the presence of a fœtus.

ild. On the other hand, the examination ill be most satisfactory in women of a spare abit, and who have the abdominal parietes laxed.

It was before stated that during the first ree months we cannot expect much infor- ation from the altered size of the uterus, but at, after the lapse of another month, the ange might be ascertained both externally d also per vaginam; and it may be here lded that in a case of doubt we may make esc two modes of examination mutually con- mative of each other, by applying the finger one hand to the os or cervix uteri, and shing that part upwards, and then with the her hand gently pressing down the tumour lt in the abdomen. If we thus feel its scent upon the finger in the vagina, it affords most certain proof that the tumour is the erus in a state of enlargement. But we must gain recollect that a certainty even of this will t be sufficient to assure us of the existence pregnancy, because the enlargement may ise from other causes than the presence of a tus, such as hydatids, polypus, dropsy, or cumulated menses within the uterus, or scir- ous thickening of its substance. In the case polypus or scirrhus, the great solidity of e organ would at once undeceive us; but in her circumstances we might be able to ascer- in merely that the cavity of the organ was creased in capacity without being able to termine the exact course of its enlargement. t the same time the presence of several of the mptoms of pregnancy might afford a very rong moral conviction of the existence of that ndition; while, on the other hand, we may iscover such a want of correspondence be- ween the state of the uterus and the other mptoms apparently indicating a certain pe- od of pregnancy, as would be sufficient to ecide our opinion on the negative side of the uestion.

We have already spoken of the mode of ex- mining externally to discover the presence of fœtus in utero, and alluded to another form f examination per vaginam, to which we ught to resort for this purpose. As we have o English name for this mode of examination, is still designated by its French name.

Ballottement.—This mode of examination thus to be instituted. The patient may be xamined in the upright position, or placed ing with the shoulders much raised. One or wo fingers are then to be introduced into the agina and carried upwards until their points re applied to the anterior section of the cervix teri, and as high up on that part as they can e conveniently made to reach without using orce, and they must be carefully kept in con- tant contact with the part to which they have een applied. The other hand of the examiner s to be placed on the abdomen over the terine tumour, which should be pressed lownwards towards the cavity of the pelvis; nstantly on our doing this, the fingers which ave been kept applied to the cervix should be mpressed against it with a quick and slightly erking motion upwards, when something will be felt to have bounded away from the fingers, upon which it will, in the course of three or four seconds, be felt to drop again with a gentle pat.

Should this be distinctly felt, it is proof positive of a fœtus in utero, there being no other condition or disease of the organ in which a solid body can be felt in this way floating in its cavity; and it possesses this great advantage over many other modes of investigation, that it is equally applicable to the dead as to the living fœtus. But we must be prepared for occasional disappointment in this test as in others, inasmuch as the most carefully conducted examinations of this kind have failed of success when there was really a fœtus in the womb of sufficient bulk to be thus felt, as we have ourselves experienced. This difficulty may arise in some cases from the fœtus being unusually small, or from the cervix being unusually long; and in some instances we were satisfied it has arisen from the uterus lying too much beyond the reach of the finger at the time of the examination.

The time at which we may resort to this examination with the best prospect of success is generally said to be from the fourth to the sixth month. Our experience leads us to say that it is not likely to be satisfactory until after the end of the fourth month, but from that till the end of the sixth it will be found most available, and often completely decisive.* In the earlier periods of pregnancy the fœtus is too light to be felt, and in the more advanced its presence is ascertainable by other means, and besides it is then too large and too much confined to be made to float or move about thus freely.

It is desirable that the bladder and rectum should be quite empty when we make this examination, that the uterus may have as much space as possible for its descent into the pelvis, and so be brought as much as possible within reach of the examiner's finger. We must be careful not to mistake the movement of the uterus for that of the fœtus, an error into which we shall be particularly liable to fall if we remove the fingers from their contact with the cervix while making the examination. In one instance of enlarged uterus we knew the pulsation of one of the arteries to be mistaken for the drop of the fœtus on the finger.†

Application of auscultation.—Since the appearance of the memoir of Dr. Mayer‡ of Geneva, in 1818, and the subsequent observations of Kergaradec and Laennec, the application of auscultation as a means of detecting pregnancy has been much cultivated, and with results highly beneficial to the interests of science and our powers of making a correct diagnosis.

* Gardien specifies four months and a half; Gooch from the fifth to the seventh.

† On this subject see *Baudelocque*, tom. i. p. 206.—*Desormeaux*, Dict. de Méd. tom. x. p. 400.—*Velpeau*, Traité des Accouchemens, tom. i. p. 185.—*Gooch*, On Female Diseases, &c. p. 215.—*Gardien*, Traité Complet, &c. tom. i. p. 507-10.—*Mahon*, Méd. Lég. tom. i. p. 160, note by Fautrel.

‡ Vide Bibliothèque Universelle, Nov. 1818.

The phenomena thus ascertainable are, the pulsations of the fœtal heart, and a peculiar sound audible in that part of the uterus to which the placenta is attached, and hence called the placental sound or murmur *(bruit placentaire)*. We shall first consider the modes of investigating these, and then state the advantages which this mode of examination enjoys above others, and the defects under which it labours as a general means of diagnosis.

The placentary sound is the one first capable of being examined, and may be heard as soon as the uterus has become sufficiently developed for its fundus to arise above the anterior wall of the pelvis: this happens in the fourth month of gestation, before which period we do not believe the placental sound can be ascertained. We are aware that cases are recorded in which it was supposed to have been heard so early as the tenth week. If so, we have not been so fortunate as others, although we have very many times indeed carefully repeated our examinations, but never succeeded until four months of pregnancy had been completed.*

The characters of this phenomena are, a low murmuring or somewhat cooing sound, resembling that made by blowing gently over the lip of a wide-mouthed phial, and accompanied by a slight rushing noise,† unaccompanied by any sensation of impulse. This sound is in its returns exactly synchronous with the pulse of the mother at the time of examination, and varies in the frequency of its repetitions with any accidental variation which may occur in the maternal circulation. Its situation does not vary during the course of the same pregnancy; but in whatever region of the uterus it is first heard, it will in future be found, if recognized at all, for it is liable to intermissions; at least we shall occasionally be unable to hear it where we have already heard it a short time before, and where we shall shortly again recognise it. In relation to the regions of the abdomen, its seat will of course vary in proportion to the progressive advance of the pregnancy. According to our experience it will be most frequently heard about the situation of the fallopian tube of the right side, but it may be detected in any of the lateral or anterior parts of the uterus.

The other phenomenon differs in every one of its circumstances from the placentary murmur. It results from the contractions of the fœtal heart, which, when conveyed to the ear, are heard as rapid pulsations without any of the murmuring sound of the *bruit placentaire*. These pulsations vary in number from 120 to 160 in the minute, while the mother's pulse at the same time may not exceed the usual standard; and should it happen to do so, the pulsations of the fœtal heart will not be found similarly affected. By this want of correspondence and permanently greater rapidity, they are distinguished from the pulses of the mother. The impulses of sound communicated to the ear are in general very delicate and feeble, resembling very much the ticking of a watch heard through one's pillow at night.* This phenomenon is not ascertainable, according to the writer's experience, until five months of pregnancy have been accomplished,† and then requires for its recognition very great attention on the part of the examiner, and also a practised ear. As pregnancy advances, the sound becomes more distinct. Its seat or source being the heart of the fœtus, and the fœtus having in most women a great disposition to change its posture, the situation of the sound will consequently be different at different times, especially from the sixth to the eighth month. It is, however, most frequently and most readily heard on one or the other side, and at about the middle of a line drawn from the umbilicus to the anterior and inferior spinous process of the ileum, and more frequently on the left side than on the right.

This mode of ascertaining the existence of pregnancy has this great advantage over almost every other, that it detects not only the presence of a fœtus, but proves its life also. On the other hand, however, should life be extinct, auscultation cannot possibly afford us any information; and here lies the great defect under which its application labours when compared with other modes of examination, to which also it is inferior in not being available during that period of pregnancy which is most obscured by doubt. Again, from the fact that both phenomena are occasionally inaudible‡ even in the case of a living and healthy fœtus, it will not justify us in giving a negative opinion. The bruit de cœur once heard is of course decisive, because there is no other sound which can be mistaken for it; but not so with the placental murmur, which may be so imitated, either artificially, as by pressure, or by disease, that the nicest and most practised ear cannot detect any difference. A case most strikingly illustrative of this statement was not long since under the writer's care, in which enormous enlargement of the uterus, of that kind which has been called vascular sarcoma, was accompanied by this phenomenon in its most perfect condition; and in another case of abdominal tumour (supposed to be of the spleen) pressing on the aorta, this sound was equally distinct: moreover, it may at any time be imitated by pressing the end of the stethoscope over the region of the iliac vessels.

At all times this kind of examination requires great care and nicety on the part of the examiner, and complete silence around him, for the sounds are very often almost imperceptible. We have the very highest authority for be-

* "Je ne l'ai rencontré que dans la seconde moitié de la grossesse. Si Laennec et M. de Leus, qui disent l'avoir reconnu avant la fin du troisième mois, ne se sont pas mepris, il me parait par cela seul impossible de l'attribuer à la circulation utero-placentaire." *Velpeau*, Traité des Accouchemens, vol. i. pp. 190-1.

‡ See case related in the section on *Quickening*, &c.

lieving that the formation of a correct judgment by their means requires more care, and is beset with greater difficulties than are found in investigating all the diseases of the chest.* We must recollect that, from their occasional intermission, it may happen that we shall not be able to give a satisfactory opinion until we have several times repeated our examination. To make this examination, it is by no means necessary that we should be practised stethoscopists, or even use the stethoscope at all, since the naked ear will detect the sounds sought for with perfect accuracy; but the use of the tube is for many reasons preferable.

It appears not unimportant to mention here, that our success will sometimes depend on our making a proper degree of pressure with the end of the instrument, since the seat of the sound which we seek to discover may not, and very often is not, in contact with the surface on which we apply our ear or our stethoscope; and under such circumstances the intervention of a fluid, such as the liquor amnii, will effectually prevent the transmission of the sound, until, by gently increasing the pressure on the integuments, we carry them inwards, and by displacing the intermediate fluid, whether air or water, we bring them into more immediate contact with the source of the sound, and obtain a solid medium for its transmission.†

Substances expelled from the uterus.—The expulsion from the uterus of solid or organized substances, presenting occasionally very unusual or anomalous characters, excites not unfrequently suspicions of the existence of pregnancy in the unmarried, and perhaps the perfectly chaste. Under such circumstances we may be applied to for an opinion as to the nature of the substance expelled, and are expected to declare whether it is or is not the product of conception. Inasmuch as character and fair fame of the individual depend on our answer, the greatest care will be required in making such an examination, and the utmost caution in forming or pronouncing an opinion. To this duty no person can possibly be competent if he have not previously made himself intimately familiar with the appearance and structure of the ovum, particularly in the earlier periods of its formation; and this knowledge he may take it for granted he never will attain to by descriptions in books or plates, nor by any means except repeated examinations of the structure itself, under every circumstance and condition in which it may be found: more especially when it is altered in its characters, as it usually is, by abortion.

The substances thus expelled may be, 1. an early ovum; 2. a mole; 3. uterine hydatids; 4. the membrane produced in dysmenorrhœa; to each of which we shall now turn our attention.

1. *An early ovum.*—When the product of

* "L'étude des phenomènes dont nous venons de parler dans cet article demande incomparablement plus d'attention que celle de tous ceux que presentent les maladies de la poitrine." *Laennec*, tom. ii. p. 466.

† The author of the article AUSCULTATION in the first volume of the present work, gladly avails himself of the present occasion to correct some mistakes which he has committed in respect to the appropriation of certain opinions therein advanced.

In treating of the utero-placental circulation, with reference to the variety of sounds which accompany it, we gave it as *Dr. Ferguson's* opinion that "the most constant variety is a combination of the bellows or sawing with the hissing sound, commencing with one of the former and terminating with the latter;" and in another place we stated that "*Dr. Ferguson* had not observed any variety of the sounds to be peculiar to particular stages of pregnancy." Now the fact is that both these remarks belong to *Dr. Kennedy*, and are taken from an excellent paper by this gentleman, published in the fifth volume of the *Dublin Hospital Reports*. In transcribing the extracts which we had made, we inadvertently inserted Dr. Ferguson's name in place of Dr. Kennedy's, and referred to a paper by the former gentleman in the *Dublin Medical Transactions*, from which we also had been making extracts. We are much obliged to Dr. Kennedy for having enabled us to correct our mistake.

In respect of certain other statements made by us in the same article, we most readily afford Dr. Kennedy the opportunity of giving his own explanation by extracting a passage from a communication with which he has favoured us.

Extract of a letter from Dr. Kennedy to Dr. Forbes:

"You appear to have misunderstood me when you state, 'there seems little ground for believing with Dr. Kennedy that the placental arteries themselves have a share in the production of the sound any farther than by their action promoting that of the uterine arteries.' Now if you will refer to p. 241 of my paper you will find that I merely deem it possible that the passage of the blood through the arterial tubes and cells of the *maternal part* of the placenta may have *some effect* in producing it; and in p. 244, speaking of the *possibility* of its operating so, add that the point *still admits of doubt*. From this it will be seen that I by no means commit myself, either in the manner or to the extent that your statement implies. The fact is, that although my explanation may not have been sufficiently explicit on this point, yet the manner in which I endeavoured to explain the maternal part of the placenta's assisting in producing the soufflet, (if it did so at all,) was that which you more distinctly state, namely, by promoting the action of the uterine arteries. But even of this I was not, nor am I as yet quite satisfied. I however thought myself called upon candidly to state facts and inferences as they presented themselves to me on my investigation, leaving it to others to draw what conclusions they thought proper from them.

"There is still another point to which I wish to draw your attention, as, from the manner in which you quote me, my meaning is very equivocally conveyed. You say, 'Dr. Kennedy denies M. Ollivry's statement, that the soufflet is immediately extinguished on the removal of the placenta, the death of the fœtus, and the tying the cord, the sound becoming abrupt,' &c. From this it might be concluded that I stated the soufflet always to continue after delivery, death of the fœtus, &c. an inference widely at variance with the fact, and such as was never intended by me. You will find, p. 244, Dub. Hos. Rep. vol. v. the passage which you quote; it runs thus: 'Neither does the sound (the soufflet) *invariably* cease, as we might be led to conclude on the authority of Dr. Ollivry, on the separation or expulsion of the placenta; but provided the uterine arteries at this part, from imperfect contraction of the uterus, continue pervious to blood, a soufflet will still continue,' &c. Here you will at once perceive how much the words 'immediately extinguished,' in place of 'invariably cease,' effect the nature of the statement."

May 1833. J. F. *Edit.*

conception is expelled within a month from the time of conception, the most careful and skilful examination may fail in detecting its true character. After this period its structure is sufficiently distinct to be recognized by any one well acquainted with it, and who will take *sufficient time* to examine it; for this also is absolutely essential to the formation of a correct opinion. The ovum, when thus expelled, is generally infiltrated with firmly coagulated blood, and the pressure which it sustains while it is forcing its way through the contracted and rigid cervix of the uterus, so condenses its texture as to reduce it apparently to the condition of a solid homogeneous mass. The real structure of the body cannot be ascertained by any examination instituted at the moment, but must be gradually made out by first immersing the substance in water for a day or so; and then, by agitation and washing, the coagulated blood must be removed, while with delicate blunt instruments we gently separate the component parts of the mass *under water*, until at length we ascertain its real character. This process may occupy us for a time varying from three or four days to a week, before we are able to satisfy ourselves perfectly. Haste may completely defeat the object of the examination.

If in the progress of such an investigation we discover a fœtus, or even a part of one, it would of course be decisive; but this may not be the case, and yet we may recognise all the other component parts of the ovum presenting several structures which are never produced by disease.* First, we may have the decidua covering either partially or completely the substance under examination, distinguished by its soft, rich, pulpy appearance and strong red colour, its external or uterine surface rough and unequal, and, when well freed from the coagulated blood, exhibiting numerous small round foramina,† capable of admitting a pin: its internal surface is smooth, and exhibits little or no appearance of these openings. This coat may be found attached to the ovum, or entirely torn away and separated from it during its expulsion; but in either case these characters mark the true decidua, and are not found in the products of disease. Within this outer coat another is found immediately investing the membranes of the ovum, the outer surface of which is smooth, and its inner completely filamentous, receiving the beautiful arborescent villi which cover and shoot from the surface of the chorion, forming the bond of union between it and this inner decidua. The discovery of these arborescent villi or capillaries is proof positive of the nature of the product, as they are never found presenting like characters, except upon the chorion or uterine surface of the placenta.

2. *Moles.*—With regard to those solid fleshy masses called moles, which are occasionally expelled from the uterus, there is a great discrepancy in the opinions of writers of authority, some of whom maintain, with Mauriceau, that they are the result of conception alone, and of course positive proofs of pregnancy; while others either think this very doubtful, or deny it altogether, and suppose that they are merely accidental formations of a morbid character. "By the term *mole*," says Denman,‡ "authors have intended to describe very different productions of, or excretions from, the uterus. By some it has been used to signify every kind of fleshy substance, particularly those which are called *polypi*; by others, those only which are the consequence of imperfect conception when the ovum is in a morbid or decayed state; and by many, which is the most popular opinion, every coagulum of blood which continues long enough in the uterus to assume its form, and to retain only the fibrous part as it is properly called, is denominated a mole." "True moles," says Voigtel,§ "are distinguished from the false and other growths of the uterus by their not deriving their origin from the substance of the womb or its membrane; but by their being always the consequence of conception." This is at once assuming that conception is the sine-quâ-non without which a mole cannot exist,—an opinion which is supported, to a certain extent at least, by the experience of Mr. Burns, who says, "It is the opinion of many that these substances are never formed in the virgin state, and no case that I have yet met with contradicts the supposition."‖ Foderé¶ thinks that the true mole is always the result of intercourse between the sexes, and that those substances which are discharged from the virgin uterus are merely condensed coagula of blood, which of course may form in the chaste as well as others. Baudelocque** considers the mole and the false conception as one and the same.

On the other hand, we find the matter thus stated by Dr. Smith: "Moles are disorganized masses that form in the uterus; and continuing for some time to increase, cause some of the symptoms of pregnancy. They have been found in females who never had any intercourse with the other sex."†† Ruysch makes a similar assertion, and adds that he has seen them in women so advanced in years as to be beyond the reach of suspicion. A case came before the parliament of Paris in 1781, in which the female sued for damages for seduction. Twenty months after this was alleged to have been committed, she brought forth a mole. The parliament decided against her on the score of character, and they added that "the causes of

* See a case related by Mr. Lemon in the Edinburgh Medical and Surgical Journal, vol. xi. p. 96. The writer has in his museum more than one specimen illustrative of this absence of the fœtus where the other parts of the ovum exist.

moles were as uncertain as the time of their gestation, *and that there were instances of girls, and even of nuns, who had produced moles without any previous criminal connexion.*" Foderé, who quotes this case, disapproves altogether of the view taken by the court.*

It is to be observed here that this is a mere question of fact, of which different views have been taken, and opinions formed by authors or practitioners according to the opportunities afforded them of judging. The writer does not feel prepared to undertake to reconcile these conflicting opinions, but it appears to him almost certain that much of the discordance has arisen from substances of very different characters having been indiscriminately classed together under the general term of moles, some of which were undoubtedly neither more nor less than diseased ova or remnants of such, while others were as certainly either merely condensed coagula, or perhaps uterine polypi. Hence Mahon† appears perfectly justified in making the following remarks:—"The existence of moles properly so called is extremely doubtful, since they may all be referred to some one or other of the substances of which we have spoken, viz. a placenta, which had continued its growth, the fœtus having perished; the degenerated remains of the after-birth; coagulated blood; sarcomatous tumours or polypi of the uterus. The two first cannot exist except after sexual intercourse; the other three may be found independently of it.‡ This is the distinction which it is of the greatest importance to make in questions of legal medicine, that we may not without cause compromise the reputation of the unmarried girl or the widow of irreproachable life and conduct."

In this view the writer entirely coincides, and thinks the medical jurist would not be justifiable in pronouncing any such mass expelled from the uterus as proof of pregnancy, except he can detect in it either the fœtus or a part of it, or some other of the component structures of the ovum.§ In the instances which have come under our immediate observation, the women were all either married or avowedly indulging in sexual intercourse, and the masses expelled, when examined, were found to contain the product of conception degenerated or greatly altered by disease. The last of these substances which came under our observation was expelled from the uterus immediately after the discharge of a healthy ovum, containing a well-formed fœtus of four months, at which period of pregnancy the woman, according to her own account, had arrived. The substance had the external characters usually considered as those of a mole, and was of the form and size of a large orange. When opened, no trace of a fœtus could be discovered, but there was a small remnant of an umbilical cord, which was ragged at its unattached extremity: the fleshy envelope varied in thickness from an eighth to half an inch, the thickest part being that where the placenta was situated, the internal surface of which exhibited very remarkably the tubercular disease represented in Denman's ninth plate.* Morgagni† relates a similar case, and quotes Hartman and Gutterman. Mr. Lemon's case has been already referred to.

3. *Uterine hydatids.*—Of the nature of these productions, and their necessary connexion or otherwise with conception, there exists, as in the case of fleshy moles, a complete want of accordance in the opinions of authors. Some maintain that they are not necessarily the result of conception, while others as strongly, and, as it appears to us, with much greater reason and truth, consider them as the product of disease attacking the ovum. Without entering into lengthened details on this subject, it appears proper to quote a few of the most respectable opinions on each side of this question before stating the result of our own experience on the subject. Dr. C. M. Clarke‡ thus expresses himself:—"It is probable that the existence of pregnancy is not necessary for the production of this disease. It has been believed to exist independently of this state; and perhaps a morbid condition of organized lymph may have the power of originating this disease under certain circumstances, but what these circumstances are is not known." Gardien's opinion is that "hydatids may be met with in girls as well as women; however, although they are independent of sexual intercourse, they are much more frequently met with in women who have borne children, and especially when they have arrived at the turn of life."§ Denman says, "These have been supposed to proceed from coagula of blood, or portions of the placenta remaining in the uterus, and this opinion is generally true; but there is sometimes reason for thinking that they are an original production of the uterus independent of such accidental circumstances, and sometimes the precursors of organic disease in that part."‖ Of these opinions we think we are justified in saying at least that there is so much of conjecture in them that they weigh very little in the determination of this point; and it is, moreover, to be observed that these writers admit elsewhere, as indeed do all who have written on the subject, that the existence of hydatids in utero is

§ It has been already remarked that these are not unfrequently found without any part of a fœtus. This is noticed also by Voigtel in describing different species of moles. "In others," he observes, "from an originally imperfect development of the ovum, or an injury to the fœtus at its first formation, it appears either as a shapeless mass, or *the fœtus itself is completely destroyed*, and *only its membranes and the placenta* continue to grow for a time and get thickened and fleshy, or filled with fluid only, or form membranous, fibrous masses, or hydatids, or assume other unnatural appearances." Voigtel, op. cit.

always accompanied by the ordinary symptoms of pregnancy. The weight of authority appears to us very decidedly in favour of the necessary connexion between these substances and previous conception. Beck declares that he "can find no case on record where hydatids of the uterus have been formed *independent of sexual conaerion*."* Baudelocque and Voigtel consider them merely as a variety of the mole, and as such the result of impregnation.† Desormeaux thus speaks of them: "It is superfluous to say that the development of these masses of hydatids is most frequently, if not always, the result of conception: at first it is impossible to distinguish this affection from pregnancy, *or, to speak more correctly, pregnancy exists* with all its phenomena, and it is impossible to discover when the degeneration into hydatids takes place."‡ Velpeau is perhaps even more decisive on the point: his words are, "the mole and hydatids of the uterus being but the products of conception degenerated, give rise to the same phenomena as true pregnancy."§ We shall quote only one other authority, to which, however, we attach very considerable value. Madame Boivin has published a very ingenious and satisfactory pamphlet‖ expressly on this subject, and she brings forward a vast quantity of information connected with this affection, which she appears to have studied with unusual attention; and the result of her observations she announces to be that hydatids in the uterus are in all cases the result of conception.¶ She notices the fact that these formations are not attached immediately to the internal surface of the uterus, but are surrounded by an investing membrane having all the characters of the *decidua vera*; and she maintains that the hydatids originate in the filamentous vessels which spring from the external surface of the transparent membranes of the ovum; in regard to both which points we coincide in her views, and have in our possession preparations shewing both facts. Our own belief, then, is that uterine hydatids do not occur except after sexual intercourse, and as a consequence of impregnation. We never met or heard of a case in which their presence was not accompanied or preceded by the usual symptoms of pregnancy;** and in every instance under our immediate observation, the women supposed themselves with child, and when the contents of the uterus were expelled, there was found either a blighted fœtus or some other part of the ovum.

It may not be amiss to notice here an argument from analogy which has been brought forward against this view of the question, viz. that hydatids being formed in other situations, as the brain, &c., why may they not occur in the uterus also, independently of any such circumstance as intercourse or conception? To this we would reply, first, that the hydatids produced in the situations alluded to differ, *toto cœlo*, in their characters from those of the uterus; and, secondly, that whenever hydatids are formed, it is always in connexion with serous membranes, which do not exist in the uterus until the ovum is deposited there, whose membranes are essentially serous. Still it must be confessed that our knowledge on this point is by no means sufficiently precise, nor our collection of facts sufficiently extended, to warrant us in pronouncing positively on the question, or asserting decidedly, in a case of suspicion, that a woman was pregnant merely because she discharged hydatids from the uterus, except we could detect along with them some constituent part of the ovum, or in an examination after death find in the ovary the true corpus luteum, which ought to put an end to all doubt. It would be presumptuous and absurd to maintain that, because we had always found them in connexion with one particular cause, there might not be some other also capable of producing them; and as there may be a doubt, we must let the accused have the benefit of that doubt. Again, in giving an opinion we should be prepared to make allowance for such a case as this:—a woman loses her husband by death or departure, when she is, perhaps, in the third or fourth month of pregnancy; shortly afterwards she miscarries, and the placenta or some other portion of the ovum is retained, and gives rise to the production of hydatids. This new product may be retained for many months,* and being then expelled, might very unjustly excite suspicion against a perfectly chaste person; for, although the result of impregnation in such a case, they might obviously be no proof of a pregnancy occurring subsequently to the absence of the husband.

4. *Membranes expelled in dysmenorrhœa.*—The circumstances attending dysmenorrhœa have sometimes given rise to a suspicion of pregnancy and early abortion, because the female may have pains resembling those of labour, accompanied by red discharge, and followed by the expulsion of a substance somewhat resembling the decidua. But it only requires a little examination and inquiry into circumstances to detect the difference between these two products and the real nature of the case. In the first place, we learn that such occurrences are habitual with the person at every menstrual period; the symptoms of pregnancy have not been observed; nor does the state of the breasts correspond to the existence of that condition. Again, the substance expelled in such cases will be found deficient in several of the characters of the true decidua: it is thin, flimsy, and very unsubstantial in its texture,

* In Madame Boivin's work, p. 74, there is a table shewing the number of months which intervened in thirty-two cases between the commencement of pregnancy and the expulsion of the hydatids. Some interesting cases are detailed by Nauche in a well written article on this subject. See Maladies propres aux Femmes, partie i. p. 182.

nd has not the vascularity, nor the foramina r the reception of the nutrient vessels from the erus, which are so distinctly observable in the ecidua vera; and lastly, the most accurate xamination will not discover within it any of ie transparent membranes of the ovum. We nmot more appropriately close our observaons on this membrane than by quoting the pinion of Denman, who, of all the moderns, as best described it. "As the first cases in hich this membrane was discharged were iose of married women, a doubt arose in my ind whether it was not really a consequence f early conception; but I have lately had the ost undoubted proofs that it is sometimes ischarged by unmarried women, and may be rmed previous to and without connubial comunication; and that the uterus has occaonally or constantly, in some women, the roperty of forming it at or in the interval etween the periods of the menstrual disharges. It seems particularly necessary to stablish this fact, as the appearance of this embrane has more than once given rise to rroneous opinions and unjust aspersions. Nor this the only circumstance in which some omen, at each period of menstruation, have ymptoms like those which accompany pregancy or parturition."*

Accidental circumstances.—Under this head it is intended merely to notice certain peculiarties sometimes observable in pregnant women, which, although generally deserving but little ttention in such an investigation, may still be emembered with advantage on account of the onstancy with which they occur in particular ndividuals, and the assistance which they may onsequently afford in confirming or modifying ur opinion. Such is, for instance, the alteration so often observed to take place in the eatures and expression of the face, which has een made a subject of remark since the days f Hippocrates, who mentions it. The features f the face in general become sharper, especially the nose, which seems as if it were lengthened, and the mouth appears larger; the eyes re sunk, and often surrounded with a brownish r livid areola, and assume a languid expresion. A marked change in the temper is very ommonly observed also, so that a woman who was under ordinary circumstances extremely mild and sweet-tempered, becomes, when pregnant, irritable and capricious. Strange appetites and antipathies are well known as frequent attendants on pregnancy in many persons, some of whom will long to eat unusual and even revolting articles, while others, immediately after conception, are seized with an unconquerable aversion to species of food which were previously particularly agreeable to them. We have seen several well-marked instances of this, and in particular one, in the case of a lady who assured us that she always knew when she was with child by feeling a violent antipathy to wine† and tea, which at other times she took with pleasure. We had an opportunity of observing the accuracy of this indication in three successive pregnancies of the lady alluded to.* The occurrence of pains in the teeth, face, and other situations, are with some the invariable accompaniments of pregnancy. In some women the same condition developes very singular idiosyncrasies, such as the occurrence of dark blotches over the face and other parts of the skin, an instance of which is at present exhibited in a patient under the writer's care. Lecat relates the case of a woman whose face in three successive pregnancies became quite black.† Camper observed the same circumstance. The occurrence of salivation in consequence of pregnancy has been already noticed. Some women always have varicose veins during gestation, who are not subject to such an affection at any other time. Mr. Ashwell mentions that in some individuals frightful dreams have been found a very good diagnostic sign; and he informs us that Dr. Haighton used to relate the case of a lady under Dr. Lowder's care, who was compelled to hire a nurse to awake her when her countenance became very much discomposed.‡ A very curious case is recorded by Dr. Bennewitz in Osann's Clinical Report for 1823, of a young woman who in three successive pregnancies was affected with diabetes mellitus, which completely ceased after delivery, but always returned when she again conceived.§ In first pregnancies we can gain little or no information from such accidental peculiarities, but their constant occurrence in successive instances ought to give them value in our eyes; the degree of value, however, must depend altogether on the distinctness with which we can ascertain their existence, or the reliance which we can place on the sincerity of those who report them to us.‖

The blood, urine, and pulse.—It is very generally asserted that the blood of pregnant women *always* presents the buffy coat and other characters of inflammation,¶ and this change in that fluid is even noticed by authors as one among the rational evidences of pregnancy.** The very general belief in this as a fact established, has probably arisen from the circumstance that pregnant women are seldom bled except when labouring under some form of inflammatory disease; but experience has fully taught us that no reliance whatever can be placed on the condition of the blood as an evidence of pregnancy. It is quite obvious that a woman exhibiting many of the symptoms of pregnancy, and yet not with child, may have her system under the influence of inflammatory action sufficient to cause the appearance of the blood frequently noticed in

* Introduction to Midwifery, pp. 161-2.

pregnancy; and on the other hand the blood of pregnant women will be very often found not presenting the characters supposed to be peculiar to it. This we have seen proved in several instances, and perfectly recollect the first case which particularly arrested our attention on this point; it was that of a very fat and robust woman who was seized with puerperal convulsions, and her blood exhibited not the least trace of inflammatory character. We have observed the same absence of such an appearance in blood drawn in the earlier periods of gestation to prevent abortion; and within the last few days we witnessed a very satisfactory instance of the same kind in the case of a lady in the ninth month of pregnancy, whom we judged it expedient to bleed for a very distressing cough, accompanied with pain in the chest and great irritation of the bladder: the abstraction of blood gave her the most immediate and decided relief, but it appeared in every respect perfectly natural and healthy.

A peculiarity in the urine of pregnant women has long been a matter of popular belief; and Savonarola, who wrote in 1486, gives a minute detail of the changes which that secretion undergoes in the different periods of pregnancy: up to about the sixth month, according to this writer, "the urine is clear, and of a pale citrine colour, with a cloud on its surface; and about the middle of the fluid, a deposit like carded wool; but as pregnancy advances towards its close, the urine becomes redder and turbid when stirred." This condition of the urine Foderé thinks entitled to consideration, having, as he says, "verified the accuracy of the observation."* Still more recently M. Nauche has brought this subject before the profession.† He speaks of it as a discovery of his own, and does not appear to be aware of the observations previously made by others: his words are: "By allowing the urine of pregnant women or of nurses to stand for some time, in thirty or forty hours a deposit takes place of white, flaky, pulverulent, grumous matter, *being the caseum or peculiar principle of milk formed in the breasts during gestation.* The precipitation is more readily procured by adding a few drops of alcohol to the urine." To this observation he subjoins a very strong case, in which he ventured to affirm the existence of pregnancy in a woman who was subsequently examined, both per vaginam and with the stethoscope, by several medical men, and pronounced not to be with child; but her delivery shortly afterwards evinced the accuracy of his previous diagnosis. The editor of the Lancet informs us in a note, that he had "applied the test in one case, and found it perfectly correct." We have ourselves tried it in several instances, and the result of our trials has been this: in some instances no opinion could be formed as to whether the peculiar deposit existed or not, on account of the deep colour and turbid condition of the urine; but in the cases in which the fluid was clear, and pregnancy existing, the peculiar deposit was observed in every instance; and we think its appearance would be best described by saying that it looks as if a little milk had been thrown into the urine, which having sunk through it, had partly reached the bottom, while a part remained suspended and floating through the lower part of the fluid, in the form of a whitish, semi-transparent, filmy cloud. And in some cases in which pregnancy was suspected, but did not exist, no such deposit was observed; but it is superfluous to say that there is such a host of accidental causes capable of altering the condition of the urine as ought to make us very cautious indeed how we ventured to attach credit to a symptom so equivocal.

We may apply the same observation to the state of the pulse, which has been made a subject of remark since the days of Galen. We shall only observe that in pregnant women the pulse is almost always stronger and more rapid than is natural to the individual at other times; but we cannot tell in a particular instance what may be the exciting cause of the increased action; we cannot even be sure that it is not natural to the person, and at all events we are certain that there are a thousand circumstances of disease or accident which may equally produce it.

Unusual conditions of the female.—Before entering on the last division of our subject, which will treat of the post-mortem examination, it appears necessary to advert to certain conditions in which a female may become pregnant, and her case be thereby rendered more obscure; as when, for instance, conception takes place,—1. in early youth or advanced age; 2. during the existence of disease, especially of a kind calculated to prevent conception, or to render its occurrence very improbable; 3. without the woman being conscious of having incurred the risk; 4. under circumstances not likely to be followed by such a result, as where copulation was only partially accomplished, &c. &c.

1. *The age of the individual.*—This may be such as, judging from what we observe in the ordinary course of nature, would appear either to preclude the idea of impregnation, or at least to render its occurrence extremely improbable. The limits of the generative faculty in women are generally those of the function of menstruation, but in some rare instances women have been known to conceive before the catamenia had begun to appear,* and after their cessation.

Conception before the age of fourteen is very rare, but it appears that instances of it have occurred. Bruce mentions that in Abyssinia he has frequently seen mothers of eleven years of age; and Dunlop witnessed the same in Bengal.† La Motte delivered a girl who had not completed her thirteenth year.‡ Instances of conception at nine and ten years of age are recorded by Joubert Schwrigius § and others,

§ *Smith*, p. 493, note, and Ballard, note on Metzger, p. 485.

but they scarcely appear deserving of credit; yet we find Dr. Good expressing his assent to such relations, and quoting Haller* and Professor Schmidt† in support of them.‡ The earliest instance of pregnancy known to the writer was that of a young lady who brought forth twins before she had completed her fifteenth year. Sir E. Home knew two instances, in one of which a girl of thirteen, and in the other a girl of twelve, gave birth to children.§

So also pregnancy very seldom occurs after fifty, especially in women who have not previously borne children; but instances have from time to time occurred at unusually late periods in women who had formerly conceived. In the statement sent to parliament by Bartholomew Mosse when endeavouring to procure a grant for the Dublin Lying-in Hospital, he mentions that eighty-four of the women delivered under his care were between the ages of forty-one and fifty-four; four of these were in their fifty-first year, and one in her fifty-fourth.‖ The succession to an estate was disputed in France because the mother was fifty-eight years old when the child was born: the decision was in favour of the fact.¶ Colomb adduces a similar case, and Knebel** two, one of fifty-two years, and the other of fifty-four. "In May 1816, Mrs. Ashley, wife of John Ashley, grazier, of Firsby near Spilsby, at the age of fifty-four was delivered of two female children, which with the mother were likely to do well."††

While writing these observations, an eminent accoucheur of Dublin (Dr. Labatt) informed us that he some time since attended a lady who was married when forty years of age, and that after remaining barren for ten years, she conceived for the first time when she was past fifty, went to her full time, and after a difficult labour bore a living child.

Capuron‡‡ quotes several cases of child-bearing in advanced age, among which are the following:—Pliny records the case of Cornelia, of the family of the Scipios, who at the age of sixty bore a son who was named Volusius Saturninus. Marra, a physician of Venice, mentions that he treated a woman for dropsy who was really pregnant, and he was deceived by her age, which was sixty. La Motte tells of a woman who refused to marry until she was fifty-one, in order that she might escape child-bearing; but she was disappointed, and bore a child. Valescus de Tarenta mentions a woman who continued to menstruate beyond sixty, at which age she bore her last child: Capuron adds that it was generally believed in Paris that a woman in the Rue Harpe bore a daughter at the age of sixty-three, and nursed it.

The occurrence of such cases, however rare, should at least have the effect of making us extremely cautious in pronouncing against pregnancy, merely because the individual may have exceeded by ten or fifteen years the period of life after which the generative faculty ordinarily ceases to manifest itself; or because the woman may have lived for many years a married life without conceiving, and then shew symptoms of pregnancy. A highly interesting case of this kind is, at the moment of writing this, under our care. A lady now in her forty-third year, who was married to her present husband twenty years ago, remained without any promise of offspring until within the last few months; but having missed her menstruation in September last, and finding her size increasing, the writer was requested to see her in January, when she exhibited evident symptoms of pregnancy: she has since under the writer's care been delivered of a healthy boy after a natural labour of about *four hours*. Dr. Gooch relates a case almost exactly similar, which occurred in "a woman of forty-two years of age, and who had been married twenty-two years without ever being pregnant," when she at length conceived, and brought forth a child at the full time.*

2. *Complication with disease.*—Pregnancy not unfrequently takes place in diseased states of the system, which would, *à priori*, render its occurrence very improbable, and which, when it does occur under such circumstances, give rise to an unusual difficulty in recognizing its existence. From this circumstance have from time to time arisen some very lamentable mistakes in practice. Thus women who have been long labouring under a general infirmity of health and with very irregular menstruation, or even a total suppression of that discharge, may conceive, and under such circumstances the phenomena of pregnancy are likely to be much obscured, or even their existence at all rendered very doubtful. Such a case is mentioned by Professor James of Philadelphia, in which a woman conceived after having had the menses suppressed for nearly two years before.† Diseases which increase the size of the abdomen, as they on the one hand often induce the supposition of pregnancy when it does not exist, so on the other hand they sometimes render its detection a matter of great embarrassment. Several instances have occurred in which women labouring under dropsy, even when the complaint was the result of serious organic disease, and had existed for a long time, have proved with child, and from the

† Hosack's Med. and Phil. Register, vol. iv. p. 422.

combination of circumstances thus produced great doubt and difficulty are likely to arise, especially when the woman is not herself aware of her condition, as happened to the wife of the king's counsel mentioned by Mauriceau, who was treated during seven months of her pregnancy for dropsy, and then brought forth a child.* In some instances very grievous errors have been committed. Mauriceau relates two cases of this kind, in one of which the woman had been nine years affected with dropsy in an extreme degree, but had during that time given birth to four children.† M. Chamsern had a patient who was tapped one hundred and sixty-nine times, and during the course of the disease she bore and suckled two children, though during each pregnancy it was found necessary to tap her three times.‡ Foderé mentions two women who, being pregnant, were tapped under the idea that they had dropsy:§ the uterus fortunately was not wounded; but in another case of distended bladder accompanying pregnancy and mistaken for dropsy, the practitioner tapped the patient; "death was the consequence, and on examination it appeared that the trochar had passed through both sides of the bladder, through the uterus, and even into the head of the child."‖ Capuron mentions that Marsa, a physician of Venice, treated a woman for dropsy, who was pregnant, being deceived by her age, which was sixty.¶ In a case which occurred to the writer, pregnancy remained a matter of the utmost doubt until the seventh month; the woman died two days after delivery, and the liver was found tuberculated, hard as cartilage, and diminished to about one-third of its natural size. "The bare possibility of such cases," says Gooch, "is a strong reason for never tapping a married woman without having the uterus previously examined by a person skilful in such examinations." Beck makes the following observations on this subject: "The most difficult case of concealed pregnancy that probably can occur, is when it is accompanied with ascites. The motion of the fœtus cannot be perceived, and it is added by Foderé, that the uterus does not take on its ordinary development. Yet many cases are on record where females with this disease on them have been delivered of healthy children. In suspected cases the practitioner should weigh the symptoms and ascertain whether they are all referable to the disease. His medicines should be mild, and patience exercised as to the event."*

Enlargement of the ovary is another disease which may either simulate pregnancy or co-exist with it,† and the abdominal enlargement increasing may be mistaken for the progress of the disease; when both ovaries are affected, pregnancy is of course much more improbable, yet it has occurred. Morgagni declares that even in disease of both ovaries, if there remain healthy a portion containing one vesicle, the woman may conceive.‡ A case very lately occurred in this city, in which a lady with ovarian enlargement on both sides, and of considerable size, became pregnant, and her true condition was not recognized until pregnancy was very far advanced, when the application of the stethoscope detected the pulsations of the fœtal heart. Under such circumstances a proper examination of the uterus per vaginam ought to enable us to detect the nature of the case. On the other hand, the existence of such a disease has repeatedly given rise to the suspicion of pregnancy. In the celebrated case of the Demoiselle Famin, published at Berlin and Paris by Valentin, in 1768, a charge of pregnancy and child-murder was erroneously instituted in consequence of an extreme case of ovarian dropsy.

The writer had once an opportunity of examining a very remarkable case, which presented a combination that could hardly fail to be attended with infinite doubt. A woman was received into the Cork-street Fever Hospital in 1828, with considerable enlargement of the abdomen. Her history, as far as it could be learned, was, that eight years before she had been in labour, which, after continuing for two days, suddenly ceased, and the child, as she expressed herself, rose up into her stomach: no delivery followed. After remaining in bad health for about two years, she again experienced the symptoms of pregnancy, and gave birth to a child, which did not survive; but the former child still remained in the cavity of the belly, and during its continuance there she bore three children, the last of whom lived. Ultimately a fistulous opening formed near the umbilicus, which was enlarged, and the original child removed; it was in a state of wonderful preservation, measured twenty-two inches in length, and had attached to it about two feet of the umbilical cord.§ Some of the most formidable diseases of the uterus have been found not incompatible with conception, and even the completion of the full term of gestation. Thus, instances of the concurrence of polypus uteri, and pregnancy have been several times witnessed;‖ and in some cases

the placenta has been found attached to the polypus.* The writer has a preparation in which an early ovum is thus connected. Levret,† Bach, Joerg, and Dr. Maclarlane have recorded cases in which the fœtus reached its full time under such circumstances. Even cancer and fungoid diseases of the uterus have been proved not to prevent the occurrence of pregnancy,‡ and a scirrhous cervix has been found an obstacle in the time of labour.§ Gardien expressly states that numerous facts within his knowledge have proved to him that women may carry their children to the full time although labouring under cancer in the ulcerated state.‖

Women have been impregnated although afflicted with complete external prolapse of the uterus. M. Guillemot has written a very interesting paper on this subject, in which he has collected from various sources nine cases of the kind, the first two of which are particularly remarkable as examples of gestation accomplished where the prolapse was complete.¶ In the third case impregnation occurred while the uterus was completely external.** Another of the cases happened in the practice of the great Harvey, who gives us the following account of the matter: "And now at this time it was large and dangling between her leggs. It grew at last bigger than a man's head, being then a hard tumour, and hanging downe to her knees did much pain her, so that she could not goe but upon all foure. I did suspect it to be a cancer of the wombe, and therefore did bethink my selfe of a ligature and cutting it off: but the following night an infant perfectly shaped, of a span long, was cast out of that tumour, but it was dead."††

We have thought it advisable to enter thus fully into the statement of such unusual conditions, lest a prepossession on our part against the possibility of such occurrences should act unfavourably, either by closing our eyes against the evidence before us in extraordinary cases, or making us less careful in their examination from a pre-conviction that pregnancy could not under such circumstances exist.

3. *Conception without the knowledge of the woman.*—That a married woman, or any female who has indulged in sexual intercourse, may become pregnant without being aware of her condition, is a fact too notorious to require further observation than the mere mention of it: the question which we propose to consider here is,—can a woman become pregnant in consequence of intercourse, of the occurrence of which she was not conscious, and so find herself with child without being aware of having incurred the risk? Improbable or even absurd as such a supposition may at first sight appear, the possibility of such an accident is established by too many facts testified by high authority, to permit incredulity on the subject. The belief that consent and pleasurable sensation on the part of the woman are conditions necessary to conception is now universally known to be without foundation in nature, and of course no longer influences legal decisions: formerly, however, it was otherwise, so that in case of rape, if pregnancy followed, it was presumed to prove consent, and it was so laid down by Dalton;* but Lord Hale says that this opinion of Dalton seems to be no law.† "That so absurd a notion as that conception evidenced consent should in modern times have obtained amongst any whose education and intellect were superior to those of an old nurse is indeed surprising; at this day, however, facts and theory concur to prove that the assentation of nature in this respect is no ways connected with violation of mind."‡ "It is a fact," says Capuron, "which experience has more than once confirmed, that a woman may become with child while in a state of hysteria, under the influence of narcotics, during asphyxia, drunkenness, or *deep sleep*, and consequently without being conscious of it, or sharing the enjoyment of the man who dishonours her;" and in proof he mentions having attended a young woman who was got with child while totally unconscious, being buried in a deep sleep produced by punch given her by her paramour.§ She became aware of her condition for the first time when she felt the sensation of motion in the fourth month. Foderé expresses a similar opinion, and quotes several instances in which the occurrence took place, one of which is particularly remarkable.‖ MM. Marc¶ and Raye

Delorme* speak of such a fact as established by experience. Dr. Gooch says, "it is not necessary that the woman should be sensible at the time of impregnation," to which observation the following case is subjoined: "A maid at an inn, who was always thought to be virtuous and bore a good character, began to enlarge in a way which excited suspicions of pregnancy; she solemnly declared that she never had connexion with any man. At length she was delivered, and was afterwards brought before a magistrate to swear to the father; but she repeated her former declaration. Not long afterwards a postboy related the following circumstances: that one night he came late to this inn, put his horses into the stable, and went into the house; he found all gone to bed except this girl, who was lying asleep on the hearth-rug, and without waking her he contrived to gratify his desires." "This shews," he adds, "that impregnation may take place without the knowledge of the female."†

In reference to this question Beck remarks, "In females habituated to sexual connexion, or where sleep is unnaturally produced, there is no doubt of its occurring; whereas in the opposite cases the probability is greatly lessened;"‡ and in a note on this passage he quotes the following case: "A pregnant female in her last moments solemnly declared that to her knowledge she never had connexion, but that a person in the family some time previous had given her some wine to drink, after which she fell into a profound sleep. She was not, however, conscious of any thing having occurred during that state, but mentioned the circumstance as probably explaining her situation."§ A case very much resembling that related by Dr. Gooch has just been mentioned to the writer by Mr. Cusack, which occurred under his own observation. A servant woman at an hotel in Nenagh proved pregnant, and solemnly declared that she was not conscious of having had intercourse with any man. Suspicion, however, fell upon an ostler in the establishment, who subsequently acknowledged that he believed he was the father of the child; that having found the woman in a deep sleep from fatigue, caused by long-continued exertion and being kept out of bed two or three nights in succession, he had connexion with her, and, as he believed, totally without her knowledge, as she did not evince the slightest consciousness of the act at the time, or recollection of its occurrence afterwards: the parties were married with mutual consent.

We once attended a patient who even in her dying hour protested in the most solemn manner that she was not conscious of sexual intercourse; and when we recollect that delivery has occurred during sleep, we cannot doubt but that coition, which is so much less likely to disturb, may be consummated during sleep with a female accustomed to sexual indulgence without her being afterwards aware of it. That such an event must be of very rare occurrence is certain, but we cannot deny its possibility, and therefore we are furnished with an additional reason for refusing implicit assent to the statements of females, who, as they will in ordinary cases of illegitimate pregnancy, deny the possibility of their condition with the most unparalleled effrontery and the most solemn and imposing protestations, whilst we should, on the other hand, recollect that impregnation may possibly have been effected without their knowledge; so that, however highly we may esteem their general credibility in other matters, in this they may either try to deceive us or be themselves deceived; we must therefore form our opinion not by what we hear, but by what we can see and feel.

The following case is quoted by Bruhier, Foderé,* and others,† from the Causes Célèbres, to shew the possibility of conception during a state of complete asphyxia or apparent death. "A young friar being on a journey, arrived at a house where they were about to bury a young girl, whom they believed to be dead. He proposed to pass the night in the chamber with the coffin and watch the body. In the course of the night, while examining the body, his passions were so excited by the beauty still remaining, that he determined on satisfying them even under such circumstances. He departed early next morning, and in the course of the day the apparently dead revived, proved to be pregnant, and at the end of nine months brought forth a child, to the great amazement of her friends as well as her own. The friar returned to the place about this time, confessed himself the father of the child, and married the mother, having procured absolution from his vows, which he had taken against his will."

4. *Presence or absence of the hymen.*—It seems almost unnecessary to remark that the presence of the hymen, however perfect its condition, cannot be assumed or depended on as a conclusive proof against the previous occurrence of impregnation, for although it certainly ought to be considered as strong presumptive evidence in favour of virginity, so many cases have been witnessed and put on record by authors worthy of credit, in which that membrane has been found co-existing, not alone with pregnancy, but even with labour, that the fact no longer remains a matter of doubt. Meckel‡ remarks that "the hymen cannot be considered a certain physical sign of virginity, because, on the one hand, it has been often found entire not only in women who had frequently indulged in sexual intercourse,§ but even in some who had brought forth fœtuses advanced even so far

is the seventh month."* The writer was once consulted by a young person whom he found to be pregnant, and whose hymen was as perfect as it had probably ever been; but the opening through it was such as to admit the finger to pass without difficulty, and the girl acknowledged that she had on more than one or two occasions enjoyed the embraces of a very young gentleman, on whose youth it appeared she had relied for immunity from the usual consequences.† The existence of the hymen at the time of labour has been detailed by Ambrose Paré, Willis, Ruysch, Nœgele, Baudelocque,‡ Mauriceau,§ and many others: the cases related by the last two are particularly remarkable. Dr. Davis‖ also refers to more than one case of this kind. Velpeau¶ mentions having met with the hymen entire in the body of a woman of forty, "who had long cohabited with her husband, but without having children." The writer once witnessed a similar case in an old lady of 80, who had been married and lived thirty years with her husband without having children: when visited by the writer, she had been some years a widow, and examination of the parts became necessary in consequence of an affection of the urethra; the hymen would not permit the passage of the point of the little finger without difficulty.

On the other hand we believe it is a matter of universal agreement, that there are many causes besides sexual intercourse capable of destroying this membrane, which there is also good reason for believing may in some cases have been originally defective from imperfect conformation of the part.** In another part of this article the imperforate hymen has been noticed, and its effect in inducing suspicion of pregnancy by preventing the discharge of the catamenia. And it is scarcely necessary to observe here, that in such a case the mere discovery of the obstacle would be proof positive against the condition suspected. Among the Jews a discharge of blood, as the consequence of the laceration of the hymen in primis nuptiis, was considered so unequivocally the test of virginity, that it was made a subject of legislature, and the woman to whom this did not happen was liable to be stoned to death.†† Gardien mentions that the Jewish custom prevails to a certain extent at the present day amongst the Bedouin Arabs; and Mahon, on the authority of Chappe, speaks of a similar custom as at present existing in Siberia and in certain parts of Russia.* It has been remarked by Foderé, Mahon, and others, that the state of the hymen may vary much in the same individual at different times and under different circumstances; and the latter mentions a case where a man not finding it existing in his bride took great offence, but afterwards finding a totally different condition of the part, recognized his error and was satisfied.† Marc has recorded a very remarkable case illustrative of this, and, as he says, "showing that, when the hymen is of the semilunar form, it may disappear for a time, and return again."‡ "A young girl, not 13 years of age, formed an illicit intercourse with a man, in consequence of which she was severely affected with syphilis, for the cure of which she was brought to the hospital of La Pitié: on examination by Dr. Serres and others, there was found extreme dilatation of the vagina, injury of the external genitals, and total absence of the hymen: she was cured, and then they were greatly astonished to find all the physical marks of virginity existing, especially a well-marked semilunar hymen. MM. le Docteur Fournier, Pescay, and Marc were appointed by the Medical Society of Emulation to examine the fact."§

As a suitable conclusion to this section we shall notice a very remarkable case recorded by Nysten, forcibly illustrating the necessity of attending to these unusual conditions, as not being incompatible with pregnancy, which in the case alluded to occurred in combination with several such. In this instance, 1. the pregnancy was ovarian; 2. the girl was only thirteen years old; 3. she had never menstruated; 4. the hymen was perfect; 5. the vagina so contracted that it would scarcely admit the tip of the finger; 6. the organs of generation and the breasts like those of childhood."‖

Examination of the uterus and its appendages after death.—It is unnecessary to repeat here what has been already particularly set forth with regard to the state of enlargement in which the uterus must be when containing the product of conception. In relation to our present subject, the first and most obvious fact to be noticed is, that when an examination is made after death, and the uterus found of its naturally diminutive size, it is proof positive against the present existence of pregnancy. If, on the other hand, we find the organ enlarged, and its condition apparently corresponding to the period of pregnancy supposed to exist, nothing but a careful examination of its contents, or other cause of enlargement, can determine the question at issue. We will here only observe that nothing less than the distinct and unequivocal detection of the ovum or some of its component structures ought to satisfy our

minds, or justify us in giving an opinion in the affirmative.*

Another condition of the uterus which may present itself, is that in which it is found enlarged but empty, exhibiting, however, several of the changes which accompany gestation: these, however, upon examination will only afford evidence sufficient to convince us that the organ has recently been distended by something contained within it, and which had been attached to its internal surface by a vascular connection: the substance expelled may or may not have been the product of conception; and the most careful examination of the appearances remaining, or of the structural changes effected, will not enable us to pronounce safely on the precise nature of the cause which had produced them. Thus, for instance, in a case where hydatids have been expelled, we could not determine by examination of the uterus alone, whether the conditions there observable were the result of true pregnancy and the expulsion of a fœtus or ovum, or whether they might not have been produced by some other cause unconnected with conception: we may not, in fact, be able to tell without further investigation whether the woman have recently conceived or not, a question which it may be occasionally of paramount importance to be able to answer: we must therefore turn our attention in another direction, and seek for proof of impregnation in the appendages, particularly in that part of them which is more especially the seat of conception. This leads us at once to investigate the value of that peculiar change in the ovary, by which, after the vivification of the germ, there is produced a new structure, to which has been applied the name of *corpus glandulosum*, or more generally, *corpus luteum*,—a production the presence of which is by some considered incontrovertible evidence of impregnation. Others, however, with equal confidence discredit the value of its presence, and assert that its existence may be owing to causes altogether accidental and independent of sexual intercourse, and that consequently it cannot be taken as certain evidence of conception. It becomes, therefore, a matter of vital moment to examine the truth of such assertions, and to determine, if we can, how far they coincide with or depart from absolute matter of fact, which alone can be the measure of their correctness, and consequently of their value. In order to do this, the first thing which appears to us essentially necessary is, that we should have a clear idea of what a true corpus luteum is, and of what is not a corpus luteum.

If this inquiry should appear to any one superfluous, it is only necessary to turn to the generality of books in which it is mentioned, and then compare the descriptions to be found there with the object as it exists in nature, and we must be convinced how faint is the resemblance between the portrait and the original. We are inclined to think that the naming of this substance has given rise to much of the error which exists and is propagated on the subject, the colour being assumed as the only characteristic necessary to constitute the corpus luteum. Whenever small spots, or even points, of a yellow hue are met with in the ovaries, they are supposed to be true corpora lutea. We recollect distinctly the first time our attention was drawn to the subject was at a demonstration of the structure of the ovaries, when two spots, each not larger than a grain of mustard-seed, and of a yellow colour, were exhibited as specimens of corpora lutea, and as proving that the woman had, during her life, borne two children.

A trial took place some years ago in Edinburgh, which, while it evinced the necessity for a correct knowledge of this subject, which might occasionally arise even under circumstances not apparently connected with its existence, proved but too plainly how little was known about it. A prosecution was instituted against four medical students for exhuming the body of a lady in Glasgow. The body was so disfigured that it could not be identified: the ovaries were, however, examined, and it was reported that there was in one of them a perfect corpus luteum, which would be sufficient to prove that the remains were not those of the lady in question, who was a virgin, and advanced in life. On the trial there was a complete contradiction between the medical witnesses, one half of whom affirmed the appearance in the ovary to be a true corpus luteum, while the others maintained that it was not; so that no satisfactory inference could be drawn from the fact. The body was afterwards identified by a dentist producing a cast which he had taken of the gums.

If we examine the ovaries of a woman who has recently conceived, we observe that the one which has supplied the germ differs in several remarkable particulars from its fellow of the opposite side: it strikes the eye at once as being larger and more vascular; to the touch it feels fuller and softer: we perceive further, that this increase of size of the one is not so much the result of an increased development of the whole substance or body of the organ, as of the addition to it at one part, of a tumour projecting more or less from its natural outline, as we find in the eye, where the circumference of the cornea projects from the outline of the globe, the segment of a smaller circle being superimposed on that of a greater.

When we examine this protuberance, we find that the increased vascularity of the organ is nearly confined to its limits, and very frequently we perceive that the colour of this part is completely different from that of the rest of the substance, giving the notion of deep or dull yellow seen through a slightly reddish medium; and lastly, we observe on some part of the external covering of this prominent part a distinct cicatrix, or appearance as of a rent imperfectly united.*

* See section on *Substances expelled from the uterus.*

* In the case examined by Sir E. Home and Mr. Clift, where the woman died eight days after impreg-

We should observe here that these external changes by which we recognise the existence of the corpus luteum within, are to be seen most remarkably in some of the lower animals. In cows it is not unusual to see the corpus luteum projecting almost like a parasitic tumour from the side or end of the ovary; the same may be said of the sheep, and of animals which naturally have the Graafian vesicles very prominent, as the hedgehog or common sow, in which they absolutely project from the surface: in this animal the ovaries after conception appear literally like bunches of round berries, from the great prominence of the numerous corpora lutea.

Having satisfied ourselves of the presence of the external characters, we proceed to examine the internal structure; in order to do which we should make a section of the ovary, carrying the knife through the centre of the prominent part so as to divide the ovary into two longitudinal sections, by which we expose the corpus luteum presenting the following characteristic appearances.

In *form* and *size* it is almost always an oval, with its longer axis varying from four to five eighths of an inch, and the shorter from three to four eighths; its thickness is generally less than its breadth.*

Its texture is obviously and strikingly glandular, resembling a section of the human kidney;† or, as some one has said, it is like a miniature of the particular sections of the brain called by anatomists *centrum ovale*. William Hunter describes it as "tender and friable, like glandular flesh."‡

It is very vascular, small vessels being very frequently visible without any preparation; but if fine-coloured injections have been previously thrown into one of the branches of the spermatic arteries going to the ovary, the vessels of the corpus luteum will be filled with the colouring matter, and are to be seen very distinctly running from its circumference towards its centre.

Its colour is, as its name implies, a dull yellow, very similar to that of the buffy coat of the blood; exhibiting generally, when recently exposed, a slightly reddish tinge, "*ex flavo rubens*," Haller.

Its centre exhibits either a cavity or a radiated white cicatrix according to the period at which the examination is made: if within the first three or four months after conception, we shall frequently find the cavity still existing, and of such a size as to be capable of containing a grain of wheat;§ this cavity is surrounded by a strong white cyst, and as gestation proceeds, the opposite parts of this cyst approximate and at length close together, by which the cavity is completely obliterated, and in its place there remains a white cicatrix, whose form is best expressed by calling it radiated. Of this latter appearance it ought to be observed here that it is visible as long as any distinct trace of the corpus luteum remains, and forms an essential character, distinguishing this body from every other that might be confounded with it.

After the period of gestation has been completed, or the contents of the uterus prematurely expelled, so that gestation ceases, the corpus luteum soon begins to exhibit a very decided alteration in all its characters, until at length it is no longer to be found in the ovary. The exact period of its total disappearance we are unable to state; but we have found it distinctly visible so late as at the end of five months after delivery at the full time, but not beyond this period; and the corpus luteum of a preceding conception is never to be found along with that of a more recent, when gestation has arrived at its full term; but in cases of miscarriage repeated at short intervals, it may. At the time of delivery the corpus luteum is neither so large nor so vascular as at the earlier periods of pregnancy, except the woman should happen at the time of her death to be labouring under inflammation of the uterine system, in which case the corpus luteum partakes of the turgescence of the other parts, and very remarkably of their increased vascularity.

In the ovary of a woman who died of inflammation of the womb a few days after delivery, and which is preserved in the writer's museum, the white central cicatrix is very distinct, and externally the ovary continues to exhibit the superficial cicatrix and the alteration of form produced by the projection of the part containing the corpus luteum. In another preparation, which shews the appearance of the corpus luteum in a woman who died of pneumonia exactly five weeks after delivery at the full time, it is diminished in size to about one-half of its original dimensions, is closer in its texture, and its colour was becoming indistinct in numerous points, so that it appeared paler, but the radiated central cicatrix is quite distinct; its vascularity also was diminished, as fine injection could not be got to pass into it: the external surface of the ovary exhibits the greater size and prominence of one part, and the fissure on it is still well marked; and it is particularly deserving of remark here that there is *only one cicatrix* observable on each ovary, although the woman from whom they were taken had borne six children.

In another specimen in our collection, taken from the body of a woman who died in the twelfth week after delivery, the external prominence was greatly diminished, but was still

nation was supposed to have taken place, "the right ovarium had a small torn orifice upon the most prominent part of its external surface. We slit it open in a longitudinal direction, in a line close to the edge of this orifice; the orifice was found to lead to a cavity filled up with coagulated blood, and surrounded by a yellowish organized substance." Philos. Trans. 1817. p. 254.

† See De Graaf, p. 177.

‡ Anatomy of the Gravid Uterus, p. 14.

§ "Cavea dimidiam lineam lata, non profunda," *Haller.* We once met with this central cavity in the ovary of a cow recently impregnated, large enough to receive the end of the little finger.

sufficiently obvious to indicate the exact situation of the corpus luteum, as was also the superficial cicatrix: the corpus luteum itself had lost much of its colour, and what remained became, on immersion into spirits, of a light grey shade; the texture of its substance was more condensed, and resembled that of a cut apple; and its dimensions, especially in breadth, are reduced to about one-third or rather less, but the central radiated cicatrix is still distinctly observable.

Lastly, in the case of a young woman who died *five months* after giving birth to her first child, the ovary retained very little of its increased size or altered form; the prominence was hardly to be recognized; but the external cicatrix was perfectly obvious. When opened, the corpus luteum exhibited its peculiar colour only in one very small spot, rather larger than a mustard-seed, within which is still observable the central radiated cicatrix; the yellow colour completely disappeared when immersed in perfectly pure rectified spirit diluted with water.* Beyond this period we have never detected the existence of the corpus luteum: the vulgar notion, however, is that it is a permanent structure, and that consequently we have only to examine the ovaries after death to enable us to tell not only whether a woman has borne children, but the exact number of her offspring, from the number of corpora lutea existing in the ovary. This is quite an error, and probably arose from a misconception of the meaning of such an expression as that of Haller, when he says—"Numerum credo eundem esse, qui est fœtuum;"† or, as in another place, "Numerus corporum luteorum est in ratione fœtuum."‡ By this expression, however, he only meant that their number was the same as that of the fœtuses lodged in utero in one gestation, which indeed we find expressly stated by De Graaf, whose words are—"Deteguntur, unus aut plures, prout animal ex illo congressu unum aut plures fœtus in lucem edet."§ Hence, when there is only one fœtus, there is only one corpus luteum. In cases of twins or three children, there will be a corresponding number of these bodies in the ovary or ovaries, for they may be all formed in one ovary only, or some in each. This suggests a circumstance of great importance connected with the number of these bodies which may be found; which is, that occasionally a corpus luteum may be discovered without a fœtus, or a greater number of them than there are fœtuses produced at the time. Thus, in one instance we found two corpora lutea in the ovary of a woman who killed herself by medicine taken to produce abortion. She was reported to have expelled but one ovum. Haller notices this occasional occurrence, and explains it thus: "Si unquam absque fœtu corpus luteum in ovario repertum est, quod est rarissimum, credibile est eum fœtum abortu perditum aut alio modo destructum disparuisse."* We have had several opportunities of verifying this observation, and, amongst other instances, we once found ten corpora lutea in the ovaries of a sow, but only nine fœtuses in the uterus; but at length, after a very diligent search, we discovered in one of the cornea the remains of another fœtus which had been blighted and was in a state of partial decomposition. Haighton also observed this occurrence, but adds that "the uterus in these cases has borne the marks of an early and recent abortion;"† and Cruikshank, as mentioned in another place, speaks of the corpus luteum as a certain mark of conception, "whether the embryo is visible or not."‡ We may remark that from such facts follows of necessity this circumscription of the conclusion to be drawn from what we may observe in the ovaries,—viz. that the presence of a corpus luteum does not prove that a woman has *borne a child*, although it would be a decided proof that she had been impregnated and had conceived; because it is quite obvious that the ovum, after its vivification, may be, from a great variety of causes, blighted and destroyed long before the fœtus has acquired any distinct form. But the converse will not hold good. We believe no one ever found a fœtus in utero without a corpus luteum in the ovary, and that the truth of Haller's corollary, "nullus unquam conceptus est absque corpore luteo,"§ remains undisputed.

Considering the results constantly presented to us by examination, we feel utterly at a loss to imagine what could have induced the following assertion of Sir E. Home: "The remains of the corpus luteum at nine months *after impregnation of the ovum*, are so indistinct as hardly to be recognized; but in the opposite ovarium there is commonly a corpus luteum far advanced, forming another ovum; and it will be found that all the preparations of corpora lutea taken from the ovaria of women who die in childbed, actually belong to this new ovum not yet completely formed."‖ Now, our experience convinces us of the contrary of every statement here made, and we think that one question will be sufficient of itself to shew their inaccuracy: premising that we deny altogether the statement that there is "commonly" found a second corpus luteum, we ask, if this corpus luteum always found in the ovaria of women who die in childbed belongs to the ovum not yet completely formed, how does it happen that we always find on its surface the cicatrix through which the ovum has already escaped?

A similar and equally erroneous idea obtains very generally with regard to the cicatrices on the surface of the ovaries, which have been already noticed as marking the situation of the corpus luteum. These are supposed by many to be permanent and ineffaceable, and of course

* This does not happen when the corpus luteum, taken during gestation, or just at the time of delivery, is placed in contact with the same fluid.

certain indications of the number of children borne by the woman during her life, or of the number of times she had conceived. But such is not the case; the ovaries of women who have borne several children will sometimes be found exhibiting only one or two of these rents or marks on the surface, a very distinct instance of which has been already noticed; the woman in this case having given birth to six children, and yet the ovaries exhibited only one cicatrix on each. On the other hand the effects of inflammation, or the bursting of small abscesses in the ovary, may produce cicatrices which cannot be distinguished from those which are caused by the escape of the impregnated ovum. There is a passage in Beck's Jurisprudence which evinces extremely little practical acquaintance with this subject, implying one error, and distinctly asserting another. His words are, "Upon examining the ovaria, if it be done a short time after the ovum has escaped from them, a corpus luteum is *generally* found, which vanishes soon after, but *leaves a scar for life*."* Dr. Smith appears to confound the cicatrix with the corpus luteum itself, in the following passage: "In the place from which one of these bodies (ova) had been conveyed, a cicatrix was formed which received the name of corpus luteum."†

Having thus far described the characters of the true corpus luteum as accurately as repeated observations and dissections of a great number of women, and a much larger number of brute animals, have enabled us, we wish to declare, first, that we never in any one instance saw the corpus luteum, having the characters we have described as belonging to it, except in females who had previously been impregnated and had conceived; and our firm conviction is, that such a corpus luteum was never found in a virgin animal.

As, however, different opinions have been entertained on this subject, it becomes necessary to examine them and ascertain their value. The views entertained by those who deny the necessary connexion between the formation of the corpus luteum and sexual intercourse followed by conception, are principally two. According to the one, the corpus luteum is a provision for conception, by which the ovum lodged within it is prepared and fitted for impregnation. According to the other view the corpus luteum is properly the effect of impregnation, but may also be produced by other adventitious circumstances causing high excitement of the generative apparatus independently of sexual intercourse. The first of these opinions is generally supposed to have originated with the late Sir E. Home, but it is only justice to say that he merely revived a theory which had been exploded and lain dormant for a long series of years, as appears very clearly from a passage in Wrisberg. This writer, after stating that multiplied observations both in the human race and in quadrupeds proved that the corpus luteum was not to be found in the ovaries "ante congressum fœcundum et inde pendentem conceptionem," adds, "ruit itaque ingeniosum potius quam naturæ congruum, de usu et functione corporis lutei, latum judicium conceptionis materiem ex parte sexus sequioris comprehendere et secernere."* The opinion here alluded to was that of Malpighi, Santorini, Valisneri, and Bertrandi; and it is remarkable that Sir E. Home should have promulgated it anew without even noticing its former existence, and that he should have done so on the data furnished to him by a single case,† in which he examined the body of a young woman who died a few days after conception, when he found an ovum in the uterus, and a corpus luteum in one of the ovaries. From this he concludes at once that this was the commencing provision for a future conception, not the result of the former; but the reasons are not stated.

It has been already shewn that a similar notion was entertained many years ago, and its accuracy disproved by observation; but it is not altogether satisfactory, nor consistent with the spirit of philosophic inquiry, to reject an opinion merely because it has been already exploded, however high may have been the authority for its rejection. We must, therefore, examine this doctrine upon its own merits, before we can refuse it our assent. In the first place, then, if such a statement were correct, corpora lutea ought to be found in the ovaries of almost all women examined just before or during the period of life in which they are apt for conception. No one has ever asserted that this is so; and in point of fact we know it is not the case. In the second place, if such were the relation of the corpus luteum to conception, it ought to be found in a state of greater development, as the distance of time from the former conception increases: now we have demonstrative proof that exactly the contrary happens. In the third place we find that their number corresponds to the number of fœtuses which have been produced, as already explained. Such objections might easily be multiplied, but those already stated appear more than sufficient for our purpose. The other assertion, that corpora lutea may be produced independently of sexual intercourse or conception, during periods of lasciviousness, or from the stimulus of strong passions, or unnatural enjoyments, requires a very careful examination, inasmuch as, if it be really borne out by facts, the presence of the corpus luteum in the ovary would cease to be of any value whatever as a proof of impregnation; and believing, as we think we have full grounds for doing from a very long-continued examination of the subject, that the real corpus luteum is the result of conception, and of nothing but conception, we think we shall be able to shew that some of the assertors of this doctrine which we impeach, have in some instances merely repeated the statements of others without exami-

nation; while others have misrepresented the opinions which they quote in their support; and others, again, have mistaken for true corpora lutea accidental formations in the ovaries, having no one character, except the colour, of the bodies which really deserve the name.

Most of the writers who advocate the production of corpora lutea without impregnation, premise as a powerful support in their favour the opinion of Blumenbach, which is thus spoken of:—"In the year 1788 Blumenbach *shewed* that corpora lutea may exist in the ovaries of virgins."* Now, before proceeding to review any of the opinions or assertions built on the authority of this great physiologist, we must first examine what he has really said on this subject. His observations are to be found in a *Specimen Physiologiæ Comparatæ*,† published in 1788, and in our opinion are very far from warranting the conclusion so generally taken for granted to result from them; first, because his own definition of the corpus luteum renders it extremely doubtful whether his observations apply to the body really deserving that name, or merely to the cicatrix on the ovary connected with it. His words are: "Notum est post fœcundum coitum in muliere aliisque mammalibus femineis, in alterutro ovario *fissuram* reperiri cruentam, ex ruptû sub œstrum venereum unâ alterâve earum vesicularum quas Graafius pro veris ovulis venditaverat; idemque vulnusculum temporis progressu in *cicatricem abire cortice eleganter vascaloso cinctam*, atque Malpighii inde temporibus lutei corporis nomine insignitam."‡ And, secondly, even if we are satisfied that he there speaks of the true corpus luteum, which we very much doubt, it is very remarkable that in no one part of his paper does he speak as from personal observation or examination of the subject by himself, but confines himself to physiological reasonings grounded on the facts observed by others,§ from the consideration of which he declares his *belief*‖ in one place, and his *suspicion*¶ in another, that the fact may be so, but he nowhere asserts that he saw an instance of it; and he adds that all the cases his reading furnished him with happened in Italian girls, whose climate he appears to suspect might have something to do with the matter. The passage in which this is expressed appears to us, even from its singularity, worth quotation here; it is as follows:—"Num climati quoque aliquod tribuendum, decidere non audio, annotans tantumnodo quotquot mihi hactenus *apud auctores* occurrerunt ejusmodi haud inficiendi casus eos non nisi in Italicis virginibus observatos fuisse."** Meckel, also, is by some asserted to have maintained this doctrine; but it appears to us that so far as his observations go, they afford it very little if any support at all. He commences with these words:—"The internal organs of generation are modified not by the act of intercourse merely, but by *conception alone*. There is developed in the ovary a peculiar body called corpus luteum,"* which he then describes as resulting from a change produced in one or more of the vesicles of De Graaf; and adds, "the influence of the male semen is the ordinary and regular cause of this change, which, however, *it appears*, may be effected under the influence of other stimuli, *perhaps* by the imagination or unnatural enjoyments." Now it is, we think, quite plain, from the language of the above passage, that he is alluding to the opinions of others, and not stating a fact of which he had assured himself; and accordingly he immediately subjoins, "in truth, many of these rare cases, in which corpora lutea have been found in unmarried women, and in girls having the physical marks of virginity, allow the belief that the formation of these bodies *had been preceded by sexual intercourse and fecundation*." He afterwards makes an observation which, if properly understood and appreciated, would have prevented many of the absurdities which have been promulgated on this subject. "They speak," says he, "of corpora lutea which have been found in newborn or very young animals; but the obvious answer to this is, that *every yellow substance* met with in the ovary *is not a corpus luteum*."† What but the most complete mistake on this point could have induced an annotator on Beck's Medical Jurisprudence to hazard the following observation:—"A recent case has in my opinion completely overthrown the theory, that even strong passions are necessary to the formation of the corpora lutea: the subject was *not above five years old*, and the hymen of course entire; she died of tubercular disease in the lungs, yet in her ovaries were *numerous corpora lutea* as distinct as I ever saw them in the adult impregnated female."‡ The only comment necessary to make on this statement is, simply to remark that *one* real corpus luteum, as it is found "in the adult impregnated female," is fully as large, or even larger than the ovary of a child five years old, therefore it is *impossible* that there could in such a case be several of them.

Dr. Bostock, in his very able and instructive work on physiology,§ gives a summary of the opinions on this subject, but avoids hazarding more than a mere hypothesis himself. It is plain, however, that he inclines to the belief "that corpora lutea are not the necessary result of impregnation."‖ But we must observe that he overstates the opinion of Blumenbach when he asserts that he "decidedly maintained" such a doctrine, which we have already shewn he did not; and he is equally

inaccurate in quoting Cuvier as a supporter of this physiological heresy: it is only necessary to refer to the passage quoted,* to see that Cuvier is there not speaking of the corpus luteum at all, but of the cicatrices observed on the ovaries; *and throws out a question*, whether these may not sometimes be caused by the passage of germs, under the influence of unnatural stimuli. Dr. Seymour, in his very interesting work on the ovaria,† has given a well arranged summary of the conflicting opinions and theories on this subject, to which he has added some very judicious and pertinent remarks; but upon the particular question before us, he expresses himself at least vaguely. He however appears to believe in the *possibility* of the production of corpora lutea without impregnation, but nowhere asserts that he saw an instance of the kind; on the contrary, the result of his own investigations, as stated by himself, is so strongly against such a belief, that we mean to quote it in his own words as a very strong fact in our favour. "It has occurred to me," he says, "to have examined the ovaria in the human being, and in animals at the period of puberty in very many instances; many had ova ready for impregnation, large, projecting, vascular, *yet no corpora lutea were visible*."‡ Such, also, has been the result of our examinations of a very large number of bodies both of women and of animals, and in no one instance did we ever find a true corpus luteum except as the product of conception; and reasoning merely on the subject, we would ask, if mere imagination or highly excited desires without intercourse are capable of causing such a change in the condition of the ovary, should we not expect to find corpora lutea almost invariably in women who have been living with their husbands, or otherwise enjoying constantly the natural and perfect excitement of the generative system without conception? Of the non-occurrence of which consequence we can speak in very decided terms, from numerous opportunities of making examinations under such circumstances.

We shall now proceed to state, as briefly as possible, the opinions of those whose careful and repeated examinations of the subject fairly entitle them to the highest degree of credit. De Graaf, who is justly celebrated as an accurate anatomist and physiologist, devoted much of his attention to the generative system of the female, and in his work on this subject published in 1672,§ we find him thus speaking. "Quæ vero secundum naturam, aliquando tantum, in mulierum testibus inveniuntur; sunt globuli, qui glandularum conglomeratarum adinstar ex multis partibus à centro ad circumferentiam recto quasi ductu tendentibus conflantur, et propriâ membranâ obvolvuntur. Hos globulos non omni tempore in fœmellarum testibus existere diximus; quia *post coitum tantum* in illis deteguntur, unus aut plures, prout animal ex illo congressu unum aut plures fœtus in lucem edet." De Graaf applied to this formation the name of corpus glandulosum, which name it retained until Malpighi changed it to that of corpus luteum on account of its colour. The great Haller paid particular attention to this point, in the investigation of which he sacrificed many sheep, goats, and cows, besides great numbers of other animals; and by opening the bodies of several at gradually prolonged intervals of time from intercourse with the male, he traced the corpus luteum from its first commencement through all its successive stages of increase and decline.* He tells us, also, that he had opened the bodies of upwards of a hundred women, and met with the corpus luteum about ten times, but never except in those who were at the time pregnant, or had brought forth children.† "Quotquot feminæ nullam fecundationem ante mortem passæ sunt, tot etiam ineisæ nulla corpora lutea ostendunt." Now it is to be observed that Haller continued this investigation through many years, and was perfectly well aware of the theories of Bertrandi, Valisneri, and Buffon, with the latter of whom he corresponded on the subject, and the result of his observations he embodies in two brief but most important propositions:—"Nullus unquam conceptus est absque corpore luteo:"‡ "Corpus luteum in virgineis animalibus nullum est, ex conceptione oritur, neque prius paratum adest." The first of these propositions has never been questioned, and the truth of the second appears to us equally incontrovertible. The observations of Blumenbach were published in 1788, and nine years afterwards, or in 1797, Dr. Haighton read before the Royal Society the details of many experiments on the subject of animal impregnation,§ and thus expresses himself on this point: "I may then say that no corpora lutea exist in virgin animals, and that, whenever they are found, they furnish incontestible proof that impregnation either does exist or has preceded."‖ And again he says, "I decline trespassing on your patience, and therefore lay before you only the conclusion; which is, that in the great variety of experiments on brute animals which my physiological inquiries have led me to conduct, as well as in the extensive opportunities I have had of observing the ovaries in the human subject, I have never seen a recently formed corpus luteum unattended with some circumstance or other connecting it very evidently with impregnation."¶ In the same year Mr. Cruikshank published his account of a series of experiments also on this subject, and we find him remarking as follows:—"These calyces, on the expulsion of the ova, enlarge and become yellow, projecting above the external surface of the ovaria, and form *corpora lutea, a certain mark of conception* in all quadrupeds, and in women themselves, whether

the embryo is visible or not."* William Hunter, and his editor Dr. Baillie, speak of the corpus luteum as the product of conception, but do not even mention the supposition of its possible occurrence in any other way.†

When Mr. Angus was tried in Liverpool, in 1808, for the supposed murder of Miss Burris, great doubt arose as to whether the condition of the uterus or its appendages was such as to prove a pregnancy recently existing. "It was not until after the trial that the ovaria were examined. They were then divided in the presence of a number of physicians, and a corpus luteum distinctly perceived in one of them. Mr. Hay took the uterus and its appendages to London, and shewed it to the most eminent practitioners there. He received certificates from Drs. Denman and Haighton, Messrs. Henry Cline, Charles M. Clarke, Astley Cooper, and Abernethy, all stating that it exhibited appearances that could alone be explained on the idea of an advanced state of pregnancy. *And it appears to have been universally allowed that the discovery of the corpus luteum proved the fact beyond a doubt.*"‡ In addition to the authorities here cited, we may be allowed to add the result of our own observations, which have been now continued through a period of more than six years, during which time we never omitted a single opportunity within our reach for examining the bodies of women of all ages, and under all the varying circumstances of virginity, after intercourse, during gestation, and subsequent to delivery at different periods from conception; these opportunities having been afforded by more than one large hospital, as well as in private practice. We have also dissected hundreds of the inferior animals with reference to this point, and have in our museum preparations of ovaries exhibiting the corpus luteum in different conditions in the human female, and also in cows, mares, sheep, sows, goats, bitches, cats, hares, rabbits; and our firm conviction is of the truth of both Haller's propositions, viz. that "*conception never happens without the production of a corpus luteum*," and that "*the corpus luteum is never found in virgin animals, but is the effect of impregnation.*" And we think that those who have supposed or asserted that they may exist without impregnation, and of course be found in the virgin ovary, have been led into the error by confounding appearances and structures essentially different, and in fact having only one character in common, which is their colour, altogether forgetting that "every yellow substance in the ovary is not a corpus luteum."§ It is allowed by those writers that "the corpora lutea of virgins may in general be distinguished by their smaller size, and by the less extensive vascularity of the contiguous parts of the ovarium." ‖ Now we have seen several of these virgin corpora lutea, as they are unhappily called, and have preserved several specimens of them, and according to our experience they differ from those of impregnation in all the following particulars:—1. there is no prominence or enlargement of the ovary over them; 2. the external cicatrix is wanting; 3. there are often several of them in both ovaries, especially in patients who have died of tubercular diseases; 4. they are not vascular, and cannot be injected; 5. their texture is sometimes so infirm that they seem to consist merely of the remains of a coagulum, and at others appears fibro-cellular and resembling that of the internal structure of the ovary, but in no instance did we ever see them presenting the soft, rich, and regularly glandular appearance which Hunter meant to express when he described them as "tender and friable like glandular flesh;"* 6. they have neither the central cavity, nor the radiated cicatrix which results from its closure.

Signs of delivery.

An investigation into the proofs of delivery, whether undertaken with reference to circumstances of a social, professional, or legal nature, although not so frequently required, will be found no less important in its relations to society, nor less difficult in its details, than the examination of the proofs of pregnancy, a very clear and accurate knowledge of which latter is indispensably necessary to enable us to arrive at a satisfactory conclusion, when engaged in such an enquiry as that before us. It may, and indeed frequently does happen, that a woman with an enlarged belly arising from some purely accidental or morbid cause becomes an object of suspicion, and afterwards the sudden reduction of her size may, however unjustly, affix upon her the imputation of clandestine delivery at least; and although such charge may never be made the subject of a legal or criminal investigation, its influences would be alike unjustly prejudicial to the character of the individual, and injurious to the moral interests of society. The writer very lately saw such an instance in the case of a woman separated from her husband, who became affected with what was considered ovarian dropsy, and which enlarged the abdomen to the size of six months' pregnancy, some of the other symptoms of which state were also present. After an attack of inflammation, during which it is to be presumed the parietes of the tumour formed an adhesion with the upper part of the vagina, there took place suddenly a discharge of gelatinous fluid from that cavity, and the abdomen completely subsided in the course of a day, and the previously entertained suspicion appeared to be confirmed beyond a doubt; but on examination the woman had not about her one of the signs of delivery; yet had not the case been at once investigated, loss of reputation at the least would have inevitably, though most undeservedly, followed. In a very interesting case related by Foderé, the life of an innocent woman was very near falling a sacrifice to the

* Description of Gravid Uterus, p. 14.

aw under circumstances somewhat similar. 'A young woman had her menses suddenly suppressed in consequence of a fright, and sought every aid to restore them without effect: he was at length married with a view to induce their return, which succeeded after a time, nd she discharged a great quantity of fetid natters. This fact was proved by the husband nd the medical attendants. It so happened ust at this period that two children were found xposed and destroyed by cold; suspicion fell n this young woman, because she was known o have had an enlarged abdomen, which had ery suddenly subsided. The judges of the istrict ordered her to be arrested and examined y a physician, a surgeon, and two midwives, ho reported that they had discovered marks f delivery. In consequence of this, the unortunate woman was condemned to death for oncealing her pregnancy, and making away ith her children. An appeal, however, was ade to parliament against this sentence; and consequence of two consultations, held by everal physicians and surgeons of the greatest minence, she was acquitted."*

Delivery may be *concealed* with the hope of ving shame, or still more criminally with the ntention of destroying the offspring; and where nfanticide is charged, the law requires proof f delivery, and the finding of the child. Or gain, delivery may be *feigned* for the purose of obtaining marriage with a paramour, gratify the wishes of a husband, or to rrest property from the lawful heir. Perps the most singular case of the kind on cord is that related by Capuron,† in which young woman, with a view to obtaining arriage with her lover, feigned pregnancy and en delivery, and so far succeeded completely her attempt; but after some time, being lled on to produce the child, and refusing to so, she was accused of infanticide, and rought before the criminal tribunal, where she onfessed the fraud which she had practised, nd the motives by which she had been actuad; but she was then called on to prove at she had never been delivered, and an inestigation by medical examiners was ordered, e result of which was a report that they could nd no sign of delivery of either recent or cient date, whereupon she was acquitted and scharged. A similar instance of pretended elivery appeared not long since in a Berlin ournal, as having occurred at Sirakovo in the rcle of Posen, where a young woman, anxious fulfil the ardent desire of her husband to ve an heir, pretended to have been suddenly d unexpectedly delivered, and stole an int to support the falsehood: the case was ndered more atrocious from the real mother ving in consequence of the theft been subcted to the accusation of infanticide; the ct was, however, happily discovered, and the lprit consigned to the punishment due to er crime.‡ Dr. Male tells us that a surgeon as called to a pretended labour, and a dead child presented to him, but there was no placenta; he therefore proceeded immediately to examine the woman, when he found the os tincæ in its natural state, nearly closed, and the vagina quite contracted: the fact was that the woman had never been pregnant, and the dead child was the borrowed offspring of another: it appeared that she was induced to practise the artifice to appease the wrath of her husband, who frequently reproached her for her sterility.

With reference to whatever object this inquiry may be entered on, it is very important to consider, in limine, what are the limits of time within which the signs of ordinary delivery can be detected, and also whether a woman who has given birth to a child necessarily retains any mark or symptom by which her delivery can be ascertained after an interval of many months or years. With reference to the first of these questions, it must be recollected that there is a remarkable difference in the effects produced by parturition on the system of different individuals, as well as in the merely physical changes made in the condition of the parts more immediately concerned in that process, arising partly from the greater strength or tonicity in the constitution of particular persons, and the consequent rapidity with which the parts restore themselves to their original state, and partly depending on the period of pregnancy, and the size of the ovum or fœtus which has been expelled. As a general rule, however, it is agreed on by all who have directed their attention carefully to the subject, that the time within which we may expect satisfactory information has certainly expired when ten days have elapsed from the time of delivery; but we are not to assume this extension of the time suited for the inquiry as implying that we may safely postpone our examination so long, or that up to the end of that period we can obtain all the evidence we require: such is by no means the fact, and experience will soon convince us that in general within a week the condition of a healthy woman who has not sustained any accident in delivery is so restored as to render the result of any such investigation a matter of much uncertainty; many of the most marked alterations in the parts of generation disappearing, "so as to leave no trace remaining eight days after delivery."* Such also was the opinion of Bohn and Albert, in conjunction with Antoine Petit and Louis, when they met in conference on the case of a woman of Mantes who was accused of infanticide, and whom they pronounced innocent on the grounds of her not having been examined as to the fact of her delivery until after the expiration of a month. We were not long since called on to examine a woman five days after delivery at the full time, and were particularly struck with the degree in which the parts had restored themselves to their natural condition, especially

* Méd. Légale, tom. i. p. 476.

the os and cervix uteri, which hardly differed from their natural unimpregnated form and size. If the contents of the uterus have been prematurely expelled, the signs of delivery, at whatever time investigated, will be found indistinct in proportion to the immaturity of the ovum; so that, after abortion at an early period, so little change is made in the condition of the uterus and other parts, and the woman may exhibit otherwise so few of the signs of pregnancy even when examined within a day or two after the occurrence, that it may be found impossible to form any thing approaching to a decided opinion,* excepting a very careful examination of whatever substance may have been expelled, should that be within our reach; when, if the structures of the ovum be satisfactorily detected, and we have sufficient proof that such body was expelled by the woman, there can no longer be any doubt. While writing these observations we are in attendance on a lady who miscarried a few days since, with little or no pain, but with considerable hemorrhage, at the close of the second month; and in twenty-four hours afterwards we found the os and cervix uteri almost completely restored to their natural state; the vagina and external parts hardly if at all dilated and very little relaxed; the breasts exhibited very imperfectly the appearances which accompany pregnancy, the ordinary sympathetic symptoms of which had been almost entirely absent. Now in such a case as this it would be utterly impossible to arrive at more than a very ill-established probability except by finding the ovum, which in this case was expelled entire and perfect, in which state we have preserved it.

As to the second point, or our being able to ascertain by personal examination whether a woman has ever at any former period been delivered or not: it is plain that we may be able to establish the negative of the question from the existence of some physical condition, such as a perfect hymen, which would be incompatible with the birth of a mature child; this would not, however, prove that abortion had not taken place; but such a state of imperfect development or of imperforation might be discovered, as would preclude altogether the notion of either pregnancy or delivery. But the question of most practical importance is this,—supposing a woman to have been a mother, does there remain any mark or sign by which the fact of delivery can at any future period be established? The reply to this question which experience warrants appears to be, that in a very great majority of cases we should be totally unable to discover any such certain indication of a former delivery; for although in some instances there are to be found appearances which point strongly to a probability of such an occurrence having taken place, they are very seldom indeed such as ought to be considered decisive of the question; while in other cases where parturition has occurred repeatedly, not one of the signs usually insisted on is found to have continued permanent. We very lately examined a patient who had borne five children and nursed three of them, the youngest being now five years old; the breasts were small, but neither flaccid nor pendulous; the nipples short, with not the least shade of brown colour in the areolæ, which exhibited only the delicate rose colour so often observed on that part of the virgin breast; there were neither lines nor spots of any kind on the abdomen; the os uteri was small and natural; the vagina contracted, and the fourchette perfectly entire. It should be mentioned that this lady never carried her children beyond the end of the eighth month. But the remarkable case of Aimée Perdriat, related by Fodéré,* shews very forcibly that the lapse of a few weeks may be sufficient to render impossible the detection of the signs of delivery: the facts were briefly these:—On the 11th of June, early in the morning, Aimée Perdriat left her master's house and went to that of a friend named Rosina, living in the fifth story of the house, begging permission to lie down, as she was unwell with colic: in about an hour afterwards a person living in the third story heard an extraordinary noise in the water-pipe, as if a heavy body was falling forcibly through it. Aimée was not visited by any one except Rosina and another young girl, who came to ask if she wanted any thing. About five hours afterwards Rosina observed blood on the stairs and on the floor of the room, and Aimée remarked that her menses were flowing very profusely. Suspicion was excited, and on the 17th the privy was opened, when a child, placenta, and two bloody cloths were found. Two surgeons examined the body, and reported that there were no marks of violence present, except that the umbilical cord was *torn* off; that it was a full-grown child, and in their opinion had breathed after birth, and had fallen alive into the place from whence it was taken. Aimée was arrested on suspicion of being the mother of this child, and the suspicion was increased by her refusing to submit to the examination of a midwife, and having absconded from Paris: she was brought back, and on the 15th, 17th, and 27th of July, being more than a month after the supposed delivery, she was examined by Baudelocque, Dubois, Ané, Dupuytren, and Lafarge, who declared that they could not discover any sign indicative of delivery having taken place at the time in question. In consequence of this she was acquitted, the judges leaning to the side of mercy; but the circumstances of the case must impress us with a moral conviction of the woman's guilt.

The presence of shining broken streaks, like the remains of cracks, in the skin of the belly, caused by the previous distension of that part during gestation, and which when once

* "Avant les deux premiers mois revolus de la grossesse surtout lorsqu'il ne s'agit pas d'une primipare, l'art ne presente aucun moyen concluant de determiner par l'examen de la femme si un avortement a eu lieu."—*Marc*, Dict. de Méd. vol. iii. p. 193.

* Tom. ii. p. 18.

produced are permanent, is a sign very generally acknowledged as of value; but then we have just seen that a woman may have been repeatedly delivered without the formation of any such marks; and on the other hand we know that any cause capable of stretching the abdominal integuments to the same degree may equally give rise to their production; a remarkable instance of which we lately saw in a man labouring under general dropsy, whose abdomen was literally covered with such streaks, and there were also several on the thighs, prepuce, and other parts of the body. It sometimes happens also, especially in young women of a full habit, that when the breasts have been greatly and rapidly enlarged during pregnancy or after delivery, the skin covering them is in like manner injured, and silvery lines are formed which never afterwards disappear. We have already related the particulars of a case in which we discovered, by the presence of these marks, a delivery which had taken place two years before; and this day, in consultation with Surgeon Conolly on a case of doubtful pregnancy, where previous childbearing was at first resolutely denied, the recognition of these silvery streaks induced us to press the party strongly on the subject, when she confessed that she had given birth to a child nineteen months before. It may be satisfactory to enquire here, whether there is any other affection of the mammæ which might give rise to such a condition of their surface. The mere accumulation of fat we certainly think would not, and the existence of diseased enlargement would not be likely to give rise to mistake; but there is one fact on this subject which deserves to be borne in recollection,—namely, that the application of leeches to the breasts as a means of restoring the menstrual discharge, lately recommended by Dr. Loudon,* has been followed, as he tells us, by these organs becoming "swelled to an enormous degree;" and as this swelling takes place very rapidly, it seems reasonable to suppose that it might produce a similar disorganization of the integument; but we have no evidence from experience on the subject. We have, on several occasions, when examining the state of the os uteri in women who had borne children, observed that its labia felt jagged, and sometimes as if a portion had been torn and remained separated from the rest: we should attach some consideration to this state of the part, because it is not likely to be produced by the expulsion of any accidental formation from the cavity of the uterus, and we have never met with it except after childbirth. The value of the evidence to be obtained from a lacerated state of the perineum will be fully considered presently. Before proceeding to investigate in detail the present circumstances of any case submitted to us for examination, we should endeavour to possess ourselves as fully as possible of the previous history of the woman, if that be not already known to us, which may have been on the one hand such as would greatly tend to render probable the occurrence of delivery, or on the other hand to diminish, or perhaps altogether forbid, our belief in its possibility. We may, for instance, learn that she had been for several months observed to be increasing in size, and exhibiting other symptoms of pregnancy previous to the time at which delivery was suspected to have taken place; or we may have reason to know that she had been long labouring under some form of disease, which, while it rendered the occurrence of pregnancy extremely improbable, was at the same time such as would be likely to induce many of its symptoms. The age also of the individual may be such as would tend greatly to confirm us in a negative opinion; and even supposing that we are satisfied that conception had occurred, this may in no measure facilitate our investigation, but may, on the contrary, involve us in further difficulty. It has been already shewn that a woman may be pregnant, and that the fruit of her womb may be blighted at any period, but may be retained in utero until the full time is accomplished, while the size of the abdomen happening from some other accidental cause to continue increasing until the expulsion of the degenerated ovum occurs, the woman may be suspected of having brought forth a child; nay, it may even happen, however paradoxical such an assertion may at first sight appear, that pregnancy and utero-gestation, even when their full term has been nearly accomplished, and the life of the fœtus distinctly recognized, are not necessarily followed by the birth of a child, as is proved by the facts of the following very remarkable case which the writer saw about three years ago with Surgeon Whitestone and Mr. Mulock. Mrs. C. of Charlemont street became pregnant for the fourth time, and up to the seventh month matters went on favourably; but after that time she ceased to feel the motions of the child, which had been previously very active; she, however, continued to increase in size up to the end of the ninth month, when the membranes having protruded into the vagina and ruptured, a great quantity of horribly offensive fluid and gas made their escape, but no child could be discovered: in a few days afterwards the placenta and cord came away completely macerated, and all the interstitial matter so completely removed as to present a most perfect ready-made preparation of the umbilical or placental vessels, even to their most minute capillary terminations;* but nothing remained of the child except the bones, many of which were subsequently discharged from time to time during the two years which the patient survived. The facts of this case appear to us sufficient in themselves to demonstrate the imperfection of the rule of law concerning concealment of birth, in order to prove which it is held sufficient to ascertain that there has been a pregnancy or a delivery; for in this case pregnancy was clearly ascertained, the mo-

* Edinburgh Med. and Surg. Journ. vol. xxxviii. p. 61.

* It is preserved in the writer's museum.

tions of the child were strongly felt, and the full term of gestation was accomplished, yet no child was born. It may also be observed here, that should such a case as this give rise to the suspicion of infanticide, the accusation could not be sustained, because, in order to do so, the existence of the child must be proved and its body found; and in suspected cases, whether of *concealed* or *feigned* delivery, we should very carefully examine the child if possible, for the purpose of ascertaining whether its state corresponds to the supposed or pretended time of delivery, and to the other circumstances of the case, as by so doing the attempted fraud may sometimes be at once detected. If, for instance, a woman feign to have been delivered two or three days before, and produce as her own a child with the cord separated and the umbilicus quite healed; or, on the contrary, if delivery be asserted to have taken place a month before, and the cord be found still attached to the navel, such incongruities would be so far decisive against the truth of the woman's account. Other discrepancies, such as want of correspondence between the development of the child and the period of pregnancy accomplished, or the interval after delivery, will readily suggest themselves, and ought to be very carefully attended to. Having made these general observations, we have next to consider in detail the individual signs by an examination of which we may be enabled to form an opinion as to the recent occurrence of delivery, when such inquiry is instituted within a proper time after parturition is supposed to have taken place.

1. The face is generally a little paler than usual, the eyes are somewhat depressed, and not unfrequently surrounded by a slightly brownish circle, and the whole expression of the countenance resembles that of a person recovering from a slight indisposition; the pulse is more or less accelerated, the skin softer and warmer than usual, and relaxed with a moisture which has in many a peculiar and sometimes very unpleasant odour.

2. The state of the breasts ought to be a subject of particular attention, especially if examined about the third or fourth day after delivery, at which time they are generally full, tense, and hard, or even knotty under the hand, and if pressed or drawn they yield a lactiform fluid; the nipples appear turgid, and the areolæ are dark and otherwise altered, as already fully described.

3. The abdomen is found full, and its integuments greatly relaxed or even thrown into folds, especially in those who have borne several children; and we recognize those light-coloured broken streaks or cracks already mentioned, which are generally most numerous from the groins and pubes towards the umbilicus; and if the hand be pressed pretty firmly over the lower or pubic region, we feel,—4. the uterine tumour produced by the volume of the imperfectly contracted uterus, which is felt about as large as the head of a new-born child, and rising three or four inches above the brim of the pelvis, into the cavity of which it can be traced by the hand, and lying towards one or other side.

5. The state of the os uteri, vagina, and external parts, next claims our attention. By an examination per vaginam we detect the enlarged state of the uterus and its identity with the abdominal tumour, and at the same time we ascertain the condition of the os uteri, which in a recently delivered woman is found gaping open, so that two or three fingers might be introduced into it with ease; its margins are flabby and very much relaxed, and not unfrequently feel as if divided by several small fissures. If the examination happens to be made within a few hours after delivery, the patulous state of this orifice is such that its margins cannot be distinctly recognized, so that we feel at a loss to distinguish between it and the cavity of the vagina, of which it seems as if it were a continuation. This latter part also is greatly relaxed and dilated, in consequence of which its internal surface is rendered smooth, its natural rugæ being obliterated by the recent distension of its tissues. From the same cause, also, the external parts are swollen, not unfrequently contused or even torn, especially after a first or a difficult labour, and partake of the relaxed state of the internal parts; there is also found issuing a peculiar discharge, to which we apply the name of lochia.

6. Laceration of the perineum. When a woman for the first time gives birth to a full-grown child, it frequently happens that the thin fold of integument constituting the anterior edge of the perineum, and called the fourchette, is torn, and sometimes the rent extending further backwards divides the proper substance of the perineum to a greater or less extent; this, however, is merely a contingency, which may or may not take place, and is, in fact, of rather rare occurrence, except in the simpler form first mentioned, but if recognized in the greater degree, is a very strong proof of delivery having preceded.

7. The lochia. From the time of delivery, a sanguineous discharge is eliminated from the genitals, and continues to flow for a period varying between four or five days to as many weeks, according to the peculiar habit or constitution. In general the discharge continues red for the first three or four days, and then becomes nearly colourless, or acquires a slightly brownish or dirty greenish hue, from which it is sometimes vulgarly called *green waters*, and after a week or eight days it ceases altogether. This discharge has a peculiar odour,* not easily named. Loder compared it to the smell of 'fish-oil;' others speak of it as a sour smell, but any one who has been much about lying-in women, especially in the wards of a lying-in hospital, must be aware of the peculiarity of this odour, which Dr. Beck informs us it has been found impossible by any artifice to destroy.†

* *Marc*, Dict. de Méd. tom. i. p. 227; *Foderé*, t. ii. p. 13.

† Elem. Med. Jurisp. p. 94.

Should such an assemblage of symptoms as here enumerated be recognized as at once sting in the case submitted for examination, doubt could be entertained of the fact of ivery, there being, to use the words of aussier, "no disease or affection besides turition which can possibly produce the ole series of signs above described;" but we y not enjoy the advantage of having before such a satisfactory combination of proofs, l may be under the necessity of forming our nion when only some of these signs can be ected, and others are entirely absent; and en we come to examine them separately, we ll find that they must be received in evi- ice with very great caution, and with various difications of their value, by which the ofs which they afford will be found little re than merely presumptive. Thus it is vious that the expression of the countenance, well as the state of the pulse and skin above iced, may be induced by any indisposition exertion which may have depressed the dily strength of the woman, and otherwise ordered the functions of her system. The te of the breasts has been already very fully sidered in the former division of this article, that it appears only necessary to observe here t, as on the one hand such a circumstance as expulsion of hydatids is capable of inducing at functional activity in the mammæ and an undant secretion of milk, so on the other nd it occasionally happens in weak, delicate men, that little or no alteration is perceived the breasts after delivery; and it was elsewhere remarked that in such persons a similar nt of sympathy is sometimes observable ring pregnancy, so that the changes in the olæ are but imperfectly established. Still we fully warranted in considering a full breast, th abundance of milk about the third or fourth y after delivery is supposed to have taken ace, as a very strong indication of such an currence. "It is possible," says Mr. Burns, or this secretion to take place independently pregnancy, but not with the appearances just scribed."*

The fulness of the abdomen and relaxed te of the integuments, as well as the appear- ce of streaks or cracks, may all arise from y cause capable of producing the same de- ee of distension as occurs in consequence of egnancy, such, for instance, as dropsy or larged ovary, or they may be the result of former pregnancy; while, on the other hand, ey may not be found when delivery has really d recently occurred. As to the uterine tu- our, we must expect to find it distinct or herwise in proportion to the recency of the livery and the period of pregnancy at which took place, the fatness or tenuity of the abdominal parietes, and the degree of activity with which the contractile action of the uterine fibres may have proceeded, from which results in a great measure the difference in the degree of development which this tumour presents in different persons at the same interval of time after mature parturition, being smaller, and in consequence less easily felt, in some at the end of four or five days than in others after double the time. Besides this, a tumour may be felt so situated, and yet may not be the uterus. To satisfy ourselves on this point, we must conjoin the examination per vaginam with that already made externally; and even when we have ascertained the exact nature of the tumour, we must recollect that it may equally arise from the organ having recently expelled a mole, a large mass of hydatids, or even a considerable accumulation of retained menstrual discharge;* which accidental circumstances might also produce the dilated and relaxed state of the os uteri, in which the vagina and external parts would participate. But from such causes as these there would be found neither swelling, contusion, nor laceration of the internal organs; nor could the os uteri be rendered patulous merely by increased secretion, such as long-continued leucorrhœal discharge, which sometimes induces extraordinary relaxation of the other parts. Laceration of the fourchette, although a very common occurrence in childbirth, does not always take place. We have already spoken of a lady who bore five children without sustaining any injury to that part; and within the last few days we examined a young girl of sixteen, and of very diminutive stature, who had borne a full-grown child some months before, and the fourchette escaped uninjured. Many such instances as these have come under our observation;† but should a laceration of the perineum be discovered, it is a proof of immense importance. We must, however, recollect that it may present itself under conditions indicating a more or less remote date as that of the delivery which caused it: thus it may be found a fresh unhealed wound, or the margins of the laceration may be perfectly healed or even callous, but quite disunited and separate from each other; or, lastly, complete union may have taken place, so that the presence of a rigid cicatrix is the only evidence remaining of the occurrence of the accident. Now should we happen, in an examination of this kind, to discover a fresh laceration of the perineum, in connexion with others of the signs we have been considering, especially the relaxed and dilated state of the os uteri, vagina, and external organs, and the presence of the abdominal tumour, it ought to be considered as decisive of the fact of recent delivery; but neither of the other states of the parts would be equally conclusive as proof of a *former* delivery, because they might have been produced by causes totally unconnected with childbirth, as happened in the case of a girl who was romping with a young man, and, losing

* Principles of Midwifery, seventh edit. p. 547. appears proper to notice here a remarkable dis- epancy between the opinion of Mr. Burns, as ove stated, in his own words, and as quoted by . Beck in his Elements of Medical Jurisprudence, ird edit. p. 94, where he is made to assert the act contrary, the word *impossible* being substituted r *possible*, as it stands in the text.

* See section *Suppression of the menses.*

† See also *Marc*, loc. cit. and *Fodcré*, tom. ii.

her balance, fell backwards on the point of the leg of a stool, which tore through the perineum and entered the vagina, causing a frightful laceration. Or it may have been caused by some surgical operation on the part, as in the case related by M. Berard, where it was found necessary to divide the perineum in order to accomplish the removal of a pessary which had lain several years in the vagina.* About two years ago a patient applied to the writer for relief, as she was labouring under prolapse of the uterus and incontinence of urine: on examination there was also found extensive laceration of the perineum, but none of these accidents were the result of delivery. The unfortunate woman had led an abandoned life, and was the victim of a horrid outrage committed by three or four drunken ruffians, who, having first violated her, forced a broken stone into the vagina, which tore the perineum and the neck of the bladder. The stone had been removed in the hospital, but the lacerated parts never recovered the injury. As to the lochia, we cannot expect to obtain much information of a satisfactory kind from that source, especially if the examination is not made very soon after delivery. We have known the discharge cease after the second day; and even when this is not the case, we must take care that we do not confound with it some discharge of a different nature, such as the menstrual, or perhaps one of a morbid origin, from either of which, however, a careful examination of the uterus and external organs would almost certainly enable us to distinguish it.

It appears to us that we cannot more appropriately conclude this review of the ordinary signs of delivery than by quoting the words of two very distinguished writers on such subjects. "The relative value," says Dr. Paris,† "which each of the signs possesses will be better appreciated after we have considered the diseases whose effects may resemble them; but as a general principle we are anxious to enforce the necessity of always considering the consecutive signs of parturition collectively, and not individually; under such circumstances the practitioner can never be betrayed into an erroneous conclusion." "Other circumstances," observes Mr. Burns,‡ "may also concur in confirming the opinion of the practitioner; as, for instance, if the patient give an absurd account of the way in which her bulk suddenly left her, ascribing it to a perspiration, which never in a single night can carry off the great size of the abdomen in the end of a supposed pregnancy."

Delivery without consciousness.—Having in a former part of this article discussed the possibility of impregnation being effected without the woman's knowledge, as during sleep, and having alluded to the fact of delivery sometimes taking place under similar circumstances as an argument *a fortiori* in favour of the credibility of such an occurrence, it seems necessary now to consider briefly that question. That a woman may be delivered without being sensible of if she be at the time labouring under cerebr oppression or derangement, as in coma, in del rium, in puerperal convulsions, stupified b narcotics,* or by ardent spirits,† is a fact of r peated observation; but it is not pretended th in such instances the woman could be *afte wards* ignorant that she had been delivered The occurrence of delivery after the life of th mother has become extinct, and consequent effected by the independent contractile pow of the uterus, has been attested by so man authors of established credit, that we cannot re fuse it our belief; having received the testimon of Foderé,‡ Buffon,§ Leroux,‖ Levret,¶ Bu delocque,** Bichat,†† and others‡‡ of equall high authority, who have recorded instances the fact, to which for the present we sha merely refer, as below, and proceed to notic two or three facts more directly in proof of de livery during sleep or insensibility. For the firs of these the writer is indebted to Dr. Douglas one of the most experienced practitioners in thi city, and whose correct and ingenious exposi tion of the evolution (improperly called spon taneous) of the fœtus is so well known to the profession. In a letter to the writer, Dr. Doug las states that he was called about six o'clock A. M. on the 26th September, 1828, to attend Mrs. D. of the county of W——, but then re siding in Eccles-street. On his arrival he found the house in the utmost confusion, an was told that the child had been born before the messenger was dispatched for the doctor; and from the lady herself he learned that about half an hour previously she had been awakened from a natural sleep by the alarm of a daughter about five years old, who had slept with her for some nights before; and this alarm had been occasioned by the little girl feeling the move ments and hearing the crying of an infant in the bed: to the mother's great surprise she found she had brought forth her child without any consciousness of the fact. Mrs. D. had had several children with favourable labours. In the London Practice of Midwifery,§§ a work generally ascribed to a late very distinguished practitioner, we find the following account. "A lady of great respectability, the wife of a peer of the realm, was actually delivered once in her sleep: she immediately awaked her hus-

id, being a little alarmed at finding one more bed than was before." To these accounts wish to subjoin the details of a very remarkable case, from a source which leaves no doubt the accuracy of the relation. "A fright duced by the dangerous situation of her y son, when eighteen months old, brought in Mrs. Durant an alarming illness attended h some singular phenomena, the most singular of which respected her memory. The ill- s happened in July; she was then advanced months in a state of pregnancy, and was, en perfectly insensible, delivered of a child. awaking from the insensibility, which had tinued for three days, she imagined it was month of *January*. Her mental powers erally were but slightly impaired, and soon ained their former perfection; nor was her mory affected except as regarded the preling six months: of that time she had forten *all* the events. Some accidental circumnce might afterwards occasionally produce a n of thought, which would bring an event of t six months to her recollection. Several of most important, however, were never reed, *nor could she, I believe, to the hour of death remember that she had then been pregnt.*"*

Examination after death.—Having elsewhere scribed the signs of pregnancy which may be covered after death, it will not be necessary y to say much in addition to the observations eady made. In such an examination our ention should be directed to the same objects ich we have been just considering as the oofs of delivery which may be recognized ring life, almost all of which may be also astained after death, provided, as before in- ed on, the investigation be undertaken within proper time: in addition to these means, by ening the body we are enabled to satisfy rselves more precisely of the exact condition the uterus and its appendages. Should death e place during or immediately after the act parturition, especially from hemorrhage, the erus may be found lying in the abdomen, a tened flabby bag, from eight to ten inches g, its mouth gaping wide open, so that the nd would pass through it without resistance; parietes are soft and relaxed, its cavity often ntaining large coagula of blood, and its inter- l surface covered with the soft and pulpy reins of the decidua, which, if the part be imrsed in fluid, appear as flocculent processes hering to and springing from it in great numrs,† while the portion to which the placenta had been adhering is distinguished by ving less of these deciduous flakes, the subnce of the organ in that situation appearing if laid bare, and exhibiting several semilunar d apparently valvular openings in its structre. But these conditions will be greatly ered should the woman have survived delivery a few days, so as to afford time for the erus to contract; and the change produced will be in proportion to the time since delivery and the energy with which the organ may have exerted its contractile powers, so that in some instances it may be found as large at the end of a week, as in others where the examination is made within two or three days. It would therefore be very difficult, if not impossible, to assign the exact dimensions which the uterus will present at given periods after mature delivery; and should it have occurred prematurely, these dimensions will of course be thereby still further affected. When delivery has taken place at the full time, and the uterus has contracted perfectly, if an examination be made within a day or two, it will be found about seven inches long and four broad; its external surface having a vascular appearance, and not unfrequently presenting patches of a purplish colour; its substance, divided by the knife, is found from an inch to an inch and a half thick, of the consistence, and nearly of the colour, of firm muscular fibre, of which it appears to consist; and the cut surface displays the orifices of a great number of very large vessels. Its internal surface differs little from the description already given; the Fallopian tubes and ovaria, or at least one of the latter, are found turgid and vascular, and lying more confined to the sides of the uterus. At the end of a week the organ has diminished to a length of between five and six inches, and after a fortnight does not exceed five inches in length; its vascularity is diminished, and the thickness of its parietes reduced about one-third; but the density of their structure is found increased in a like proportion, so that the orifices of the vessels are much less distinct, and the colour of the muscular substance has become much paler. After this period little information is likely to be obtained from an examination of the uterus merely; for although it probably is not reduced to its original unimpregnated condition before the end of the fourth week, the alterations which can be appreciated towards the conclusion of that period are too liable to have been induced by contingent causes to allow of our attaching value to them as proof of delivery. Under such circumstances, our attention would be more profitably directed to an examination of the ovaries and the existence of the corpus luteum, the value of which has been already so fully considered that it appears now only necessary to remark, that although its existence is proof positive of previous conception, it can be received as evidence of recent delivery only when it is found in connexion with other circumstances indicative of the occurrence of that event,* in which case it ought to be considered as a very powerfully corroborative proof.

We may sum up the substance of these observations in the following general corollaries:—

1. The signs of delivery are most distinct after the birth of a full-grown child; and least so when the uterine contents have been expelled at an early period of pregnancy.

2. The proofs are more distinct in proportion

to the recency of the delivery, and any examination made after the lapse of ten days from the time of the delivery is not likely to afford satisfactory information, the most decisive signs in general disappearing within a week.

3. The third or fourth day generally presents the results of delivery very distinctly, the condition of the breasts being then most remarkable from the active secretion of milk.

4. A first delivery is more easily detected than subsequent ones.

5. We cannot safely rely on any of the signs of delivery viewed separately, but must consider them collectively, and their mutual relation and correspondence with each other, and with the other collateral circumstances of the woman's case and history.

6. The chief points of attention ought to be the state of the external parts and of the breasts.

7. There are certain physical signs which, when present, are sufficient to establish a negative decision; such are, for instance, a perfect hymen, or an imperforate state of the parts.

8. But, on the other hand, a woman may have borne children, and no one mark remain by which the fact of delivery could be proved after the lapse of even a few weeks.

9. A woman may be delivered while in a state of insensibility, or even during deep natural sleep; so that her child may perish merely from want of attention, and without any moral delinquency on her part.

(W. F. Montgomery.)

PROGNOSIS, προγνώσις, foreknowledge. The important place which in medical science is justly assigned to the faculty of foreseeing and predicting the future may be inferred from a consideration of the objects which it embraces. The principal of these are—the question whether a disease is remediable—the degree of danger which attends it—its probable duration—the circumstances which may be expected to arise during its course—its tendency to recur—and the probability of other diseases supervening.

The necessity of ministering to that instinctive anxiety with which mankind contemplate the prospect of life or death, of renovated health or protracted suffering, would of itself be sufficient to rank the faculty of prediction among the most essential qualifications of the physician. It, however, derives a stronger claim to this distinction from its important influence in the treatment of disease. Nor is there, perhaps, any one qualification more adapted to produce confidence in the patient and his attendants, and thus to insure compliance with the injunctions of the physician, than the power of predicting with accuracy what will happen in the course of a disease. Again, in a multitude of cases, how powerful an ally does he obtain if he can inspire the patient with hope by his cheering predictions! On the other hand, it often happens that, in diseases attended with little danger, there is a temporary increase of disorder and suffering. If this be foreseen and cautiously announced, disappointment and despondency, such as might retard or even prevent recovery, will be avoided. There are, besides, various circumstances incident to the progress of malady such as the appearance of fresh symptoms, the supervention of some new disease, which if foreseen, may be modified, or perhaps wholly prevented; while, in many acute affections, the anticipation of those periods and conjunctures which experience has shown to be often critical, may suggest means calculated to insure a favourable and decisive effort of nature.

It is not, however, merely in its relation to the treatment of disease that the art of prognosis is important to the physician. He will find it an influential and honourable means of promoting his own reputation; and, what he should still more value, one that may often be made subservient to the dearest and most momentous interests of his patient. That he whose days are numbered by the progress of a mortal disease, should, while his powers are adequate to the task, set his worldly concerns in order is a position which few or none will call in question; but the necessity of preparation for another and an eternal state of being can be duly appreciated by those only who have a just perception of the awful nature of the interests at stake. Such, however, may be the physical or moral condition of the patient, or such the nature of his malady, that the announcement of danger might in many cases seem calculated to accelerate the fatal event, and to counteract the measures devised for his relief. Since then, the issue must often be foreseen by the physician alone, the question of disclosing or concealing his anticipations will frequently place him in circumstances of the most serious responsibility. It would be foreign to the proper object of this article to attempt the delicate task of establishing general rules for the solution of such questions. It will suffice to say that the judgment of physicians would be more generally sound, and their conduct more wise, in this as well as in other parts of their professional duties, if their own minds were more deeply imbued with the importance of the truths and obligations of religion.

The qualifications and attainments which are essential to the art of prognosis may, in general terms, be said to comprehend all those which give superiority in the other departments of medical science. Some, however, are more peculiarly requisite. As a foundation, the accurate discrimination of disease is obviously indispensable; and hence the necessity of those habits of close observation, and of that extensive knowledge of pathology and of the signs of disease, upon which success in diagnosis depends. But in a multitude of cases the mere recognition of a disease is a very inadequate guide to the prediction of its future course and ultimate event. Something beyond this is wanted; and here we see remarkably exemplified that practical superiority which is acquired by men of clear understanding and natural good sense, who have had the advantage of long experience and an extensive field for observation.

The difficulties which are inseparable from ıe subject, and the sources of error and dis-)pointment with which it abounds, are early rced, and often painfully so, upon the atten-on of the physician. Before, however, expe-ence shall have taught him the lesson, he ill do well to exercise great caution in his edictions. Let him bear in mind, on the ıe hand, that the most formidable symptoms ometimes occur when there is no real danger; ıd on the other, that a moment of delusive dm is often the prelude to the sudden ap-earance of indications of approaching death. et him remember, that however accurate may e his diagnosis, his estimate of what is ex-essively called the vis vitæ may and often ust be most imperfect. If such considera-ons as these have their due influence on his ind, he will shrink from a rashness of pre-ction no less injurious to his own reputation an to the welfare of those whose life and alth are intrusted to his eare.

Of the grounds of prognosis.—The first and ost obvious means for predieting the event disease is derived from an attention to the crease or diminution of its more prominent mptoms. But although common sense and perience suffieiently attest the general value this guide, a very limited extent of observa-on will shew that the cases in which it is an nperfect or fallacious one are numerous and nportant. So far, indeed, is it from uniformly dicating the ultimate event of death or reco-ry, that it often fails to resolve the immediate estion, whether the patient is getting better worse. Experience has taught us that the ost conspieuous and distressing symptoms of any diseases are, at least in part, the result what is termed an effort of nature to obtain lief, and that their disappearance merely an-ounces the approaching fatal termination of e struggle. Thus the anasarca which sooner later attends most organic diseases; the uta, colliquative sweating, and diarrhœa of thisis; and the saccharine urine of diabetes, ten cease in the extreme stage of those ma-dies, but cease only to give place to death. e may perhaps refer to the same elass of cts that delusive calm, sometimes accompa-ied by an appearance of revival, which so ten precedes the fatal issue of acute diseases, , for example, of eneephalic inflammation, llow fever, and puerperal peritonitis. Expe-ence further shews that the disappearance of ıe set of symptoms is often a mere precursor f others of equal or greater severity. Thus ıe cold stage of ague is presently replaeed by ıe hot; and the eessation of spasmodic asthma d of serofulous disease of the cervieal glands frequently but the forerunner of pulmonary nsumption. On the other hand, in acute iscases, a marked increase in the severity of ıe symptoms is a common prelude to a salu-ry crisis; while the erisis itself eonsists in the ppearance or aggravation of some circum-ance which, either in kind or degree, is ssentially morbid.

As we thus find that the apparent increase or eerease of a malady eannot be by any means uniformly relied upon as indicating its event, we must have recourse to those materials which *experience* has collected for our guidance. In its application to the prognosis as well as to the treatment of diseases, experience presents itself in a twofold character; first, as entitling us to infer that a certain event will result from certain existing circumstances, merely because it has been ordinarily found to follow them; and, secondly, as the foundation of those generalizations and deductions which constitute the science of pathology. From the age of Hippocrates to that of Morgagni, the art of prognosis, or at least what was valuable in it, was almost exclusively founded upon the former kind of experience; for whatever was derived from pathology was always hypothetical and mostly erroneous. The writings of our own illustrious Sydenham strikingly exemplify the contrast between the value of accurate observation and the fallacy of mere speculation, however ingenious.

The cultivation of pathology in modern times has unquestionably produced an important influence upon prognosis, as well as upon every other branch of practical medicine. It would be foreign to the immediate object of this article to inquire how far that influence has been beneficial, or to what extent its benefits have been associated with mischief. It may, however, be asserted in general terms, that while, on the one hand, pathology has given an increased precision to our views of the nature, and consequently of the event of many diseases, especially of those which we call organic, yet, on the other, a propensity to generalize from inadequate data, and to attribute to the science a perfection which it has by no means attained, has unquestionably led to much error. And there can be no doubt that in the present state of medical seience he who combines a simple and accurate observation of individual circumstances with an enlightened but cautious application of pathology, will be found the most sagacious in prognosis as well as the most successful in practice.

The application of experience to prognosis is greatly facilitated by the aid which nosology affords in creating abstract notions of disease apart from the peculiarities of individual cases. Hence arises a natural division of the subject into two parts. The first embraces prognosis as considered in its relation to *diagnosis*, and comprehends those general conclusions as to the future which are drawn from the known history and tendency of any given disease. The second comprehends those particular circumstances which belong to the individual case, not being included in the abstraet notion of the disease itself.

The value of an aecurate diagnosis as an index of the future is often indisputably great. In many affections it at once informs us whether we must regard the disease as curable or incurable, and whether death or recovery may be expected. Thus, when the existence of hydrophobia on the one hand, or of hysteria on the other, is clearly aseertained, we are able to predict the ultimate event with a confidence

little short of certainty. If a case be identified with tuberculous phthisis or schirro-carcinoma, we at once perceive that the probability of recovery is extremely small. The great majority of diseases, including fevers generally, and indeed most acute affections, are, however, in their own nature, neither essentially curable nor incurable, fatal nor free from danger; and hence, in order to predict the result, we must take into account the circumstances of each individual case: and even when the ultimate event may be learnt from the diagnosis alone, we must still have recourse to them to determine many questions of great interest both to the patient and the physician, as the duration of the disease, the event of particular symptoms, the expectation of new ones, &c. Numerous cases also occur in practice, to which diagnosis is wholly or in a great measure inapplicable; and although in judging of the future some light may be derived from their apparent analogy to known diseases, much will necessarily depend on a consideration of individual circumstances. But not only is diagnosis in many cases unattainable, it is also often unnecessary. How much of that tact which experience gives is independent of any pretensions to accuracy in referring a case to its nosological position! This is remarkably exemplified in the anomalous affections of young females; and frequently also in those which attend the final disappearance of the menses.

It is to be observed that the limits between the two divisions under which it is proposed to arrange the several materials of prognosis are by no means always precise. It may often be doubtful whether a particular symptom is an essential character of the disease in the abstract, forming part of its diagnosis, or merely an accidental circumstance, influencing our judgment of the event. And it not unfrequently happens as a consequence of this uncertainty, that a symptom which was formerly referred to one of these two heads, is in the progress of pathology found to belong to the other.

1. *Of the prognosis of disease as deduced from its diagnosis.*

The prognosis of particular diseases will of course be included in the articles allotted to them in the present work. It will be our more appropriate object here to generalize the subject as far as is practicable, by considering diseases as grouped together in natural families. In adopting a classification for this purpose, the point to be chiefly aimed at is its facility of application, and as no pretension is made to a perfect nosological arrangement, it is unnecessary to enter into a defence of that which will be employed in the following pages. It will be sufficient if the reader be advertised of the sense in which words employed to designate the several families of disease are used, and if the same words be always used in the same sense.

In the progress of this attempt to apply pathology to the subject of prognosis, the imperfect state of that science, or at least its limited applicability to questions of a practical nature, will often be apparent. In many diseases, and perhaps even in the majority, it may adequately account for their tendency and ultimate event; but in many others our knowledge of these points is matter of simple experience, admitting as yet neither of useful generalization nor of explication by any known laws of pathological science.

We propose to consider the different families of disease in relation to the following objects of prognosis: 1. their curability; 2. their danger; 3. the particular circumstances which may be expected to arise in their progress; 4. the supervention of new diseases; 5. their duration; 6. their liability to recur.

1. *Curability.*—The question whether a disease is remediable or not is in its nature quite distinct from that of the degree of danger which attends it. It is true that in many affections, as, for example, hydrophobia, the former appears almost solely determined by the latter, so that we have little or no reason for judging a cure to be hopeless further than our experience of the incompatibility of the disease with the preservation of life. Such cases, however, more properly belong to the next head.

Some diseases appear to be absolutely irremediable either by nature or art; in others, on the contrary, a cure may be almost certainly predicted, and between these extremes we meet with every shade of difference.

Many cases of disease which, to speak with pathological accuracy, must be called irremediable, inasmuch as the structure of the affected part cannot be perfectly restored, are yet, in a practical sense, sufficiently curable, because the alteration of structure, though permanent, is productive of no inconvenience. This is well illustrated in inflammations of serous membranes leading to adhesions of moderate extent.

Of the various forms of *idiopathic fever* (using the words in their ordinary acceptation) no one variety can be considered as in its nature incurable, since it is their general character to have a more or less determinate course and duration, and thus to cease spontaneously when they are not destructive of life. Some varieties, as the plague and yellow fever, (and perhaps the present epidemic cholera ought to be classed with them,) must, however, be deemed in a high degree incurable, because in a large proportion of cases they prove fatal, and as such they will be considered under the next head. In others, as the ordinary continued fevers of this climate and intermittents, (when they are not inveterate, and their local cause can be avoided,) general experience justifies a pretty confident expectation of recovery. The prognosis in remittent fevers is generally good in proportion as the remissions are distinct, or as the affection approaches to the character of an intermittent. As to symptomatic fevers (among which almost all of those which are called hectic, and probably also infantile remittent fever, must be included,) their very designation implies that the question of their curability is contingent upon that of the

primary disease to which they owe their origin.

It may be said of *acute inflammations* as of idiopathic fever, that none of them is, *per se*, incurable. In some, however, as for example acute hydrocephalus and laryngitis, the hope of cure is greatly diminished by the danger which attends them. In many others there is a tendency, more or less strong, to results which constitute organic disease, and which are often wholly irremediable. One of the principal of these results of inflammation is the deposition of coagulable lymph or fibrine, constituting what are called false membranes. These are most frequent in the serous membranes, where they generally cause adhesions between the opposing surfaces, and become eventually organized, and often even secreting tissues. In such an advanced state their removal is certainly beyond the reach of art or nature; and even in their earlier stages there is no evidence of absorption ever taking place, while expulsion is of course out of the question. Although adhesions of serous membranes are thus irremediable in a pathological sense, yet in a practical point of view they are ordinarily scarcely to be recognized as constituting disease. In the pleura and pericardium they are not unfrequently found to have been almost universal without having produced any appreciable inconvenience. The same may be said of the adhesions which are artificially produced by stimulant injections for the cure of hydrocele. Owing to the mechanism of the abdominal viscera, adhesions between different portions of the peritoneum appear more often to interfere with their functions, but by no means uniformly so. Inflammation of mucous surfaces exhibits much less tendency to the production of false membranes, and when they do take place, the prognosis is widely different; for by the conjoined operation of muscular contractions and mucous secretion, the membrane when formed is commonly detached and expelled, unless, as is often the case in croup, its presence has speedily caused death. Hence permanent and incurable adhesions are of rare occurrence. According to the views of Laennec, the hepatized state of the lungs consists in effusion of coagulable lymph into the air-cells, and he seems to regard it as removable by the powers of nature in every stage of its progress. It is, however, probable that the consolidation thus produced is often permanent and irremediable. In iritis there is a great tendency to the formation of organized adhesions, for which a surgical operation is the only resource. Those effusions which take place in the cellular and white fibrous tissues in inveterate gout and rheumatism, appear to be almost wholly incurable. The submucous cellular tissue is probably the seat of the thickening which constitutes permanent or organic stricture. When this is recent, mechanical pressure has some power in producing absorption; but more commonly its destruction by caustics, &c. is the only effectual remedy.

Ulceration, when it is the result of acute inflammation and does not destroy life, may be regarded as curable, though probably the integrity of the organization of the part is never perfectly restored. The deficiency is, however, very rarely discoverable, the eye being the principal exception, and that by no means a constant one. Suppuration, another result of acute inflammation, occurs in two forms. In the one it is merely an altered secretion from the surface inflamed, and unless it take place to such an extent as to be destructive of life, admits of cure. In the other it assumes the form of abscess, and, when not fatal, is remediable in various ways, as by absorption, by ulceration and the evacuation of its contents, or by the aid of surgery. Among the occasional effects of acute inflammation, softening and gangrene may be included. The former, which is principally met with in the cerebral tissue and mucous membrane of the alimentary canal, appears to consist in a disorganization wholly or in great measure irremediable. In gangrene reparation is utterly hopeless; although, when life is preserved, nature sometimes effects what may be called a cure by the separation of the diseased part. It is possible that some other alterations in the condition of parts occasionally result from acute inflammation. They will, however, be more conveniently considered under the general head of organic changes and lesions of structure.

Inflammation seems in general to be more intractable when it attacks parts of low organization, as bone, cartilage, white fibrous tissue, and consequently joints. Chronic inflammation is also commonly less under the control of remedies than acute, and more peculiarly so when, as is often the case, it is connected with a cachectic habit of body, as in scrofula, syphilis, mercurial erethism, &c. It is probably owing in part at least to the scrofulous habit with which acute hydrocephalus is so commonly connected, that every mode of treatment is found ineffectual in a considerable number of cases.

Under the term *profluvia* may be comprehended all those cases of mucous or mucopurulent discharge which cannot properly be referred to inflammation. It will thus include many forms of bronchial catarrh, diarrhœa, and perhaps dysentery, catarrhus vesicæ, and leucorrhœa. None of these is in itself incurable, but every one of them may be and often is so, from being symptomatic of some organic disease, and even when idiopathic they are often very unmanageable.

Hemorrhages, if not so profuse as to be fatal, may be considered as remediable, except when they are symptomatic of organic disease, as hemoptysis attending tuberculous phthisis, and hematemesis and melæna when referable to disease of the liver or other abdominal viscera. In those forms of hemorrhage in which the effused blood finds a ready exit, the integrity of the part is left untouched; but when the effusion occurs in the substance of an organ, the case is widely different. Not only does a coagulum remain, but its presence

is necessarily accompanied with a dilaceration or compression of the substance of the organ; and though the coagulum is often ultimately removed by absorption, the structure of the organ may be irreparably injured. Here, however, as in regard to the organic results of inflammation already adverted to, we must bear in mind that what is pathologically incurable may be unattended with any appreciable morbid effects. Thus, in the case of cerebral hemorrhage occurring in hemiplegiac attacks, every symptom of inconvenience sometimes disappears, not only before cicatrization of the breach has been effected, but even before the coagulum is absorbed. On the other hand, cases are not wanting in which the palsy has been permanent, though absorption and cicatrization had taken place. Pulmonary apoplexy, which Laennec refers to effusion into the air-cells, is considered by that pathologist to admit of perfect restoration of the healthy condition of the organ. The hematemesis of young females, and other hemorrhages which appear to be vicarious of the menstrual discharge, are striking examples of a favourable prognosis being justified under circumstances apparently the most alarming. The hemorrhagic disposition in scurvy being peculiar in its cause, is no less so in its prognosis, which wholly depends upon the power of changing the diet and other circumstances to which the disease owes its origin.

The peculiarly intractable character of most of the forms of *dropsy* is well known. Though this is chiefly, it is by no means wholly to be explained by the dropsy being merely symptomatic of some organic disease; for chronic hydrocephalus and ascites are often, and hydrocele is almost always, idiopathic, yet they are commonly but little influenced by medical treatment. Anasarca and hydrothorax are much more manageable, and even when symptomatic of organic disease, may often be removed for a time by the use of diuretic and other remedies. The powers of medicine in hydropericardium and œdema pulmonum are not much known, principally because the diagnosis of those affections is very obscure. Many forms of dropsy admit of temporary relief by surgical means; hydrocele alone (or almost so) of a permanent cure, namely, by the artificial excitement of inflammation in the serous membrane, which leads to universal adhesion of its opposing surfaces. Ovarian disease can hardly in strictness be recognized as a form of dropsy, and if it be, it is very far from affording an exception to the general intractable character of the family.

Under the designation of *cachexiæ* it will be convenient for our present purpose to include several diseases which have little in common except the impossibility of assigning them a local seat. Some of them are very little amenable to treatment. This is almost proverbially the case with scrofula in its various forms, among which may be included tuberculous diseases generally. Lues and mercurial disease, when inveterate, are very difficult of cure; and diabetes, which may properly be noticed here, is well known to offer an almost hopeless prognosis. In chlorosis, on the contrary, and in scurvy, (when the circumstances which engender and maintain the disease can be reversed,) the prospect of recovery is generally good.

Under the head of *organic disease, lesions, and other changes of structure*, may be comprehended all those deviations from the natural organization of parts which are not distinctly referable to inflammation, or at least not commonly so. As a whole, they are very little remediable, though in the following enumeration many exceptions will be noticed. In hypertrophy and atrophy the prognosis varies greatly with the tissue affected; thus, by the judicious employment of remedial means, great changes may be effected in the bulk of the adipose tissue, and possibly of the muscles of locomotion; whereas in the hollow muscles, as the heart and urinary bladder, which present the two most common and well-marked instances of hypertrophy, such means seem to avail little or nothing. The contrast of the two cases perhaps countenances the opinion of some pathologists, that hypertrophy of the heart is essentially different from that increased bulk of voluntary muscles which results from their increased use.

The development of the natural tissues of the body in parts into the healthy structure of which they do not enter, is an occurrence which rarely if ever admits of remedy. Such are ossifications (with which may be conjoined exostosis and anchylosis) and cartilaginous degeneration. The fatty degeneration of the heart and liver may perhaps be included with them.

New formations are either organic or inorganic. According to most pathologists, tubercles are to be enumerated among the latter. Though the absorption of these bodies is generally admitted to be impossible, there is a mode in which nature has provided for their removal, namely, by the process of softening, or, as it is often called, ulceration; and from recent investigations it appears that the cavities which are thus produced in the lungs are occasionally obliterated by a kind of cicatrization. Of course this, in a pathological sense, is a very imperfect mode of cure, since there is no restoration of the pulmonary substance; and not only is it both rare and imperfect, but owing to the continued deposition of tuberculous matter in other parts of the lungs, it is commonly in the end unavailing.

The occasional expectoration of tubercles is far too rare and partial to modify the general prognosis of the affection. Other varieties of inorganic formations are melanosis, the contents of encysted tumours, gouty concretions, and urinary and bilious calculi. The first is in no way remediable; the others are occasionally got rid of by expulsion or ulceration, but more often not without the aid of surgery. In the opinion of Andral, medullary sarcoma is an inorganic deposition, not a degeneration: it appears to be wholly beyond the reach of remedies.

The organized new formations, as sarcomatous

tumours, polypi, and hydatids, though occasionally removed by spontaneous ulceration, are in general wholly inaccessible to remedies, if we except those which surgery provides. Perhaps ovarian disease may properly be placed here. As has been already observed, it is unaffected by medicine; tapping affords but a very temporary relief; and excision is scarcely practicable except in that early stage of the disease in which it occasions far too little inconvenience to dispose the patient to submit to a formidable operation.

The organic diseases which seem to consist rather in a change or degeneration of the natural structure of the part than in any new formation, such as scirrho-carcinoma and some visceral indurations, softening of the brain and spinal cord, mollities ossium, cataract, &c. do not admit of cure unless by surgical operations; and even then the prognosis is often bad, as in scirrho-carcinoma, and still more in medullary sarcoma, (regarded by some pathologists as a degeneration,) because the disease, though extirpated from one part, may already exist, or is liable to make its appearance in another, implying not a merely local malady, but a morbid state or tendency of the system. Indurations of the liver and spleen, occurring in inveterate ague, appear to be very little under the influence of remedies. If bronchocele and sarcocele properly belong to this division, they afford well-known exceptions to the ordinary incurability of this class of organic diseases.

Dilatations of hollow muscles and canals, when produced by mere distention, are generally curable (supposing the cause removed) in an inverse proportion to their duration, as is seen in the urinary bladder and passages, and in the colon. Even where the dilatation is rather the effect of want of tone or contractile energy the case does not seem to be hopeless; at least Piorry alleges that he has watched the gradual diminution of dilatation of the cavities of the heart; and we know that varicose veins are sometimes reduced in size by the effects of pressure. There is reason to believe that a tympanitic state of the stomach and intestines is sometimes caused by mere want of tone, and admits of cure by proper treatment. The pathology of ileus is imperfectly known; but if, as Dr. Abercrombie inclines to infer from his researches, the only essential circumstance is a dilatation of some portion of the intestinal canal, it may properly be noticed here. The danger that attends this severe affection is well known to be great, but it cannot be regarded as incurable. Dilatation of the bronchi and enlargement of the air-cells (the pulmonary emphysema of Laennec,) are, as far as is known, incurable. Aneurism rarely consists in mere arterial dilatation: such, however, appears to be occasionally the case, especially in the aorta; and it is more particularly in this form of the disease that, in the estimation of some writers, the mode of treatment proposed by Valsalva produces a beneficial effect.

Permanent strictures of canals, from effusion of lymph, have been already noticed among the effects of inflammation: those which depend on muscular contraction only are in a considerable degree remediable by mechanical means. Of permanent contractions of the hollow viscera we know little.

Breaches in the solids.—The reunion of fractured bone is generally practicable, unless in some particular states of the constitution, as pregnancy, lues, and scurvy. The only alleged ordinary exception is the neck of the thigh bone. Lacerated white fibrous tissue, as ligaments and tendons, also readily reunites. The reunion of torn muscles appears to be effected by cellular tissue, not by the reproduction of muscular fibre. It is probable that the hollow muscles and muscular canals would be generally repaired in the same manner were not their rupture mostly attended by fatal consequences; and the same may be said of the solid viscera, as the liver, &c. In the case of bloodvessels being torn or cut through, a peculiar provision is made for the repair of the injury. The separated ends are not reunited, but the circulation is carried on through collateral branches. Divided nerves are said to be reunited by nervous tissue. Excretory ducts, the pulmonary cells, and the cutaneous and cellular tissues are all susceptible of reunion.

Ulcerations generally admit of repair by the processes of granulation and cicatrization; but least so when the system is under the influence of any of the affections already mentioned as cachectic, especially scrofula and syphilis. Of the peculiarly intractable character of ulcers in the former of these we have instances in the articular cartilages, and in laryngeal and tracheal phthisis. With regard to excavations formed by the removal of morbid depositions, we know that healthy abscesses, when emptied, readily heal, and that even the less manageable ones are to a considerable extent curable. It has been already stated, that when life is preserved for a sufficient time, the powers of nature are occasionally adequate to the reparation of tuberculous excavations of the lungs, and hemorrhagic cells in the brain. In some of the congenital breaches, as the hare-lip and imperfect palate, a cure may be effected by operation. In spina bifida, all attempts to cure or even palliate the affection have commonly failed; and in the case of unnatural communication between the cavities of the heart, no means can possibly be of avail.

Displacements.—The prognosis in dislocations of the joints is mostly good, provided the attempt at reduction be not too long delayed. Though the lateral curvature of the spine is often, at least in its origin, merely a displacement of certain portions of the column, it is far from being uniformly a curable affection. The angular curvature rather belongs to the head of diseased structure than to that of displacements. When invagination of the bowels is from above downwards, and no adhesions have been formed, there is good reason to believe that replacement is often spontaneously effected: when, however, adhesions have taken place, the cure must be all but hopeless. The prognosis appears to be also very bad in every circumstance of that rare form of intus-susception which is from

below upwards. External herniæ, when not strangulated, are mostly replaceable either spontaneously or by taxis; and when strangulated, often admit of cure by the division of the stricture. Even in cases which from adhesions or other causes cannot be relieved in this way, a sort of cure is occasionally effected, either spontaneously or designedly, by the formation of what is called an artificial anus. Diaphragmatic and other internal herniæ are wholly inaccessible to the resources of art. Prolapsus of the uterus and anus, when not inveterate or of great extent, generally admits of cure or relief, either by means directed to increase the tone of the parts, or by mechanical support. In the latter affection, when both these means fail, excision of the protruded portion is often resorted to with success. Retroversion of the uterus is almost peculiar to the impregnated state of the organ, its immediate cause being generally distention of the urinary bladder; and when this is removed, the womb readily recovers its proper position, either spontaneously or by manual assistance. Inversion is perhaps never relieved except by the latter means.

When fluids escape from their natural seats by ulceration or disruption, the prognosis is very various, depending on particular circumstances. That of air into the cellular tissue, constituting external emphysema, generally ends favourably, either by spontaneous absorption or by the aid of punctures. Pneumothorax and abdominal tympanitis are much less curable, being almost always the result of organic lesions. The same may be said of effusions of urine, in which, however, remarkable instances of the curative resources of nature, when aided by the prompt and judicious interference of surgical art, are occasionally met with.

Under the general designation of *functional disorders* may be included all those which are not constantly and necessarily associated with visible changes in the condition or organization of parts. Hence, while in most of the preceding classes of disease, pathology throws more or less light upon the question of curability, in the present it almost wholly fails us. Indeed in many of the most intractable and fatal cases of these affections no morbid appearance whatever can be found after death, or at least nothing beyond slight changes in the vascularity of the part whose functions had been disturbed, and which are considered by the best pathologists rather as effects than causes of the disorder. It is true that the functional disturbance is sometimes associated with, and apparently dependent upon, inflammatory or organic disease; and where the existence of this can be known, it must of course materially influence the prognosis.

In reviewing these disorders, it will be most convenient to arrange them according to the organs or functions most prominently disturbed; and so widely do they differ in regard to their prognosis, and so insusceptible are they of any satisfactory generalization, that it will be necessary to speak of most of them individually.

Functional affections of the nervous system, including disorders of sensation and of the muscles of voluntary motion. Two of these, viz. tetanus and hydrophobia, the pathology of which is extremely obscure, are so fatal, that in the former a cure is comparatively rare, and in the latter almost unknown. The convulsions of infants, though much less commonly fatal than the preceding, are a source of great mortality in the first years of life. In those of puerperal women there is generally a tolerably good prognosis, except where they have been produced by very profuse hemorrhage. Apoplexy is another affection often incurable by reason of its immediate fatality; and even when it does not destroy life, but disappears either spontaneously or by the use of remedies, the ultimate prognosis is greatly influenced by its known tendency to recur. Palsy and insanity, though not of themselves very frequently mortal, are often wholly incurable, and commonly but little under the influence of remedies. Palsy, at least in two of its forms, viz. hemiplegia and paraplegia, is more often connected with visible or organic changes than any other affection of this class. Yet even were the existence of such changes more certainly ascertainable than it can be, it would be necessary to use great caution in drawing inferences as to the prognosis. Thus we have the testimony of Dr. Abercrombie, that in cases of hemiplegia the effused blood may be absorbed and even cicatrization effected, and yet the paralysis occasionally remain; while in other cases the paralysis may disappear before absorption has taken place. While so much obscurity hangs over the pathology of these affections, it need not surprise us that remarkable and unlooked-for instances of recovery, even from inveterate palsy, sometimes occur; and hence we properly draw the distinction between a bad and a hopeless prognosis. If aphonia be considered as a form of paralysis, it affords a striking instance of the uncertainty of prognosis in such affections; since, on the one hand, our anticipations of success from the use of remedies should be anything but sanguine, while, on the other, we know that sudden and complete recovery not unfrequently takes place even when the affection has existed for years.

The prognosis in epilepsy is on the whole bad, the malady often resisting every mode of treatment, even in cases in which after death no pathological cause can be detected. On the other hand, hysteria, which sometimes very nearly resembles it, is generally curable; as in fact are most diseases which depend upon a disordered state of the menstrual function. Catalepsy is probably but a modification of hysteria, and like it generally admits of recovery; as also does chorea. Delirium tremens too often ends fatally to allow in general of a very sanguine prognosis. Hypochondriasis, which seems to be intermediate between dyspepsia and insanity, partaking in some measure of the characters of both, is probably on the whole less curable than the former, and more so than the latter.

With regard to morbid sensations, pain,

ough commonly but a symptom of other fections, constitutes of itself the whole cha- cter of one family of diseases, the neuralgiæ. ike the functional disorders just spoken of, ey are sometimes connected with organic or her appreciable disease of some part of the ervous system, but more often not, even when ey are found utterly incurable. The neural- æ, though often irremediable by any mode of eatment, do not on the whole justify a very favourable prognosis. It must, however, be uch influenced by the particular seat of the in. Thus the tic douloureux, many forms of ad and back-ach, gastrodynia, and angina ctoris, are in general far less remediable af- tions than pleurodynia, sciatica, and lumbago. ith regard to the pains of the chest, chiefly curring in females, and referred to the inter- stal nerves, the pathology is obscure, but the ognosis generally good.

With regard to functional affections of e thoracic organs, the cases ordinarily de- gnated spasmodic croup most commonly end vourably. Some authors, however, deny the istence of the disease. Spasmodic asthma, en when apparently independent of organic sease, is confessedly a very intractable affec- n, the prospect of a perfect cure being on the hole but faint. The same may be said of lpitation and angina pectoris, even in the sence of organic disease; and when, as is en the case, they are associated with it, there n be little or no hope of recovery.

Of the various modifications of functional sorder of some one or more of the digestive gans, there is none which can be regarded as its nature incurable, though many, perhaps st of them, are often very obstinate.

The ischuria renalis, though but a functional sorder, is so often fatal that the prognosis is from good. An exception must, however, made as to those cases in which it is a mptom of hysteric affection. Two other rbid conditions of the renal function, namely, secretion of albuminous urine, and the osphatic diathesis, are perhaps mostly con- cted with organic disease; at any rate they commonly very incurable maladies. Dia- tes has been already noticed as being rather constitutional disease than a mere local affec- n of the urinary organs.

In amenorrhœa, when it is not symptomatic some other disease, the ultimate prognosis generally good, though the affection is often ry tedious and unmanageable. Dysmenor- ea is perhaps even more so.

Congestions.—Although either a general or rtial derangement of the balance of circula- n between the arterial and venous systems y mostly form one link in the chain of cir- nstances which constitute diseases, it is very ubtful whether any one which is recognized nosology can be said essentially to consist in ch a state. If, however, it be otherwise, we y safely assume with respect to prognosis, t though the derangement may be sometimes structive of life, or may eventually lead to emediable changes of organization, it cannot nstitute a disease in its nature incurable.

Parasitic animals are chiefly intestinal worms and hydatids: the former are mostly accessible to the powers of medicine; but the latter, being rarely in open canals, cannot be expelled by such means; so that the question of curability very much resolves itself into that of the practicability of a surgical operation.

2. *Danger to life.*—A large number of diseases are in themselves neither so entirely destitute of danger as to cause no alarm, nor so generally fatal as to excite it in a very high degree. The estimate of danger in these affections must therefore depend on the particular circumstances of each individual case, a subject which forms the second part of the present article. There are, however, other diseases which occupy the two extremes of the scale, some being very commonly fatal, and others as commonly devoid of danger. It properly belongs to a general view of the subject of prognosis to attempt an analysis of the circumstances which determine the location of a disease in either of these two extreme classes. As we have already seen that the light which pathology throws upon the question of curability is frequently very imperfect, so will that science be often found an inadequate guide to the discovery of the extent of danger. It may be premised as a general position, that the ultimate issue of disease, whether in death or recovery, can be less certainly foreseen in acute than in chronic affections.

A. Diseases, invariably or very commonly fatal, may be thus classified in relation to the circumstances which seem to determine the danger.

a. Those in which the whole system receives a sudden and overwhelming shock, most apparent in the disturbed balance of the circulation, and commonly attended with a morbid state of the circulating fluids. In this way certain forms of epidemic fever, especially the plague and yellow fever, (and the spasmodic cholera ought probably to be included,) are very often fatal in their first, or, in the language of Dr. Armstrong, their congestive stage; and sometimes even before the manifestation of any local or characteristic symptoms. It is apparently in an analogous way (though the nervous system is then often more prominently affected than the vascular) that life is sometimes suddenly extinguished by violent accidents or the agency of certain poisons.

b. Those in which organs of great importance to life, or having very extensive sympathies, are affected with inflammation or other considerable disease. Thus encephalic inflammation generally, and especially acute hydrocephalus, apoplexy, carditis, pericarditis, and organic disease of the heart, extensive phlebitis, croup, laryngitis, asphyxia, peripneumonia, peripneumonia notha, and severe or extensive disease of the gastro-intestinal mucous membrane, may all be regarded as dangerous affections. In many of them, and perhaps more particularly in those which are seated in the encephalon, even if we were always able during life to ascertain the extent and degree of the local disease or disorganization, we should

have a very uncertain guide for the prognosis of danger, since the researches of pathology shew that these bear no definite relation to the fatal tendency. The amount of functional disturbance probably affords a better criterion. The cases of cerebral abscess related by O'Halloran strikingly exemplify the occasional retention of life when disorganization of an important organ has proceeded to a very great extent.

c. The tendency to a fatal event seems in some diseases to be rather owing to the kind of morbid change or to its extent, than to the importance of the organ affected. Of the first kind of cause we have examples in strangulated hernia, in gangrene generally, in cynanche maligna, and perhaps in ileus; of the second, in fevers when fatal after re-action, in confluent small-pox, diffuse inflammation of the cellular tissue, and extensive peritonitis.

d. Diseases which are fatal by gradual exhaustion, including the greater part of mortal chronic diseases, as phthisis pulmonalis, laryngeal and tracheal phthisis, chronic bronchitis, empyema, tabes mesenterica, psoas abscess, some organic diseases of the liver, scirrho-carcinoma, medullary sarcoma, peritoneal accretions, ovarian disease, diabetes, &c. It is to be observed, however, that few chronic diseases terminate fatally without the supervention of disease in the bronchial or gastro-intestinal mucous membrane, especially the latter; and such a complication must undoubtedly have an important influence in determining the fatal event, and also affords a ground for predicting its approach. Profuse hemorrhages may be classed among diseases which are fatal by exhaustion. The most common examples are, the rupture of aneurisms, wounds of arteries, and puerperal hemorrhage. In some forms of apoplexy internal hemorrhage seems to be, in part at least, the immediate cause of death.

e. Intense pain, though not often of itself fatal, seems to be occasionally so. Gastrodynia perhaps affords the most frequent and decisive examples.

f. In some affections the prediction of death is rather founded upon the high probability that another and fatal disease will supervene than upon the danger which immediately arises from the existing one. The termination of ischuria renalis in apoplexy or coma is perhaps the most considerable instance.

g. The fatal tendency of puerperal peritonitis seems to be much more explicable by the peculiar condition of the system at large immediately after parturition, than by the seat or intensity of the local affection.

h. There are two diseases, namely, hydrophobia and tetanus, in a very high degree dangerous to life, yet so obscure in their pathology that it seems impracticable to unite them with any other class of mortal diseases.

B. Diseases which in themselves are rarely fatal may be thus classified:—

a. Those in which, although there be general disturbance of the nervous and circulating systems, it is moderate, and unattended by any considerable local affection, such as the ordinary intermittent and continued fevers of this country.

b. Inflammations of parts not essential to life, or not having extensive sympathies with other parts of the body; such as those of the eye, tonsils, parotids, mammæ, testicles, prostate, urethra, vagina, joints (including articular rheumatism and gout), lymphatic glands, and cellular tissue.

c. Organic affections of similar parts, as cataract and many other affections of the eye, bronchocele, hydrocele, sarcomatous and encysted tumours, and hydatids. The principal exceptions are when these affections are such as are considered specific, as scirrho-carcinoma and medullary sarcoma.

d. Certain functional disorders, as epilepsy, catalepsy, chorea, hysteria, insanity, hypochondriasis, the neuralgiæ in general, spasmodic asthma, nervous palpitation, dyspepsia, amenorrhœa, and most of those disorders which are connected with it, as chlorosis and vicarious hemorrhages. Nowhere is the imperfection of pathology, as a guide to prognosis, more apparent than in relation to this class of affections: for example, it is by experience only, and an experience which does not admit of generalization, that we judge of the wide difference in respect of danger between epilepsy, hysteria, and syncope on the one hand, and hydrophobia and tetanus on the other.

3. *Circumstances which may be expected to arise in the course of a disease.*—Although a distinction may properly be made between the appearance of new symptoms during the progress of a disease, and the supervention of new diseases, it must necessarily often be arbitrary, and sometimes obscure; since it wholly depends upon the fact of such symptoms or circumstances being or not being recognized by nosologists as separate diseases. Those which are not generally admitted as such may be arranged under three heads, *critical*, *non-critical*, and *intermediate*, that is, such as are critical in a lower degree, denoting merely a temporary alleviation of the malady.

Critical.—It is to be premised that, though a particular circumstance may in one disease be critical, it may in another, or even in a different stage of the same, be non-critical. Thus profluvia, hemorrhages, and tumours, which towards the termination of fevers are often critical, are mostly not at all so in the earlier periods of their progress. Whether critical circumstances be the cause, sign, or effect of the termination of the malady, is a question of little moment in relation to prognosis, though it may be one of much interest with regard to practice.

In treating of critical circumstances, we find a distinction of much practical importance, namely, as they indicate the permanent removal, or merely the temporary disappearance of a disease. The former are chiefly seen in continued fever and acute inflammations. Why, in such affections, one symptom or circumstance is critical rather than another, is a question involved in much obscurity. What has been called the constitution of the season appears to

ve considerable influence. Thus in some idemics, fevers most commonly terminate by eating; in others, by purging; though perps the most frequent mode is by copious inary deposits. In other cases the crisis is arked by hemorrhages, abscesses, buboes, or rbuncles, There seems in fact little beyond ere experience of the prevailing tendency, to ide us in the anticipation of the particular cumstance which is likely to mark the solun. The constitutional predisposition of the dividual has, however, probably some share; d also the characters of the disease, in regard the organs or functions which are most ominently disturbed. It might indeed be njectured that when the function of an organ s been interrupted by disease, it would, at e cessation of that disease, be renewed with gmented energy. And perhaps, as a general sition, this has some foundation in truth. seems to be in degree illustrated in the asmodic cholera, in which affection, while the rce of the disease falls very much upon the gans concerned in digestion, healthy bilious cretion often marks its favourable termination. ne position must, however, be received with nsiderable limitation. Thus, as Laennec ates, peripneumonia much more often termiates with urinary deposits than with copious uta.

In those affections which are characterized accessions or paroxysms returning at interals, the termination of the paroxysm is very mmonly marked by some critical circumance. Such is the sweating of ague, the exectoration in some forms of asthma, vomiting pyrosis, perhaps the swelling of the foot in gular gout, sleep in epilepsy, and the secreon of lithic acid in some of those painful affecons of the loins which are too indiscriminately lled fits of stone or gravel, there being often o evidence whatever of the passage of such oncretions.

Intermediate.—In many diseases we can redict, with more or less certainty, the occurence of circumstances which, though they by o means denote the cessation of the malady, ommonly imply a certain measure of relief. uch are dropsical effusions and hemorrhages n organic diseases and chronic inflammations f important organs, as the brain, heart, lungs, nd liver. It is true that such an occurrence ay itself constitute a more troublesome or imediately dangerous disease than the primary ne which it tends to alleviate; and perhaps his is more particularly the case in regard to he brain, owing to the mechanism of the ranium. But even there we have strong reasons or supposing that hemorrhage occasionally, nd serous effusion more often, serves to mitiate existing diseases. Effusion into the joints nd neighbouring tissues, in gout and articular heumatism, is also generally attended with ome alleviation of suffering. In hectic and in emittent fevers, sweating, urinary deposits, and ther secretions, make an imperfect solution; nd this is observable, though in a less degree, n the daily history of even continued fevers.

Non-critical.—Under this designation may be comprehended all those circumstances, whether they be pathological changes or functional derangements, which make up the history of a disease, and which consequently may be predicted when that history is known. It is evident that prognosis of this kind is chiefly available in those affections which have a more or less determinate course and regular succession of events, the occurrence of which may be foreseen from the commencement. Such is the series of events which constitute a fit of ague, and the succession of symptoms in acute exanthemata, gout, syphilis, yellow fever, and epidemic diseases in general. The following may be instanced as some of the more considerable examples of non-critical circumstances whose occurrence may be predicted in certain kinds of disease.

a. In fevers and febrile affections generally, daily exacerbations and remissions in the symptoms may be looked for, commonly more or less nearly corresponding with the hours of sunset and sunrise. These are most conspicuous in the fevers called remittent, (as indeed their designation implies,) including infantile remittent fever, and in hectic fever; in which latter some authors distinguish two daily exacerbations, namely, about noon and sunset. Among acute inflammations, rheumatism and gout present these daily variations most conspicuously. In many cases of neuralgic affections and chronic rheumatism, the daily accessions occur at very different hours from those above named, governed by circumstances which are wholly unknown, and as to which it is impossible to generalize.

b. In inflammations, certain pathological results, varying with the tissue or organ affected, may be more or less confidently predicted. Thus inflammation of the mucous membranes, the skin, and cornea, is most liable to pass into ulceration; that of the former also often leads to softening, and occasionally, as in croup and diphtheritis, to effusion of coagulable lymph, or false membrane. Serous effusion, and the formation of false membrane resulting in adhesions, are the most common effects of inflammation of serous membranes. Erysipelatous inflammation frequently tends to gangrene; so also, in the opinion of Dr. Abercrombie, does inflammation of the muscular tissue, as in the enteritis of Cullen, and in ileus. Inflammation of the cellular tissue, kidneys, tonsils, mammæ, and, in India, that of the liver, ends chiefly in suppuration and abscess. In gout and rheumatism there is a tendency to those effusions into the white fibrous tissue which cause stiff joints; and in gonorrhœa, to the thickening which produces stricture. The pathology of phlegmasia dolens is yet involved in much obscurity; but as a point of prognosis, it deserves notice that its appearance may be often foreseen when much pain is felt in the groin soon after parturition.

c. Certain organic affections have a pathological course peculiar to themselves. Thus tubercles pass through the process of softening; scirrhus goes on to carcinoma; medullary sarcoma to hemorrhage; and ulceration of the

articular cartilages to abscess and sinuses in the surrounding parts.

d. In diseases which cause long confinement to bed, and are attended with much emaciation and general loss of vital power, the occurrence of bed sores is to be apprehended. Hence they often appear in protracted fevers, phthisis pulmonalis, inveterate lues, the worst cases of insanity, &c. Somewhat analogous to this is the tendency of punctures in anasarcous limbs to cause gangrene.

e. Perhaps in most fatal chronic diseases, and certainly in phthisis pulmonalis, the appearance of slight delirium may be expected to precede death.

f. Lastly, some individual diseases are liable to circumstances peculiar to themselves, and not admitting of being generalized. Thus the disappearance of cynanche parotidæa is very commonly attended by swelling of the testes or mamma; and inveterate ague produces indurations of the liver and spleen.

4. *Supervention of new diseases.*—There are many varieties as to the mode in which this occurs. Thus the disappearance of the primary affection, and the development of a secondary one may be simultaneous; and if the nature of both diseases be the same, the substitution of one for the other is called metastasis or translation. Again, there may be an interval between the cessation of the first affection and the appearance of the second, as is sometimes observed when phthisis pulmonalis follows measles. Or, lastly, the two may co-exist. It is to be observed, that although some diseases always supervene in the same way, this is by no means the case with all: thus disease of the heart and pericardium may either replace articular rheumatism or co-exist with it. It may perhaps be assumed as a general position, subject, however, to exceptions, that when the primary disease is acute, the supervening one commonly supplants it; but when it is chronic, they go on together.

The circumstances under which new diseases supervene upon previously existing ones may be thus generalized:

a. A great degree of vascular disturbance of the system at large is very prone to end in local inflammation, its particular seat being apparently in great measure determined by the predisposition of the part. Thus local inflammations very often occur in the course of fevers and acute exanthemata; and hysteritis or peritonitis follows profuse puerperal hemorrhage. Perhaps the frequent appearance of encephalic inflammation after violent concussion may be referred to the same head.

b. It has been already observed that chronic diseases of important organs, as the lungs, heart, brain and its membranes, liver, and mesentery, very commonly lead to disease of the gastro-intestinal and bronchial mucous membranes.

c. Diseases attended with great exhaustion, as protracted fevers, phthisis pulmonalis, diabetes, diarrhœa, and hemorrhages, generally induce anasarca. In organic diseases of important viscera, not only does dropsy take place in the cellular tissue, but also often in the cavities; and as a general though not universal rule, more especially in those with which the diseased viscera are more particularly connected. Thus hydrothorax and hydropericardium are found to supervene upon disease of the heart and lungs; ascites upon those of the liver and abdominal viscera generally; while most organic affections of the encephalon sooner or later cause serous effusion into the ventricles, or between the membranes.

d. Many cases of supervening disease seem referable to the relation or sympathy which subsists between different tissues of the same organ, and between the external and internal parts of the same region of the body. Some of these cases are strictly metastatic; in others, the primary and secondary diseases co-exist. We have examples in inflammation of the brain and its membranes ensuing upon erysipelas of the face and scalp, upon injuries of the latter, and upon otorrhœa and ophthalmia; in pleurisy occurring in peripneumony and phthisis; in the alternation of abdominal dropsy with diarrhœa or dysentery; perhaps also in anasarca following scarlatina, though in other exanthematous affections little or no tendency of this kind is observed.

e. Continuity of tissue, together with close alliance in function, is a cause of secondary diseases, most conspicuously seen in the mucous membranes. Thus, stricture of the urethra and disease of the prostate are apt to lead to disease of the bladder; and the latter, including vesical calculi, to disease of the kidneys. Common catarrh is often followed by an analogous affection of the rectum and urinary bladder, and by an herpetic affection of the upper lip; the diphtheritis of Bretonneau is very prone to pass into croup; and cynanche maligna, and occasionally pertussis, into bronchitis. An American anatomist states that he has traced the continuity of the white fibrous tissue of the limbs with that which enters into the structure of the pericardium, and thence deduces an explanation of pericarditis supervening upon rheumatism. A more simple and natural explanation appears to be that rheumatism is a disease which attacks muscles and fasciæ generally, and therefore, among the rest, occasionally affects the heart and pericardium.

f. The supervention of a new disease seems sometimes to arise from a peculiar sympathy or relation between parts which are neither contiguous, nor immediately connected in function. We have examples in the chylopoietic viscera and encephalon: thus encephalic inflammation not unfrequently ensues upon hepatitis; while the latter is sometimes produced by injuries of the head. So in fevers, meningeal inflammation is found to follow that of the gastro-intestinal mucous membrane, or the reverse. Again, infantile remittent fever is often the precursor of acute hydrocephalus.

g. When a constitutional predisposition or diathesis, such as the scrofulous or tuberculous, subsists, various diseases will either call it into activity for the first time, or, if it had previously been developed in an organ in a latent and

nsuspected state, make its presence manifest. This latter is perhaps often the case in regard to the apparently exciting causes of phthisis pulmonalis. Thus all diseases which occasion great prostration of strength, as protracted fevers, exanthemata, diarrhœa, diabetes, and chlorosis, are apt, in the predisposed, to lead to tuberculous disease or external scrofula. So also inflammations or other diseases of the organs most liable to these affections will often call them forth: thus pneumonic inflammation, bronchial catarrh, and sometimes pleurisy, will pass on to phthisis pulmonalis; and inflammation of the mucous membrane of the small intestines into tabes mesenterica. Perhaps the frequent termination of spasmodic asthma in phthisis may be properly classed with the preceding facts. If the constitutional diathesis be already manifested in one organ or tissue, there will be much reason to suspect its present latent existence, and future development in others. Thus external scrofula is often the precursor of phthisis pulmonalis and tabes mesenterica; acute hydrocephalus has been observed to supersede threatened consumption; and Dr. Baron states that accretions may be expected to take place in the pleura, when they already occupy the peritoneum. So, also, the extirpation of medullary sarcoma in one organ is commonly unavailing, owing to its existence or development in others.

h. The disappearance of a morbid action or secretion of a part, or the absence of its accustomed return, is very often followed by disease in some other parts; more especially if the constitution had been long habituated to the preceding affection, or if that affection had suddenly disappeared. Cases of this kind constitute a numerous family, apparently very capricious in their individual characters, and little susceptible of useful generalization. Thus the disappearance of cutaneous diseases, profluvia, hemorrhages, purulent discharges, &c. may give rise to internal diseases of all kinds and localities, the particular nature and seat being of course very much influenced by the patient's age, habits, &c. as is illustrated by the well-known liability of aged persons, under such circumstances, to apoplexy and palsy. The following cases may be enumerated as of most frequent occurrence, and consequently of most practical importance in regard to prognosis:—the various forms of irregular gout, which (whatever be our view of the pathology of the disease) may be fairly considered to be caused by the absence or premature recession of the disorder from the extremities; hysteria and vicarious hemorrhages, resulting from amenorrhœa; the various diseases to which women are subject when they cease to menstruate, of which scirrho-carcinoma is the most important, if not the most frequent; apoplexy and palsy, following the suppression of hemorrhoids in the aged; the alternation of gout and gravel; the occurrence of hernia humoralis, when gonorrhœa is hastily stopped by astringents; the termination of ischuria renalis in fatal coma; and the occurrence of some general and fatal disease after extirpation of a merely local one, as scirrho-carcinoma of the breast.

i. The obstruction of excretory ducts by the impaction of concrete matter frequently gives rise to disease. Thus jaundice is often caused by biliary calculi lodging in the ductus communis; and it occasionally happens that both the ureters are obstructed by calculi so as to induce ischuria renalis.

k. It is more particularly in regard to the brain and nervous system that we meet with instances of one functional disorder passing into another; though, as is often the case, both may be independent of any vascular or organic change. Thus epilepsy and chorea occasionally lead to fatuity, and mania to complete amentia.

l. There is a question of much practical interest in regard to prognosis which is entitled to some notice in this place; namely, whether there is a general tendency in functional disorders to pass into inflammation or organic disease. Notwithstanding the statements of Dr. Wilson Philip, the general experience of physicians seems to furnish a negative answer to this question, as it respects the most common of all functional disorders,—those of the digestive organs: and the same may be said of palpitations of the heart. In some of the functional disorders of the brain and nervous system, especially mania and epilepsy, pathologists have however, in a large proportion of cases, noted appearances of vascular derangement, and in many, even of disorganization; as especially the Wenzels, in regard to epilepsy. Unnatural vascularity of the spinal chord is also said to be commonly found in fatal cases of tetanus and hydrophobia, and even in those of spasmodic cholera; but it is very doubtful whether it constitutes any important part of the pathology of these affections. Perhaps the same may be said of the morbid vascularity generally found in the kidneys in fatal cases of diabetes.

5. *Duration of disease.*—The distinction between acute and chronic diseases of itself implies some sort of prognosis of their duration, yet necessarily a very imperfect one, not only because the limits of the two classes admit of no precise definition, since the same kinds of disease sometimes belong to one, sometimes to the other; but also because there is a wide range of duration among diseases referred to the same class, as for example between a twenty-one days' fever, and the worst forms of plague and spasmodic cholera. Fevers in general are considered acute affections; the only considerable exception being those which are symptomatic of organic diseases, and which mostly assume the form of hectic. Inflammations, with very few exceptions, may be either acute or chronic; and so difficult is it often found to determine to which class a given case ought to be referred, that many modern pathologists have resorted to the expedient of distinguishing a third and intermediate class, which they call subacute.

Profluvia, hemorrhages, and dropsies, diseases which have much natural affinity with inflammations, are, like them, both acute and

chronic; mostly assuming the latter form when they are symptomatic of organic affections. The cachexiæ are in their nature chronic; and it is well known that when inflammation occurs in persons whose constitutions are infected with scrofulous or tuberculous disease, it commonly assumes a chronic, and at most a subacute form. Organic changes and structural lesions are necessarily chronic. Of functional disorders, some are essentially acute, as apoplexy, hydrophobia, and tetanus; others almost always chronic, as dyspepsia and hypochondriasis; many, sometimes one, sometimes the other, as paralysis and the neuralgiæ; and, lastly, some are of an intermediate or anomalous character, being chronic as a whole, but acute as to the successive paroxysms, as epilepsy and spasmodic asthma.

However uncertain the prognosis of the duration of diseases may commonly be, it is, as a general rule, much less so in acute than in chronic affections; and in some of the former it is in a considerable degree determinate. Of these we find examples in certain endemic or epidemic fevers, as well continued as intermittent and remittent; in some of the exanthemata, especially small-pox and measles, and some varieties of herpes; in acute inflammations in general, including hydrocephalus acutus; in acute profluvia, especially when epidemic, as catarrh and dysentery; in hydrophobia, tetanus, and perhaps ischuria renalis. The acute diseases, whose duration can least be calculated upon, are such as are associated with the scrofulous or tuberculous diathesis, or with secondary syphilis; those inflammations in which the inflammatory action is but slight, as pertussis; and such as are prone to shift their seat, as especially rheumatism.

Of course in proportion as the nature of the disease itself throws little light on the question of its duration, we are obliged to have recourse to the particular circumstances of each individual case, and in chronic diseases these constitute almost our sole guide.

A subsidiary means of predicting the duration of some acute diseases is derived from the knowledge of what are termed *critical days*. They have been chiefly observed in fevers, and in this work are properly treated of under that head. A general notice of the subject is all that can be attempted here.

Critical days are those on which experience has shewn that fevers most commonly terminate. Authors have more particularly noted as such the third, fifth, seventh, ninth, eleventh, fourteenth, seventeenth, and twentieth, being separated in the earlier stages by periods of two days, in the later of three, and perhaps even more. Supposing the distinction to be founded in truth, we are thus able to predict with more or less confidence, at any period of a fever, that it *may* terminate on the next critical day or on any subsequent one, but that its cessation is not likely to occur at any intervening time.

The term critical days properly denotes nothing more than the fact of termination, without any reference to its being favourable or the reverse. As to this point some authors have, however, made a distinction of days in regard to fevers generally, and with more appearance of truth as to some particular diseases. Thus Sydenham, in his admirable description of small-pox, has noted the eighth day in the distinct form, and the eleventh in the confluent, as those on which the disease is most apt to terminate fatally.

It is obvious that the mere knowledge of the existence of critical days can be of little avail for prognosis if there be no means of predicting on which of them a disease is likely to terminate. This has been supposed to be in some degree furnished by certain intervening days called *indicative*, because the occurrence of particular symptoms on them is considered to denote the termination of the affection on the next critical day.

The law which determines the series of critical days in fevers of a continued type seems to be a modification of that which regulates the periodical recurrence and termination of the paroxysms of intermittents, and the less definite course of remittents. It seems indeed as though the existence of critical days was most discernible, and consequently most available for prognosis, in proportion as fevers tend to the remittent character; and it is probably owing to the slight tendency to this character in the common continued fevers of our own country that the subject so little either occupies our attention or influences our practice.*

6. *Liability to recurrence or relapse.*—By the former of these words is properly meant the re-appearance of a disease after an interval of exemption from it; by the latter, its renovation during the period of convalescence. There are very few diseases that may not, and that occasionally do not, recur when circumstances favour their production. With some, however, it very rarely happens: such are, 1. diseases which are almost uniformly fatal; 2. those epidemic fevers which appear to be partly propagated by infection or contagion, as plague, yellow fever, and typhus, and also rubeola, scarlatina, variola, pertussis, influenza, and perhaps spasmodic cholera. It is to be observed that diseases which are manifestly contagious, without being epidemic, such as syphilis, are by no means indisposed to recur. 3. Diseases which are almost peculiar to infancy and childhood, or the adult age, are of course not likely to recur in after life: such are infantile remittent fever, convulsions, porrigo, chorea, chlorosis, and perhaps epistaxis. 4. The organic results of some diseases seem to oppose an obstacle to their recurrence. Laennec asserts that this is the case with extensive adhesions from pleurisy, and it is certainly so with hydrocele when cured by exciting adhesive inflammation.

The diseases which most frequently recur may be distinguished into two classes, accord-

* One of the most exact and satisfactory reports which has appeared of late years on the subject of critical days in the fevers of our own climate is to be found in Dr. Welsh's account of the epidemic fever of Edinburgh in 1818.

g as the recurrence is regular and periodical, irregular and as it were accidental. Those hich ordinarily belong to the first class are w in number, the principal being intermittent vers. In these, the type being once known, e are able to foretel the appearance of the ext fit. The prognosis must, however, be rmed with some limitation, since not only ay art interfere, but there appears to be very ften a natural tendency in these fevers to cease pontaneously after a certain though variable umber of paroxysms. Some neuralgic affec- ions, especially headach, frequently assume a eriodical character, observing the ordinary eriods of intermittent fevers, and that even hen they cannot be referred to malaria. The nly other diseases which are often observed to eturn periodically are gout and spasmodic sthma, and in these the periods of recurrence orm no part of the general character of the lisease, but vary in each particular case. There are besides numerous other affections which occasionally observe very exact periods of return. The principal are hemorrhages, especially hemorrhoids; profluvia, as diarrhœa; and some functional disorders, as mania, epi- lepsy, and jaundice. But as these peculiari- ties belong to the individual, and not to the disease, they are of no general interest in prognosis.

The liability of diseases to return irregularly and accidentally may in general terms be as- cribed to the continued influence of some cir- cumstance which stands in the relation of a cause, either predisposing or exciting, but more commonly the former. Such causes may be thus classed:

a. Organic disease frequently gives rise to the repeated recurrence of other diseases, and these may affect either the part in which the organic disease is seated, or others more or less remote. Of the former we have examples in the liability to repeated attacks of pleurisy, peripneumony, bronchial catarrh, and hemo- ptysis, which attends the presence of tubercles in the lungs; in the tendency to spasmodic stricture, where permanent stricture exists; in the frequent occurrence of partial peritonitis and ascites, when the liver is organically dis- eased; of menorrhagia, in cases of scirrhous uterus; and of affections of the intestinal mu- cous membrane, in disease of the mesenteric glands. We have examples of organic disease in one part causing repeated morbid affections of other parts, in the anasarca and various hemorrhages which attend diseases of the heart, and in hematemesis and melæna ac- companying that of the liver.

b. Nearly allied to the preceding description of cases is the well-known tendency of chronic affections to assume more or less frequently during their progress an acute character. Perhaps this is most conspicuously seen in the serous membranes, as in the pleura, peritoneum, and arachnoid membrane.

c. In many cases the liability to a particular disease on the application of slight exciting causes seems referable to some defects, not amounting to notable disease, in the vascular or nervous apparatus of a part, the result of previous attacks. It is most conspicuously seen in affections of the skin and mucous membranes, as for example in ophthalmia, cynanche tonsillaris, catarrh and bronchitis, diarrhœa and dysentery, gleet and leucorrhœa, diseases which, if they have once occurred, often leave a manifest tendency to their repro- duction. In numerous other cases, however, the tendency in a disease to re-appear seems to admit of no such pathological explanation, nor indeed of any other satisfactory one, how- ever we may attempt to conceal our ignorance by the use of such terms as mobility, excita- bility, and the like. In many of these affec- tions the vascular system is prominently dis- turbed. Such are erysipelas, biliary calculi and jaundice, gout, rheumatism, hemorrhoids, puerperal hemorrhage, amenorrhœa, dysmenor- rhœa, phlegmasia dolens, and calculous affec- tions of the urinary organs. In others, as palsy, epilepsy, insanity, neuralgia, palpita- tion, angina pectoris, spasmodic asthma, hic- cup, dyspepsia, colic, and hysteria, the ner- vous system seems to be most affected.

d. Repeated attacks of the same disease often originate in the presence of some con- stitutional diathesis or depraved state of the general health. Hence the frequent recurrence of constitutional syphilis and of scrofulous affection of the glands and joints, the forma- tion of successive crops of tubercles in the same or different organs, and the liability to scirrho-carcinoma, medullary sarcoma, car- buncles, &c.

e. Affections peculiar to certain periods of life are liable to recur during those periods, as epistaxis in childhood, and cerebral hemorrhage in old age.

f. Affections which may be traced to the in- terruption of some function, as hysteria and vicarious hemorrhages to suppression of the menses, may of course be expected to recur as long as the interruption continues.

The practical application of our knowledge of the liability to the recurrence of disease under the several circumstances now enume- rated, consists chiefly in the avoidance of the occasional and exciting causes, since the per- manent and predisposing ones are for the most part beyond our reach.

By the term *relapse* is properly signified the renewal of a disease during the period of con- valescence, or before the effects of the pre- ceding attack have entirely disappeared. Hence it is almost exclusively applied to acute dis- eases, especially fevers and febrile affections generally, including acute inflammations. The liability to relapse may be said in general terms to be in an inverse proportion to the complete- ness of the recovery. In epidemics it appears to depend in part upon their prevailing character and tendency, being much greater in some than in others; and it seems to be a general rule that when an affection, which ordinarily terminates by some marked crisis, has receded without such an occurrence, or when it has

disappeared early and suddenly, without running its usual course, there is a more than common danger of relapse. It is also laid down as a maxim by Hippocrates and other writers who treat of critical days, that when fevers end on non-critical days the patients are peculiarly liable to a relapse.

II. *Of the prognosis of disease as deduced from the particular circumstances of individual cases.*

Our judgment of the future in many cases of disease is greatly influenced by the consideration of their being *primary* or *secondary*, *idiopathic* or *symptomatic*. The question of the curability and probable duration of a secondary or symptomatic affection is commonly very much involved in the prognosis of the primary one. This general rule, however, requires some limitation. Thus dropsical affections, which are symptomatic of organic disease of the heart, are not unfrequently removed, at least for a time, though the primary affection be wholly incurable. There is, however, in such cases, as has been formerly observed, great liability to a recurrence of the secondary malady.

The principal cases in which prognosis is influenced by the secondary or symptomatic character of the disease may be classed under the following heads.

a. Fever which is symptomatic of local inflammation of an acute character cannot be removed while the inflammation subsists. With regard, however, to the febrile state which attends local diseases of a more chronic and passive nature, and which often assumes the form of hectic, the same position cannot be assumed, except with considerable modification. Here we not only often meet with great spontaneous variations, the causes of which are mostly but little known, but we even find the hectic fever, to a certain extent, under the control of remedies. Thus the power of sulphuric acid to diminish the sweating is generally admitted, and the influence of bark is attested by high medical authority.

b. When local inflammation or other disease arises during the progress of continued fever, it is by no means necessary that the primary affection should cease before the secondary one can admit of removal. Indeed, when the local affection does not proceed to disorganization, it more commonly disappears before the cessation of the primary fever. It may perhaps be assumed as a general rule that the symptoms of a local affection arising in fever are more prominent and severe than those of an idiopathic affection of the same character and tendency. The treatment of fever appears to be generally influenced by this rule, and its bearing upon the question of prognosis is obvious.

c. What has been above stated in regard to hectic fever is also applicable to other affections which are symptomatic of organic diseases; that is to say, the secondary affections are not only subject to great spontaneous variations, but may often be mitigated or removed by medical art, though the primary disease be permanent and incurable. As illustrations of this we may cite those symptomatic affections which are common to organic diseases in general, namely, hemorrhages, dropsies, and affections of the bronchial and gastro-intestinal mucous membranes, and many others which are more proper to particular ones, as pleurisy and peripneumony to tuberculous phthisis; dyspepsia, pyrosis, gastrodynia, and obstipatio, to organic diseases of the stomach; dysentery, to those of the liver; and dysuria, tenesmus, &c. to diseases of the urinary and genital organs.

d. Affections which are symptomatic of a deranged or interrupted function are mostly very unmanageable till the latter is restored. The most remarkable examples are furnished by the various diseases which attend amenorrhœa, such as hysteria in all its forms, regular and irregular, hematemesis, obstinate vomiting, suppression of urine, &c. While the menses are absent or defective, these affections are very little under the control of remedies; but though they often assume a threatening aspect, experience teaches us that there is very little danger to life. For our knowledge of the great and extensive influence of derangements of the digestive organs in producing or maintaining various morbid affections, we are very much indebted to the sagacity of Abernethy. These affections sometimes present a formidable aspect, such as violent palpitation of the heart or interruption of its action, angina pectoris, palsy, and even a state like apoplexy; others, though less alarming, are very distressing, as neuralgia and asthma; and all of them, however generally exempt from actual danger, can only be treated with success by means which act upon the primary disorder.

e. Besides the above principal varieties of symptomatic affections, there are some more anomalous ones which deserve notice; especially worms and teething, which give rise to convulsions and various other diseases of children; and pregnancy, the origin of a long list of disorders, as vomiting, indigestion, costiveness, &c. These are all more or less subject to the general rule, that the removal of the symptomatic affection is in a great measure dependent upon that of the primary one.

f. When one disorder succeeds to or takes the place of another, the prognosis does not appear to be in general different from what it would have been if the secondary affection had occurred primarily. Dr. Cheyne, however, states that hydrocephalus supervening upon and displacing enteric disease, is more dangerous than when it occurs primarily. On the other hand, insanity is found much more often to admit of recovery when it is induced by some preceding affection, as fever or pregnancy, than when it arises spontaneously.

g. When primary and secondary diseases subsist together, the complication generally makes the prognosis additionally unfavourable; as, for example, when ulceration of the intestinal mucous membrane is superadded to

hthisis pulmonalis. Sometimes, however, the tal termination of a disease appears to be tarded by such complications, as in the well-nown case of mania suspending the progress f phthisis.

In many kinds of disease the prognosis is uch influenced by the nature of the *exciting auses*. The following may be noted as some f the more prominent examples of this ind.

It seems to be a general rule that epidemic isorders are more tedious, unmanageable, and angerous, than affections of the like nature nd intensity which appear sporadically, and rise from some known causes peculiar to the ndividual, such as exposure to cold, intem-erance, &c. This is very observable in regard o affections of the bronchial and gastro-intes-inal mucous membranes. There seems to be n exception to this rule in some diseases which are traceable to the influence of marsh niasmata; as, for example, neuralgic affections, which are then more curable, supposing the uture action of the cause be avoided, than when they arise from cold, &c.

Local inflammations, abscesses, and ulcers, when originating from an external injury or other cause which affects the part only, gene-rally afford a much better prognosis than when they appear spontaneously; because in the latter case they have generally a constitutional origin, often of the nature of a cachectic dia-thesis. Tetanus, however, is more fatal when the affection is produced by a local injury than when it is referable to a cause acting on the system at large, as cold. We may here advert to the well-known fact, that in fractures or other severe local injuries, the prognosis is more unfavourable when the violence done to the part is accompanied with a general shock to the system.

In some affections of the nervous system, the prognosis appears to be partly influenced by the nature of the exciting cause, though in a way which cannot easily be explained. Thus epilepsy and insanity are said to be peculiarly intractable when they have been first brought on by fear or terror.

The mode of invasion is a point of much importance in the prognosis of many acute diseases, as fevers and febrile disorders gene-rally, including the exanthemata. The first shock is sometimes so violent, or the progress of the disorder so rapid, that before remedial means can operate, life is extinguished, or ir-reparable disorganization produced. This is often seen in severe epidemic diseases, as plague, spasmodic cholera, &c.; and, among local inflammations, in meningitis and oph-thalmia. If we except cases of the above de-scription, it may be laid down as a general rule, that in proportion as the first invasion of an acute disease is well-marked and decisive, it will be found not only more controulable by remedies and shorter in duration, but also less likely to terminate fatally, or to cause per-manent disorganization. On the other hand, where a disease is insidious and imperfectly developed in its commencement, remedies are generally less efficacious; and even were it otherwise, the early diagnosis is often so ob-scured as to prevent their being resorted to with sufficient promptitude and energy. Chro-nic affections are generally more or less indis-tinct at their commencement, and are very often so much so as to baffle all attempts at precise diagnosis. In proportion as this is the case, the prognosis is commonly unfavourable, the efficacy of remedies being mostly less decisive, and the event often revealing an ex-tent of disease little suspected in its earlier stages.

Regularity or irregularity of progress, as a guide to prognosis, is applicable only to dis-orders which have a pretty marked and deter-minate course, as especially to the exanthemata. In these affections, any considerable deviation from the accustomed course, as a premature disappearance of the eruption, furnishes an unfavourable augury; such cases not unfre-quently ending fatally, even when there has been no peculiar severity of symptoms, or other circumstances, to excite alarm. Gout is an-other disease in which irregularities are often the precursors of dangerous and sometimes of fatal consequences. There is one disorder which affords an apparent rather than a real exception to the preceding rule. It is well known that, in intermittent fevers, changes in the accustomed hours of access of the paro-xysms, whether they occur spontaneously or are caused by the use of remedies, often predict the approaching cessation of the malady.

In many diseases, especially those of a chro-nic character, the prospect of recovery is much influenced, and in general unfavourably so, by the length of their *past duration*. This in-fluence seems to result from various causes, of which what may be called the force of habit is perhaps the most considerable. Its operation is conspicuously seen in many of those affec-tions which are chiefly referable to the nervous system, as well as in others in which the oc-currence of some secretion or other form of evacuation indicates disorder of the vascular apparatus of the part affected. Of the former we have examples in epilepsy and the neu-ralgiæ; of the latter in hemorrhoids and leu-corrhœa; while spasmodic asthma and gout are cases of a somewhat mixed character. In all these affections, and in many others of the same kind, the hope of recovery is in general small in proportion to their duration, and to the influence of habit which that duration implies. Another cause which renders the duration of a disease unfavourable to the hope of recovery, is its tendency to produce changes in the orga-nization of parts. Perhaps all the affections commonly called nervous have more or less of this tendency, as, for example, epilepsy and asthma. It is, however, more conspicuously seen in some other diseases, as ague, gout, and rheumatism; in all of which the inveteracy of the affection is found to be increased by the production of organic changes. A third mode in which diseases become more intractable by continuance, is by diminishing the vigour of the system, and consequently its powers of re-

sistance. This is illustrated in many kinds of chronic discharges.

The cases in which the prospect of recovery is improved by the duration of the disease are chiefly those in which it is observed to have a natural tendency to exhaust itself after long continuance. Examples are furnished by some of the chronic cutaneous diseases, as porrigo, and perhaps lepra. A tendency of the same kind is in some instances connected with age. Thus external scrofula and dyspepsia, however intractable during the earlier periods of life, are often found to diminish or disappear in mature and middle age.

With regard to the influence of the duration of disease upon its danger, it is obvious that all those affections which have a tendency to destroy life, either by inducing fatal disorganization, or by exhausting the vital powers, become increasingly dangerous in proportion as their continuance is prolonged.

Of particular symptoms.—In the infancy of pathology a great number of symptoms which, either singly or in conjunction, are now known to indicate certain kinds of disease, merely served as guides to predict the event of individual cases. Thus, much of what Hippocrates has said on the subject of prognosis more properly belongs to that of diagnosis; and it is probably in a great measure owing to the change above noted in the relative position of these two branches of medical science, that while the latter increasingly occupies the attention of physicians, and has given birth to many valuable systematic works in our own times, the former has, for the last half century, almost ceased to be the subject of distinct treatises.* That part of prognosis which is independent of diagnosis being thus restricted in its materials, will not require a large proportional space in this article. It will be found that in local affections generally the most prominent symptoms are essentially diagnostic, and therefore foreign to our present object. In affections of a more general nature, such especially as fever, the case is different; and numerous symptoms present themselves which do not appear to be diagnostic of any particular state of disease, but which greatly influence our judgment of the event. These will necessarily occupy a prominent place in the following enumeration. It must, however, be borne in mind that in many cases our knowledge is too imperfect to enable us to determine with certainty what symptoms are properly diagnostic, and what are merely prognostic.

It is a general rule that the disappearance of the several morbid circumstances in the condition and functions of the body which constitute disease marks the approaching return of health; and, in fact, great part of the prognosis of particular diseases, as stated in systematic works, is of this kind. It seems, however, useless to extend an article like the present by an enumeration of points so self-evident. The chief exceptions to the above rule are to be found in the disappearance of one or more morbid circumstances while others remain. Indeed, in a large proportion of cases of disease, the prognosis is rather deduced from a general consideration of all the symptoms than from changes in particular ones; and hence arises an imperfection inseparable from this branch of the subject.

As the consideration of every individual morbid symptom would be at once tedious and unprofitable, it will be sufficient to particularize those which are most important and of most general application to the subject of prognosis.

Symptoms chiefly referable to the nervous system.—Delirium being one of the most common symptoms of fevers and febrile disorders generally, cannot in itself be considered unfavourable. In two of its forms, however, it indicates a threatening state of disease; namely, the delirium ferox, which perhaps mostly implies meningeal inflammation; and the muttering delirium which is one of the characters of typhus and adynamic fevers. An access or increase of delirium sometimes precedes a crisis in fevers; and, on the other hand, its cessation, though a favourable occurrence when conjoined with other marks of lessening disorder, is not unfrequently but the commencement of stupor and coma, or a part of that delusive calm which has been already adverted to as sometimes taking place before the fatal termination of many acute affections. In encephalic inflammations generally, including acute hydrocephalus, the violence and duration of the delirium is one measure of the severity and consequent danger of the disease. In acute pulmonary affections and also in jaundice, the occurrence of delirium has always been regarded as more or less alarming. That which frequently follows some local injuries does not appear to denote peculiar danger. In chronic diseases generally, particularly in phthisis pulmonalis, its occurrence is one of the most unequivocal indications of the approach of death.

Besides delirium, there are other modifications of mental disorder very common in fever and encephalic inflammations, which, when they are prominent, generally denote a severe and formidable disease. Such are, an expression of great confusion in the countenance, corresponding confusion of thought, and want of any recollection of things said or done immediately before.

The expression of great anxiety in the countenance and manner is a very unfavourable symptom in acute affections; while hope and cheerfulness, when not arising from delirium, are of good omen, being at once a cause and an indication of amendment. In many chronic affections, however, these indications are reversed. Thus in dyspepsia, jaundice, hypochondriasis, &c., anxiety and depression of

* In a list of fifty works appended to the article *Pronostic*, in the 45th vol. of the Dict. des Sciences Médicales, which was published in 1820, thirty-five are of dates prior to 1700, (a majority of them being rather comments on Hippocrates than original treatises,) fifteen between 1700 and 1777, and none later.

rits by no means imply any well-founded rm; while, on the other hand, in phthisis lmonalis there is often confidence of recovery en to the last period of existence.

A strong presentiment or anticipation of ath is at all times ominous, since, apart from ery consideration of its foundation, it often pears to be the cause of its own fulfilment. ie same may be said of a confident anticipa- on of recovery, whatever be its source; for hether connected with religious impressions, excited by the prognostics of pretenders to e healing art, it often produces the most traordinary effects.

The opposite states of preternatural suscep- bility and complete insensibility of the organs the external senses are alike unfavourable mptoms in fevers and febrile diseases. fence, a very contracted or dilated and im- oveable condition of the pupil, as well as rabismus, and that state of the eye in which remains constantly half closed with only the hite part visible, have always been considered f bad omen in such affections. It is, how- ver, to be observed that deafness is a frequent ccurrence during convalescence from fevers; nd that extreme sensibility of the eyes and f the whole surface are not uncommon in ysterical affections, and of course of little noment.

In febrile disorders, sensibility to suffering, vith complaint of pain, are generally favour- ble, while the total absence of both is always bad symptom. Severe attacks of local pain re not unfrequently the precursors of a crisis; nd a peevish sensibility to uneasiness of any kind is proverbial as an indication of approach- ng convalescence.

In acute inflammations severe pain in the ffected part cannot in general be considered s alarming. The principal apparent exception s found in enteritis; in this case, however, the severity of the pain seems chiefly owing to spasmodic affection of the muscular coat of the intestine. Throbbing pain is a well-known precursor of suppuration.

With regard to local pains, severe headach is an unfavourable symptom in peripneumonia notha, and perhaps in pulmonary affections generally. A sudden and violent attack of pain in the head, preceding apoplexy, denotes a very dangerous form of that disease. Very severe pain in the loins has been observed to precede the confluent form of small-pox, and at the invasion of febrile disorders in general, mostly portends an attack of considerable violence.

Pains which are prone to shift their seat, as in acute rhematism, are generally less manage- able than such as are fixed.

The sudden disappearance of pain, without any known or satisfactory cause, is always alarming, as is seen in ileus, enteritis, and hernia, although in these cases it has been too exclusively regarded as an indication of com- mencing gangrene.

The sensation of pricking in palsied limbs often precedes the recovery of their power.

In fever, constant lying on the back, with the legs drawn up, a continual tendency to sink down in the bed, or general rigidity of the trunk and limbs, are all unfavourable symptoms; while recumbency on the side, with occasional changes of position, and a flexible state of the muscles, are of good omen. In peritoneal inflammation great retraction of the lower extremities upon the trunk indicates a severe affection; while their occasional extension, together with the capability of sitting upright, are sure signs of the subsidence of the inflammation.

Convulsions and spasmodic affections are much worse symptoms in the advanced than in the early stages of fevers, and are generally less alarming in women and children than in adult males. Indeed, in young children (as Sydenham remarked in small-pox) their occurrence at the invasion of febrile disorders is often rather favourable than otherwise. In general it is not so much their severity as their continuance and frequent recurrence which imply danger. Among the different forms of convulsive movements, subsultus tendinum, picking at the bed-clothes, &c.; tremors of the hands and lips, and grinding of the teeth, are more peculiarly alarming, as being common indications of approaching dissolution.

A propensity to keep the hands and feet out of bed, and the trunk uncovered, commonly denotes a state of severe disease. Any form of paralysis occurring in fevers and acute inflammations is generally more or less alarming. Severe rigors are not ordinarily unfavourable in acute affections, as they tend to produce speedy reaction. In chronic diseases they are much more often so, mostly implying internal suppuration.

Extreme debility, or loss of muscular power, almost always justifies alarm.

Somnolence, occurring at an advanced stage of febrile affections, if it be associated with other indications of their decline, and especially if it follow some form of crisis, is highly favourable. In other circumstances, however, it is often but the beginning of a state of torpor, eventually passing into fatal coma. Sleep which is hurried or disturbed by convulsive startings, or in which the eyes are half open, shewing the white part only, or in which the lower jaw drops, is of bad omen. Constant wakefulness is always an unfavourable symptom.

Of all the indications of approaching death, and of all the forms in which it takes place, perhaps none is more general than coma. Yet coma does not invariably portend death. In fevers attended with much cerebral disorder, and in idiopathic affections of the encephalon, more particularly in children, it is not unfrequently recovered from. In pulmonary affections it is almost always a fatal symptom.

Circulating system.—The prognosis deduced from the action of the heart and arteries varies greatly in different diseases and under different circumstances. Extreme weakness, with great frequency, and perhaps irregularity of the

pulse, is one of the most constant precursors of death. The principal exception is found in cases of profuse hemorrhage, when the pulse often remains full and vibrating, almost to the last moments of life. A very great degree of frequency, such as any excess above 150, is of itself almost invariably indicative of danger; and under some circumstances, especially after parturition, a pulse even above 100 justifies the apprehension of impending mischief. In cerebral affections more particularly the pulse is liable to great variations of character, and these are sometimes valuable for the purposes of prognosis. Thus in apoplexy, the transition from a small, weak, and rapid pulse, to a full, strong, and labouring one, is always alarming. Mere irregularity or intermissions, especially when met with in advanced life, are by no means so alarming as is popularly supposed; and the most vehement palpitations of the heart, alternating with protracted intermissions, are met with in those sympathetic affections of the organ which experience shews to be attended with little real danger.

Syncope is chiefly an alarming symptom when it is connected with disease of the heart and larger arteries, or is the result of extreme exhaustion, as from profuse hemorrhage.

With regard to morbid conditions of the blood, the separation of a thick and tenacious coat of fibrine, with great contraction of the coagulum and concavity of its surface, though mostly indicative of active local inflammation, or of a general inflammatory diathesis, cannot in itself be regarded as an indication of danger. The dark, grumous, or pitch-like blood, which is commonly met with in the first or congestive stage of severe febrile disorders, and in some other affections, though a much more formidable appearance, does not by any means necessarily imply great danger, since it often disappears after one or more bleedings, as in diabetes and fevers. That dissolved and watery state of the blood in which it resembles claret, and is scarcely or not at all coagulable, such as is often seen in purpura, is much more alarming than either of the two preceding.

The prognosis of hemorrhage, when considered as a separate disease, has already been adverted to. As a symptom of other diseases, it is often an important guide to their prognosis. In febrile disorders it is presented under two very different aspects; in the one appearing as a critical symptom, and denoting the favourable termination of the malady, in the other constituting an occurrence of much danger. The distinction between the two must of course be drawn from the circumstances under which the hemorrhage takes place. The modifications of hemorrhage in which the characters of the effused fluid are widely different from those of natural blood, such as the black vomit of yellow fever, and the alvine discharges in melæna, are always alarming. Hemorrhages, when occurring in chronic affections, as in tuberculous disease of the lungs, scirrho-cancer, organic disease of the heart, &c. though often producing some temporary relief, must always be considered as very unfavourable in relation to the ultimate event.

Respiratory system.—There is scarcely any more certain indication of severe and dangerous disease than great disturbance of the respiratory function, if we except those cases in which it is referable to some spasmodic affection of the organs, of which asthma is the most considerable example. Slow, labouring, and irregular, or hurried and feeble respiration, is one of the most common precursors of death; and where an audible rattle in the throat is also heard, that event may almost invariably be pronounced near at hand. Spasmodic asthma is almost the only case in which orthopnœa does not imply a formidable state of disease. Stertorous breathing, which is in a great measure peculiar to severe cerebral disorders, is always more or less alarming. Extremely fetid breath in fever is unfavourable.

Deep sighing is sometimes one of the most prominent indications of such a degree of exhaustion after hemorrhage as leaves little hope of rallying. Moaning is chiefly observed in children, especially in acute hydrocephalus, and is an unfavourable symptom.

In chronic diseases which are attended with cough and expectoration, these symptoms are commonly observed to cease before death. In aged persons, the disappearance of an habitual bronchial affection is always an alarming circumstance, being generally a prelude to some fatal attack, as of apoplexy. The prognosis to be drawn from the character of the sputa varies with the nature of the existing disease. Thus purulent expectoration, when associated with tuberculous disease, is always alarming; in chronic bronchitis it is less decidedly so, and in acute bronchial affections supervening upon fevers, &c. the prognosis is often good, even though the excretion be of an alarming extent and duration. This is perhaps still more strikingly observed in abscess of the liver communicating with the bronchial tubes.

Notwithstanding many occasional exceptions, it cannot be doubted that the frequent appearance of blood mingled with the sputa must be ordinarily regarded as a very unfavourable circumstance. Fetid and black sputa are always alarming.

Hiccup occasionally precedes a favourable reaction in some cases of acute disease, as for example in the epidemic cholera; but much more commonly it appears in the advanced stages of both acute and chronic diseases as one of the indications of approaching death. In fevers, hurried or inarticulate and scarcely intelligible speech is generally an unfavourable symptom.

Organs of digestion.—Perhaps there is no one single circumstance indicative of approaching convalescence of such general value as the return of the tongue to its natural state; and, on the other hand, its various deviations from that state are among our best guides for judging of the severity and probable danger of disease. A perfectly dry tongue, whether its surface be polished, of a livid red or mahogany colour,

covered with a rough coating of brown or blackish fur, is at all times indicative of severe and commonly of more or less dangerous disease; while a natural degree of moisture almost always justifies a favourable augury, except in affections which are attended by hectic fever. Redness of the tip and edges, with unnaturally prominent papillæ, is too commonly met with in acute diseases of most kinds, especially those in which there is much irritation of the gastro-intestinal mucous membrane, to be regarded as unfavourable, unless when it is peculiarly vivid; but in chronic affections, continued redness of the tongue commonly justifies apprehensions. Paleness is not a threatening symptom, except when it is one of the results of alarming hemorrhage. The temperature of the tongue may be said in general terms to furnish the same indications as that of the surface of the body. An extreme degree of coldness has lately excited much attention, as being one of the characteristic symptoms of the present epidemic cholera in its worst form. The opposite states of tremor and of rigidity with retraction of the tongue, have been noted as unfavourable symptoms in fevers and other acute diseases.

Brown or black sordes on the lips, gums, and teeth, always denote more or less of danger. Bleeding of the gums, when it occurs late in fever, as part of a general hemorrhagic disposition, is an unfavourable symptom. The lips, more than any other part of the body, indicate, by their livid or purple colour in severe affections of the organs of respiration and circulation, that want of arterialization of the blood which is almost always an alarming symptom. Coldness of the lips and dropping of the under lip and jaw are among the features of the well-known facies Hippocratica. Salivation has been occasionally noted as critical in fevers, but its value in prognosis is chiefly seen in those cases in which mercury is given with a view to produce its specific effect. In these its appearance often warrants the anticipation of a favourable change. An aphthous state of the mouth and fauces is generally alarming, but more decidedly so in chronic than in acute affections, and in adults than in children.

An unnatural degree of appetite is sometimes observed to precede the development of severe inflammation of the gastro-intestinal mucous membrane; but it is chiefly in relation to convalescence that the appetite is a guide to prognosis, for its return, after a period of more or less complete anorexia, is one of the surest marks of returning health. Its sudden manifestation by a craving for some particular kind of food, after severe and protracted cases of fever, has been often noted as the first indication of a recovery which had previously been despaired of.

In febrile disorders, intense thirst always implies a severe affection; but its apparent absence, under circumstances in which it is ordinarily present, is a far more dangerous symptom, as being one of the indications of a general loss of physical sensibility.

Difficulty of swallowing, when it results from loss of muscular power in the œsophagus, as in the advanced stages of fever, hydrocephalus, apoplexy, and palsy, is always an alarming symptom. When it arises from some mechanical obstruction, the prognosis of course varies with the nature of the particular cause.

Vomiting at the commencement of febrile disorders cannot be considered as unfavourable, unless it be very severe and protracted. In acute affections of the gastric mucous membrane, as well as in chronic diseases of the stomach, it may furnish some kind of index, though certainly no constant or sure one, of their severity and danger. Though vomiting is popularly associated with the very notion of cholera, it is of itself no guide to our prognosis in that affection, being sometimes very inconsiderable in its most severe form. In cerebral affections, unless it recur very frequently, it is often rather a favourable symptom, indicating the continuance of physical sensibility. Thus after concussion, it is one of the marks which distinguish a temporary suspension of the cerebral functions from a state of perfect coma. Vomiting of black matter, as in yellow fever, and sometimes in melæna,—of putrid, as in some very bad forms of fever,—and of fæces, as in ileus, are all alarming symptoms. There is one case in which the most protracted and uncontroulable vomiting can hardly be considered dangerous, —namely, when it is merely a symptom of hysteria. In pregnant women, especially in the earlier months of gestation, it is often peculiarly obstinate, without giving just occasion for alarm.

Diarrhœa, like other evacuations in febrile affections, occurs under two circumstances widely differing in their relation to prognosis; being in the one case critical, in the other a cause of exhaustion, often connected with severe disease, or even disorganization of the intestinal mucous membrane. Diarrhœa is also critical in some other affections, especially those in which there is much congestion in the abdominal viscera; it also often marks the solution of colic and ileus. Black and pitchy stools are sometimes met with in critical diarrhœa; but when evacuations of this kind, instead of marking the solution of an acute disease, assume a more chronic character, as in melæna, the prognosis is mostly unfavourable. Hemorrhage from the bowels is sometimes critical in fevers, but is more often one of the results of a general hemorrhagic tendency which rapidly exhausts the patient's remaining strength. Involuntary passage of the fæces is under all circumstances alarming. Diarrhœa, when it occurs in the course of chronic affections, commonly renders the prognosis increasingly unfavourable, because it mostly implies the extension of disease to the intestinal mucous membrane. In such cases it very often ceases for some hours before death, being one indication of the approach of that event. Great insensibility to the action of emetics and purgatives is an alarming symptom in many cerebral diseases, especially the acute hydrocephalus.

A tympanitic state of the intestines generally denotes danger, though, as Dr. Abercrombie has shewn, it is sometimes recovered from, even after enteric inflammation. A hard and tumefied state of the hypochondria and neighbouring parts has been long noted as an unfavourable symptom, except when, as is sometimes the case, it precedes a critical diarrhœa. Great depression of the abdomen, so as to make the hips and false ribs prominent, is indicative of a threatening state of things.

If we except some severe affections of the biliary system, met with in tropical climates, a copious secretion of healthy bile is generally a favourable occurrence. It was found very commonly to indicate recovery in the epidemic cholera of India. Jaundice supervening upon cerebral affections is a dangerous symptom, and in all circumstances that form of it in which the skin is of a green hue justifies a much worse prognosis than the yellow variety.

Urinary organs.—A complete, or nearly complete cessation of the renal function is always dangerous (unless when it is part of an hysteric affection), being very commonly followed by fatal coma, both in children and adults. Retention of urine from insensibility of the bladder is an unfavourable symptom in fever; its involuntary discharge is still more so. Bloody urine is occasionally critical; but more often, like other hemorrhages in the advanced stages of fever, it implies danger. Of all the occurrences which mark a crisis or favourable turns in fevers and inflammations generally, none is more common in our own climate than a copious deposition in the urine, sometimes of bilious matter, but more often of sediments chiefly composed of lithic acid and its compounds. In fact, when these are found in the urine, the prognosis is almost always good, except in cases attended with hectic fever; whereas the presence of the earthy phosphates as commonly denotes a dangerous state of disease. Albuminous urine is decidedly unfavourable, unless perhaps in cases of acute dropsy.

Sexual organs.—Amenorrhœa is a common attendant of many chronic diseases, generally occurring when they have made some progress, and, consequently, giving a more unfavourable aspect to their prognosis.

The skin and subcutaneous tissue.—As to colour: a livid, purple, or leaden hue of the lips, cheeks, and surface generally, is a symptom indicative of danger. Sudden and frequent variations of colour, a circumscribed flush of the cheeks, extreme pallor, or its opposite, a very high degree of redness (when not from an exanthematous affection), are all unfavourable symptoms. In eruptive disorders, the imperfect development of the eruption, an unnatural colour of it, or its premature recession, are circumstances generally more or less alarming.

As to temperature: the opposite extremes of intense heat and death-like coldness are both alarming. Partial and unequal distribution of heat, especially that sense of burning which is often felt in the palms and soles in chronic diseases attended with hectic fever, and also frequent variations of temperature, are unfavourable. Coldness of the extremities is one of the most familiarly known precursors of death.

Moderate perspiration, if diffused over the body, attended with warmth, and not of long duration, is almost never unfavourable, and often critical. The extremes of dryness and moisture, like those of heat and cold, are dangerous; but especially moisture when combined with cold, as in the cold clammy sweats which often denote approaching death. Partial sweating, as of the head, chest, or extremities (as in phthisis pulmonalis), is always unfavourable. Perspiration of a fetid, cadaverous, or urinous odour, is an alarming symptom, unless it belong to hysteria. Sydenham observes that sweating in the eruptive fever of small-pox denotes that the disease will assume the distinct form.

Petechiæ, vibices, ecchymosis, and oozing of blood from the skin, are always unfavourable symptoms, though in various degrees, depending on the particular circumstances in which they occur.

When œdema or anasarca appears towards the termination or after the cessation of acute diseases, it is rarely alarming, and is sometimes even critical. On the contrary, in chronic and organic diseases it always confirms a prognosis already unfavourable; and in these cases its disappearance, especially when sudden, is often among the indications of approaching death.

Abscesses and buboes are analogous to excretions, inasmuch as they are sometimes critical, and at others complications, which increase the patient's sufferings and accelerate his death.

Emaciation, even to a great degree, is rarely alarming when it is the result of acute disease. In chronic diseases it almost invariably renders a prognosis otherwise doubtful decidedly bad. To this head may be referred most of those well-known features which together make up the facies Hippocratica; namely, the pointed nose, sunk eyes, shrivelled ears, hollow temples, and pale, black, livid, or lead-coloured complexion.

Besides those circumstances which form part of the disease itself, there are others pertaining to the individual affected, the climate which he inhabits, the season of the year, &c., which often materially influence our prognosis of the future. An attempt to estimate the value of all these with any degree of exactness would involve an extension of this article much beyond the limits assigned to it; a brief review of some of the leading facts is, therefore, all that can be attempted.

Sex.—The influence which sex has on prognosis is chiefly referable to affections of the sexual organs, especially of the female. It has been already observed that the various morbid affections which are apt to occur about puberty, or for a few years after, when the menses are absent, such as hemorrhages, disorders of the digestive organs, different modi-

ations of hysteria, &c., though often very vere and apparently threatening, scarcely ever stify alarm, unless they are complicated with ed local disease, as tubercles, &c. The sudn suppression of the menses, as from cold terror, is very apt to be followed by severe d often tedious disorders of various kinds. orbid affections occurring about the time of e natural cessation of the menses often assume very formidable character, resulting in scirus of the womb or breast, or organic disease other kinds. The various local affections nich immediately depend on pregnancy, as miting, hemorrhoids, œdema, &c., may of urse be expected to cease with their cause. flections which partially or wholly disappear nen conception takes place, such as phthisis d mania, may be expected to return with ual or increased energy after parturition. The ognosis is considered more unfavourable in egnant females than in others, after severe juries and surgical operations. It may perps be assumed as a general rule, that in the egnant state local affections are attended with mptoms more severe than those which would company them under other circumstances. If is be the case, a better prognosis will comonly be justified than would otherwise be missible.

Age.—The difficulties and sources of error hich are inseparable from the art of prognosis nder all circumstances, are found to be pecurly great in relation to the diseases of infants d young children. In them the powers of e are easily overwhelmed or soon exhausted, that affections comparatively slight are often pidly and unexpectedly fatal. On the other and, if those powers are adequate to sustain e shock of disease till its violence is past, covery commonly takes place with peculiar pidity, and often under circumstances appantly the most desperate. If there be one ass of affections more peculiarly dangerous an others in the earliest periods of life, it is evere injuries of the skin. Hence burns, even very inconsiderable extent, and small blisters, e often speedily fatal. As children are much ore constitutionally disposed to convulsive flections than adults, their appearance is in neral proportionately less alarming; yet viont, or rather protracted convulsions, are very equently the cause of death in infants. In ildhood, the prognosis of surgical operations commonly better than at other periods of life, ot only from the activity with which nature rries on the work of reparation, but from the bsence of those depressing moral causes which t a more mature age so often paralyse the hysical powers of the system.

In many affections the prognosis is greatly odified by the advance from childhood to uberty, and from puberty to manhood and old ge. Of the former we have illustrations in ickets, external scrofula, epilepsy, chorea, and inary calculus, disorders which, when most ractable in childhood, often spontaneously prove and disappear about puberty, or in the pproach to manhood. On the other hand, some of these very affections, especially epilepsy and chorea, not unfrequently make their first appearance about puberty. Indigestion arising from irritability of the gastric mucous membrane, a very common and troublesome affection in youth and early manhood, often gradually diminishes with the approach of middle age. The influence which age has upon prognosis in regard to many disorders of females has been already considered in connexion with the subject of sex.

The circumstances of very advanced age are in some respects analogous to those of infancy, in others conspicuously different. The vital powers being feeble, as in infants, are easily overwhelmed; and thus comparatively slight attacks of bronchial inflammation, vomiting, purging, hemorrhage, &c., often rapidly carry off old people. But unlike the early stages of life, the power of reparation being no less feeble than that of resistance, many diseases, not in their nature directly fatal, admit of very imperfect recovery, and often lead to gradual exhaustion. Fractures and ulcers of the surface are examples familiar to every one.

Constitution, &c.—In persons of vigorous constitution, whether of the sanguine or melancholic temperament, acute disease, though often vehement and proportionately dangerous, is commonly more under the control of active remedial measures than in those of an opposite habit. Weakness and exhaustion not only predispose to inflammatory affections, but also render their occurrence more dangerous, even though they may not assume a very intense or vehement aspect. Persons of delicate form, lax fibre, and great physical and moral susceptibility, whether their temperament be sanguine or melancholic, are so liable, under various and even opposite circumstances, to become the subjects of tuberculous or other incurable chronic affections, that in them the prognosis of the ultimate event of even slight disease is generally more or less doubtful.

In almost all circumstances of disease, a calm, equable, and cheerful constitution of mind tends to render the prognosis more favourable. In cases of severe local injury, and after surgical operations, it is found to be of the greatest importance.

With regard to habits of life, the peculiar danger of almost every severe malady, and often of trivial ones, to gluttons, drunkards, debauchees, and those whose constitutions are broken down by alternations of excess and privation, is familiarly known. This partly explains the frequent extreme fatality of epidemic diseases in armies, especially when moral causes of a depressing nature are superadded.

In connexion with facts of this kind may be mentioned the far greater mortality of infants in foundling than in lying-in hospitals; no advantages of cleanliness, ventilation, and care, compensating for the deprivation of that mode of sustenance which nature has provided for the first months of existence.

A marked constitutional tendency to any

form of disease, whether it be hereditary, or common to the members of a family of the same generation without the suspicion of inheritance, or peculiar to the individual himself, generally makes the prognosis decidedly more unfavourable.

Climate often influences the prognosis of disease. In tropical countries acute diseases are commonly more vehement in their attack, more rapid in their progress, and more apt speedily to cause irremediable disorganization, than in temperate regions. Hence the prognosis is generally more unfavorable. On the other hand, temperate climates, being most commonly variable, are more apt, by the repeated irritation which frequent and sudden changes in the atmosphere produce, to render chronic affections, and especially those of the respiratory organs, incurable and ultimately fatal. It is perhaps from a similar cause that syphilis is generally found to be a more tractable and less dangerous disease in warm than in cold and variable climates. Convulsive affections, particularly tetanus, are observed to be not only more common, but also more fatal in hot countries. It is hardly necessary to state, that in all diseases which arise from local causes, such as marsh miasmata, the prognosis must be proportionately bad while exposure to the influence of those causes continues.

Season.—The season of the year is a circumstance of some importance in the prognosis of many diseases. This is in general better in spring and summer than in autumn and winter; and more particularly so with regard to scrofulous and tuberculous affections, and diseases of the pulmonary organs, among which measles may be enumerated. It has been noted from the time of Hippocrates downwards, that autumnal intermittents are both more severe and more intractable than vernal ones; and perhaps the observation is generally applicable to continued fevers, though subject to much exception.

The varieties of form and character assumed by diseases in different years, or at different periods of the same year, and which mark what Sydenham calls the constitution of the season, of course involve corresponding varieties in the prognosis. The experienced tendency of particular epidemics is indeed often found to be a more certain guide to our judgment of the future than could be derived from a mere consideration of the symptoms; a point which has been justly insisted on by Dr. Gooch in relation to puerperal or peritoneal fever.

The effect of remedies previously tried, whether in the same person under a preceding similar attack, or (as in the case of epidemics) in other persons similarly affected, is often an important aid to our prognosis of their operation, and consequently of the event of the malady.

PSEUDO-MORBID APPEARANCES. There are three conditions in which any tissue or organ of the body may be found, between which it is necessary to discriminate with accuracy, in order to form correct inferences in morbid anatomy. The first of these is the natural or healthy, which we find to present certain varieties either of colour or density, according to the age of the subject. The second is the abnormal or morbid, and is to be regarded as the result either of some perversion of the development of a part, or of the influence of disease upon it. The evidence of this condition is derived in the one case from some congenital malformation, and in the other from certain appearances which the texture of the part exhibits, and which vary in aspect and extent, according to the duration and violence of the disease: these are the morbid appearances. The third condition differs from both of those above-mentioned, yet in some points resembles the morbid. This condition is in general produced by causes which come into operation after death; sometimes, however, they may partially take effect a short time before death; and sometimes it may owe its rise to other causes, hereafter to be noticed, and only in action during life. The appearances which characterize this condition of the tissues of the human body may be denominated *pseudo-morbid appearances*, as being liable to be confounded with and as it were simulating those which are morbid.

Although the attention of pathologists has been a good deal directed to this subject of late years, we find but little written upon it, and the term pseudo-morbid in limited use. Dr. Yelloly, in a paper published in the fourth volume of the Medico-Chirurgical Transactions, was the first to point out that the mucous membrane of the stomach may exhibit an increased degree of vascularity under certain circumstances, independently of inflammatory action. In France, the extravagant assertions of Broussais, who, in order to establish a favourite hypothesis, pronounced every increase of redness to be indicative of inflammation, had the good effect of inducing anatomists to inquire whether other causes than disease could similarly alter the aspect of the tissues. By the researches of Trousseau and Rigot,* and also of M. Billard,† much light has been thrown upon the post-mortem changes which occur in the body, and which give rise to appearances often very similar to those of inflammation. We are likewise indebted to John Hunter, Allan Burns, and more recently to Dr. Carswell and Orfila for much interesting and valuable matter, which we shall presently have occasion to notice.‡

It may be well to state our reasons for the

* Archives Gén. de Méd. October and November 1826, and July 1827.

† De la Memb. Muqueuse Gastro-intestinale.

‡ Although distinct treatises on this subject are rare, we must not omit to state that it has received due attention in several modern works, either on morbid anatomy in general, or on particular parts

doption of a hybrid term, *pseudo-morbid*, in preference to others more generally in use. Let it be observed that we employ the term in question to denote those appearances in any given tissue which might be mistaken for the effects of morbid action in that tissue. To apply the terms *cadaveric* or *post-mortem* to such phenomena would be to limit their number and causes; whereas it will appear in the sequel that some tissues of the body may present appearances which must be regarded as *pseudo-morbid*, and which result from the action of causes operating *before* death. We are not aware that the term is employed by any writer except the author of an analysis of MM. Trousseau and Rigot's papers above-mentioned, which is to be found in the 28th volume of the Edinburgh Medical and Surgical Journal, and Dr. Christison, in his very valuable and elaborate work on Poisons. Under this denomination, then, we would be understood to include all appearances in the dead body which might be mistaken for morbid appearances, whether they arise from the action of causes antecedent to death, or whether they be strictly such as are now generally spoken of as *cadaveric* or *post-mortem* appearances.

In the great majority of cases, a more or less gradual diminution of the vital powers precedes dissolution. The influence of life in preserving the integrity of the membranes of the body, whether it act through the nervous system or in any other way, gradually diminishes, and a corresponding change is manifested. This is most conspicuous in the capillary circulation, which becomes impeded to a variable extent in several places, the vessels being less capable of resisting the force of gravitation. This disturbance of the capillary circulation may be noticed in almost every tissue in the body. In the agony of death, the same cause, it is natural to expect, will operate to a greater degree, and at the same time the occasional muscular contractions, which often mark the final struggle, must mechanically cause irregular distributions of the blood in the sanguiferous system. The extent to which these irregularities take place is in general proportionate to the strength of the patient (inversely), to the duration of the struggle, and in some cases, we conceive, to the degree of fluidity of the blood itself (directly). Any one who has ever watched a patient in the last stage of typhus fever will not want further testimony in favour of the accuracy of the preceding statements. The general cutaneous *hyperæmia* of the back and dependent parts indicates that the laws of gravitation have begun to operate to a much greater extent than during the state of health.* We may also adduce the *pneumonie des agonisans* of M. Laennec, the *engouement de position* of Andral, or the *pneumonie hypostatique* of Piorry, as additional corroborative evidence.

But even when life is in full vigour, local sanguineous determinations may occur independently of the immediate operation of disease on the part in which they appear. Thus the performance of particular functions may cause an afflux of blood to the particular organs; as for example, while the function of digestion is going on, we find that a marked change is produced in the colour of the mucous membrane of the stomach. Again, if any obstacle occur to the free return of the venous blood, there is in general formed a congestion of the capillary system to a greater or less extent; this is more conspicuous where the veins are destitute of valves, as in the mesenteric veins, the pulmonary veins. Hepatic disease, by compressing one or more ramifications of the vena portæ, and some forms of disease of the heart, are very frequent causes of the local determinations to which we allude.

With the cessation of life is removed all opposition to the full scope and play of gravitation and chemical affinities, the former of which was partially in operation during life. The manner in which the fluids seek the dependent parts is clearly to be attributed to the action of gravitation. In fact it has been proved to be so caused, over and over again, by the simple experiment of turning the body occasionally, so as to change the dependent parts; in this case the blood is invariably found to leave the vessels that were before lowest to seek those that now are so. Bodies being usually placed supine after death, the integuments on their posterior surfaces are uniformly found congested, but if the body be placed immediately after death on the face and abdomen, a similar congestion will present itself in the integuments covering those parts.

The effects produced by the operation of chemical affinities are apparent in the alterations in the texture, the density, and the specific gravities of the tissues: gases are evolved, new fluids are formed, and the membranes are often considerably discoloured; in short, in the action of these affinities consists the putrefactive process, whereby new compounds are formed, and the former constituents of the body almost wholly vanish. We find considerable variation in the period of commencement and rapidity of course of this process, not only as regards different bodies compared with each other, but also with respect to particular parts of the same body. The age and habit of the individual, the quantity of the fluids, the kind of death, as well as the circumstances which preceded it, the season of the year, climate, state of the atmosphere, are so many circumstances which exert a powerful influence on the rapidity of the phenomena of this process, as must be familiar to every one who has studied anatomy even in the most superficial manner.

To the action of these same chemical affinities.

of it. We need hardly refer to Andral's invaluable Treatise on Pathological Anatomy. In Laennec's work, also, and in those of Bertin and Hodgson, constant allusion is made to appearances supposed to be cadaveric or produced in the agony of death.

* See an interesting essay by Bourdon, entitled "De l'Influence du Pesanteur sur quelques Phenomênes de la Vie." Paris, 1823.

we think, may be fairly attributed, at least in part, a very evident cadaveric phenomenon; namely, that increased porosity of the membranes by which the contained fluids are allowed to transude through the coats of the canals or sacs which hold them. We say *increased* porosity, for it must be admitted as the result of recent experiments, that transudation may take place to a slight degree even during life.* Life, then, must be supposed to operate in limiting this porosity, by preventing the action of the chemical affinities; when life ceases, these affinities come into play, and there takes place a separation of the molecules of the tissues to a degree proportionate to the extent of action of the same affinities. There is no part of the body in which we do not observe this phenomenon; it is not confined to sacs with simple parietes, but extends also to those of which the walls are compound; we observe it to take place through the coats of vessels, through the walls of any or all of the membranous viscera, and even through serous membranes.

The alterations which are produced, then, on the several organs or membranes of the body by the action of the agencies above detailed, may be stated in general to be—1. such as affect the colour of parts; 2. such as alter their density or consistence; 3. such as alter the contents of a natural cavity, as for example a serous sac, by increasing or diminishing the quantity, or altering the nature of fluid in it.

We proceed to consider these effects as they manifest themselves in the different parts of the body, and we shall adopt the order usually followed in making a post-mortem examination, commencing with the external integument and the cellular tissue, then proceeding to the contents of each of the three great cavities, head, thorax, abdomen; and, finally, to the arterial and venous tissues.

1. *The external integument.*—The alterations in colour which the skin presents after death, are almost the only phenomena which it exhibits liable to be mistaken for those of disease; and even they are so distinct in the mode of their formation, that any mistake must arise from a very superficial examination. Spots of various degrees of redness, and also varying in extent, are almost uniformly observable on the dead body. In general they are of a dark red, which increases in depth of colour with the length of time that has elapsed from the death of the subject. As this cutaneous discoloration is principally owing to the influence of gravitation, we find it uniformly on the most dependent parts, the occipital portion of the scalp, the posterior surface of the neck, the back, nates, posterior parts of the thighs and legs. That it is confined to the skin may be seen by cutting into the corion where the redness exists. It is moreover to be observed that this redness is vascular, and that the surface of the skin presents the appearance of a râniform distribution of vessels. This is important, as characterizing the kind of discoloration arising from gravitation, and distinguishing it from that which may be the result of the pressure of ligatures or vestments, &c. on the surface before death; for in this latter the redness will be found to be diffused and uniform, without any appearance of vessels.

But cutaneous discolorations or lividities may occur in situations not dependent, and at a more advanced period after death, being phenomena purely cadaveric. When decomposition has fully set in, and gases are being disengaged in the stomach and intestines, the surface of the skin of the face and neck becomes of a livid colour; the superficial veins are full, and streaks of a dark colour indicate the course of most of them. This congestion Chaussier attempted to explain by attributing it to the compression of the right auricle of the heart by the diaphragm, which was pushed up by the stomach distended with gas; and he states that by producing a similar distention of the stomach artificially, viz. by the introduction of a fermenting mixture into it, he was enabled to exhibit similar effects on the cutaneous capillary system. The compressed right auricle causes in the blood a retrograde motion from venous trunks to branches, from the branches to the capillaries, which is the more easily done, as at this period the blood has to a considerable degree resumed its fluidity. To this fermentation and gaseous development may be attributable, as Chaussier further observes, the passage of pieces of food from the stomach into the pharynx, larynx, and bronchi, the passage of worms into the bronchi, nasal fossæ or mouth.*

2. *The cellular tissue.*—The subcutaneous cellular tissue is generally more or less discoloured in the neighbourhood of or immediately beneath the cutaneous discoloration. Here, however, the change of colour takes place from a two-fold cause,—the gravitation of the fluids in the vessels, as well as the transudation of the serous portion of the blood through the vascular parietes. These two causes generally reduce the subcutaneous tissue to an anasarcous condition, which of course increases with the progress of decomposition; the serous portion of the blood, too, becomes more and more tinged by the colouring matter. We need hardly refer to the common appearance of the cellular membrane under the integuments of the back, with which every student of anatomy is familiar, in proof that this is the ordinary condition of that membrane, and that too within a very short period after death, as the effect of gravitation and transudation. But as putrefaction advances, and the blood resumes its fluidity, we observe ecchymoses to form in the subcutaneous tissue, the distinction of which from the effects of contusions before death is sometimes an important task for the medical jurist, and is rendered

* See the experiments of Foderé on absorption; of Dutrochet; and the Observations of Bouillaud on Dropsies.

* *Chaussier*, Médecine Légale, & Table des Phénomènes Cadavériques.

ore difficult by the fact that these ecchymoses
) not seem to be formed under the influence
' gravitation, being found even in elevated
rts. Although it does not strictly come
ithin the range of this article, it may be pro-
r to mention that the following circum-
ances, noticed by Orfila, will assist in distin-
ishing these cadaveric ecchymoses from such
: may have been formed by violence or other-
ise before death:—1. Their situation, which
ill generally be found in those localities where
ie cellular tissue is very lax and distensible,
; in the occiput, loins, eyelids, and scrotum;
. the general evidence of an advanced stage
f putrefaction presented by the dissolving
ondition of all parts of the body; 3. the uni-
ormity of colour presented by these ecchy-
ioses, which is not usually observed in those
ade during life.*

Subcutaneous ecchymoses, however, may be
roduced by direct violence applied to the body
hortly *after* death, as has been proved by
xperiment by Dr. Christison, and as may
ften be seen in the dissecting rooms. Effu-
ions of blood into the intermuscular cellular
issue, it is important to bear in mind, may
kewise be produced by violence to the body
fter death. During the winter 1830-31, we
ad occasion to notice this fact upon bodies
vhich, from the then imperfect state of the laws
egarding dissection, were conveyed to London
ightly packed in boxes from distant parts of
he country. In such bodies extensive extra-
asations of blood into the cellular membrane
etween the muscles of the back were uni-
ormly present. This fact had been likewise
reviously well ascertained by the happily de-
vised experiments of Dr. Christison on the
ccasion of the murders committed at Edin-
urgh.†

We do not find any induration of the cellular
issue of a pseudo-morbid character; but it
nay be remarked, although the fact cannot
have escaped the most superficial observer, as
a post-mortem result, that this tissue is fre-
quently emphysematous, and, indeed, always
so after a certain period in the work of decom-
position, but sometimes very soon after death,
as in some low and putrid fevers, &c.

3. *The head.*—On opening the cranium, the attention is first directed to the quantity of blood contained in the small venous trunks which are seen ramifying on the surface of the dura mater and in the sinuses. It was long ago noticed by Vicq d'Azyr, and subsequently by Marc, that the straight sinus and torcular Herophili uniformly contain coagulated blood, in consequence of the blood when fluid flowing to that dependent position. On the same principle we may expect to find the superficial veins of the dura mater more distended towards the posterior portion of that membrane. With respect to the general appearance of the dura mater, the anatomist has only to take care that he attributes a condition of hyperæmia of it, whether local or general, to its proper cause: in consequence of the fibrous character of this membrane it is not liable to a diffuse discoloration, such as some of the other tissues are, nor do we find any alterations of its consistence which are at all likely to be mistaken for morbid ones. In fact it resists the putrefactive process for a considerable time, as do all membranes of the same nature. It is proper, however, to remember that a *hyperæmia* of this membrane may be developed in the progress to decomposition, by the disengagement of gas in the stomach, and the compression of the right auricle, in the same manner as Professor Chaussier supposed some cutaneous lividities to be produced, as already alluded to.

When the dura mater, with its adherent layer of arachnoid, has been slit up, so as to expose the visceral layer of the latter membrane, and in fact to open into the arachnoid sac, the anatomist generally looks first for some effusion between this membrane and the subjacent pia mater. We fear that in general too much stress is laid upon the occurrence of effusions between the arachnoid and pia mater. Here what is really a natural condition is very apt to be mistaken for a morbid one; and, on the other hand, the total absence of effusion is too often regarded as indicating a state of health, when such a conclusion can be by no means constantly deduced. The interesting discoveries of M. Majendie relative to what he has termed the cephalo-spinal fluid, deserve more attention than seems to have been bestowed upon them by most practical pathologists. The principal conclusions at which he has arrived are the following:—1. That in the state of health there exists a fluid between the visceral layer of the arachnoid and the pia mater, both of the head and spine; the quantity of which is never below two ounces in the adult, and often amounts to five in subjects of large stature, and whose cranium is not of small dimensions;—that the fluid contained in the spine communicates with that in the head, and vice versâ, so as to pass freely from one cavity to the other;—and that a portion of the same fluid is found in the lateral, the third and fourth ventricles of the brain, which communicate with the space between the arachnoid and pia mater by an opening situated at the inferior extremity of the fourth ventricle, between the upper part of the spinal marrow and the valve of Vieussens. 2. That this fluid may be demonstrated in full quantity either during life, or at a short time after death; but after a period of little more than twenty-four hours it becomes absorbed, and therefore diminished in quantity, or altogether removed: if after that period sub-arachnoid effusion of this kind exist, it is to be considered either as entirely a post-mortem appearance, or the remains of the natural effusion, to which had been added a quantity of fluid, the result of morbid action. 3. That a diminution as well as an increase in the quantity of this fluid is capable of producing serious disturbance in the functions of these important portions of the nervous system. It is plain, therefore, from the above abstract of Majendie's discoveries respecting this cephalo-spinal fluid, that it would be always

* *Orfila*, Leçons de Médecine Légale.
† Ed. Med. and Surg. Journal, vol. xxxi. p. 243.

difficult, and often impossible, to decide whether a sub-arachnoid effusion be a natural, a morbid, or pseudo-morbid phenomenon. Unless the effusion be very considerable, and have been found very shortly after death, we cannot with certainty pronounce it to be the effect of disease. But those which are found forty-eight or seventy-two hours after death are for the most part pseudo-morbid, being caused by the transudation of the serous part of the blood through the vascular parietes, so much so that, in opening a body two or three days after death, we may invariably expect to find sub-arachnoid effusion to a greater or less extent. We conceive that a due attention to these facts connected with the cephalo-spinal fluids will sufficiently account for the surprise or disappointment which some have expressed respecting the want of coincidence between the severity of symptoms and the extent of effusion.

The degree of colour of the pia mater is often increased by the same causes which we have already enumerated as influencing post-mortem sanguineous determinations: in this case it will always be found that the other tissues within the cranium which admit red blood are similarly congested. In some cases this congestion may go so far as to produce extravasation; and if the body has lain long after death, the serum effused between the pia mater and arachnoid will be more or less tinged with the red particles of the blood. We may here remark further, that sanguineous extravasations from apoplexy, if extending into the cavity of the ventricles, will communicate their colour to the cephalo-spinal fluid, provided the natural communication of the internal cavity of the brain with the sub-arachnoid cavity be not interrupted.

With respect to the encephalon itself, it may be stated that in general (such obvious cases as apoplectic clots, abscesses or tumours being excepted) it is extremely difficult, nay, often impossible, to decide between the morbid and pseudo-morbid states of this organ. This latter state is such as manifests itself by a change in the colour and consistence of the cerebral tissue. As to colour, we find it, here as elsewhere, influenced by the quantity of fluid blood in the viscus: in the cortical substance, from its much greater vascularity, that discoloration is most likely to appear; and it is of the first moment to distinguish it from the redness of inflammation, because we find that the same colour may be the result of an active determination of blood to the brain, as well as arise from a mechanical congestion of its membranes and substance. To determine this question it will be necessary to note accurately certain collateral circumstances—the condition of the arterial and venous system of the head generally—the degree of plenitude or vacuity of the heart, whether it afford any obstacle to the free return of the blood, or by an increase in its propelling power magnify the momentum of the columns of blood to the head—the position in which the head of the individual has been laid since death—and also whether putrefaction has begun, or the degree to which it has advanced.

The alteration in consistence, by a diminution of it, *(softening,)* is the most constant and obvious change which the brain and spinal marrow present. This softening is equally the result of disease and of the tendency to decomposition. Before proceeding to indicate the distinctions between these two kinds of softening, it may be well to notice that in the state of health different parts of the cerebro-spinal axis present a marked difference as to consistence. Thus, in the adult, the spinal marrow is softer than either the cerebellum or cerebrum; the cerebellum than the brain; both these parts softer than the pons Varolii. In the child the spinal marrow is firmer than the brain, and more resisting than in the adult.*

The morbid and pseudo-morbid softenings present many characters in common, as to situation, colour, smell: indeed, we have no sign sufficiently free from ambiguity to indicate either of these conditions with certainty: both attack the grey substance most frequently, and before the white; both exhibit the same varieties and shades of colour—with this exception, that in the morbid softening we often see the affected part of a bloody tinge, arising from a slight sanguineous effusion: sometimes a purulent infiltration is found, which is obviously decisive. In the extent of these two forms of ramollissement, we have a more certain indication of their cause; the pseudo-morbid will generally be found to pervade the whole cerebral mass, varying perhaps in degree according to the above-mentioned scale of natural variations of consistence, but the morbid ramollissement is almost invariably circumscribed. We say *almost*, because a morbid ramollissement has been met with of unusual extent, occasionally in the adult, but more frequently in the new-born infant. A state of general ramollissement of the brain is met with in cases of general anasarca, and differing very much from morbid softening. It arises from the infiltration of the brain by the fluid effused in the cranium and beneath the arachnoid. It can be produced in the dead body by injecting water through a small opening made in the head; the whole fluid injected will not be found in the serous membrane.†

M. Orfila suggests the propriety of pronouncing with caution on a morbid ramollissement merely from its locality being defined, because the cadaveric softening does not begin at the same time in all parts; the fornix, septum lucidum, and walls of the lateral ventricles, being the situations in which it first shews itself.

The spinal marrow is remarkable for the rapidity with which it softens. Every anato-

* *Orfila*, Exhumations Juridiques, tom. ii. p. 225. Such is undoubtedly the case at the usual period after death when post-mortem examinations are made. But we are disposed to think with Calmeil, that immediately after dissolution the spinal marrow is of firmer consistence than the brain. The Essays of this author on the Anatomy and Physiology of the Spinal Marrow are well worthy the reader's attention. Vid. Journal de Progrès des Sciences Méd. tom. xxxi.

† *Gendrin*, Hist. Anat. des Inflammations, vol. i. p. 188.

t knows that in order to dissect that organ sfactorily he must obtain it from a body te recently dead, and that even then a short osure to the air causes a rapid diminution ts consistence. The internal grey substance ms more prone to this diminution of conence than even the white, and hence the at diversity of opinion among anatomists ecting its exact form and characters in tate of health. However, in this organ re does not appear, so far as we at present w of its morbid states, any difficulty in tinguishing the pseudo-morbid softening n that which is caused by disease; for the umscribed locality of the latter, with the mented vascularity of the surrounding por-, and slight sanguine tint of the softened t, will in general be sufficiently character-c. We are not aware that such a decidedly hological general ramollissement of the cord been found as we have noticed in the in.

4. *The thorax.*—On opening the chest in usual way, the membrane of the pleura first racts notice. After the lapse of some time m death, an effusion is invariably found in s serous sac, which is liable to be mistaken a morbid one. The subserous cellular sue and the pulmonary substance being undantly pervaded by fluids, it follows that ransudation of them must necessarily occur er a certain period, and of course they will collected into the sac of the pleura. The ody colour of this fluid, its serous cha-ter, the absence of any organizable matter ch as serous membranes are prone to secrete, sufficient to prove that this is not a morbid cnomenon; moreover, it will seldom be und except in a body examined at least ty-eight hours after death, and its quantity ll be in proportion to the condition of the dy as to decomposition. Sometimes, but rely, gaseous effusions take place in the eural sac; they are in general complicated th old pleuritic effusions, and result from eir decomposition, thus constituting one of e species of pneumothorax described by ennec. Whether this disengagement of gas kes place before or after death is not easily termined; probability is in favour of the ter, but the experiments of Gendrin seem to dicate the presence of a variable quantity of s in the chest in very acute pleurisies, ap-aring just when the inflammation seems to ve arrived at a certain degree of violence.

In the mucous membrane which lines the r-passages, from the larynx and trachea to the inutest bronchial ramification, discolorations cur from various causes, which are extremely kely to deceive even a practised eye. In the rynx, trachea, and larger bronchi, this disco-ration is not so variable. We here find a ssive hyperæmia from the gravitation of the ood, in which case the mucous membrane is ly partially congested. We also find here a ngestion from obstruction to the circulation nerally, dependent on disease of the heart; t in the minute bronchial ramifications we nd not only the influence of gravitation or transudation after death producing alterations in the aspect of the membrane, but likewise these causes are apt to take effect in the struggle of death, or even some time before death in very debilitated persons. The progress of putrefaction in general produces a very marked and diffuse brown colour of the mucous membrane, much more intense in the smaller tubes. To be able to decide upon any one of the above species of hyperæmia of the bronchial membrane will require a careful consideration of coexisting circumstances. In the latter instance the general condition of the pulmonary and the other tissues as to their state of preservation, will materially assist; in the other cases the injection is ramiform, and the membrane does not appear so uniformly dyed, the redness being chiefly limited to dependent parts; and the state of the heart or great vessels will assist further in deciding upon the true nature of the redness. These circumstances will direct us in discriminating any of these different forms of redness not only from the others, but also from that which is produced by inflammation. Inflammatory redness, it should be remembered, is often accompanied with some secretion, either a viscid and adherent mucus, or a pseudo-membranous exudation, or even purulent fluid, all which are unequivocal proofs of the morbid nature of the colour of the membrane.

In examining the pulmonary tissue itself, we experience considerable difficulty in distinguishing between its pseudo-morbid and morbid conditions. We can say with confidence, from tolerably extensive opportunities for studying the subject, that there is no one point in morbid anatomy more difficult to pronounce upon with certainty, than whether a hyperæmia of the lung be inflammatory or not. Every one must have experienced how unsatisfactory are the signs of the second stage of pneumonia—the *engouement* of authors. It is obvious that this difficulty is greater the longer the period which may have elapsed since the death of the subject. It however rarely happens that a patient dies in the first stage of pneumonia; most frequently we find that the disease has in one portion of the lung advanced to its second stage *(red hepatization)*, and very frequently the third stage *(grey hepatization)* is exhibited in the same lung along with the two preceding. Where either of the forms of hepatization exists, there can be little doubt as to the nature of the congestion in any other part of the lung. Moreover, we may remark that the inflammatory congestion affects the upper as well as the dependent parts. The following observations from Andral will show how he estimated the difficulty of laying down any distinction between inflammatory and the pseudo-morbid hyperæmia. "It is," he says, "in the lungs as in the intestines, where a local accumulation of blood may be found in the dead body, which has had no share in producing any of the morbid phenomena observed during life, but was formed during the last moments of existence, or after life ceased altogether. Hence it follows that the existence of a simple congestion, especially when it occupies the most dependent portions

of the lung, is not sufficient to prove that a process of irritation or inflammation had been going on there during life. Does an alteration in the consistence of the part afford a more certain criterion to judge by in such cases? For a long time I was of opinion that when the lung was red and gorged with blood at its posterior portion, and at the same time was softer and more easily broken down than natural, it was a proof that the hyperæmia was caused by inflammation; but I have since altered my opinion, and am now convinced that whenever the sanguineous congestion is so great that the lung contains a larger proportion of blood than of air, the pulmonary parenchyma is invariably soft and friable. The reason of this fact will readily be understood if we reflect that, when the lung contains a much larger proportion of air than of blood, the parietes of the bronchi, when pressed by the finger, press in their turn on the compressible fluid they contain, and in this way, by compressing or expelling the air, retire before the pressure of the finger, and so escape being ruptured. But when the lung contains a larger proportion of blood than of air, the former fluid being almost wholly incompressible, the pulmonary tissue cannot recede from under the finger, and is therefore easily ruptured."* And in another section he remarks, "as the anatomical characters of the hyperæmia are precisely the same in both these cases, it follows that, in this instance at least, the true nature of the lesions found on dissection can only be known by the nature of the symptoms observed during life."†

We can hardly suppose it possible that gangrene of the lung and any post-mortem congestion of it could be confounded together. The peculiar smell from a gangrenous spot is a certain indication of its true nature. However, if any condition do appear closely to resemble gangrene, by carefully washing the suspected portion of lung in clean water we shall in general succeed in exhibiting the sound pulmonary texture.

In the pericardium the signs of disease are so very obvious that we know of no phenomenon which that membrane can present which could be considered pseudo-morbid. There is found, however, in its cavity, after a certain time, a sero-sanguinolent effusion in small quantity, which, like a similar one above noticed in the pleura, is to be regarded as a cadaveric result. (See Hydro-pericardium.)

Except after the lapse of a considerable time from death, we have never seen any post-mortem condition of the substance of the heart which could be mistaken for a morbid one. We not uncommonly meet with softening of the muscular texture of the heart; and this may arise from so many different causes, that Andral has enumerated six varieties of it; with any of these may be confounded a true cadaveric softening, which, however, generally does not appear for a long time after death. The best criterion of the true nature of a softening of the heart's parietes may be formed from the state of the internal membrane; if that membrane be healthy, or do not partake in the diminished consistency of the heart's parietes, then the great probability is in favor of this condition being the result of disease. But when the internal membrane is of a deep red colour, and is more or less softened, while at the same time there is no appearance of any lymph or other product usually resulting from inflammatory action, then we consider it impossible to determine with certainty to what cause the softening is to be attributed. In some instances the blood has been known to transude through the walls of the heart, and form ecchymoses either between the fibres or on the external surface. Such ecchymoses will want the regularity of form which those formed during life would possess, and rarely, if ever, take place except in an advanced stage of decomposition. We have twice seen numerous ecchymosed spots on the hearts of patients who died of purpura hemorrhagica; but these should be considered as morbid, and attributable to the same cause as the cutaneous ecchymoses.

The internal membrane of the heart often presents an obviously pseudo-morbid alteration in its colour. When the examination of a body does not take place for forty-eight hours after death, or in very warm weather for a longer period, we may invariably expect to find this membrane of a red colour to a greater or less extent. That portion which lines the dependent parts of the cavities will always be found so, and to a greater degree than the rest, because the colouring matter sinks through the coagulum so as to come immediately in contact with the internal surface of the heart; and this will account for the fact, that except at a very advanced period in the cadaveric decay, this redness generally appears in patches, and those most intense which are most dependent. A precisely similar redness will occur under circumstances which can leave no doubt that it took place during life; but as this subject is closely connected with the appearances of the internal coats of arteries, we shall defer any farther remarks upon it till we come to that section of our article.

The fibrinous masses which are almost uniformly found in the cavities of the heart are not to be considered in every instance as morbid productions, as the older pathologists thought; in general they are formed after death, or immediately before it, and merely form the natural disposition of the fibrine to assume the solid form. However, some of these coagula have been found organized, some containing pus, others with pieces of bone on them or in them; whence we must conclude that these fibrinous masses may be formed before death, and produce considerable disturbance of the circulation.*

5. *The abdomen.*—Of all the serous membranes, the peritoneum is most liable to *morbid* effusions. But in this cavity, as well as in that

* Andral's Pathol. Anatomy, by Townsend, vol. ii. p. 508.

† Op. cit. vol. ii. p. 509.

* Dr. Harty has given a very elaborate narration of the symptoms of two cases, which in his opinion were produced by these so-called polypi of the heart. Dub. Med. Transactions, vol. i.

the pleura, we generally find a post-mortem asion after thirty or forty hours; which, like t of the pleura, is in general coloured by re or less admixture with blood. This fluid l always, except it be in very great quantity, found in the pelvic portion of the perito- m. In the serous membrane itself, we ow of no pseudo-morbid appearance likely occur, except we name that softening pro- ced by contact with the acid contents of a rforated stomach, which we shall presently no- e more fully. The discoloration arising from ntact with the gall-bladder is too evident to mistaken for disease.

In examining the exterior of the intestinal tube the intestines lie in the abdominal cavity, we serve appearing through the serous coat vas- lar ramifications more or less numerous and ore or less filled with blood. Here we observe ll illustrated the effects of gravitation on the ood within the vessels of the intestines; ose coils which are lowest, namely those ich hang into the cavity of the pelvis, always esenting the deepest colour, and also the ost depending portions of all the parts of e canal.

There is no membrane of the body which esents pseudo-morbid colouration arising from many different causes, as the gastro-intesti- l mucous membrane: we speak now of the lour which results from particular distribu- ons of the blood in its vessels. In the first ace, we may notice that the *act of digestion* oduces an increased degree of redness of the ucous membrane of the stomach as well as the small intestine. The effect produced digestion on this membrane has been well oticed by Gendrin; he says that the mem- ane becomes of a rosy hue, deeper in young an in old subjects; and that it is owing to e action of this function may be very well ferred from the fact that only that portion of e membrane is coloured which is in contact ith the chymous mass. It is also remarked ound the portions of digested matter which e found in the lower part of the small in- stine. It appears, too, that the degree of lour depends very much upon the quality of e food, being less intense when the food is f a bland nature. This has been proved upon wo dogs, to one of which milk only had been iven, to the other an equal quantity of rich roth highly seasoned; the mucous membrane f the latter was of a deep red colour, while hat of the former was very slightly altered. asting also has the effect of altering the colour f this membrane, giving it a rosy hue in its whole extent; in this way differing from the ffects of digestion, which produces only a partial colouring.

A third cause of alteration of colour results rom "the passive hyperæmia," to adopt the anguage of Andral, "which has always a ten- dency to take place in the last moments of life n the parts abounding with capillaries." In his case the colour is generally of a darker hue, and the greatest quantity of blood is found in the vessels of the depending portions of the intestines.

Any obstacle to the free return of the venous blood, whether it reside in the liver, or from compression of the vena portæ itself, or whether it is to be found in the heart, will produce increased vascular injection of the mucous membrane; the blood in such cases will be of the venous kind, and the injection extensive, and even universal; varying, however, according to the period before death at which the obstruction commenced.

Such are the circumstances which operate before death in producing pseudo-morbid colouring of the mucous membrane. In the true inflammatory redness, there is generally some degree of thickening of the membrane, as well as a viscid mucous secretion in variable quantity. The redness, too, is not affected by position, being equally great on the upper as in the depending portions; and in a more advanced stage of the inflammation there may be lymph or purulent matter.

After death, we find the blood accumulating with greater rapidity, and in a more marked manner in the depending parts. This phenomenon may be observed as to the mode of its occurrence, by removing a coil of intestine, tying it at each extremity, and hanging it up; after some time the blood will be seen to leave the upper part, and accumulate in the lower portion of the intestine. If there be much blood in the capillary system of the mucous membrane, we observe another cadaveric phenomenon, after the body has lain for some time: the mucous membrane, and of course the villi, are gorged with blood, which presently begins to ooze out upon the surface, and to pass into the cavity of the intestine. This we lately saw well exemplified in the case of a young gentleman who died of fever, and whose body we could not obtain permission to examine till five days after death. All the upper portion of the small intestine was free from sanguine congestion, but that part of it which lay in the pelvis was found to be of a dark red hue externally; the mucous membrane being gorged, especially at its inferior part, and the cavity of the intestine full of fluid blood. This phenomenon is easily explained if we consider how freely the blood passes from the larger mesenteric veins to the villi, which moreover, from the researches of Ribes, appear to contain more veins than arteries; it is also further accounted for by the great facility with which an intestine may be inflated by blowing air into its principal venous trunk. Contact with the spleen produces a redness of a different kind, being more of a uniform stain or tinge of the membranes in its vicinity. This obviously arises from transudation of the blood from this vascular body through its coats. After a certain period we find the blood to transude through the coats of the larger vessels of the stomach and intestines so as to produce a more or less continuous stain, or extravasation of blood in the cellular membrane on each side of the trajet of the vessel. This appearance must be familiar to every one who has examined a stomach in an early stage of decomposition; the stain is distinctly visible on the mucous

surface, and may also be noticed on the peritoneal surface. The period at which this transudation may take place will very much depend on the season, the temperature of the room, and perhaps the state of the blood.

There are two other causes of discoloration which it is well to remember, although the appearances they produce may not be very apt to be mistaken for morbid ones. One of these is the presence of gases in the cavity, which may alter in various ways the colour of the blood collected in the coats of the intestine. The action of the bile too, by soaking into and combining with the mucous membrane, produces a very obvious change in its colour, and this may even extend into the stomach. There is a third cause of discoloration resulting from the action of the gastric acid on the blood, which we shall notice more fully after considering the other effects of that acid.

In inspecting the alimentary canal, we should not neglect to observe accurately the nature of its contents, for sometimes some coloured fluid may be found among them which may impart its colour to the membrane. Dr. Christison quotes a case in which a suspicion of poisoning had arisen from the inspector hastily referring the altered colour of the inner membrane of the stomach to inflammatory action. It was ascertained that the deceased was in the habit of taking a strong infusion of corn poppy, *(papaver rhœados,)* which, when administered to dogs, produced appearances identically the same. The inference was obvious.*

It will thus appear, that in attempting to form a judgment as to the precise nature of any coloration of the alimentary mucous membrane, there are numerous sources of fallacy which it is important to avoid. It is in the stomach that most of these pseudo-morbid appearances occur, but many of them likewise are to be met with in the intestines. They may be classed as follows: 1st, those which are produced antecedent to death, and 2nd, those which are strictly post-mortem or cadaveric. Under the former are comprehended, 1, those produced by the stimulus of digestion; 2, those resulting from long abstinence; 3, the result of passive hyperæmia toward the close of life; 4, such as arise from a disturbed state of the circulation owing to a retardation in, or obstacle to, the free return of the venous blood. Under the cadaveric may be enumerated, 1, that arising from post-mortem hypostasis, which is sometimes accompanied with cadavaric hemorrhage; 2, that produced by contact with a vascular body like the spleen; 3, those stains or streaks resulting from transudations of the blood through the coats of the larger vessels, more especially of veins; 4, that produced by the action of gases evolved into the cavity of the intestine, upon the blood contained in its vessels; 5, that from imbibition of the bile; 6, that from contact with some coloured fluid in the intestine forming part of the ingesta; and, lastly, that produced by the action of the gastric acid, of which we have yet to speak.

* Vide Christison on Poisons, p. 121.

Attenuation or thinning of the mucous membrane is occasionally met with as a morbid phenomenon. We sometimes, however, find it caused mechanically by a continued distention of the tube. Thus Billard relates a case in which he found a mass of lumbrici in a portion of small intestine, which was so distended by them that it almost equalled the cœcum in volume, and its wall was so thin as to permit the worms to be seen coiled up in its interior. We lately examined the body of a young girl, in which the cœcum was distended with fæces to such a degree that it extended across the upper outlet of the pelvis to the left iliac region. From the excessive attenuation of the wall of the intestine, the fæces were distinctly visible through it.

Softening of the mucous membrane is an alteration of texture which equally takes place under the influence of morbid causes as of others of a different nature. Nobody denies the existence of softening of the gastro-intestinal mucous membrane consequent upon inflammation; but it may reasonably be doubted whether it arises from that cause so frequently as has been supposed. Neither can this alteration of consistence be considered as a frequent result of the putrefactive process, for unless the membrane be exposed to air, we find that it softens slowly. Andral has found its consistence unimpaired eight or ten days after death, and in bodies which exhibited abundant signs of advanced putrefaction. Even when exposed to the air it softens slowly, as Billard did not perceive any change till the sixth day of the exposure of a portion of mucous membrane, and in a situation where the sun's rays could exert their full influence upon it. Hence we may with reason reject putrefaction or decomposition from the list of causes of this alteration, seeing that the majority of post-mortem examinations take place within forty-eight hours after death.

To John Hunter we are indebted for the first notice of what must be considered a very important fact, viz. that in the body of an individual dead soon after digestion has commenced, the mucous membrane of the stomach, the great end especially, may be found dissolved, and even the wall of that viscus perforated, and this through the solvent power of the gastric juice, "that menstruum which the stomach itself has formed for the digestion of food."* Without inquiring into the grounds on which so many subsequent writers or experimenters attempted to refute or deny Hunter's hypothesis, we shall content ourselves with referring the reader to Dr. Carswell's very able paper on this subject,† in which he will find the opinions of Jæger, Laisné, Gairdner and others, fully discussed, and pass on to state the facts which appear fully to establish the original opinion of the great British physiologist. The first circumstances in favour of this opinion are those related by Hunter himself, viz. the fact of having found a solution of the

* Hunter's Animal Economy, p. 231.

† See Edinb. Med. and Surg. Journ. v. 34, p. 282.

omach in two persons killed suddenly and ortly after having taken food; the frequency the solution in fishes, who generally died of blence and with the stomach full, and in other imals killed violently and during digestion. Spallanzani, Adams, Cooker, and Carlisle terwards confirmed these experiments. Some ilures, however, occurred in the attempts to oduce this phenomenon at pleasure in ani- als, and hence the confidence of subsequent perimentalists was somewhat shaken. Some bservations strongly corroborative of the Hun- rian doctrine were published by Allan Burns; e found the stomach dissolved and perforated, nd not only this, but every viscus with which ne fluid that escaped from the stomach came contact was also softened in its walls; and a still further confirmation, he observed, n examining the body two days after his first spection, that the solution had extended con- derably. Recently Dr. Carswell, in the aper above referred to, has fully succeeded in roving that this softening takes place in ealthy animals killed during digestion, and hat, in whatever part of the stomach "this nction was going on most actively, or an ac- umulation had taken place of the products of ecretion, there the organic alterations had also ccurred." Finally, a case has occurred to Dr. Sharpey, as related by Dr. Christison, precisely analogous to that of Mr. Burns. "On proceeding to open the body of a child or the purpose of dissecting the nerves, he marked that the stomach was perforated and elatinized, but the adjoining parts uninjured. He then sewed up the body in order to shew ne appearances to some of his friends next ay. By that time the peritoneal surfaces of ne spleen and left kidney were found much oftened and pulpy where they lay in contact with the hole in the stomach."*

Such, then, is the evidence upon which we would attribute a form of softening (and per- aps the most frequent) of the mucous mem- rane of the stomach to the action of the astric juice, and it may be added that this ction may go on to produce a perforation of he wall of the stomach. The softening is enerally observed at the most depending part, most commonly the great sac: here the mem- rane appears like jelly, yet hardly so firm. "When raised between the fingers the coats crumbled to pieces like a recent pseudo-mem- rane," and often the serous coat is similarly oftened. The only alteration of colour in he mucous membrane is that of being ren- lered rather whiter than the natural hue. The perforations resulting from this cause of course vary in extent according to that of the softened issues; we find them, therefore, of all sizes, sometimes so great as to involve a considerable portion of the stomach. The margins appear half dissolved, fringed, and generally formed of the serous membrane, and for a considerable distance round the mucous membrane is gelati- nized. Moreover, as has been first noticed by Dr. Carswell, the bloodvessels distributed on the softened parts and also on every part which had come into contact with the fluid, were altered in colour, so as to form brownish, brownish black, or pure black arborescences. When the fluid could not come in contact with the membrane, the vessels exhibited their natural colour. It may be stated further that the fluid found in these stomachs at once reddened litmus. In the instances of this form of perforation which have occurred in the human subject, no symptoms whatever of gas- tric disease were present before death, the patients having died of disease of some other organs or by violence. Thus, according to an abstract which we take from Dr. Christison's work, it has been found in women who died of convulsions after delivery, in children who died convulsed or of hydrocephalus, after death from suppuration of the brain both idiopathic and traumatic, from diseased mesen- teric glands, from nervous fever, and after sudden death from fracture of the skull and hanging.

The softening of the mucous membrane thus formed is to be distinguished from that which is the result of morbid irritation during life, as well as of that produced by the intro- duction of irritant poisons. Cruveilhier has described a condition of this membrane in the stomach of children, which he calls "*ra- mollissement gélatiniforme*." This softening, like that above described, extends to the other coats of the stomach and even causes perfora- tion. In short, this affection described by Cruveilhier has the strongest possible resem- blance to the pseudo-morbid softening of Hun- ter; but the evidence adduced in favour of its morbid character is derived from certain sym- ptoms supervening a short time before death. We know of no means whereby we can dis- tinguish between these two alterations, except, perhaps, the dark colour of the blood con- tained in the vessels of the softened part, which, if the alteration described by M. Cru- veilhier were the effect of morbid irritation, would not be likely to occur. On the whole, however, we are strongly disposed to the opinion that the *ramollissement gélatiniforme* of Cruveilhier is a pseudo-morbid phenomenon, and identical with that caused by the action of the gastric juice.

In a true pathological softening there are uniformly present some additional signs of in- flammation; thus, we sometimes have redness of the membrane, and generally an increased opacity and a thickening of the submucous tissue; and it may be indifferently found on all parts of the stomach, even where the gastric juice could not come in contact with it; more- over, here likewise we have not the black dis- coloration of the blood which is a remarkable character of the softening by the gastric juice.

The perforation which results from this softening must be distinguished from that caused by inflammation or by rupture. The existence of signs of inflammation in the serous membrane would be unequivocal evi- dence; but sometimes the perforation or rup- ture occurs at too short a time prior to death

* Christison on Poisons, p. 127.

to allow of the production of peritoneal inflammation, in which case the appearance of the margin of the opening, the state of the surrounding membrane, and of the submucous tissue, will assist in forming a conclusion.

We have alluded to the effect which the gastric fluid produces when brought into contact with the blood in the vessels of the stomach. The effect is nearly similar to that produced in the case of poisoning by acetic acid, related by Orfila in the Annales d'Hygiène for July, 1831, namely, a black or brownish black discoloration of the blood, without affecting the coats of the vessels. In the instance under consideration, however, the discoloration is not so extensive as in that of poisoning by the acid, the quantity of acid in the gastric juice being so small. But we sometimes meet with a brownish black discoloration from morbid action, which may be distinguished chiefly by the fact of its occupying the villi of the membrane, and by the gradation through which the colour passes from red to brown, and from brown to black; to which we may add that the discoloration by the gastric juice is most conspicuous in the large trunks. The absence of all appearance of transudation, as well as the state of the other tissues, will sufficiently indicate that the black colour is not caused by putrefaction.

In the parenchymatous viscera of the abdomen there are no pseudo-morbid appearances worthy of notice; they are chiefly such as are produced by mechanical obstacles to the free course of the blood, or such as are caused by the operation of the principle of gravitation. In some bad states of the blood the liver and spleen have been found softened in their texture to such a degree that they almost appeared to be thus altered by putrefaction; however, in general, the effect of putrefaction is to diminish the size of those organs, while the reverse often takes place in the case to which we allude.

6. *The bloodvessels.*—It is not uncommon to find considerable vascularity of the cellular membrane forming the external investment of arteries. The minute vessels ramifying in this tissue, called vasa vasorum, are minutely injected, and form beautiful arborescences freely anastomosing over the surface of the arterial tube. These often are produced as a mere mechanical effect, or as the result of gravitation. The alterations of colour which the internal coat of arteries exhibits deserve particular attention. Every one must have observed that if an artery be slit open, its coagulum or blood removed, and its inner coat exposed to the air, it quickly acquires a bright-red colour. Again, if the blood remain fluid for some time after death, if its fibrine be less contractile than in the healthy state, the inner coat of the arteries will be generally found to be deeply coloured. In examinations made when putrefaction has fully set in, a similar colouring of the same tissue will uniformly be seen. Again, if a coagulum exist in an artery, and the colouring matter have sunk to its most depending part, that portion of the inner coat will be coloured which is in contact with the colouring matter of the clot. Finally, by inclosing some blood in an artery, and keeping it there by ligatures, we are able to produce a red colour in its internal membrane. Such are the different ways in which a red colour or stain of the inner coat of arteries may be produced, very similar to that which is the first indication of inflammatory action in it. In veins similar discolorations, and from the same causes, are observed, and in them those arising *post mortem* take place much more quickly than they do in arteries. The red colour of the inner membrane of either arteries or veins can be but little depended on as a sign of inflammation; nor, indeed, can we derive any conclusion from it at all unless it be accompanied with an albuminous exudation or other unequivocal product of inflammatory action.

In the preceding detail of the various pseudo-morbid alterations which are to be met with in the principal tissues of the body, our design was, not to exhibit to the reader the difficulties in the way of forming a correct estimate of the condition of any structure, but to convince him, and in the most practical way, of the necessity for and utility of observing great caution in deciding upon the presence or absence of disease. We shall bring this article to a close by stating a few conclusions suggested by the consideration of the subject, which may serve as useful directions in making or recording post-mortem examinations.

1. Before proceeding to examine a body, the inspector should invariably ascertain, with as much accuracy as possible, the length of time which may have elapsed since the death, and it should be noted in the record of the inspection. The neglect of this has rendered many apparently valuable cases, noted in some of our standard works, utterly inconclusive. We allude more especially to cases in which serous effusion has been found round the brain or spinal marrow. 2. The reporter of post-mortem inspections should in no case content himself with merely stating what he conceived to be the state of a tissue, as, for instance, "*that such a membrane was inflamed*," but he should be careful to note, as clearly and as concisely as may be, the appearances which presented themselves, and any concomitant circumstances calculated to unfold the true nature of those appearances, whether morbid or pseudo-morbid. This precaution need not, however, preclude any remarks as to the impression conveyed at the time of examination, but it is obvious that it will have the advantage of recording a plain statement of facts, from which each reader may have equal means of deriving a conclusion. 3. There are some points respecting the examination of certain parts worthy of attention. In every case of suspected disease of the spinal marrow, the spinal canal should be opened before the head, in order to form an estimate of the precise quantity of fluid that may happen to be effused. The advantage of this is apparent from what we state respecting the free communication between the two portions of the cephalo-spinal fluid. The brain should not be removed from the cranium until the ventricles

e been examined, that as little as possible of fluid may escape. Of course this is only licable where the head is opened before the ne. As to the manner of opening the head, have generally preferred to do so by sharp strong blows of a hammer, so as to crack skull round, the head being supported by other hand, and not placed upon so unding a fulcrum as a table or block. We e found this method preferable to that of ing, which, we conceive, disturbs the parts e, and, unless the saw be very sharp, is ays extremely tedious; not to mention the iculty of preventing the saw from injuring dura mater, or even the substance of the in itself.

(R. B. Todd.)

PSORIASIS.—The term *psoriasis*, (scaly er; dartre squameuse,) from ψώρα, a scab itch, was first employed by Dr. Willan denote a cutaneous disease, which consists entially in a greater or less degree of inmmation of the rete mucosum and contiguous face of the cutis; and in the secretion of unhealthy epidermis, forming itself into les which exfoliate, and are renewed with ater or less rapidity. The natural transpion through the affected parts is almost apletely interrupted, and its place supplied the exuberant growth of a morbid cuticle. oriasis is so closely allied to lepra that some ters* have proposed to conjoin them under head, which in a practical point of view uld be attended with no inconvenience. th are well marked scaly diseases, and the erence between them consists in the more fect circular regularity of lepra, its inflamed rgin, raised scaly circumference, and usually pressed centre; while the outline of the ches of psoriasis is irregular, and their ntre rather elevated than depressed. Yet connexion between the two diseases is so imate, that we sometimes observe both ms of eruption in the same individual; pts of lepra being intermixed with the more gular and extended patches of psoriasis.

The elementary character of psoriasis is a ly surface with inflammation of the subent vascular tissue; but to these are geally superadded the formation of fissures l excoriations, discharging a thin fluid, ich concretes into crusts, intermingled with formed upon true scales; and in severe l protracted cases there also occurs overowth of the cutis, which acquires unnatural ckness and solidity. This affection is atded with heat and itching, which, although dom altogether absent, become at times re intense and distressing: during these ecerbations the inflamed skin flushes with t, and swells up into ridges like an erectile sue.

Psoriasis varies much in the rapidity of its ogress: it generally appears first in the form of small, red, shining spots which become covered with scales; and under these other scales are formed, while the first loosen and fall off. Thus the scales thicken, the spots multiply, enlarge, coalesce one with another, and form large patches. In other instances of this disease, considerable portions of the integument are affected at once, becoming rough, harsh, and chopped. Psoriasis is usually preceded by languor, lassitude, and loss of appetite: and is accompanied in its early stage by more or less of febrile disturbance, which is always most strongly marked in those cases where the disease is suddenly developed. It is very often periodical in its attacks, disappearing and recurring with marked regularity at certain seasons of the year. In the case of a lady, whose leg has for many years been affected with a large patch of *psoriasis inveterata*, the disease uniformly disappears during pregnancy, leaving a pale, wrinkled surface similar to the scar of a burn.

Causes.—Psoriasis is not generally believed to be contagious; but Dr. Willan,* it appears, had observed *psoriasis guttata* to occur among the children of the same school or family at the same time: and we remember to have been consulted by two ladies having this disease on their necks, who were impressed with the belief that they had received it from their female attendant. Its hereditary nature is generally admitted; and several instances in proof of this opinion are known to us. Psoriasis is more frequently seen among the lower than the upper classes of society, and oftener among females than males, occurring especially during disorder of the uterine functions, as in chlorosis and after parturition. Persons of a full habit and dark complexion are most subject to this disease; and a distinct tendency to it is indicated by a dry and husky state of the skin, with languor of the circulation. It is more especially a disease of cold climates, and its occurrence is much promoted by the keen, dry winds of spring, and the sudden alternations of temperature which take place both at that season and in autumn. Hence it has been observed to recur particularly at these periods for successive years, and to be then most aggravated; but we have known psoriasis to be most severe during the heats of summer.

Various occasional causes appear to give rise to this disease; such as chilling the stomach by large draughts of cold water while heated,† the sudden exposure of the body to cold after violent exercise, acid and indigestible substances taken into the stomach. In children psoriasis appears sometimes to originate from the irritation of dentition; and in adults it has been observed to arise during great mental anxiety, grief, and apprehension‡—most probably from the influence which these states of the mind exert over the digestive organs. There is reason to believe that both gout and

‡ *Bateman*, Synopsis, p. 38.

urinary calculus are connected with psoriasis, not as causes, but concurring consequences of the same disordered condition of the stomach and bowels. Numerous local irritations are productive of psoriasis affecting the hands and arms, as in washerwomen, bakers, and others.

Dr. Willan* has mentioned that both *psoriasis guttata* and *psoriasis diffusa* are sometimes the sequel of *lichen* and *prurigo;* and we recollect an instance where *psoriasis inveterata* appeared to have been the consequence of *eczema rubrum*. We have observed also the disease last named degenerate under our eyes into *psoriasis guttata*.

Psoriasis has been divided by Dr. Willan into numerous species, of which only four deserve particular consideration; the rest being regarded as mere varieties, for which a brief notice will suffice.

1. *Psoriasis guttata*, (drop-like scaly tetter.) This appears in the form of irregularly shaped spots, some no bigger than a pin's head, others nearly as large as a sixpence; which multiply, extend, and coalesce into patches, all of them covered by white glistening scales, excepting those in the face, where they appear merely as red spots, rough and slightly elevated. It is seldom attended with much inflammation of the skin. Its type is sometimes acute, at others chronic; the former is most frequent in children, in whom it occasionally overspreads nearly the whole body in a few days; the latter is usual in adults. When the progress of *psoriasis guttata* is rapid, it is always accompanied by general feverish disturbance, and in many cases preceded by muscular pains. It appears most frequently in spring, and sometimes recurs annually at that season for several successive years. This is the most common form of psoriasis, constituting, according to Rayer,† three-fifths of all the cases which are met with.

2. *Psoriasis diffusa*, (diffuse scaly tetter). The character of this species is considerably more inflammatory than any of the others, and it is more nearly allied to impetigo and eczema; indeed Alibert has described one form of it under the name of dartre squameuse humide.‡ The skin affected by this eruption is much more hot, red, and tender, more frequently presents fissures and excoriations, and is much less closely covered with scales, which differ from those of the foregoing species in being occasionally of a brownish tint, more irregular in their form, and placed more edgewise on the surface. Diffuse psoriasis sometimes appears at once over a large extent, the skin becoming harsh, cracked, red, and scaly: at other times its progress can be traced from the formation of minute, elevated spots, covered with distinct scales, which after a time are connected by the inflammation of the intervening spaces; these in their turn become scaly, and the whole is at length changed into one continuous eruption. Again, in other cases, the disease appears in small separate patches, which may remain distinct, but are also apt to extend and coalesce, acquiring ultimately the characters just described. The cuticle becomes rent into fissures, which discharge a thin, serous, and sometimes bloody fluid, while the cutis, which is always more or less turgid from inflammation, at length suffers a real overgrowth. The development of this disease is usually attended with constitutional disturbance, which is afterwards maintained by the continued irritation of the inflamed skin. The heat and itching are often very troublesome, and any additional excitement from increased temperature, or the friction of the clothes, produces a distressing aggravation of the symptoms. In children this is particularly remarkable, for in them diffuse psoriasis appears in a severe form, generally from the age of two months to two years. Dr. Willan* was led to erect this into a distinct species *(psoriasis infantilis)* in consequence of the affection of the mucous membrane of the nostrils which usually accompanies it, and the intermixture of scaly patches with smooth shining elevations, which in the cleft of the nates often assume the appearance of moist flattened condylemata. But we have seen this occur in other squamous diseases, apparently from the mere action of heat and moisture preventing the scales from forming, and increasing the morbid turgescence of the affected spots. The disease in this altered form is more amenable to treatment, the flattened elevations yielding in general readily to the application of sulphate of copper.

When diffuse psoriasis continues its progress unabated, it either destroys the patient by the effects of cutaneous irritation, and of the accompanying morbid condition of the alimentary mucous membrane; or more frequently it degenerates into the inveterate form *(psoriasis inveterata)*. But the severity of the disease is usually limited to a few months, after which it becomes greatly ameliorated or disappears altogether, again to recur during the variable weather of spring or autumn, most frequently the former, but sometimes at both seasons.

The causes of this species of psoriasis are the same as those already enumerated; but it appears oftener to originate from the application of irritating substances to the skin, and exposure to sudden alternations of temperature: hence arise the local varieties which occur in washerwomen, bakers, shoemakers, workers in metals, and cooks. The first of these is often very severe, affecting the hands, wrists, and fore-arms, particularly about the part up to which they are usually immersed in the washing-tub. It arises from the irritation of the soap, and the alternate exposure of the skin to hot water and

* On Cutaneous Diseases, vol. i. p. 156. To the works of Dr. Willan, and of his pupil and follower Dr. Bateman, the writer of this article gladly acknowledges the heavy debt which he owes. Not to have drawn from the rich treasures left us by those distinguished physicians, would have been at once discreditable to himself and unjust to his readers.

† Maladies de la Peau.

‡ Maladies de la Peau. Pl. 13. Another form of the same species has been named by him *dartre squameuse orbiculaire*. Pl. 14.

* Vol. i. p. 170.

d air, and is most frequent in spring and nter.

The bakers' itch *(psoriasis pistoria)* is con- ed chiefly to the back of the hand, where skin is more tender than in the palm, and ere it is exposed both to the irritation of the ur and to the strong heat of the oven. We e also observed a cutaneous affection some- at similar on the hands of cooks, arising from posure to the scorching heat of the fire.

3. *Psoriasis inveterata* (inveterate scaly tet- ; dartre squameuse lichénoide). This, as name imports, is the most obstinate of all the ms of the disease, sometimes originating in diffuse species, at other times being the con- quence of *prurigo senilis* or of *eczema ru- m*. It is characterized by an exceedingly ckened state of the cuticle, which appears in n layers of a glistening white colour, re- nbling the shining bark of a tree, or the skin a dried fish; divided not into the mosaic of thyosis, but by transverse lines and fissures: often encases a part or the whole of a limb, d sometimes extends over the greater part the body, leaving unaffected a portion of face, or perhaps the palms and soles. The ges of the divided cuticle are usually curled vards, and these chinks open and close with motions of the body, which in such cases are t unfrequently attended with a rustling or ght crackling noise. A quantity of thin id, sometimes tinged with blood, oozes from fissures, and occasionally large portions of thickened cuticle are detached, leaving a ght red and exceedingly tender surface, at st discharging copiously a watery liquid, and n becoming covered with a hard dry epi- rmis, which separates from time to time in ge plates. The formation of scales and flat- ied crusts is so rapid in this disease, that great antities are found every morning in the pa- nt's bed,* resembling in this respect the de- ne of mercurial eczema, in which, however, appearance is produced by the drying of the ous discharge rather than the formation of e scales. When the cuticle is thus exten- ely and deeply diseased, the nails participate the change, becoming thickened and brittle, quently separating and being renewed.

4. *Psoriasis gyrata*, (serpentine scaly tetter). is very rare species of psoriasis is chiefly re- rkable for the red waving ringlet-like stripes ich it presents on the back or breast of the tient; the figures on one side of the spine, or one breast, often bearing a near resemblance those on the other. It is unnecessary to de- ibe minutely the fantastic shapes which it metimes exhibits; suffice it to say that the l colour of these tortuous stripes is partly aded by a thin covering of light branny les, which are constantly being thrown off d renewed. It is distinguished from herpetic d impetiginous eruptions, to which it bears a mote general resemblance, by the absence of sicles and pustules. Like other species of oriasis, it is much influenced by the weather and the seasons of the year—subsiding in sum- mer, and becoming more intense in spring and autumn.

Such are the great divisions of psoriasis founded on its peculiar forms and the degree of its severity, and under them, especially the diffuse species, may be ranked all the local va- rieties which have been described by Dr. Wil- lan and others. The most important, and per- haps the most common of these varieties, is that which affects the palms of the hands, *(psoriasis palmaria:* dartre squameuse cen- trifuge:) it is characterized by inflammation and thickening of the skin of the palm, with scales dispersed over the surface; and very often fis- sures, from which thin fluid oozes, attended with heat, itching, and sometimes considerable pain on extending the fingers. Patches of the same description appear also on the inside of the wrist and on the sides of the fingers; the nails likewise are affected in protracted cases, becoming thickened and opake, and mouldering away or being cast off. This is often observed to be an hereditary disease, and in those dis- posed to it the nails usually possess an unna- tural brittleness which makes them snap under the scissors. In such individuals the exposure of the hands to a cold dry wind, or frequently moistening them, is almost sure to induce some degree of psoriasis. The same affection is seen also on the soles of the feet, but in a less severe form, and rarely accompanied with fissures, as the feet are much better protected from cold, and very seldom exposed to the air while moist.

Diffuse psoriasis is sometimes seen on the scalp, producing an inflamed state of the skin, and a copious formation of white scales: in some instances the bulbs of the hairs become affected, and baldness is the consequence. The skin around the different natural apertures of the body is also subject to psoriasis, which, from the movements of the parts, is almost always productive of painful fissures. Thus it is met with on the edges of the eyelids *(psoriasis oph- thalmica)*, the lips *(psoriasis labialis)*, the nos- trils, and on the verge of the anus and prepuce *(psoriasis preputialis)*. When the lip is affected with psoriasis, it is most commonly the prola- bium of the under lip: its causes are obscure, but Rayer* states that he has twice observed it in persons who were great talkers, and addicted to the practice of biting their lips. The scro- tum is likewise subject to this disease, and that generally in the inveterate form *(psoriasis scro- talis.)*

Treatment.—The treatment of psoriasis is rendered of much greater importance than that of many other cutaneous diseases by the severe suffering which in many of its forms it pro- duces; by its long continuance, sometimes for a lifetime; and by the obstinacy with which, after an apparent cure, it returns on a change of season, or the application of some slight occa- sional cause. It very seldom exists to any con- siderable extent along with a general healthy

* *Willan*, on Cutaneous Diseases.

* Maladies de la Peau, t. ii. p. i. p. 35.

state of the frame: the system is usually either oppressed by the effects of a luxurious and indolent mode of life, or enfeebled by bad health, or by scanty nourishment and clothing, neglect of cleanliness, and the other concomitants of poverty. In both of these cases a change in the mode of living and in the state of health must be accomplished before we can hope to derive permanent benefit from the employment of remedies. A strict regimen, extending to every particular of diet, clothing, and exercise, suited to the peculiarities of the individual, must be the first step in our treatment. Should much irritation exist, and the strength of the patient permit, blood should be taken by venesection or cupping; and in the local varieties, such as the palmar and ophthalmic, leeches in the vicinity will be found useful. A general antiphlogistic regimen should be pursued, the use of spirituous liquors abandoned, and even wine and ale very sparingly, if at all, allowed; pickles, sour fruits, vinegar, shell-fish, baked meats, pastry, highly seasoned dishes, and other indigestible food, should be carefully avoided. The bowels ought in every instance to be freely opened and kept in regular order: in many cases a sustained purgative treatment by calomel and saline medicines has succeeded in effecting a cure. In the hands of M. Biett* this mode of treating psoriasis has proved highly advantageous; but it has been strongly opposed by Willan and Bateman, whose opinion on this subject has tended in no small degree to prevent British practitioners from making a fair trial of its efficacy. Of this practice our own experience does not enable us to speak with confidence; but we believe that it will be found to be suited only to those cases where there exists a tendency to plethora. Psoriasis, we have already stated, is sometimes combined with an opposite condition of the system, as it is met with in delicate chlorotic females. In these a course of tonic medicines, consisting of the preparations of cinchona and steel, will be necessary, if not as the immediate means of cure, at least for the purpose of preparing the body for the successful employment of other remedies.

Mercurials as well as purgatives have been denounced in general terms by Willan and Bateman,† as unsuited to the treatment of psoriasis; and it must be admitted that the full action of mercury in this disease is positively injurious, as Willis‡ long ago discovered. But it will not be denied that this remedy, when judiciously managed, in small and alterative doses, possesses a great power of correcting many of the disordered states of the digestive organs, and of restoring to the skin a soft and perspiring condition. The mercurial pill, mercury with chalk, Plummer's pill, and corrosive sublimate, have in our hands proved very serviceable, both in psoriasis and other scaly affections. One of the numerous remedies which have been employed internally for the cure of this disease is sulphur: it may be considered to act both as a revulsive, and by its immediate effect on the skin, through the pores of which, even under scaly disease, it is exhaled in the form of hydro-sulphurous gas. Among the different modes of exhibiting this popular remedy, may be enumerated the sulphureous mineral waters, sulphur conjoined with soda, with magnesia, or with cream of tartar; and lastly, the diluted sulphuric acid, which was given by Dr. C. Smyth in very large doses, and according to his report, with excellent effects.* It is proper here to remark, that the sulphuric acid, when taken diluted, undergoes decomposition in the alimentary cavities; and that by its continued use the body becomes impregnated with sulphur, just as when that substance itself has been administered.

We are furnished with still more powerful remedies of a revulsive character in the tincture of cantharides and the different preparations of arsenic. The former of these was first recommended by Dr. Mead† in cutaneous diseases, and since his time its reputation has undergone many vicissitudes. Dr. C. Smyth, Dr. Falconer, and Dr. Willan, speak of the tincture of cantharides as altogether inefficient in the treatment of scaly disease; but M. Biett,‡ at the Hospital St. Louis, has revived the use of this medicine in psoriasis, and found it to possess great efficacy. Our own experience has convinced us of its utility, but we have been repeatedly obliged to relinquish its employment in consequence of its effects on the urinary and generative organs. Arsenic, which was first introduced by Dr. Fowler in the treatment of squamous affections, has maintained its character among British practitioners with little or no interruption, and has even gained a place in the estimation of the physicians of France, notwithstanding the denunciations of the school of Broussais. M. Biett uses the solutions of Fowler and Pearson, and has also introduced into practice the arseniate of ammonia, of which he speaks very favourably. He employs, likewise, with advantage, the arsenical pill formed of the protoxide and black pepper: each pill contains one-thirteenth of a grain of arsenic, and two daily are considered by him as the maximum dose. Iodine is another medicine of the revulsive class, from which we anticipate very beneficial results in the treatment of psoriasis, but as yet our limited trials do not enable us to speak of its effects with confidence. Before taking leave of these powerfully acrid substances, it is necessary to caution the younger portion of our readers against employing them

ng the existence of constitutional disturb- or irritation of the digestive organs, and oint out the necessity of attentively watching effects, that any inflammatory movement eleterious influence on the stomach or brain be immediately counteracted. In some s, when the appearance of such symptoms obliged us to suspend these medicines, t benefit has been obtained from blood- ng, both in allaying the irritation which had caused, and subduing the cutaneous tion.

here remain to be noticed some other reme- of the revulsive tribe which possess a eer- degree of efficacy in scaly diseases. The ure of white hellebore (veratrum album), pitch given in large doses in pill, are both ly recommended by Dr. Bateman: from atter we have seen beneficial results. The or potassæ has occasionally proved useful soriasis, as we have repeatedly experienced; when this disease exists along with the diathesis, as in gout and calculus, (no un- l combination,) its property of correcting ty affords a prospect of decided benefit.* bitter sweet (solanum dulcamara) has vise obtained considerable reputation for cure of psoriasis; its effects are rather nar- than revulsive; but its sensible action, e doses usually prescribed, is seldom very ous. The belief in its efficacy as a remedy scaly eruptions rests on unexceptionable ority;† and the remarks of Dr. Gardner‡ ne defective mode in which the decoction sually prepared may serve to explain much at disappointment which has of late been rienced in its exhibition.

soriasis being remarkable for the severity of ocal effects, we are naturally led to attempt cure by means of topical remedies; and ough these alone will rarely prove effectual, ust be acknowledged that, without their iously directed aid, we shall rarely if ever eed in obtaining a satisfactory result. We often enabled to relieve the patient's suffer- by such applications, as infusion of almond or of bran, decoction of poppy-heads, weak t lotion, emulsion of bitter almonds, lotions aining hydrocyanic acid, cream or fresh er, neats' foot or almond oil. A still more ing effect on the whole frame will be pro- d by the use of a tepid or moderately warm , to which a quantity of bran or a little car- te of soda or potass has been added. A fa- ite remedy among the French for the same ose is a bath of greasy dish-water (eau de elle grasse)—rather an unseemly applica-

After due attention has been paid to the of the general health, and when the rity of the local irritation has somewhat ided, we may proceed to employ the warm , from 96° to 104°, with such friction as he easily borne, in order to stimulate and soften the skin, and detach the scales. The simple vapour bath, or this combined with sulphur or iodine, affords still more powerful means of softening the surface and exciting the skin to a healthy performance of its functions, and the secretion of a sounder cuticle. Such baths certainly form a valuable addition to our means of curing every variety of scaly disease, and often enable us to subdue affections which would formerly have resisted all our remedies.* But the vapour-bath, in its different modifications, is a remedy which always demands the watchful care of the physician: its excitement not unfrequently proves too great, requiring its suspension, or even the abstraction of blood. Baths of mineral waters, especially those impregnated with sulphur, have long been resorted to with benefit for the cure of psoriasis; and similar baths, formed artificially by means of the sulphurets, will often be found of great service, provided the disease is not in too active and irritated a state. In the slighter forms of psoriasis, as when it is confined to the face and forehead, a sulphurated lotion, prepared by infusing sulphur in boiling water, has often proved highly advantageous. The internal use of the sulphureous mineral waters, or of corresponding medicines, may be beneficially conjoined. Saline mineral waters and sea-water have likewise been employed in this disease, and from the latter we have seen excellent effects; but chiefly we believe from the influence of sea-bathing in improving the general health. In one very aggravated case of diffuse psoriasis, where the disease was in an active and increasing state under the use of the arsenical liquor, the patient commenced sea-bathing, and anointed the eruption merely with fresh butter: a speedy amendment followed, and the affection almost wholly disappeared in about a month, but it was not eradicated.

Although the transpiration from the affected surface is much obstructed in psoriasis, it is not wholly suppressed; and there are still left many interstices from which an insensible perspiration is exhaled. By covering the part with oiled silk, we retain this and preserve the skin in a continual vapour bath, which softens it, and tends to restore it to a healthy state. The benefits of such a practice have been long known in the treatment of several local forms of psoriasis, as that of the palms; and the plan may be usefully extended even to cases where a large part of the body is affected. Great benefit is also derived from merely protecting the patches of psoriasis from the action of the atmosphere, which is remarkably evinced in that of the lips, nostrils, and eyelids. Any mild adhesive cerate will answer the purpose; but it is usual to employ one containing a very small proportion of the nitrate, or the white precipitate of mercury. Dr. Willan states that in psoriasis of the lips, nothing but the mildest cerate or plaster can be borne; and that its constant use is indispensable to a cure.

But ointments are employed in psoriasis, not

* *Rapou*, Traité de la Méthode fumigatoire.

merely to protect and soften the surface, but as strong topical stimulants, to excite the healthy actions and remove the thickening of the skin. Those in most common use are, the ointment of nitrate of mercury, the pitch ointment, and one composed of equal parts of these two. We are indebted to M. Biett for the introduction of remedies of vastly greater power, formed from the preparations of iodine. Of these the most efficient are the ointments of the iodides of mercury and sulphur,* which we have found fully to merit the praises he has bestowed on them. It is necessary for the success of these stimulating ointments that they should be well rubbed into the spots and patches at bedtime, washed off with soap and water in the morning, and if the situation of the eruption permit, again rubbed in, and the same process carefully gone through twice daily. In cases of solid thickening, both of the cuticle and cutis, sometimes seen, particularly in the knee and elbow, where even these powerfully stimulating ointments prove unavailing, we have derived great benefit from the application of strong acetic acid. The agency of this liquid in removing the most obstinate horny warts, and thinning the cuticle, when vinegar and sponging has been long employed, first directed our attention to it as a remedy in psoriasis; and the result of our trials has been highly satisfactory—the diseased cuticle separating in flakes, and a new surface being exposed of a much more healthy character. The application of the acid, which requires to be repeated, is hot and painful, especially when there are excoriations or fissures, but these ought to be protected by some mild cerate. Blisters have likewise been had recourse to in obstinate states of psoriasis, and with marked benefit; but their effects appear to be less permanent than those of the acetic acid. When there is oozing of fluid from the patches of psoriasis, advantage will be derived from the use of astringent lotions, as the liquor alum. compos. and solutions of corrosive sublimate, or of sulphate of copper; and when the effusion of moisture has thus been dried up, and the parts are a little hardened, which readily takes place, some mild adhesive cerate may be applied at bedtime and washed off in the morning. By steadily persevering in this plan, very troublesome cases of the local forms of psoriasis have been completely cured. In some of these obstinate varieties, particularly that of the scrotum, fumigations with sulphur and with cinnabar have effected a cure.

The long list of remedies which has now been reviewed, furnishes in itself abundant evidence of the intractable and rebellious nature of psoriasis; but it is not without reason that they have been enumerated, for it is well known to those familiar with chronic diseases of the skin, that a change of remedies is frequently required; and that one will at length succeed when all others have failed.

Should our efforts to effect the cure of psoriasis have proved unavailing, it will be proper, if the patient's circumstances and general health permit, to recommend his removal to a more genial or even a warm climate, where the habitually increased activity of the cutaneous functions, and the change which his constitution is likely to undergo, may render successful the modes of treatment which were previously without effect.

When the cure of psoriasis is about to be accomplished, the scales rapidly drop, and soon cease to be reproduced; the thickening and inflammation of the skin gradually yield, at length the affected spots appear as if slightly depressed, having a somewhat darker tint than the healthy skin, and occasionally we observe around these cicatrices a pale or white border. The completion of these changes of the diseased surface affords satisfactory evidence of the cure of psoriasis; and without this cicatrization, the mere absence of scales amounts only to a temporary amendment.

(W. Cumin.)

PUERPERAL DISEASES.—The object of this article is to present a general view of the parturient and puerperal states, and of the various diseases which may occur, singly or combined, in their varied circumstances. Such views of an important class of morbid affections are frequently of more practical value than the most laboured treatises on individual diseases. But the present class is one of peculiar moment; no other is so complicated in itself, and none excites such deep interest in the minds both of friends and of the physician.

The class of puerperal diseases must be viewed as embracing all those morbid affections which arise out of the state of pregnancy,—the act of parturition, the complicated condition of the system and organs which immediately follows parturition, and the function of lactation.

In the early period of pregnancy, several organs, but especially the stomach, sympathize with the new condition of the uterus, and suffer severely.

In the later periods of pregnancy several causes combine their influence especially to endanger the state of the brain. It is upon the conjoined and separate operation of these causes that our attention should be particularly fixed in regard to the diseases of this period; for it is frequently by their co-operation alone that the morbid influence upon the brain is brought into activity, whilst it may occur, afterwards, that one or even several of these causes may be removed, and yet a remaining one may renew or continue the morbid effect upon the brain which they had conjointly begun. The causes which co-operate in the last period of uterine gestation, in inducing a morbid state of the brain, are chiefly uterine and intestinal irritation, concurring with the actual pressure of the gravid uterus upon the various viscera and

sels situated behind it, and the state of thora of the vascular system especially, asioned by this pressure.

During parturition, the contractile efforts of uterus and of the abdominal muscles add other source of danger to those already men- ned; and it is at this period that the brain is st subjected to fulness and pressure, and t convulsions or even apoplexy are apt to cur.

Several sources of danger are removed when ivery has taken place; and yet this is not ays sufficient to protect the patient from attack of convulsion, for this terrible ction has first occurred even after delivery l been effected. In this case, especially, suspect that a state of intestinal load and tation has been the exciting cause of the con- sion. This observation confirms the remark eady made, that when several causes have operated to induce a state of danger, some y be removed, and yet, if one remain, it y lead to the most disastrous events. This culiarity in the study of puerperal diseases not be pointed out too often or too ongly.

Convulsions do occasionally occur after de- ery, even although the system be in a state exhaustion from hemorrhage. The state of neral exhaustion is not, we believe, incom- ible with a state of fulness of the brain; but s kind of convulsions will be found, we nk, frequently to involve also a state of in- tinal load and irritation.

The danger may arise, however, immediately er delivery, more directly and simply, from tate of inanition and exhaustion, the effects an emptied condition of the uterus and domen, of abstracted pressure upon the cera and vessels along the spine, and per- ps of loss of blood.

To these sources of danger after delivery ist also be added the effects, perhaps, of otracted suffering, of violent pain, of mental rm, and of what may be termed the 'shock' parturition.

There is another series of puerperal affections ich do not occur for the most part until me hours at least after delivery. These ections consist principally of uterine, peri- neal, or venous inflammation, of the effects of estinal irritation, of the effects of loss of ood, or of two or more of these combined. ere are two other sources of irritation in the ndition of the mammæ, and occasionally of e uterus; and there is that terrible disease, e epidemic puerperal fever.

Considering the important and sudden change ich takes place in the condition of the uterus parturition, we cannot be surprised that this gan should frequently be the subject of in- mmation in the puerperal state. Neither can be matter of surprise that its appendages, the ljacent viscera, and the peritoneum at large, ould not unfrequently participate in this orbid condition. And when we further con- er the degree of violence to which the brain s been subjected during parturition, we must : led to expect that this important organ should be left by that process in a state of proneness to inflammation; and this is pre- cisely the case: for next to the viscera of the abdominal cavity, the brain is perhaps the organ which is most apt to become affected by puerperal inflammation, though in fact puer- peral phrenitis is a far more rare disease than has been supposed.

We have further to consider the peculiar condition of the internal surface of the uterus after parturition. M. Cruveilhier has compared it to that of a wound. However this may be, phrenitis and inflammation of the absorbents are among the most formidable of puerperal diseases, diseases arising from this peculiar state of the internal surface of the uterus.

There is another not less fertile source of puerperal disease in the state of the alimentary canal after delivery. This state consists, in general, of a loaded or disordered condition of the large intestines, but is sometimes also induced by improper things taken into the stomach. It is most important to observe that the effects of stomachal or intestinal irritation are very similar to those of inflammation, as it affects the head or abdomen; for on the just diagnosis of these cases depends the proper application of the remedies.

Similar observations apply to the effects of loss of blood when these are of the remote cha- racter, and attended by the phenomena of re- action.

In this case the head is apt to be so affected as to lead to the idea of inflammation of the brain; and the heart, so as to present the sym- ptoms of disease of this vital organ.

But it is rare that these sources of disease act thus distinctly; it is far more usual to observe them co-operating to produce mixed cases. One of the most frequent of these is puerperal mania. It is in such complicated cases that all the attention and energies of the mind are required to appreciate the influence of each, and to adapt the remedies to this complicated form of disease.

There is not unfrequently, also, a source of irri- tation in the state of the uterus itself. A certain degree of after-pain is usual in almost every case; but a state of irritation and pain is frequently kept up by the presence of clots of blood, and the efforts for their expulsion. This state of the uterus is full of dangers; not in itself, but by masking and concealing the beginning of dan- gerous diseases: pain of an inflammatory kind is too apt to be neglected, under the impression that it is but the usual after-pain.

A similar remark may be made in regard to the irritation excited during the establishment of the secretion of milk. This process is apt to be attended by pain, fever, and affection of the head, which frequently mask the beginnings of puerperal disease.

Both these sources of irritation concur to add complexity to the character, and difficulty to the diagnosis of puerperal diseases, and to con- stitute that peculiarity of this study to which we have already alluded.

The first of these classes of disease might perhaps be denominated *parturient*, whilst the

second might be distinguished by the epithet *puerperal*; the former occurring chiefly in or near the act of parturition; the latter usually some hours afterwards. There is a third class of morbid affections which follow still more remotely upon child-bearing, and which consist principally of the more continued effects of intestinal disorder or of loss of blood, and issue, for the most part, in an inability to support the drain occasioned by lactation.

A fourth series of puerperal maladies, using this term in its most extended sense, arises out of undue lactation itself. They consist in the various forms and effects of exhaustion, and constitute a most important and interesting subject for renewed inquiry; for we believe them not to be at present by any means fully understood.

There is still another consideration which is full of interest in regard to puerperal diseases,—namely, the state of health of the patient previously to her confinement. That which most frequently modifies the puerperal state is disorder of the general health, which may possess very various characters. It frequently occurs, from such a state of general disorder, that the recovery after confinement is tardy, the secretion of milk scanty, or even morbid, affecting the health of the infant; and that there are many local affections, especially of the head or of the heart, which are full of pain and suffering.

We have now taken a rapid survey of the principal causes of puerperal diseases. It may be truly said that many of these causes co-operate in every case; but it is also true that each puerperal disease is to be referred to one or two of these causes more especially. Every case of puerperal affection may, therefore, be considered as a case of modified disease, requiring that the mind of the physician be active and comprehensive, so as to embrace the numerous circumstances of the disease. This is true in a degree which scarcely obtains in any other class of diseases; and it is on this account that we have represented the study of puerperal diseases as requiring peculiar habits of inquiry and investigation.

Of the morbid affections which occur in the parturient state.—The term parturient is adopted to express the condition of a person just before, just after, and during the act of parturition. A brief notice of the morbid tendencies of this state is a necessary introduction to the more detailed account of some of the morbid affections which occur in that which may perhaps be more properly termed puerperal. The distinction between the parturient and the puerperal states will be found to be at least of great practical utility.

We have already cursorily alluded to the principal causes of apoplexy and convulsions, as they occur in the last stage of utero-gestation, and in the act of parturition. It is our present object to enter into this important question with somewhat more detail.

The first cause enumerated as conducing to these affections of the brain was uterine irritation. That this species of irritation does indeed dispose to disease of the brain, is sufficiently obvious from the occasional occurrence of convulsions in cases even of dysmenorrhœa or painful menstruation.

A second exciting cause of affection of the brain, probably not very different in its nature from the former, is found in the parturient effort of the uterus when labour has begun. The effect of labour-pain upon the vascular system of the head is sufficiently seen in the flushed state of the countenance; and the attack, or the recurrence of convulsion, not unfrequently takes place with each uterine effort.

With the uterine efforts must, however, be conjoined those of the abdominal and other muscles, in our estimation of the influence of labour-pains upon the state of the brain.

The third cause of affection of the head in the parturient state is stomachal or intestinal load or irritation. It appears almost unnecessary to adduce any example of the influence of these causes upon the vascular system and nervous origins within the head. The presence of indigestible substances in the stomach, and of indurated or otherwise morbid fæcal matters in the large intestines, are amongst the most usual causes of apoplexy and convulsions in those who are predisposed to these affections, and especially in the puerperal state. The late Dr. John Clarke published an interesting and important paper, to which we shall have occasion to revert hereafter, upon the morbid influence of oysters, taken at this period, upon the brain; and it cannot be doubted that other indigestible substances have frequently, perhaps unsuspectedly, produced the same deleterious effect. One of these effects was convulsion. And it is to be particularly remarked that the cases published by Dr. Clarke all occurred after delivery, and of course even after some of the predisposing causes of puerperal convulsion had ceased to operate.

But a still more frequent concurrent cause of convulsion or of apoplexy in the parturient state is a loaded condition of the large intestines. The operation of this cause is frequently made obvious by the effects of purgative medicines and enemata in these cases, both in the relief they effect in the symptoms of affection of the brain, and in the character of the alvine evacuations: the quantity of scybalous fæces which have thus been evacuated in some instances would appear incredible, were not the torpid and dilated condition of the intestine taken into the account.

Nor can there be any doubt that the gravid uterus itself acts by its size and by its pressure upon the descending aorta, in inducing fulness of the vessels of the brain in the latter period of utero-gestation. It is on this principle that delivery frequently secures the patient against the recurrence of the fit of convulsion. When the pressure of the gravid uterus falls more particularly upon the vena cava, the effect of interrupted circulation is of course observed in the lower extremities, chiefly under the form of œdema, but perhaps of phlegmasia dolens.

It usually happens, as we have observed already, that apoplexy or convulsion occurs

parturient state from the conjoined operation of several of these causes; and it is only by an attentive consideration of all of these sources of danger, that the attack is to be prevented in the first place, and its recurrence in the second.

It is important also, with the view of prevention, to consider the probable condition of the encephalon itself immediately leading to an attack of convulsion or apoplexy. It is doubtless one either of irritation or of fulness. Every cause of these morbid states of the brain must therefore be carefully removed and avoided, whilst their effects are combated by the most vigorous remedial measures.

This is the more important, because each recurrence of convulsion is not only attended by immediate danger, but aggravates the morbid condition of the brain, and augments the tendency to the repetition of the paroxysms of convulsion. The same observation may be made of each contractile effort of the uterus and abdominal muscles during parturition, which, like the fits of hooping-cough in other circumstances, has in some instances led to convulsion.

The state of the system which obtains immediately after delivery is in many important circumstances different from that which exists during pregnancy and in the act of parturition. The emptied state of the uterus and abdomen constitutes in itself a source of inanition; and there is usually more or less of loss of blood, and sometimes even an extreme degree of hemorrhage, so that the system in general must be considered to be in a state of exhaustion. There can be no doubt that this very exhaustion alone has in some instances induced convulsion; but it is probable that in many, some of the causes of this terrible affection which have been mentioned, and especially a state of uterine, stomachal, or intestinal irritation, have concurred to produce this effect.

The more usual immediate consequences of delivery and of uterine hemorrhage is a state of syncope; this is more or less severe and alarming according to the degree of loss of blood and of the susceptibility to its effects, and varies from the slightest degree of faintishness to such a state of syncope as may endanger life.

Similar effects are sometimes to be attributed to the protracted sufferings of a lingering labour, in other cases to the violence of pain, and in others to alarm and dreary apprehensions and anticipations on the part of the patient. These circumstances sometimes lead to sudden death, an event which may occur immediately upon delivery. In such cases, cordials given during the last stage of labour, the recumbent position guardedly preserved, and the immediate and careful application of the abdominal bandage, may save the patient.

Perhaps the condition of the system under the influence of some of the circumstances of parturition cannot be better expressed than by the term 'shock;' and it may be aptly compared to a similar state under very different circumstances, and especially those of a painful operation. This state of shock seems to consist of a partially suspended power and action in the system. It may be suddenly fatal, or it may yield to reaction, which may or may not pass the boundary of health; or, lastly, after some feeble efforts, it may lead to a gradual but irretrievable sinking of the vital powers. This subject has not been sufficiently noticed in medical writings, especially in connexion with the parturient state.

One of the influences of shock still requires to be mentioned. Many causes of disorder may long remain dormant, or may be affecting the system in the most gradual manner only, until they are called into a more active operation by some kind of shock. This is particularly true in regard to intestinal irritation. This cause of disorder may long subsist in an inactive state, until, by the occurrence of some shock to the system, it is brought into but too effective operation. It is for this reason that the effects of intestinal irritation are so frequently observed in the puerperal state and after various accidents, without which this cause of constitutional derangement might have long remained inoperative, or at least insufficient for the production of acute disease.

In the treatment of apoplexy or convulsions before delivery, and even after delivery, except in cases of profuse uterine hemorrhage, the principal remedy is bloodletting; the second object is the removal of all those exciting causes of the disease which have been mentioned; and the third is cupping of the occiput and neck.

In the case of hemorrhage, the remedies are still the removal of the exciting causes and cupping.

A state of exhaustion from loss of blood generally from the system, does not protect the brain from a state of vascular fulness. This is abundantly proved in the excellent paper of Dr. Kellie, in the Medico-Chirurgical Transactions of Edinburgh, and by the fact of the occurrence of convulsions, and even of apoplexy, in this state of exhaustion. It is in this very case that cupping of the occiput is so strongly to be recommended. The brain, in some cases of exhaustion, is relieved by the topical abstraction of a very small quantity of blood; and this relief is not only obtained by a less expenditure of blood, but is more permanent than similar relief by general bloodletting.

The next point in the treatment is the removal, not of one or two, but of all sources of irritation—of all the possible exciting causes.

A point not less important than the treatment of these affections is their prevention. No means would conduce so much to this purpose as the invariable administration of copious warm-water injections at some period before or during labour. The large intestines would thus be relieved of their load, and a great and fertile source of future disease would be removed. And this remark applies not to affections of the head only, but to many other puerperal diseases.

Of the morbid affections which occur in the puerperal state.—The morbid affections which occur in the puerperal as distinguished from the parturient state usually commence at such a

period after delivery as may have given space for reaction to take place, after the state of inanition and exhaustion which usually obtains immediately upon parturition.

It should be observed, however, that there is scarcely a disease of the puerperal state which does not occasionally show itself before delivery. In these cases the disease usually remains stationary, or nearly so, until parturition has taken place, and then assumes its exasperated form.

In some instances, and those of the most serious kind, puerperal disease supervenes insidiously, and makes a slow and probably an unheeded and fatal progress.

Even of those puerperal diseases which commence by marked symptoms, the more serious are not always the most unequivocal in their mode of attack. Pure inflammation is, for example, less marked by rigor, heat, and other obvious symptoms, than are the effects of intestinal irritation. This is a point which requires to be enforced upon the attention of practitioners; for, in inflammation especially, it is of the utmost importance to detect the disease in its very origin.

The effects of intestinal irritation and of loss of blood are apt to produce symptoms of increased action resembling those of inflammatory disease, and prompting the use of evacuant remedies. This proceeding is attended by two sources of error: in the first place the symptoms are frequently relieved in the first instance,—a state of faintishness taking place of that of reaction,—and the physician is apt to judge that the remedy had relieved, but was used in too mild a degree to subdue the disease, and is thence led to a repetition of the measure: in the second place, after the first and second moderate use of the lancet, for instance, the reaction returns in a still more violent degree than before; and it is then imagined that the disease, though relieved, was not only not subdued, but had been suffered to make a fearful progress; the lancet is therefore again used, until it may be that the powers of the system yield, and sinking takes place of reaction; or, if the last bloodletting be considerable, the scene may be closed by a sudden and unexpected dissolution.

We now proceed to treat of each particular form of puerperal disease.

Of puerperal inflammation within the abdomen.—Inflammation within the abdomen, as it occurs in the puerperal state, may be divided into three kinds; that which chiefly affects the uterus and its appendages; that which appears to be general over the peritoneum; and that which is confined to a portion of this membrane.

A distinction of still greater practical importance is that between the acute and the insidious forms of puerperal inflammation of the abdomen. Sometimes the attack is distinctly characterized from the beginning; at other times it is of the most insidious character, perhaps to be referred back to a date anterior to parturition, or even apparently issuing out of mere labour-pain. These are points which require to be deeply impressed upon the mind of the young physician, in order that they may induce in him that degree of watchfulness in regard to these diseases which they so imperatively demand.

Inflammation within the abdomen, of whatever kind it may be, is only to be ascertained by the presence of pain, induced or aggravated upon pressure. This is the pathognomonic symptom of the disease. All the other symptoms are only accessory; and they are all, without exception, inconstant. In some insidious cases of abdominal inflammation, the tenderness even is only discovered by a careful examination; and there is sometimes pain under pressure when there is no inflammation.

These remarks will, we trust, lead to the most careful examination of the abdomen, and of the symptoms in general, in every case of puerperal disease.

The acute attack of puerperal inflammation within the abdomen is frequently marked by rigor. This is frequently in the worst cases only slight. We cannot sufficiently enforce this fact upon the attention of our readers. Some have imagined that there could be no puerperal inflammation of the abdomen without severe rigor; and they have generally supposed that severe rigor necessarily supposes an attack of inflammation. We can most unequivocally attest that both these opinions are erroneous, and contradicted by facts.

We would make precisely the same observations in regard to great heat of surface or fever. We have known many instances of acute puerperal inflammation within the abdomen unattended by heat of skin, and many cases resembling inflammation, but not in reality inflammatory, in which the heat of surface was extreme.

Frequency of the pulse is not a less uncertain indication of inflammation. We are enabled to say, from careful observation, that the pulse is but little accelerated in many cases of puerperal inflammation within the abdomen, whilst it is excessively and even alarmingly frequent in some cases in which inflammation does not exist.

In regard to pain and affection of the head, they are by no means essential attendants upon puerperal inflammation of the abdomen in its first stages, but, on the contrary, appear to denote another and different kind of morbid affection, which may exist alone or as a complication of inflammation.

Pure puerperal inflammation of the peritoneum is to be ascertained by an attentive examination of the abdomen. There is either pain increased upon pressure, or tenderness discovered upon pressure; and this is either general over the abdomen, or confined to the hypogastric region; or, lastly, in cases of partial peritonitis, to some other part of the abdomen. With the pain or tenderness there is frequently either general tumidity of the abdomen, or a local hardness; in the latter case it is frequently such as to denote an enlarged and inflamed condition of the uterus, but it occasionally arises from an affection of the ovarium

from partial inflammation and suppuration the peritoneum.

There are sometimes, and only sometimes, ckness and vomiting; there are also, in some stances, a suppression of the lochial discharge, d a flaccid state of the mammæ. But we not think the precise cases in which these fects do or do not occur, have been distinctly certained by the observation of a sufficient mber of facts.

In pure puerperal inflammation of the abomen there is not necessarily much rigor, at of skin, load of the tongue, affection of e head, or great frequency of the pulse; there on the contrary, in many instances, only a ght degree or even an entire absence of ri-r, little or no heat of surface, or whiteness of e tongue, little frequency of the pulse, and affection of the head. But the countenance, anner, and respiration, usually become highly aracteristic.

Puerperal inflammation within the abdomen marked by an expression of extreme pain d anxiety in the countenance; the brow is ntracted, and the upper lip is drawn upards in a peculiar and characteristic manner, d bound round the teeth or rather gums. ese appearances are increased on pressing on the abdomen, or they are observed at at moment if they had not been manifest fore. The countenance is generally pale and ther sunk, but with partial heats.

The manner of the patient is much changed, d has become expressive of suffering and xiety. The movements of the body are atded by pain, and are therefore suppressed; if performed at all, it is with an expression suffering in the countenance, and of caution the manner; and there is an appearance as the body had become heavy and helpless.

The respiration becomes rather hurried and xious, and it is performed principally by ovements of the thorax, those of the diaragm and abdomen being more or less, metimes completely, suppressed,—a circumnce which gives great peculiarity to the apearance of the breathing. Sometimes there is nsiderable heaving of the chest, with some rry, some noise from the ingress and egress the air, and sometimes with a sort of blowg: this state of the respiration is attended the utmost danger, being frequently one of e first symptoms of the sinking state, of hich we shall have to speak immediately, and which we wish earnestly to call the attention our readers.

The general surface is usually a little inreased in its temperature, and there is frenently perspiration.

The pulse is at first only moderately frequent, it gradually becomes more so, and it is often mall and apparently feeble.

We have already alluded to the occasional currence of sickness and vomiting. The abomen is frequently tense and tumid, as well tender under pressure: this is an affection be anxiously watched; it sometimes inases to a state of complete tympanitis. The te of the bowels is very various; there is by no means always constipation; sometimes there is diarrhœa, with or without the discharge of mucous stools.

Instead of general tumidity of the abdomen, there is frequently a distinct tumour with tenderness in the region of the uterus, in the iliac region, or in some other region of the abdomen, leading to the suspicion of an especial affection of the uterus or ovarium, or of a partial inflammation and suppuration of the peritoneum.

We have thus described the most usual form of puerperal inflammation of the abdomen in its commencement. It does not seem either possible or profitable to divide the disease into distinct stages. But it is quite incumbent upon the practitioner to trace the usual changes which are observed in this disease: these are, first, a gradual amendment; secondly, a gradual exasperation of the disease; and thirdly, the supervention of the state of 'sinking.'

Little can or need be said upon the two first of these changes. Every appearance of a return to a healthy state of the functions and general appearances of the patient will raise our hopes; but there are no points of so much importance to be watched as the expression and condition of the countenance, the manner, and the state of the abdomen.

No apparent amendment is to be at all depended upon unless it has continued and been progressive for four-and-twenty hours; this is a caution of great importance to the young physician, in guiding him in his expressions in regard to the prognosis. And even in the most favourable cases the further progress towards recovery is to be watched with the utmost care and precaution.

In the less favourable cases the countenance becomes more and more altered, the pulse more and more frequent, the abdomen more tender and tumid; the muscular powers of the patient appear overwhelmed; the respiration becomes more heaving, and, as we have usually termed it, "blowing," being somewhat audible,—a condition of the breathing always attended by the utmost danger. At this period, too, there is often some degree of delirium, alternating perhaps with slight dosing, and there are generally restlessness and jactitation, and the patient cannot bear the arms to be covered.

At this period, too, the tongue is frequently loaded and more foul, and sometimes dry; the bowels are variable, frequently flatulent and loose. The mammæ are flaccid, the lochia suppressed; the skin is clammy and wet, if not cold; the hands and wrists are often livid, and the feet cold.

This description of symptoms applies to the case of general inflammation of the peritoneum. The more partial cases of peritonitis continue longer, and affect the constitution less and less rapidly. In some instances the integuments over the seat of the inflammation have become tumid and inflamed, and an issue has at length been effected for the subjacent pus: the abscess has afterwards collapsed and healed, and the patient has slowly but finally recovered. This opening frequently takes place

about half-way between the umbilicus and spinous process of the ilium. In other instances the matter has been evacuated by the rectum, and in some rare examples by the bladder. In other cases the abscess has not been evacuated during life; but the patient has become gradually emaciated, and the health and strength have failed; there have been great frequency of the pulse and hectic, and the disease has at length, though perhaps very slowly, proved fatal. It has, however, occasionally happened that the effused fluid has been reabsorbed, and the fatal event averted.

But the acute form of puerperal peritonitis sometimes issues in a state of sudden sinking of the vital powers. The change and symptoms are such as have frequently led to the suspicion of gangrene having taken place; but no such appearance is observed after death.

This state of sinking is usually rather abrupt in its manifestation. The patient may be left not without hope the preceding night, but on being visited on the ensuing morning is found to have passed into a state of hopeless sinking. The pain has ceased, but the tumidity of the abdomen is augmented; the breathing is attended by heaving and blowing; the skin of the arms and hands is cold, clammy, and livid, the livid colour only partially disappearing on pressure; the pulse is thready and excessively frequent; the countenance is altered and sunk; the patient may be roused, but is then, perhaps, unconscious of pain, and expresses herself as being relieved; the hands are kept out of bed; sometimes there is cough, and the feet are livid and cold.

The morbid appearances usually induced in cases of inflammation of the uterus and of the peritoneum are well known.

In inflammation of the uterus there are, in different instances, exudations of serum, of coagulable lymph, and of pus, or it is the seat of distinct abscesses; and its internal surface is frequently morbidly red, and the source of various discharges. The appendages of the uterus are frequently the seat of similar morbid appearances.

The peritoneum when inflamed pours out serum, coagulable lymph, or pus; and its different surfaces are apt to be variously glued together. Frequently the intestinal canal is found distended to the utmost, as before death, by fetid gases.

In some instances pus is effused and deposited in various parts of the peritoneum, being confined by the adhesion of contiguous portions of this membrane.

There is no part of the peritoneum, and no viscus in the abdomen, which may not become the seat of puerperal inflammation and of the consequent changes of structure. The parts most frequently affected by puerperal inflammation, however, are the organs contained within the pelvis,—the uterus, its appendages, the rectum, the bladder, and the peritoneal lining of the pelvis; and then the peritoneum in general. In an interesting case, published by Dr. Ley, the spleen was found to be a principal seat of disease.

We now proceed to state the treatment of puerperal inflammation, and we must observe, in the first place, that nothing can be trusted to to save the patient but the most ample bloodletting, and, in the second place, that nothing should preclude the use of this remedy but the actual existence of the state of sinking.

In regard to the measure and the repetition of the bloodletting, many points must be taken into consideration. The earlier and the more fully this remedy is employed, the more efficacious and the safer it is, and the safer is its full repetition.

There is one point which we would particularly impress upon our readers. It is, that the bloodletting should in this disease always be performed when the patient is in the erect position; and it may then in general be safely carried to deliquium. We do not recommend this mode of proceeding with the view of producing deliquium merely, but also that this deliquium may serve us as a guide in judging of the extent to which we may carry the depletion. If the patient be sitting upright, and faint by the loss of blood, we have a security and remedy against any danger from this event in laying the patient low; but if deliquium be induced by bleeding the patient in the recumbent position, we cannot say that we think it will be always without danger. We think the plan which we have proposed at once far more safe as well as far more efficacious in subduing this disease. If it were requisite, the patient's head might be laid even lower than the rest of her body, should deliquium supervene.

The same rule may apply for the repetition of the bloodletting. If the fullest effect is desired which the patient can safely bear, let her be bled to syncope in the erect posture. She will faint from losing a larger or a smaller quantity of blood precisely in the inverse proportion of the previous exhaustion; the state of syncope will not only warn us to desist from drawing more blood, but will arrest the flow of blood itself just at the point when the patient can bear to lose no more.

This is a most important criterion for the employment of a most powerful remedy. We do not by any means wish it to be understood that it is always safe to bleed to deliquium in the erect posture; but that, when it is determined to bleed, it is important to have the boundary, which it would be unsafe to pass, at least clearly defined.

Sometimes the patient will faint on being merely placed upright: is it then, ever, and in what particular cases, safe to bleed?

The next question is in regard to topical bloodletting; and we think there is one important rule for the adoption of this remedy. It may of course be enjoined to be done immediately after general bloodletting; but it is particularly useful in those cases in which the system is obviously subdued by the general bloodletting, and yet the inflamed part remains tender under pressure. In such cases leeches, or, still better, cupping, if it be properly and tenderly performed, will prove a most useful remedy.

It is quite unnecessary to state the utility, or rather the necessity, for the administration of purgative medicines in this disease. There is good reason to suppose that some cases have been subdued even by this remedy alone; and the efficacy of purging in conjunction with bloodletting is quite undoubted. A constant catharsis should be kept up, indeed, until the disease is completely subdued.

In cases in which there is great tympanitic distension of the abdomen, an injection of warm water sometimes succeeds in inducing evacuations of flatus, which greatly relieve. We have sometimes thought that still more effectual relief of the same kind might be obtained by the introduction of a flexible tube, properly pierced, high into the large intestine.

Much and important relief may also be afforded in some cases in which suppuration has taken place, by giving exit to the pus when it plainly fluctuates and approaches the surface.

Blisters also are of great service in those cases of this disease which are not attended by much heat or irritability; but in other cases they have appeared to us to add to the patient's sufferings, to prevent sleep, and to do harm by leading to a state of exhaustion.

There are still three other powerful remedies of which a cursory mention must be made in this place. The first is vomiting, which is well known to have been so successful in the hands of M. Doulcet of Paris. The second is the spiritus terebinthinæ, recommended by Dr. Brenan of Dublin. The third is the attempt to induce a state of ptyalism by mercurial medicines and inunctions.

Emetics, like purgative medicines, but especially the spiritus terebinthinæ, have doubtless been used successfully in many cases; but we much suspect that many of these cases were not inflammation, but intestinal irritation.

Ptyalism would seem to deserve a trial; it is one of those measures which are most powerful, and yet generally unattended with risk, and it would by no means preclude the adoption of every other more prompt and efficient mode of treatment. If adopted early, it might prevent some of those protracted states of the disease which occasionally occur and wear out the patient.

During the existence of inflammation the patient should be allowed absolutely nothing but tea or gruel in the smallest quantities.

In some cases in which the pain is not severe, but the tension of the abdomen great, continued but extremely light frictions of the abdomen have done great good. They may be followed by the application of a cold lotion and by fomentation of the feet.

In cases of pure inflammation the use of opium is not desirable. The pain must be subdued by bloodletting; and every thing that by masking the pain can divert our minds from the use of this remedy involves danger to the patient. And there are seldom those symptoms of constitutional irritation which require the use of opium until the inflammation has subsided. In mixed cases we think the use of opium, especially after bloodletting, may be both necessary to subdue constitutional irritation, and beneficial in the cure of the disease.

Of the effects of stomachal and intestinal irritation.—Some of the effects of intestinal irritation may be observed before parturition; but it is far more usual to find them developed afterwards. They generally take place rather suddenly, about forty or fifty hours after delivery; but the puerperal state appears so to dispose to this affection that the presence of any cause of stomachal or intestinal irritation cannot always be borne with impunity for many days even after delivery.

This affection may, for the facility of description, be divided into the acute and the insidious; each of these forms manifests itself with general symptoms only, or with some predominant local affection.

The acute form of intestinal irritation is generally ushered in by a violent rigor. This is an important fact; for rigor, as we have already observed, has been considered as denoting puerperal inflammation, and essential to the latter disease. Neither of these suppositions is true; for puerperal inflammation may occur in a severe and fatal form without rigor; and the severest rigor may only portend an attack of the effects of intestinal irritation; and in general the latter disease is attended even with a severer rigor than the former.

In the attack of intestinal irritation there is usually, after the rigor, great heat of the surface. We have already observed that this is by no means an essential part of puerperal inflammation; indeed we do not think that it properly belongs to the latter disease, but that, when it does occur with inflammation, it denotes a mixed case and the co-existence of intestinal irritation.

In the attack of the effects of intestinal irritation there is usually earlier and even greater frequency of the pulse than in cases of puerperal inflammation; the pulse is also usually fuller than in the latter disease.

Intestinal irritation induces symptoms which are similar to those of the most acute phrenitis, or to those of the most acute peritonitis. This is a remark of the utmost practical importance; for the remedies in these different cases are totally different; and we should say that in the former the freest bloodletting must be aided by purgative medicines, whilst in the latter the freest and fullest evacuation of the intestines must be aided by bloodletting.

A mistake in either case would, in our opinion, endanger the life of the patient; and it is a foolish and idle remark to say that it is better to mistake irritation for inflammation than inflammation for irritation. It is of the utmost importance to attend to the distinctions which we have made between inflammation and intestinal irritation in regard to the treatment; for, although both bloodletting and purging are to be used in every case, yet the former is the remedy in inflammation, and the latter in intestinal irritation. If the cure of inflammation be trusted even chiefly to purga-

tive medicines, we think it will frequently proceed to the destruction of the patient; and if bloodletting should be chiefly employed, in like manner, in intestinal irritation, we believe it would leave the disease unsubdued, and eventually plunge the patient into a state of irremediable exhaustion.

The affection of the head and that of the abdomen frequently co-exist or alternate in the same case; but sometimes one of them exists to the exclusion of the other, or supervenes upon the cessation of the other; and in the latter case the affection of the head usually succeeds that of the abdomen. The diagnosis is much confirmed by this conjunction of the two affections.

In the affection of the head from intestinal irritation there is frequently the severest pain and the utmost intolerance of noise, light, and disturbance of every kind. It is in these cases principally that the pavement is covered with straw, the knocker tied, the patient's room kept dark and still, so that these very external circumstances speak a significant language to the physician. To the symptoms which have been enumerated are frequently added wakefulness and even delirium.

When the abdomen is affected from intestinal irritation, there are general pain and tenderness upon pressure, and frequently tumidity, combined with the general symptoms which we have already enumerated.

Much is effected and learnt in this case by the exhibition of large injections of warm water and of active purgative medicines, a careful examination of the evacuations, and a studious observation of the effects produced upon the disease. The fæces will be found to be scybalous, or at least offensive and dark-coloured, and in large quantity; and the relief obtained, or the return of pain, will be found to depend upon the evacuated or neglected state of the bowels.

Another point of great importance is an attentive inquiry into the diet of the patient; this inquiry frequently reveals the mystery of an attack, and of course immediately leads to the adoption of an important remedy.

In regard to the course of cases of intestinal irritation, we imagine that under judicious treatment this would always be one of progressive recovery. When a contrary event occurs, we think it is to be attributed to the misuse of remedies, and especially of bloodletting. In this manner some of the symptoms which are detailed in the succeeding section are superinduced, and sometimes a sudden dissolution has overwhelmed the practitioner with consternation.

One of the characteristics of intestinal irritation is the susceptibility to syncope upon bloodletting. This is of course much more remarkable upon a second or third bloodletting than upon a first use of the lancet. No dependence can be placed upon the appearance of the blood drawn. This may be much buffed and cupped in the puerperal state without the existence of inflammation, and in cases of the most decided inflammation these appearances of the blood may be but little observed.

We have scarcely had an opportunity of examining the state of the internal organs after death; for in general the patients affected by intestinal irritation have recovered. But no doubt that such an examination would illustrate the following important remark of the late Dr. Denman:—"We have been told that in the dissection of some who are said to have died of puerperal fever, no appearances of inflammation have been discovered; but I should suspect that in such cases some important appearances had been overlooked, or that errors had been committed as to the nature of the disease, and probably in its treatment." A due consideration of the effects of intestinal irritation will also serve to elucidate other cases of morbid affection, in which the appearances of inflammation were looked for on dissection, but were not found. This observation applies particularly to affections of the head, heart, and abdomen. In several cases of this morbid affection, which we had the opportunity of examining many years ago, no morbid appearances were found on the most careful inspection. We have already sufficiently alluded to the causes of this affection. They are for the most part obvious sources of gastric or of intestinal irritation; the former chiefly affecting the head, the latter both the head and the abdomen, either together or separately.

In the treatment of the effects of intestinal irritation, we would by no means exclude the use of the lancet. Bloodletting may be useful in such a case, for the same reason that it is useful in simple fever. But we repeat that this remedy is only subsidiary to the full and free evacuation of the bowels, and, if necessary, of the stomach. If it were trusted to alone, or with only a moderate attention to the state of the alimentary canal, or if it were used in the manner which is required to be efficient in puerperal inflammation, we are persuaded that the patient would die of exhaustion, before the symptoms would yield.

The remedies of intestinal irritation and its effects we would enumerate and arrange in the following order:—first, the full evacuation of the intestinal canal; secondly, bloodletting; thirdly, some soothing anodyne; fourthly, leeches, cupping, a lotion, a liniment, or a blister, according to the circumstances of the case, for the topical affection; fifthly, the mildest nutritious food; sixthly, the most absolute quiet, and the most perfect security from light, noise, disturbance, and every other source of excitation; seventhly, great coolness, and free ventilation of the sick room; and, lastly, a constant watching over the patient during sleep, to avoid the injurious effects of turbulent dreams on the one hand, and of too long sleep and fasting on the other. Upon each of these points we proceed to make such observations as we have learnt from practice to be of importance.

In regard to the state of the alimentary canal, it is quite obvious that an emetic is the proper remedy when the symptoms can be attributed to any indigestible substance taken; and we

would recommend this remedy, even although it might appear, from the lapse of time, unlikely that the injurious substance should still remain in the stomach.

When the case originates from intestinal irritation, we would earnestly recommend that the first remedy should be an enema, consisting of three or four pints of warm water, very slowly and gently forced into the bowels. This should be followed by an active purge; and this should, in due time, be followed by a repetition of the injection. The evacuations should be immediately carefully examined, and the effects upon the symptoms of the disease be watched.

To abate the general heat and excitement of the system, to relieve the head or the abdomen, and to ensure perfect safety, the patient should, in cases in which the strength is not particularly impaired, be raised into the erect posture, and be blooded until faintishness be induced. This effect, also, should be carefully watched and observed. If it occur from the loss of a small quantity of blood, it confirms the diagnosis; if it do not occur until much blood have flowed, it should suggest the suspicion of more than mere intestinal irritation,—of one of those mixed cases which so frequently occur, and of which we propose to treat in a subsequent section.

We do not imagine that this decided use of the lancet can ever be attended with danger, if there have been no previous loss of blood or other cause of exhaustion. But it could not be repeated with impunity. It would lead to exhaustion with the symptoms of reaction, to the state of sinking, or even to sudden dissolution; and if the case be really one of intestinal irritation, and the other remedies have been duly applied, such repetition of bloodletting will not be required.

It is an observation of great importance, that in inflammation repeated bloodletting is required, and is borne with safety; in intestinal irritation, on the contrary, the repetition of bloodletting is neither necessary nor safe.

This free evacuation of the bowels and detraction of blood are very apt to be followed by symptoms of hurry and alarm in the system. These effects are frequently prevented by the timely administration of an efficient and kindly anodyne; and we believe no anodyne is possessed of those qualities in a higher degree than Battley's *liquor opii sedativus*. Of this excellent medicine a full dose may be given, and, if necessary, repeated in five or six hours.

If this plan do not perfectly relieve the topical affection, some local remedy must be applied. In cases of cerebral affection, leeches may be applied to the temples, or cupping, or a blister, to the nape of the neck, a cold lotion over the whole head, and fomentation to the feet. Leeches, a fomentation, a liniment, or a blister may be applied, if there be affection of the abdomen.

Before the patient falls asleep, we should recommend some mild food to be taken, as gruel or panada. This plan prevents exhaustion, and frequently relieves the local symptoms by securing a more refreshing kind of sleep. For the same reason the utmost quiet must be preserved in the patient's room. The least disturbance greatly agitates the patient, and prevents the good effects of the remedies which have been employed.

Some other circumstances have been before enumerated which claim our attention in the treatment of this morbid affection; but, in order to prevent repetition, we postpone the remarks which we have to make upon these points to the next section,—upon the effects of loss of blood; in which case an attention to them is, if possible, still more necessary than in that under our immediate consideration.

On the effects of loss of blood in the puerperal state.—The effects of loss of blood usually present themselves to our notice in rather an insidious manner; they are not generally introduced by rigor, or heat, or any other acute symptom; though there may be exceptions to the last part of this rule. It is an important remark that the remoter effects of loss of blood are frequently developed in cases in which there is also intestinal irritation in a dormant form, but that they very rarely occur in conjunction with inflammation; the effects of loss of blood, when they do occur in cases of inflammation, generally denote that the inflammatory action has been subdued.

We have already observed that there is rarely either rigor or heat of surface: there may be transient chills and flushes, and slightly augmented temperature; but the countenance, and especially the prolabium, is generally pallid, and the skin is in a natural state.

The case is usually denoted by a throbbing fulness with moderate frequency of the pulse, throbbing pain of the head, and palpitation of the heart, which is apt to alternate with a state of syncope on slight exertion, or on assuming the erect posture; and there is usually a degree of panting. There is a characteristic susceptibility to fainting on taking a very small quantity of blood.

We have repeatedly known the effects of loss of blood to be mistaken for inflammation of the brain on one hand, and disease of the heart on the other. We consider this an important remark, as suggesting at once two characteristics of this affection, and the necessary caution in the diagnosis in puerperal diseases.

When the head is affected from loss of blood, there are much beating and throbbing of the temples, pain, a sense of pressure, or vertigo, with rushing or cracking noises.

When the heart is affected, there are great fluttering, beating, or palpitation, starting during sleep, hurry and alarm on awaking, sometimes with faintishness, a feeling of sinking or of impending dissolution, &c. and with the palpitation there is frequently beating and throbbing of the carotids, and sometimes of the abdominal aorta, perceptible to the touch or even to the eye. These affections sometimes recur in the form of attacks which are attended by much hurry and alarm.

Besides these more marked affections of the head and heart, which render it so necessary to distinguish this affection from inflammation or disease of those organs respectively, there are many symptoms which occur in a less marked degree or form.

There is frequently an inability to bear noise or disturbance, or even the act of thinking with attention; but there is rarely intolerance of light; the last symptom usually denoting a state of intestinal irritation.

There are frequently vertigo or faintishness on any exertion, or on assuming the erect posture; and when these two are combined, there has sometimes been a sudden and unexpected fatal termination of the patient's sufferings. In many cases there are great faintishness and urgent demand for the smelling-bottle, for the fan, or the fresh air, and for cold applications to the face or temples, and a feeling of impending dissolution. The respiration is affected in different cases with panting, hurry, sighing, heaving, blowing, moaning, gasping, catching, &c. There is in some cases an irritative cough in violent fits, or in the form of perpetual hacking, apparently arising from an affection of the larynx or trachea. The stomach is liable to be affected with retching, vomiting, hiccup, and eructation; and the bowels, even in cases in which they were not previously disordered, become variously deranged, with constipation, diarrhœa, and flatulency. There are frequently, in severe cases, urgent restlessness and jactitation. In some cases there are various spasmodic affections. In other instances there are catching pains, which are apt to be mistaken for inflammation. There are frequent changes, sudden attacks of alarming symptoms, a sense and fear of impending dissolution, urgent messages, &c. which become characteristics of this affection.

Another characteristic consists in the faintishness, gasping, or feeling of dissolution, which sometimes follows even a slight bloodletting; an awfully sudden death has immediately ensued upon a full and mistaken bloodletting at this critical period. Even the operation of purgative medicine has sometimes induced a degree of faintishness.

Every source of disturbance, of anxiety, or of alarm, and every kind of effort either of mind or body, is apt to be followed by a return or exasperation of the symptoms, and cannot be said to be free from danger. We have already remarked that an effort of the muscles and assumption of the erect posture have proved suddenly fatal. This sad event occurred to a lady who raised herself in bed in this exhausted state to make water; she fell down and expired. But when the fatal event from loss of blood is not sudden in this manner, the state of reaction sometimes yields to one of fatal sinking.

The symptoms of exhaustion with excessive reaction may gradually subside and leave the patient feeble, but with returning health; or they may yield to the state of sinking. This term is adopted not to express a state of negative weakness merely, which may continue long and issue in eventual recovery; but to denote a state of positive and progressive failure of the vital powers attended by its peculiar effects, and by a set of phenomena very different from those of exhaustion with reaction.

If in the latter the energies of the system were augmented, in the former the functions of the brain, the lungs, and the heart are singularly impaired. The sensibilities of the brain subside, and the patient is no longer affected by noises as before; there is, on the contrary, a tendency to dozing, and gradually, some of those effects on the muscular system which denote a diminished sensibility of the brain supervene, as snoring, stertor, blowing up of the cheeks in breathing, &c.; instead of the hurry and alarm on waking, as observed in the case of excessive reaction, the patient in the state of sinking requires a moment to recollect herself and recover her consciousness, is perhaps affected with slight delirium, and is apt to forget the circumstances of her situation, and, inattentive to the objects around her, to fall again into a state of dozing.

Not less remarkable is the effect of the state of exhaustion with sinking on the function of the lungs; indeed, the very first sure indication of this state is, we believe, to be found in the supervention of a crepitus in the respiration, only to be heard at first on the most attentive listening; this crepitus gradually becomes more audible, and passes into slight rattling, heard in the situation of the bronchi and trachea; there is also a degree of labour or oppression, sighing, hurry, and blowing, in the breathing, inducing acuteness in the nostrils, which are dilated below and drawn in above the lobes, at each inspiration; in some cases there is besides a peculiar, catching, laryngeal cough, which is especially apt to come on during sleep, and awakes or imperfectly awakes the patient. The heart has at the same time lost its violent beat and palpitation, and the pulse and arteries their bounding or throbbing. The stomach and bowels become disordered, flatulent, and tympanitic, and the command over the sphincters is impaired. The last stage of sinking is denoted by a pale and sunk countenance, inquietude, jactitation, delirium, and coldness of the extremities.

We now propose to detail the principles of the treatment in cases of the effects of loss of blood in the puerperal state.

In the first place the state of exhaustion from loss of blood, with or without reaction, by no means precludes the possibility of congestion within the head; and it is no less certain that the application of leeches to the temples, or of the cupping-glass to the back of the neck, relieves the symptoms of affection of the head, arising from loss of blood, in a remarkable manner. In a case given by Mr. Hey, which we regard as being of this character, and to which we shall have occasion to revert hereafter, urgent symptoms of affection of the head were twice relieved by the abstraction of but three ounces of blood from the temporal artery. This mode of treatment must not, therefore, be neglected except in

he most extreme cases, in which the loss of even so small a quantity of blood, and that from the head even, might prostrate the remaining powers of the patient.

The next point of practice which requires to be mentioned is the state of the stomach and bowels. If these were free from all disorder before the occurrence of the loss of blood, yet the state of exhaustion ever induces a deranged state of the alimentary canal. The state of the bowels must, therefore, claim our attentive consideration in every case of symptoms arising from loss of blood. Their functions and tone must be carefully restored by every means in our power, while we as carefully avoid any fresh source of exhaustion. The bowels must in particular be carefully evacuated daily. This may perhaps be best done by means of the warm-water injection so often recommended by us already, with or without the aid of a draught containing an ounce of the infusion, and two or three drachms of the compound tincture of rhubarb, and of manna.

By these means the state of irritability which is so apt to affect the system, and especially the head and the heart, in cases of exhaustion from loss of blood, is greatly obviated. But for this affection it is frequently also necessary to give some mild but efficient anodyne. The tinctura opii, the tinctura hyoscyami, the spiritus ammoniæ aromaticus, &c. are extremely useful remedies in this affection. But perhaps the best are Battley's liquor opii sedativus, or the extract of poppy, given in efficient doses.

When the head, the heart, and the alimentary canal have been thus relieved, and even during the exhibition of the medicines which have been enumerated, it is of the first importance to attend to all the following points: viz. nourishment, fresh air, quiet, soothing, sleep, &c.

It is difficult to give fixed rules for the administration of nourishment; but the first rule is to ascertain that the bowels have been properly evacuated, otherwise food will only oppress the stomach; the second is to give the nourishment itself in such forms as will prove light and easy of digestion; the third is that it should be taken at first very slowly and in small quantities. Arrow-root in water, beef-tea, panada, sago, &c. may be given frequently.

The best restorative we possess is, we believe, fresh air; but it is especially the best in the cases under consideration. The warmth and closeness of a lying-in room must therefore be forthwith exchanged for free ventilation, only observing the due precautions against giving cold.

Nothing is more essential than quiet both of body and mind. Bodily exertion leads to still further exhaustion, and perhaps even to unexpected dissolution; and every kind of mental effort or hurry not only exhausts the patient's strength, but is extremely apt to lead to those attacks of symptoms of irritability of which we have given so full a description.

The patient should be soothed and lulled in every possible way; and it is of the utmost importance to procure sleep. But it should be observed, in regard to sleep, that too long a sleep is apt to exhaust or overwhelm the patient. This is especially true if it be not preceded by nourishment. The sleep is also apt to be injurious by leading to turbulent dreams, which have the same bad effects as waking hurry of mind; the sleep should, therefore, be watched, and it should be interrupted if the patient is observed to suffer from agitation: this is best done, we think, by offering nourishment, for the patient is immediately collected, on awaking, from knowing what is doing.

There is one point which we have not hitherto mentioned as it deserves; it is the efforts made by the parent to suckle her infant. Nothing is so injurious in all puerperal diseases. These morbid affections have often appeared to be first induced by the attempt to nurse; and they have still more frequently been exasperated by it. This attempt especially involves within itself almost every thing which can be injurious in a state of exhaustion; the drain, the muscular effort, the mental excitement implied in the act of suckling, are all of the most injurious tendency in this affection.

Of mixed cases, and especially of puerperal mania.—Perhaps the cases which most frequently present themselves to our notice in practice are of a character distinct from those which have been described in the preceding sections, differing from them principally by blending two or all three of those cases in an individual patient.

Our systems of nosology have, we are persuaded, greatly erred in attempting to separate diseases from each other, and describe them as distinct, when they far more frequently occur in conjunction; so that the mind of the medical student is not at all prepared for the cases which most frequently occur to him when he first enters upon practice. A little experience teaches him the difficulty, nay the absurdity, of attempting to give each individual case a name, or to put it down in a list of diseases. Each patient, on the contrary, presents to him a new congeries of symptoms, a new complication of diseases or disorders.

To apply these remarks to our present subject, it may be truly said that puerperal cases are more complicated than any. But we have already insisted upon this point; and we now proceed to illustrate the various combinations of inflammation with intestinal irritation, or of either or both, with the effects of loss of blood.

Some cases have conjoined the most decided symptoms of intestinal irritation with those of inflammation, and, having proved fatal, have presented all the traces of inflammatory action on examination. It has already been shown that in many cases of inflammation there are none of the symptoms which denote intestinal irritation; there is an absence of rigor, of heat, of affection of the head, &c.; but the effects of inflammation are found upon dissection.

On the other hand, there have been all the symptoms of intestinal irritation, as rigor, heat, headach, with pain, tenderness, and tension of the abdomen, without a trace of the effects of inflammatory action on examination after death. The conclusion from these separate statements is obvious; inflammation and intestinal irritation may exist separately, but they may also exist together.

The effects of loss of blood are frequently observed in cases of inflammation, when the primary disease has been perfectly subdued. But they are still more apt to concur and to assimilate themselves with those of intestinal irritation, when there has been much loss of blood by hemorrhage or by bloodletting.

This subject, as well as the interesting question of the diagnosis, might be illustrated by a reference to the valuable treatise of Mr. Hey upon puerperal fever. This author, as well indeed as almost every writer upon this subject, appears to us to have combined in one description all the three different cases of which we have treated. It is not, therefore, wonderful that their works should involve many inexplicable discrepancies in the symptoms and in the treatment. Some cases have occurred without rigor, heat, or headach; others have combined all three with or without affection of the abdomen. Some have been cured without the lancet; others have not yielded to the most judicious and most ample bloodletting. It is doubtless a most important question,—how can these discrepancies be explained?

Other difficulties and other discrepancies have arisen from the addition or superinduction of the symptoms of loss of blood, in cases of inflammation or of intestinal irritation. This is a mixed case which frequently occurs, and causes much embarrassment to the young and inexperienced physician; and it has too frequently happened that the lancet has been prescribed under a false impression of inflammation; and that great danger and even immediate dissolution have ensued.

There is a mixed case which shows itself under a still different form from any which have hitherto been described; it is *puerperal mania*. We believe this disease to result, in general, from all the circumstances following parturition combined, but chiefly from the united influences of intestinal irritation and loss of blood. We purpose to pursue this subject hereafter. In the meantime, however, we would observe that we are persuaded that real puerperal phrenitis is comparatively a rare disease; that puerperal mania is seldom of an inflammatory character, and that it is especially to be treated by those measures which are suited to the mixed case of intestinal irritation and exhaustion. This opinion is confirmed by the fact of mania occurring from undue lactation, as well as from the circumstances of the puerperal state. We are inclined to attribute much more to the combined influence of irritation and exhaustion than to the mere "state of the sexual system which occurs after delivery," which has been assigned as the chief cause of this morbid affection by Dr. Gooch, in a most interesting paper upon this subject in the sixth volume of the Transactions of the College of Physicians, p. 280; although we would by no means exclude the influence of this principle altogether. There is ample evidence in Dr. Gooch's cases of the influence of intestinal disorder; and the events of labour and the circumstances of lactation ever add to this a state of exhaustion. This view is the more important, because it directly suggests the proper mode of treatment, which consists in restoring the system to a state of due health by every means in our power, whilst we adopt every measure which can soothe and allay the morbid irritability of the nervous system.

We are confirmed in this view of the nature of puerperal mania not only by a careful investigation of its causes and the good effects of the remedies which we have mentioned, but by having met with the symptoms of intestinal irritation as a prelude to those of mania.

There are frequently also many of the appearances of disorder of the general health, sometimes jaundice even; and the state of the complexion and of the alvine evacuations leaves no doubt as to the influence of the morbid condition of the intestinal canal. Bloodletting plunges the patient into a state of danger, perhaps into one of irretrievable sinking.

Puerperal mania is, in fact, in the most emphatic sense a mixed case: previous derangement of the health; intestinal irritation; loss of blood; the pain and shock, and anxiety attendant on parturition; the subsequent morbid state of the genital organs;—all these may combine with predisposition to induce the maniacal attack.

But our attention must be chiefly directed to the degree of exhaustion which obtains, to direct us what remedies to employ and what measures to avoid.

On being called to a case of puerperal mania, we have long been in the habit of asking whether the patient has or has not been bled; on this greatly depends the event of the case: if blood has been freely taken, the patient will probably die; if otherwise, most puerperal cases of mania issue well.

It must be admitted in this place, however, that puerperal mania may possibly be combined with inflammation, especially of the uterus, its appendages, or the peritoneum. This is to be ascertained by a careful examination. In such a case bloodletting must be used, and in such a case it can be borne.

Puerperal phrenitis is certainly a rare disease. This opinion was early expressed by the writer of this article, and it is confirmed by Dr. Gooch. The same remark may be made in regard to the most influential cause of puerperal mania, and the danger of bloodletting in that disease.

The symptoms in puerperal mania occur in the most insidious manner: there is a little excitement during the day, and sleeplessness at night; then something bordering on delirium; then actual delirium; and then confirmed mania.

The most important parts of the treatment

are extreme quiet of mind and of body; a regulated state of the bowels; a mild, light, but nutritious diet; a cold lotion to the head; fomentations to the feet; every soothing plan; careful watching; and time. It too frequently happens that the friends undo in one day what the physician's care has effected in many: visitors intrude; the infant is brought; conversation, excitement are permitted.

The treatment consists, in fact, much more in avoiding sources of harm than in positive remedies. Bloodletting is replete with danger; every depleting means, by adding to the exhaustion, adds to the malady. The cure depends more upon nursing than upon the materia medica. It is proper, however, to state that the mildests opiates have lulled and soothed, and obtained rest, and allayed the disease. The progress of puerperal mania has also been controlled by administering mercury so as to induce ptyalism, and avoiding its effect on the bowels.

We have thus given a rapid sketch of those puerperal diseases which are of most frequent occurrence and greatest practical interest. But here is another series of puerperal diseases of still more terrible character, of which a sketch must now be added. They consist of softening of the substance of the uterus, inflammation of the lymphatics, and phlebitis.

The first of these may be suspected whenever there are, after rigors and fever, with uterine pain or tenderness, and suppressed lochia, symptoms like those of the sinking state, the countenance becoming collapsed, the pulse extremely frequent and small, the respiration hurried and anxious, the strength prostrate.

The symptoms in inflammation of the lymphatics are very similar, and of a typhoid character; these are usually conjoined with those of peritonitis, and occasionally with pleuritis. But there are not the secondary abscesses observed in the disease to be next mentioned.

The important distinction in regard to uterine, as in the other forms of phlebitis, is between the adhesive and the suppurative. In the former the effects are localized. Uterine phlebitis of the adhesive character is attended with local pain and tenderness. The occurrence of crural phlebitis seems to constitute the disease formerly termed the phlegmasia dolens. This disease is distinguished by pain in the situation of the iliac and inguinal veins, with tension and swelling, afterwards pursuing their course down the thigh. The femoral vein is found hard, tense, elastic, painful, and tender.

The suppurative phlebitis is a far more formidable and fatal disease. It is denoted by the occurrence of terrific typhoid symptoms, and by external suppurative inflammation of the integuments or of the eye; whilst abscesses form internally in the brain, the lobules of the lungs and liver, in the spleen, in the joints, in the muscular substance, &c. It is usually attended by peritonitis.

Of the treatment of softening of the uterus, of inflammation of the lymphatics, and of suppurative and diffused phlebitis, little is known; and it would be foreign to the object of this sketch to enter upon any discussion of the subject.

(Marshall Hall.)

PUERPERAL FEVER.—See Fever.

PULSE.—The stroke or beat of an artery, as recognized, for the most part, by the finger applied to the integuments lying over it, is denominated *the pulse;* by the Greeks it was termed σφυγμὸς; by the Latins *pulsus,* whence our English term is derived.

We propose to divide the following article into three parts, which may be regarded respectively as historical, physiological, and pathological. The first will consist of a brief historical account of what was known on the subject of the pulse by the ancients, as well as the opinions that have been entertained respecting it by the moderns. In the second place, we shall inquire into the cause of the pulse. We shall endeavour to explain its different varieties, and shall point out their connexion with the other parts of the animal economy. Lastly, we shall offer some remarks on the morbid conditions of the pulse, and inquire into the degree in which they may enable us to judge of the seat and nature of disease, so as to assist us in forming our diagnosis and prognosis, and in directing our practice.

I. *History of the opinions that have been entertained respecting the pulse.*—We have a distinct notice of the pulse in the writings of Hippocrates; it is mentioned, however, incidentally, and in a few passages only, and he appears to have attached scarcely any importance to it, either theoretical or practical. It is commonly supposed that he is the first writer who employed the term pulse (σφυγμὸς) to denote the natural and ordinary beating of the artery. It would seem that the ancients usually applied the term to what we should call pulsation, i. e. the beating that is felt by the individual himself, in a part that is inflamed, or otherwise morbidly affected, without applying the finger to it. But although there are certain passages in the writings of Hippocrates where the word is used in the more correct and restricted sense, yet it must be admitted that these are few in number; a circumstance which is the more remarkable, when we consider with what minute accuracy he detailed the other symptoms of the diseases of which he has left us a distinct account. We may farther notice, that from the manner in which he refers to the pulse, he seems to have made little or no use of it, either in regulating his practice, or in forming his diagnosis. Where, for example, he gives a detailed account of the phenomena of fever, he states with great minuteness the temperature of the patient, the state of the respiration, of the secretions and excretions, and indeed all the circumstances to which the most judicious modern physician would direct his attention, except the pulse. The only use which Hippocrates made of the pulse was to assist him in forming his prognosis; but even here we meet

with little of that acuteness of observation which, on most occasions, characterizes the writings of the great father of medical science.*

It is generally agreed that Herophilus was the first physician who was fully aware of the importance of the pulse, and paid particular attention to its various conditions. He was one of the most distinguished ornaments of the Alexandrian school, and is especially celebrated for his knowledge of anatomy, into which science he introduced many great improvements. The fame of Herophilus is principally supported by the authority of Galen, who expressly notices his merits on this point.† We learn, however, from Pliny,‡ that he was supposed by some to have introduced into practice a number of unnecessary and even fallacious distinctions concerning the pulse, and that, for the most part, his opinions were derived more from hypothesis than from actual observation.

The author whom we shall next notice is Celsus. The judicious manner in which he treats his subject, the candour which he displays in referring to the opinions of others, together with the elegance and purity of his diction, have caused him to be regarded as one of our highest classical authorities. This is more especially the case on all questions of literary history, as he appears to have aimed more at giving a correct view of the state of medical science in his age, than a mere transcript of his own observations and experience. In his account of the pulse he has been supposed to revert to the doctrine of Hippocrates. When giving directions for the treatment of fever, he remarks upon the great importance of obtaining a correct criterion of the presence of the disease, and in this connexion he introduces the following observation: "We principally trust to the veins, a thing which is most fallacious, for they are frequently too slow or too quick, depending on the age, the sex, and the peculiar nature of the body." He goes on to inform us that there are various cases in which the pulse is affected by circumstances quite unconnected with any morbid condition of the body, and where we should fall into the greatest mistakes were we to suffer our judgment to be influenced by the state of the pulse.§ The multiplied and varied experience of the modern practitioner has proved that the precautions of Celsus, although not without some foundation, were carried to an unreasonable length; and that, although the pulse is affected by most if not by all the extraneous circumstances mentioned by him, yet that it still leaves us the most valuable indications of the state and nature of disease.

We now arrive at the period of the celebrated Galen, a man whose talents and acquirements were of the first order, and who from other causes obtained an ascendancy over medical opinions more considerable and more durable than had been acquired by any of his predecessors; and we may venture to add, than will be ever again obtained by any individual. There is scarcely any topic, connected either with medicine or with pathology, which Galen has not investigated; and the pulse is one on which he bestowed a peculiar degree of attention. He has devoted to this subject no less than six different treatises, some of considerable length, in which he investigates in the most elaborate manner everything concerning the use of the pulse, its causes, its different varieties, the method of distinguishing these varieties, the prognostics to be deduced from them, and other analogous subjects.*

A characteristic feature of the writings of Galen is the methodical arrangement, and the numerous technical divisions which he introduces into almost all the subjects which fall under his notice. He proceeds on this principle when treating of prognostics, which he classes under the three heads of those which relate to the concoction of the humours, to the absolute removal of the disease, or to particular crises of various kinds. Again, he supposes crises of all kinds to be derived from three kinds of powers or actions, arranging them, according to their origin, under the denominations of natural, vital, or animal; the pulse he regards as principally indicative of the different kinds of vital actions. It would carry us far beyond all reasonable limits, were we to follow our author into his speculations concerning the causes of the pulse, and the mode in which its different actions manifest themselves, so as to give rise to a most complicated system of minute distinctions and varieties, which it is difficult even to comprehend, and of which few only have probably any actual existence.

With respect to the cause of the pulse, Galen, according to his ordinary custom in such cases, attributes it to a specific faculty inherent in the heart and vessels, which he names pulsative, by which their alternate contraction and dilatation is produced. As the pulse is an effect resulting from the action of the vital faculties, it affords us one of the most correct indications by which we may judge of the strength or weakness of the vital powers in general, and of the consequent tendency to life or death, and thus constitutes one of our most valuable means of prognosis. Hence the extreme importance of making ourselves acquainted with all its variations, and connecting them with the state of the other actions and functions of the animal economy.

The use of the pulse was supposed to be to maintain the heat of the body, and to remove the excess of excrementitious matter from the blood: by considering the condition of the vital powers, in relation to these supposed

* Hippocrates enumerates a peculiar state of the pulse among the signs of disease in his treatise 'De Humoribus;' also, in various parts of his 'Coacæ Prænotiones.'

† See his treatise De Diff. Puls. lib. ii. c. 10.

‡ Hist. Nat. xxix. 1.

§ Lib. iii. cap. 6.

* The following are the Latin titles of Galen's Treatises on the Pulse: De Pulsuum Usu; Introductio in Pulsus; De Differentiis Pulsuum, 4 lib.; De Cognoscendis Pulsibus, 4 lib.; De Causis Pulsuum, 4 lib.; De Præcognitione ex Pulsibus, 4 lib.

processes, he lays the foundation for the differences in the pulse which he endeavours to establish. These differences he first arranges under the two heads of simple and compound, which he again subdivides into numerous varieties, depending partly upon the supposed quantity of motion in the vessels, the nature of this motion, the length of time which it occupies, the space which intervenes between the pulsations, the force of the vital action, and the particular disposition of the artery. Proceeding upon these principles, he forms all the supposable combinations of these different circumstances, and from them he deduces a great number of varieties, to which he gives distinct appellations, but which it would be useless to attempt to describe, or even to enumerate.

Those who are curious to obtain farther information on this point may especially consult his dissertation "On the Varieties of the Pulse," a work of considerable length, which is exclusively devoted to this particular object. It may be regarded as one of the most learned of Galen's performances, and as peculiarly characteristic of the methodical and technical manner in which he treats his subjects.

After the age of Galen we have little to detain us until the revival of medical science by the Italians in the sixteenth century. Medicine was, indeed, very assiduously cultivated by the successors of Galen, during what are termed the dark ages; and among the Arabs especially, we meet with various individuals of great eminence for their learning. But their attention was almost entirely confined to the writings of the Greeks, and particularly to those of Galen, which they regarded as standards of excellence; these they translated and re-published in various forms, and illustrated by almost innumerable commentaries and dissertations, adding very few original observations, and making scarcely any advance in the principles of the science. This system prevailed to so great an extent, that it has been asserted, and, as it would appear, without exaggeration, that for more than one thousand years after the death of Galen, scarcely a single improvement in medicine or physiology was made which was been thought worthy of being transmitted to posterity.

In tracing the history of science among the nations of antiquity, we seldom think it necessary to go beyond the limits of Europe, or the period of Grecian literature; yet it is generally admitted that the Greeks were not themselves the inventors or the originators of the arts in which they so much excelled. It is a question of very difficult decision, what was the country in which they took their rise, whether in Egypt or in India, or in some other part of the East. It is, however, certain that the Oriental nations made very early advances in various departments; and that, while Europe has been undergoing numerous revolutions, and been gradually advancing to its present state of improvement, Asia has remained much more stationary; so that, in many cases, we have reason to believe that it exhibits at this day nearly the same condition which existed perhaps two thousand years ago. This is most remarkably the case with the Chinese, both in regard to their early civilization and to the little change it has experienced; and it hence becomes a subject of great interest and curiosity to inquire into the opinions and practices of this remarkable people.

We are furnished by the missionary Jesuits with a minute account of Chinese medicine, and particularly of their opinions respecting the pulse. It appears that they paid great attention to it, and supposed that it afforded them indications of almost every change to which the body is subject, as well salutary as morbid. Thus, among other notions, it was conceived that the different organs produced by their derangement different effects upon the pulse, some of which were to be detected by examining the pulse of the right side of the body, and others that of the left. They farther imagined that from the state of the pulse of a pregnant woman, the sex of the fœtus might be ascertained. They arranged the different parts of the body under three divisions, upper, middle, and lower, in conformity with their respective situations; and they conceived, that according as one or other of these parts was affected, so a corresponding state of the pulse was to be recognized.* We might be the more disposed to inveigh against the futility and absurdity of these opinions, were we not aware that they but too much resemble some of those which were supported by the most enlightened and learned physicians of Europe scarcely a century ago.

At the revival of letters, when the human intellect began to rouse itself from its long repose, the mathematical sect of physicians sprung up. Their reasonings were, for the most part, founded upon erroneous principles, and were almost exclusively derived from physical deductions, which were inapplicable to the phenomena of the living body. Still these labours were not entirely without their use, by stimulating the mind to exertion, and by indirectly leading it to those subjects which are more connected with the principles that ought to guide us in our inquiries. It is on this account chiefly that we notice the name of Bellini, a learned professor of Pisa, who flourished in the beginning of the seventeenth century, and wrote a treatise on the pulse.† Although the fundamental principles of the sect to which Bellini belonged were, in many respects, essentially erroneous, yet they led to a closeness of reasoning which was more favourable to the progress of knowledge than the completely hypothetical method of their rivals the chemists.

It was not, however, until the immortal discovery of Harvey was generally recognised, and its importance duly appreciated, that any considerable progress could be made in our knowledge of the laws of the circulation, or that we could expect to form any just conception

* See especially the "Description de la Chine," by Du Halde.

† De Urinis et Pulsibus, 1683.

either of the theory of the pulse, or of the circumstances that might be supposed to affect it. The general turn for observation which now became prevalent in all the departments of philosophy, of which the discovery of Harvey itself may be regarded as one of the most splendid results, gave rise to various investigations respecting the cause and nature of the pulse, varying much in their respective merits and importance, but all of them professing to be derived from observation or experience, and contributing more or less to the establishment of the principles of a correct theory.

Among the first of these productions which will require our notice, is a work which appeared early in the seventeenth century, in many respects peculiar in its style and in the opinions which the author adopts, but of real value, as possessing the merit of pointing out a precise mode of ascertaining with accuracy the rate of the pulse, by means of an instrument adapted for measuring short intervals of time. This was done by Sir J. Floyer, in "The Physician's Pulse Watch," published in 1707. The instrument which he describes is indeed awkward in its construction, and must have been inconvenient in practice, but it deserves to be recorded, as being the first step of an important improvement.

In the year 1731 a singular work made its appearance, written by Solano, a native of Lucca, but who passed the greatest part of his life in Spain; it was entitled "Lapis Lydius Apollinis." In the course of his practice he had met with some cases of what is termed the rebounding pulse, and being struck with its peculiarity, and with the symptoms which succeeded it, he was led to pay particular attention to the various states of the pulse, and to the morbid changes which appeared to be connected with them. He accordingly directed his attention almost exclusively to this function, and he is said to have arrived at an inconceivable degree of acuteness in predicting the event of disease by the peculiar indications of the pulse. The result of his experience, real or supposed, forms the subject of his volume, which obtained, at the time of its publication, a considerable degree of celebrity.

The investigation was zealously pursued by Nihell, an English physician, who likewise resided in Spain, and who undertook to give to the world the principles of Solano under a more intelligible form, and divested of a degree of obscurity which is attached to the original. Accordingly, in the year 1745 Nihell published his "New and extraordinary Observations concerning the Predictions of Crisis by the Pulse."

A few years after the appearance of Nihell's treatise, a work of a similar kind was published in France by Fouquet; who, proceeding upon the plan of Solano, endeavoured to point out the connexion between certain peculiar states of the pulse and the affection of peculiar organs of the body.

The subject was still farther prosecuted by a learned countryman of Fouquet's, Bordeu, who, in the year 1756, published his "Recherches sur le pouls par rapport aux crises." In this treatise he proceeds upon the method of Solano; but he goes even beyond him in the minuteness of his distinctions, and the apparent accuracy of his discriminations; and from these he professes to draw a system of indications and prognoses, which, although in some of its parts it may not be altogether without foundation, is generally admitted to be derived from subtile and over-refined distinctions, which it is impossible to recognise, and which, for the most part, can have no real existence. It does not appear that in this country the system of Solano ever had any considerable number of adherents, while in France the learning and ability exhibited in the work of Bordeu, aided also by his reputation as an able and successful practitioner, contributed to give a degree of weight and authority to his opinions, greater than was due to their intrinsic merit. Even in the present day, we observe in the French school an attempt at nice discriminations of the pulse, which are conceived by the English to be altogether imaginary, a state of things which may probably be traced, in some degree, to the writings of Bordeu.

For the opinions which have been, of late years, generally embraced in this country respecting the pulse, we are probably indebted in no inconsiderable degree to two short, but very valuable treatises; the first consisting of an essay, which was read by Dr. Heberden before the College of Physicians in the year 1768; the latter, of the "Observations respecting the Pulse," by Dr. Falconer, published in the year 1796.

Dr. Heberden has the merit of having freed the subject from most of the subtile and over-refined distinctions which had been introduced into it, in the first instance by the followers of Galen, and afterwards by those who adopted the opinions of Solano. He informs us that his object was to direct the attention of the practitioner to "such circumstances of the pulse, in which they could neither mistake nor be misunderstood." He continues: "what I mean is, the quickness or frequency of the pulse, which, although distinguished by some writers, I shall use as synonymous terms." Proceeding upon this principle, he gives us the valuable results of his own observation on the respective frequency of the pulse at different ages and in different states of the constitution, and points out various circumstances in which the frequency of the pulse, considered by itself, without reference to other symptoms, was found to be a very inadequate criterion of the nature and degree of disease.

Nearly a similar view of the subject was taken by Dr. Falconer. Referring to the essay of Dr. Heberden, he has the following remark. "It has been reserved for the good sense and clear understanding of a physician, who does honour to our own country, to free the study of the profession from many needless incumbrances of this kind, and to direct the attention of practitioners to the only circumstance respecting the pulse which is capable of commu-

nicating accurate and distinct ideas, or of affording decisive indications." He farther agrees with Dr. Heberden, that the quickness and frequency of the pulse are to be regarded as synonymous terms, and characterizes the frequency "as the only circumstance respecting it (the pulse) of which we can form any clear or determinate idea, and which we can be assured conveys the same information to others that it does to ourselves;" while he speaks of the other distinctions as fanciful or whimsical, and as serving to perplex and embarrass the practitioner.

With the greatest respect, however, for these individuals, who may be justly regarded as among the most enlightened and candid physicians of modern times, we conceive that they have attempted to simplify the subject too far, and that, in discarding a mass of erroneous notions, they have fallen into the opposite extreme. But whatever we may think of their opinions on this point, the facts and observations which they have adduced are of the highest importance, and rest upon authority which can never be called in question.

It will be scarcely necessary to pursue the historical part of this article below the termination of the last century, for although we have many very valuable observations on the pulse of a later date, they are either contained in works principally devoted to other topics, such as general histories of medical science, and accounts of particular diseases and individual cases, or they are written for the express purpose of establishing and elucidating some physiological position, which will be more conveniently discussed in the second part of this article.*

II. *Physiology of the pulse.*—In treating of the physiology of the pulse there are various points that present themselves for our consideration. In the first place we must inquire into the cause of the pulse, and when we have ascertained the cause, we shall be prepared to investigate the exact nature of the effect, and what relation it bears to the other functions of the animal economy.

Since the immortal discovery of Harvey, it is universally admitted that the pulse depends immediately upon the action of the heart, which, by its contraction, expels a portion of blood from its cavities into the great arteries. The contraction, or, as it has been termed, the systole of the heart, must therefore correspond, in point of time, with the stroke of the artery, while, during the diastole of the heart, the artery returns to its quiescent state. But although there can be no difference of opinion on this point, there are various subordinate questions, which have been the subject of warm and protracted discussions, some of which remain still undecided.

Of these, one of the most important is, whether the arteries themselves possess any contractile power, by which they are enabled to co-operate with the heart. The contractile power of the arteries has been supported by direct experiments, and especially by those in which the blood was found to be propelled along the vessels after the heart was removed from the body; while, on the contrary, this property has been denied by other physiologists, because, in experiments made for the express purpose, the artery could not be made to contract by the application of those agents which are known in ordinary cases to stimulate the muscular fibre. There is certainly some difficulty in reconciling the apparently discordant results; but, upon the whole, the weight of evidence is in favour of the contractile power of the arteries; for it appears almost impossible to explain various phenomena without admitting this power, while the negative results that have been adduced against this opinion are explicable upon other principles. We may therefore assume it as an established point, that the blood is propelled along the vessels by the joint power of the heart and arteries.

Proceeding, however, upon this position, that when the heart contracts, a certain impulse is propagated through the artery which causes it to strike the finger, it still remains to be ascertained what is the exact nature of this impulse. We may inquire whether the vessel be actually distended, so as to have its diameter increased, or is it merely extended in length, or displaced? or without having its size actually augmented, or being removed from its situation, is it only rendered more tense or firm, or what other change does it experience? When we estimate the bulk of the blood sent into the aorta at each contraction of the heart, and compare this with the quantity of blood previously contained in the vessels, although we might theoretically suppose that the diameter of any particular artery was actually increased, it must be admitted that the increase of bulk would be much too small to be perceived by the finger, or to produce the sensation which is conveyed to us by the pulse. Hence we may conclude that the terms systole and diastole are scarcely applicable to the different states of the artery; for although we may conceive them to be technically correct, when considered as a question of theory, we cannot admit of their actual existence in any sensible or perceptible degree.

As to the extension or displacement of the artery, it appears certain that when the jet of blood is forcibly projected into a flexible tube, like that of which the artery is composed, there will be an effort produced to straighten it and to diminish its flexures, and at the same time to extend it in a longitudinal direction, as far as the texture of the organ itself and its connexion with the neighbouring parts will permit. There is, however, reason to believe that these changes, although they may actually take place to a certain extent, do not exist in sufficient degree to produce all the effect which is experienced, and we are therefore indneed to search for some other cause of the phenomena.

The solution of the problem was attempted

* For a more minute account of the opinions respecting the pulse, we may refer especially to the histories of Le Clerc and Sprengel, and to Haller, El. Phys. lib. 6, sect. 2; also to the art. *Pouls*, in the Dict. des Scien. Méd.

by Dr. Parry,* who, after proving the insufficiency of all the former modes of explanation, proposed a new view of the subject. We shall quote the words of the author, as they express, in a short compass, the fundamental positions on which the hypothesis rests. "In the larger arteries there is no sensible dilatation or contraction,—therefore the pulse cannot depend on this alternation. The chief cause of the pulse is a strong and predominant impulse of distention from the systole of the left ventricle, given by the blood as it passes through any portion of an artery forcibly contracted within its natural dimensions." The pulse is felt when the motion of the blood is impeded by the compression of the artery, and it is the resistance to this obstruction which produces the pulse. We feel much disposed to acquiesce in Dr. Parry's opinion, at least it may be asserted that there is no other which gives a sufficient explanation of the phenomena, while at the same time there is nothing in the hypothesis either repugnant to the laws of the constitution, or inconsistent with the structure and properties of the organs in question.

It will follow as a consequence of this opinion, that the pulse must be progressive, i. e. the impulse must be made on the different parts of the artery at different times, corresponding to their distance from the heart. But although this may be theoretically true, it has been questioned whether the difference be really perceptible, and many very accurate observers have not hesitated to affirm that they have been unable to recognise it. There are, however, physiologists of the first eminence, who inform us that they can perceive a difference in point of time in the beat of the different parts of the arterial system. Considering, therefore, that a positive fact, where the authorities are equal, is to be preferred to a negative one, we must admit that the progressive beat of the arteries is perceptible.

Another question which, like the last, must be answered partly from theory, and partly from observation, is whether the force of the different parts of the arterial system always maintains the same relation to that of all the other parts, and to the action of the heart. If the action of the heart be increased in a certain ratio, is that of every artery increased in the same ratio, or is the same ratio observed in every increase or diminution of action which may occur in any part of the arterial system? If the heart were the sole impelling power, this equality of ratio must necessarily be preserved; but if the arteries themselves partake of this action, and cooperate with the heart in the propelling power, it will follow that a local cause may produce a local effect; and this we in fact find to be the case.

If we suppose that the arterial system derives its power ultimately from the force of muscular contractility, and that this is exercised conjointly by the heart and the arteries, we may inquire to what change of properties or of constitution are the parts concerned in this operation obnoxious, which may produce an actual or perceptible effect on the pulse; and farther, what is the nature of the changes which would be thus produced.

The mechanical structure of the parts we may conceive to remain unchanged, but the force of contractility is perpetually varying. And although we may suppose that the heart and arteries are not under the direct influence of the nervous power, yet we are disposed to acquiesce in the doctrine of those physiologists who maintain that they are indirectly affected by it, in the same manner with the involuntary muscles generally, so that we have here another source of variation in the pulse.

The function of respiration exercises a most important influence over the circulation. The essential object of this function is to produce such a chemical change in the blood as to enable it to maintain the contractility of the muscular parts, and among others, that of the heart itself. Any interruption to this change in the nature and constitution of the blood will necessarily impede the action of the heart, independently of any direct change in its susceptibility, while a still more material change in the circulation will be produced, if both the nature of the blood and the power of the heart be simultaneously affected. The function of assimilation is still more immediately connected with the process of sanguification, and consequently with the quantity and quality of the blood, so that we have here two direct and immediate causes always in operation, which, either separately or conjointly, may contribute to affect the state of the pulse. From these considerations it will appear that, independent of any external agency, we shall have a sufficient number of changes in the powers or actions connected with the circulation, to account for all the actual varieties that are observable in the state of the pulse, and to serve us as a basis on which to construct a theory of the cause and nature of these variations.

Let us now attempt to apply these observations to explain the phenomena of the pulse. We may arrange all its varieties under the three relations of time, force, and equality, considered either simply or in combination. Thus the strokes of the artery may be in the simple relation of frequent or rare, strong or weak, regular or irregular, or we may have the combined relations of frequent and strong, weak and regular, &c. It will be a question, however, for consideration, whether all the varieties that can be actually detected are reducible to these three simple or combined relations; and in order to elucidate this point, it will be necessary to determine what are the characters of the pulse which can be clearly recognised, and are generally allowed to exist.

The first is that which depends upon the simple relation of time, constituting the frequent or rare pulse, indicating merely the number of strokes in a given period. The next variety is the quick or the slow pulse, including something beyond the mere number of beats in a

* Experimental Inquiry concerning the Arterial Pulse, 1816; with additional experiments by his Son, 1819.

given time, and taking into account the period occupied by each individual pulsation. From what has been stated in the first part of this article, it will appear that it has been questioned by physiologists and physicians, whether it is possible to distinguish between these two states of the pulse, or rather, indeed, whether this difference actually exists; whether, for example, a pulse can be at the same both rare and quick, or frequent and slow. This point formed the subject of a very warm discussion between the celebrated rivals Stahl and Hoffmann, about the beginning of the last century, the former maintaining the affirmative, and the latter the negative opinion. We have seen above, that the high authority of Heberden and Falconer is in favour of the opinion of Hoffmann, yet we have also high authorities on the other side of the question; and proceeding upon the same principle as on a former occasion, we do not hesitate to decide in the affirmative. It may indeed be impossible to discriminate between a quick and a frequent pulse where the frequency is considerable; yet in cases of less frequency, we conceive that a difference may be detected. These are the only simple relations of time.

With respect to the second class of relations, that of force, we have first the most simple character of strong and weak, depending directly upon the degree of force with which the heart propels the blood into the arteries. It may be doubted whether there be any state of the constitution in which the contractility of the heart is increased or diminished, without the action of the arterial system, taken in its whole extent, being likewise increased or diminished; nor, if this condition should exist, are we in possession of any method of detecting it through the medium of the pulse.

We may conceive a state, in which the contractility of the heart may remain unchanged, but in which the nervous energy may be increased or diminished, in which case an indirect effect may be produced on the pulse, giving rise to two possible variations, the one depending on an increase, the other on a diminution of nervous power. Then again, conceiving the muscular and the nervous powers to be derived from different sources, and not necessarily dependent on each other, we have the farther possible modifications of increased contractility, while the sensibility is either increased or diminished, and the reverse. But although some of these may be regarded as possible and even not unfrequent occurrences, it does not appear that we have any means of recognising their effects on the pulse, or of distinguishing them from each other. The only characters of the pulse which belong to the relation of strength, besides that of the simply strong and weak pulse, is the hard or soft, and what is perhaps nearly the same, or differing from it by a minute shade only, the quality which has been termed tension, where, without the actual bulk of the artery, or the force of the heart being increased, a sensation is communicated to the finger of greater firmness or density. It is probable that under one or other of these characters may be comprehended all the essential variations of the pulse which are connected with the simple relation of force.

We must next speak of those variations of the pulse which proceed upon the relation of equality. These naturally arrange themselves under the two heads of equality as to time, and equality as to force. The first constitutes the regular or the irregular pulse, and the irregularity may be of two kinds; when one beat among a certain number of strokes is omitted, as in the intermitting pulse, or when the beats generally bear no uniform relation to each other. With respect also to the irregularity of force, we have, in like manner, two varieties; the first, where there is a general inequality in the strength of the pulsations compared with each other; the second, that state of the pulse where a weaker and a stronger beat succeed each other, with at least a certain degree of uniformity. One variety of this has been termed the rebounding pulse, and there are others, much insisted upon by the older writers, and perhaps not altogether without an actual existence, where this change of force is continued through two or three strokes, constituting a kind of increasing or decreasing series, to which the terms *inciduus* and *miurus* (μείουρος) have been respectively applied.

If we now bear in mind the three general causes which we have supposed to affect the circulation, the vital powers of contractility and sensibility, and the state of the circulating fluid, we shall perceive that the relations of time, force, and equality may be, each of them, supposed capable of being influenced by the third of these causes, which will give rise to an additional set of combinations, of possible, perhaps some of them of frequent occurrence. Thus, what is termed the full or small pulse probably depends upon an excessive or a deficient quantity of blood in the vessels. That peculiar state of the pulse in which the sensation conveyed by the artery to the finger has been likened to that of a thread, a wire, or a cord, may be supposed to depend upon the small quantity of blood in the vessel, combined with an increased or diminished contractility of the heart, while the contrary state of a sluggish or an oppressed pulse, and the like, may be attributed to an unusual fulness of the vessels, the vital powers of contractility and sensibility not being increased, or even one or both of them being diminished.

The varieties in the pulse which have been enumerated above, are supposed to be derived from, or to be dependent on, the general or ordinary actions of the animal economy, and to be explicable by a reference to the principles which influence these actions. There are, however, many other variations which profess to be the result of observation and experience, but which are admitted to be altogether empirical, and of which no explanation is attempted to be given. Some of these were referred to in the first part of this article. Such are, for the most part, the different states of the pulse pointed out by Solano and his followers, and especially by Fouquet and Bor-

den. The greatest part of these we may unhesitatingly pronounce to be altogether without foundation; there are, however, some of them which are supported by such numerous and learned authorities that it would be improper to pass them by without noticing them a little more particularly.

It has been a favourite notion with many physiologists, ancient as well as modern, that diseases of the different regions of the body, for example, of the upper, the middle, and the lower, might be recognised by corresponding differences in the state of the pulse. But we may venture to assert that this doctrine is erroneous. The mere local situation of a disease can have no effect on the pulse, except as far as regards the distance of the organ from the centre of the circulation; while, on the contrary, wherever the morbid part be situated, it is easy to imagine that the function to which it is subservient, or even its texture and composition, may materially affect the condition of the circulation, and that this may possibly be detected by the state of the pulse. Antecedently to all experience on the subject, we might expect that an inflammation of any part connected with the brain or an organ of sense would produce a different effect upon the pulse from an inflammation of the lungs, and this again from a similar affection of the stomach or the intestines. We may farther conceive that an inflammation of a mucous, a serous, a muscular, or a membranous texture, would respectively impress a specific character on the circulation, as manifested by the pulse; but this will be altogether independent of the mere locality of the organ, and must be referred to a totally different principle. The idea which was long prevalent, of there being a connexion between the diseases of each side of the body and the pulse of the same side, would appear, in like manner, to be entirely without foundation.

There is, however, another set of causes which materially affect the pulse; these may be divided into internal and external. The internal are connected with the original powers or constitution of the body, or with its natural and ordinary progressive changes. Such are age, sex, temperament, and peculiar idiosyncrasies, the states of sleep and watching, of repletion and inanition, mental emotions of all kinds, and the revolution of the diurnal period. All the above are within the limits of health, and the catalogue is to be augmented by the long and melancholy train of morbid affections. Among the external causes are climate, temperature, various atmospherical changes, peculiarities of diet, modes of life, certain occupations and acquired habits. All these circumstances more or less affect the pulse, and cause it to deviate from what may be regarded as its medium or standard condition, and they are all of them objects of especial attention to the judicious and intelligent physician. The further consideration of these may, however, be more conveniently referred to the third division of this article.

III. *Pathology of the pulse.*—After having made ourselves acquainted with the physiology of the pulse, we shall be prepared for entering into the consideration of its pathology, and for inquiring into the degree in which it may serve us as an indication of the nature and seat of disease.

We have had ample occasion to remark upon the great difference of opinion that has existed on this latter point among the most eminent men both in ancient and modern times. While Hippocrates and Celsus paid but little attention to the indications of the pulse, Galen, on the contrary, fell into the opposite error, and aimed at what was considered, even by some of his contemporaries, as an excessive and over-refined minuteness. Among the moderns, the prevailing disposition has been to regard the pulse as one of the most important means of ascertaining the nature and progress of disease; and it may be asserted generally, that the pulse is among the first objects to which the practitioner directs his attention. Yet even among the most enlightened and candid of the moderns, we have opinions promulgated which must diminish the confidence we might otherwise be disposed to feel on this subject. We have seen above, that Dr. Heberden limits the characters of the pulse, which are available by the practitioner, almost to its different degrees of frequency; and with respect to its indications generally, the tendency of his observations is to show that the pulse is, in many cases, a very inadequate guide in enabling us to form our indications, and that not unfrequently it would lead us to absolutely erroneous conclusions.

In this state of uncertainty it may be useful to recur to first principles, and to endeavour to unite theory with experience and observation. If there be a state of the system in which the muscular contractility and the nervous energy are one or both of them increased, we might expect that an increased action of the heart would be the consequence, and that this increased action would be communicated to the arteries, and would, according to circumstances, produce a full, a hard, a frequent, or a quick pulse, or any combination of these conditions. If, on the contrary, the force of the heart be diminished, either directly by the diminution of its contractility, or indirectly by that of the nervous influence, the blood will be propelled with less force into the arteries, and will be moved with less facility along them. The pulse will then become languid or oppressed, feeble, small, intermitting, or irregular, according to the quantity of blood in the vessels, and the relation of this to the vital powers.

Proceeding, then, upon the united basis of theory and observation, it may be useful to consider, first, what characters of the pulse are the most distinctly perceived and clearly discriminated; and, secondly, to inquire what conditions of the vital powers or of the functions may be supposed capable of producing a distinct and specific change in the state of the pulse.

But before we proceed to examine into the relation which these various states of the pulse

pear to the different morbid conditions of the body, it will be proper to offer a few brief remarks on the effect of the circumstances alluded to above, which, independently of disease, are supposed, in a greater or less degree, to influence the circulation.

The first in point both of order and of importance is the age of the subject. The pulse of a newly-born infant is 130 or 140 in a minute, nearly twice as frequent as that of an adult; but its frequency soon begins to diminish, its mean rate during the first month being about 120. During the first year it falls to about 110; during the second year to about 100; from the third to the sixth year it may be estimated at about 90; and by the tenth or twelfth year it arrives at the state in which it remains for the greatest part of life. Numerous observations have been made for the purpose of fixing the average rate of the pulse in the healthy adult. This subject was particularly attended to by Dr. Falconer, and we find in his essay a copious collection of observations made by himself and others, in order to ascertain this point; the number which he fixes upon is 75, and there appears sufficient ground for acquiescing in his conclusion. It is further to be remarked that the pulse is more irritable in youth than in more advanced age, being more affected both by external and by internal causes.

With respect to the two sexes, it is generally admitted that the pulse of the female is more frequent than that of the male, perhaps eight or ten beats in the minute; it likewise resembles the pulse of youth in its liability to be affected by all those circumstances which influence the state of the circulation. An analogous observation may be made with respect to temperaments; in the sanguine temperament, where the constitution more resembles the state of youth and of the female, the pulse is more frequent and more irritable than in that of an opposite character. With respect to idiosyncrasies, it is obvious that no general remarks can be made; but it is important for the practitioner to be aware that individuals, who may resemble each other in all that respects age, sex, or temperament, may still have a different rate of the pulse, and this independent of any apparent morbid condition or assignable cause.

The states of sleep and watching, and more generally of rest and motion, very considerably affect the pulse. The observations that have been made on the pulse during sleep are not altogether uniform, but they tend generally to the conclusion, that the pulse becomes slower during this state. With respect to the effect of motion, every one is aware how much the pulse is increased in frequency by exercise of any kind; the degree of this increase being partly in proportion to the degree of exercise employed, and partly to the previous state of the constitution or the ordinary habits of the individual. On this subject, as well as on many other points connected with the mechanism of the pulse, we have a number of valuable observations by Bryan Robinson, a writer whose facts appear to be correct and worthy of our attention, although his physiological hypotheses are, for the most part, discarded.*

The state of the system with respect to repletion or inanition very materially affects the pulse. The taking of food increases both its frequency and its fulness, and that often in a very considerable degree. After a meal which cannot be regarded as excessive or intemperate, the pulse may be increased by one-fifth of its average number of beats, while its strength and fulness are almost equally augmented. When abstinence is carried to a great and unnatural excess, the pulse, although much diminished in strength, appears to be increased in frequency; but this occurrence can seldom be observed without the presence of some other disease, which is the immediate cause of the abstinence, and which would probably of itself affect the pulse.

Every one is aware how much the circulation is affected by mental emotions of all kinds. If we arrange them, according to the ordinary distribution, under the two great classes of exciting and depressing, we shall find that they, each of them, increase the frequency of the pulse; the former, however, for the most part, have the effect of also increasing its force, while the latter, on the contrary, render it more feeble.

It is generally admitted that the pulse undergoes a kind of periodical revolution during the course of the day, and this independent of any of those circumstances, external or internal, which might be supposed to affect it. This subject has been attended to by various physiologists, and among others by Bryan Robinson and Falconer, who have given us tables of the results of their observations. We are, however, scarcely able to draw any conclussions from them, except that the pulse is less frequent in the morning, and that it has a general disposition to become more frequent as the day advances; but it appears very difficult, if not impossible, to determine in what degree this increased quickness is to be attributed to food, exercise, or to other exciting causes.

We are still less able to draw any general conclusions respecting the operation of the external causes, which were enumerated above as liable to affect the pulse; it is less easy to observe their distinct and separate action on the system, and it may be apprehended that the operation itself is in most cases less uniform. If there be any exception, it is with respect to external temperature, which seems very generally to increase the frequency, and in most cases the strength and fulness of the pulse. Temperature, however, like all other stimulating agents, if carried beyond certain limits, either as to quantity or duration, exhausts the vital powers, and produces a state of weakness, which may be recognised by the pulse. Excessive cold exercises a directly debilitating power over the system, and produces a corresponding effect on the pulse.

* Treatise on the Animal Economy, 1732.

There is, however, a considerable diversity in the accounts which we have on this subject, in consequence of the difficulty there is in ascertaining the point at which cold may be considered as exceeding the limits of the salutary action which it exerts when in a moderate degree only. With respect to the other external causes which affect the pulse, we may remark that they are all of them points to which the practitioner should direct his attention, in order that he may learn to distinguish between the effects which proceed from these causes, and those which belong to the diseases under treatment.

To return from this digression to consider the characters of the pulse, the following may be enumerated among those which are the most distinct and unequivocal. In the relations of time, the pulse may be frequent or rare, quick or slow; in the relations of force, it may be strong or weak, hard or soft, full or small, free or compressed: in the third relation, of equality, we have the irregular pulse with respect both to time and force, with the varieties of each, the intermitting, the rebounding, the fluctuating or wavering pulse, &c.

In considering the changes that may be communicated to the pulse by a change in the action of the heart, we may remark that, of the two vital powers which contribute to this action, the nervous power is the one the most liable to variations, and the most under the influence of external agents; we therefore assume that, in most cases of increased or diminished action, the change originates in an affection of the nervous system. It hence becomes necessary to consider what are the laws which regulate the actions of the nervous system—at least, what are the changes in this action which are especially applicable to the case in question. Now there are two states of the nervous system recognised by physiologists, which must influence the action of the heart in such a way as to affect the frequency of the pulse; the first condition, which has been termed the increased mobility or excitability of the nervous system, the other a sedative operation, tending directly to diminish its action. The effect of the increased mobility of the nervous system is to render a part under the influence of the nerves more susceptible of action, while the force of the action is not proportionably increased; the operation of a directly sedative agency is to diminish the action of the parts in all respects, both as to susceptibility and to force. The diseases of hysteria and apoplexy, or rather the tendency to these diseases, may be cited as affording us, respectively, types of these two states of the nervous system; the former giving rise to frequent and irregular contractions of the muscles, the latter tending altogether to destroy their contractility. Hence we observe a foundation for what at first view might appear as contradiction, that a debilitating cause, acting on the heart, may in one case cause an increased, and at another time a diminished frequency of the pulse.

It is generally admitted by physiologists that a principle analogous to what has been described as occurring in the nervous system exists also in the muscular; that absolute force and susceptibility of action bear no necessary relation to each other, but that each of them may be increased or diminished without a corresponding change in the condition of the other. With respect to the pulse, however, it is admitted that we are, for the most part, unable to distinguish between the affections of the muscular and the nervous systems; consequently all that we can aim at is to ascertain in what manner or in what degree the morbid cause acts generally upon the powers which increase or diminish the susceptibility or force of the contractions of the heart.

It will be scarcely necessary to offer any remarks on the mode of feeling the pulse. We have, indeed, in some of the older writers, many minute directions on this subject, and in some French works, even of recent date, the "exploration" of the pulse is treated of in detail, as an elaborate art of difficult attainment. It no doubt requires accurate observation and minute attention to appreciate all the changes to which the pulse is liable, but there appears to be nothing in the subject of peculiar difficulty, or which will not be overcome by a due familiarity with the phenomena of disease. The anatomical structure of the part, and its practical convenience, render the artery at the wrist, in a great majority of cases, the most eligible part for ascertaining the state of the pulse; we may occasionally find it necessary to examine the artery in the neighbourhood of a part which is supposed to be the immediate seat of disease, and in some instances we compare the action of different arteries with each other; but these are points which scarcely require or admit of general directions.

What has been stated above bears immediately upon the second point which we proposed for consideration, viz. to inquire what condition of the vital powers or of the functions may be supposed capable of producing a distinct and specific effect upon the pulse, and what are the diseases which derive their distinctive characters from the changes consequent on these conditions. Now we shall find that the diseases in which the action of the heart is more immediately or directly concerned are those which we referred to the great class of febrile affections. These may be arranged under the two divisions of fevers that originate in, or are essentially connected with, increased action of the vital powers, and those which originate in a diminished action of these powers; the first constituting what is popularly termed inflammatory fever, the synocha or causa of systematic writers; the latter the low or nervous fever, the typhus of the nosologists. If to these we add a third class of diseases, which depend upon a directly sedative operation on the nervous system, nearly corresponding to the anæsthesiæ of the nosologists, we

shall have three great divisions, to which we may refer all the various changes in the state and condition of the pulse which can be easily reduced to any general principles.

We are now arrived at that part of the subject to which all the rest ought to be subservient, and which alone gives it its value—the practical application of our theoretical principles; yet, important as it is, on this occasion it must necessarily be passed over with a very slight notice. All that can be accomplished in an essay like the present, is to establish and illustrate certain general positions, which may be applicable to each particular disease, or even to each individual case,—a detail which would be inconsistent with the nature and the limits of our article, but which will be amply supplied by the other parts of this work.

The object of the practitioner is to ascertain, if possible, in the first instance, what is the ordinary state of the pulse of each individual, as depending upon his peculiar constitution or habits; and, secondly, how it may be supposed to be affected by the circumstances, either external or internal, which were enumerated above, and which are independent of the disease in question. In the third place, he must ascertain the state of the pulse with respect to its three principal relations of time, force, and equality, considered either simply or in combination, and endeavour to trace their connexion with the supposed cause of the disease, and with the derangement which has been induced in the various powers and functions of the system. These he will probably find it convenient to refer to one or other of the three great classes mentioned above, and he must regulate his practice, and form his diagnosis and prognosis by still farther viewing them in connexion with the other symptoms of the disease. The result of this process will be, that by referring to the physiological principles which we have attempted to establish, the practitioner will frequently be enabled to explain what would otherwise be obscure and unintelligible; yet it must be acknowledged, on the other hand, that he will meet with numerous anomalies which he will find it impossible to reduce to his system, and which can only be duly appreciated by a careful and diligent observation of the phenomena of disease, and by steadily preferring the result of experience to the deductions of any theory, however plausibly formed or ingeniously supported.

(John Bostock.)

PURGATIVES.—See Cathartics.

PURPURA.—The terms purpura, purpura hemorrhagica, and hemorrhœa petechialis, are employed to denote that affection which was formerly distinguished in medical writings by the designations of morbus maculosus hemorrhagicus, petechiæ sine febre, phœnigmus petechialis, *(Sauv.)* &c. This disease is characterized by an efflorescence on the skin, occurring independently of primary fever, consisting of red, purple, or livid spots of various sizes, (termed petechiæ, vibices, and ecchymoses,) and in its more severe form accompanied by hemorrhage from various parts of the body, chiefly from the mucous membranes. The spots are seldom elevated above the level of the surrounding cuticle; they are unattended by itching or any uneasy sensation; and on division of the cuticle by a scalpel they are found to consist of minute effusions of blood. They are therefore essentially different from every form of rash or other cutaneous eruption; and are properly considered as the result of a *cutaneous hemorrhage*.

Petechiæ (a name introduced into nosological language from the Italian *petecchia*, and supposed to be originally derived from their resemblance to flea-bites) have been long noted as a symptom in continued fevers and other febrile diseases, in which they have been supposed to indicate peculiar malignancy. (See the article Fever.) From their constant occurrence in certain epidemic fevers, these were considered as constituting a specific exanthematous disease, which was described in nosological systems and practical writings under the names of petechiæ, febris petechialis, febris purpurata, &c. The occurrence of petechiæ in continued fever, no less than in small-pox, measles, &c. is now universally allowed to be a contingent symptom, and most commonly arises from the influence of foul air, a hot regimen, the neglect of purgatives, or similar errors in treatment. It is accordingly much less frequent than formerly. *Petechial fever* is the "purpura" of Sauvages' nosology; a term which had previously been used in the same sense by Riverius, Diemerbroeck, &c. By others of the old writers it had been employed to signify affections totally different, viz. various forms of papulous eruptions and rashes, as red-gum, lichen, miliaria, nettle-rash, measles, and scarlatina.* We must therefore take care not to apply their observations to what is now termed purpura.

We owe the name of purpura in its present acceptation to Dr. Willan. In his nomenclature of cutaneous affections it is used as a generic term, to include every form of petechial eruption, febrile or non-febrile. He therefore includes under it, as a species, purpura *contagiosa*, the petechial eruption in continued fevers; a name every way objectionable, as it would tend to perpetuate the ancient errors of the idiopathic nature and specific contagion of those petechiæ. Under the names of *P. simplex*, *P. hemorrhagica*, and *P. urticans* he describes "three striking varieties" of petechial eruption independent of primary fever,—varieties which confessedly differ chiefly in degree, and which, under the general name of purpura, form the subject of the present article.

Purpura, considered by Willan as an affection of the skin, was ranked by him under the

* Willan on Cutaneous Diseases, p. 452.—Bateman, Synopsis, p. 103, (third edit.)

order "Exanthemata," or rashes, of his arrangement; to which it bears some affinity in external appearance only, but even in this respect does not agree with his definition of the order. Rayer has more correctly classed purpura (under the somewhat quaint name of hémacélinose*) under "Cutaneous and Subcutaneous Hemorrhages." But purpura cannot be correctly considered as merely a cutaneous disease, since, as Dr. Watson has well observed, "the effusion of blood (which, strictly a hemorrhage in all parts, takes the form of red or purple spots where the quantity effused is but a drop) is not confined to the skin nor to the subcutaneous tissues, but is observed occasionally on the internal surfaces also, and in the parenchymatous surface of the viscera. The disease, therefore, is properly a hemorrhage, but it is not properly, or merely, a cutaneous hemorrhage."

Purpura, considered as a hemorrhagic affection, is a most interesting subject of pathological inquiry, and demands peculiar attention from the danger which attends it, and from the obscurity which attaches to its nature and mode of cure. It has, therefore, ever since it was first distinguished from typhoid fever, attracted much notice from medical writers. For its earlier literary history, the reader must be referred to Dr. Willan's work, where he will find it amply detailed. Reference to the old writers can be of little avail for pathological and practical purposes. The first systematic account of the disease, under the name of hemorrhœa petechialis, was given in this country by Dr. Adair, in his thesis published in 1789. Dr. Bateman, in his inaugural dissertation published in 1800, described it under the same appellation. The description of purpura by Willan, in his Reports of the Diseases of London, and subsequently in his great work on Diseases of the Skin, is given with his usual perspicuity, but he was practically unacquainted with the severer cases of the disease, never having met with one which proved fatal. He considered the disease as nearly if not quite identical with scorbutus, and to be combated by similar remedies. These views were disputed by Dr. Parry and Dr. Harty, and were considerably modified by Dr. Bateman in his Synopsis. Since that period a succession of valuable and instructive cases have been published in the Edinburgh Medical and Surgical Journal, and a few in other periodical works.† Yet much remains to be done ere the pathology of purpura or its treatment can be considered as satisfactorily fixed on scientific principles.

Phenomena of the disease.—These may be referred to—1. appearances on the skin; 2. hemorrhages; 3. constitutional symptoms; 4. progress and duration of the disease; 5. circumstances noticed respecting the blood and the urine; 6. morbid appearances on dissection.

1. We have already given a general description of the efflorescence on the skin characteristic of purpura. There are three different forms of it, (well represented in plates xxvii. and xxix. of Bateman's "Delineations,") viz. the P. simplex, P. hemorrhagica, and P. urticans of Willan. The *P. senilis* of Bateman (figured in his 30th plate) is a nearly local form of ecchymosis, unattended with fever, hemorrhage, or other constitutional symptoms; we shall therefore refer to the "Delineations," and to the third and subsequent editions of the "Synopsis," for his account of it.

In the *purpura simplex*, the petechiæ are described by Willan and Bateman as occurring with little constitutional disorder. "They are most numerous on the breast and on the inside of the arms and legs, and are of various sizes, from the most minute point to that of a flea-bite, and commonly circular. They may be distinguished from recent flea-bites partly by their more livid or purple colour, and partly because, in the latter, there is a distinct central puncture, the redness round which disappears on pressure."* Purpura simplex is chiefly noticed in women and delicate children. It is thus described by Heberden:—"Cutis puerorum interdùm ubique distinguitur maculis purpureis, similibus earum quæ in febribus nascuntur. Tamen cum his adversa valetudo nulla est, neque præcessit, neque subsequitur. Aliæ *pustulæ* (scil. maculæ) vix sunt semine milii majores, aliæ sunt tres pollices amplæ. Post paucos dies cunctæ, sine medicamentorum auxilio, suâ sponte plerumque recedunt. In quodam puero sic affecto, si modò digitus leviter cuti imprimeretur, continuò sanguis ex vasis vicinis exiit, et sugillatio, tanquàm in collisis, facta est."† The latter circumstance is more frequently noticed in the next form of the disease.

In *purpura hemorrhagica* "the petechiæ are often of a larger size, and are interspersed with livid stripes and patches, resembling marks left by the stroke of a whip, or by violent bruises. They commonly appear first on the legs, and at uncertain periods afterwards on the thighs, arms, and trunk of the body, the hands being more rarely spotted with them, and the

† *Heberden*, Comment. cap. lxxviii. de maculis purpureis.

unk generally free. They are usually of a ight red colour when they first appear, but on become purple or livid; and, when about disappear, they change to a brown or yel- wish hue; so that, as new eruptions arise, id the absorption of the old ones slowly pro- eds, this variety of colour is commonly seen the different points about the same time. See Delin. plate xxviii. fig. 2.) The cuticle er them appears smooth and shining, but is ot sensibly elevated; in a few cases, however, e cuticle has been seen raised into a sort of esicles, containing black blood.... The gentlest ressure on the skin, even such as is employed feeling the pulse, will often produce a purple lotch like that which is left after a severe ruise."* The nature and seat of the small fusions of blood which constitute the pete- iæ, from which the vibices and ecchymoses ffer chiefly in magnitude, are well explained y the anatomical researches of Rayer. "On issecting the skin," he observes, "it is found at the petechiæ and ecchymoses do not all ccupy the same situation. Some are very perficial, and seated on the surface of the te mucosum; others occupy the alveoli of e cutis; the largest and darkest-coloured have eir seat under the skin in the cellular tissue. these the blood is found coagulated, but it fluid in the smaller and more superficial fusions. The vascular ramifications conti- uous to these minute ecchymoses are in their atural state. The blood is easily removed by ashing or maceration."†

The variety termed by Willan and Bateman *urpura urticans*, is comparatively rare. It is haracterised by "rounded and reddish eleva- ons of the cuticle, resembling wheals, but hich are not accompanied, like the wheals of rticaria, by any sensation of itching or ting- ng." These little tumours gradually dilate; ut within twenty-four hours or somewhat nger, subside to the level of the neighbour- g cuticle. They are commonly situated on e legs, where they are intermixed with pete- iæ; (see Delineat. plate xxix.;) they also ppear on the thighs, breast, arms, &c. The pots are not permanent, but fade, while others ppear in succession in different places. The uration of the complaint varies from three to ve weeks. Willan never observed it to be ttended with hemorrhage or fever; he states at it generally occurs in summer and autumn, nd attacks those who are exposed to daily tigue, &c., or young women who live luxu- ously and take little exercise. Some œdema f the extremities usually accompanies it, and is occasionally preceded by stiffness and pain the legs.‡

2. The hemorrhages attendant on purpura ke place from the mouth, nostrils, bronchial ubes, stomach, intestines, bladder, uterus,— short, from every part of the mucous mem- ranes. They also in some cases occur from e skin; at least this singular hemorrhage bears in some cases a close analogy to pur- pura. In all these cases the effect produced on the system is from the loss of blood; but where the hemorrhage is strictly internal, as from the serous membranes or the parenchy- matous substance of the viscera, the mischief is done by the mechanical compression or de- struction of the texture of organs essential to life. Both cerebral and pulmonary apoplexy may thus occur and destroy the patient; of which there are several cases on record.

The most frequent hemorrhage, particularly in weak subjects, and where there is an ap- proach to what has been termed the scorbutic diathesis, is that from the mouth. The gums are tender, and easily bleed on being touched. The lining membrane of the inside of the lips and cheeks, the investing membrane of the tongue, and also in some cases that which covers the tonsils and contiguous parts, pre- sent dark-coloured spots, which are usually elevated and distended with blood, which they pour out either spontaneously or on the slightest pressure. In some very unfavourable cases (as that related by the late Dr. Duncan*) these spots degenerate into gangrenous ulcerations.

The tendency to the several kinds of hemor- rhage varies at different periods of life: ac- cording to Rayer, epistaxis is the most common in children, as might be expected; uterine he- morrhage in women; and pulmonary or intes- tinal hemorrhage in male adults. The quantity of blood lost is often very considerable; and, as in other cases of hemorrhage, it is very apt to recur, and to become periodical. A case is mentioned where it returned daily at the same hour for a considerable period.

3. We have already stated that the constitu- tional symptoms are usually but slight in the varieties of the disease termed P. simplex and P. urticans. In both of these forms, occurring without hemorrhage, considerable febrile excite- ment has been observed in some cases. With regard to P. hemorrhagica, the following account of the preceding and accompanying symptoms is given by Bateman: "This singular disease is often preceded for some weeks by great las- situde, faintness, and pains in the limbs, which render the patient incapable of any exertion; but not unfrequently it appears suddenly, in the midst of apparent good health. It is always accompanied by extreme debility and depres- sion of spirits; the pulse is commonly feeble, and sometimes quickened; and heat, flushing, perspiration, and other symptoms of slight febrile irritation, recurring like the paroxysms of hectic, occasionally attend. In some pa- tients, deep-seated pains about the præcordia, and in the chest, loins, and abdomen, have been felt. In others, a cough has accompa- nied the complaint, or tumour and tension of the epigastrium and hypochondria, with ten- derness on pressure, and a constipated or irre- gular state of the bowels. But in many cases no febrile symptoms have been noticed; and the functions of the intestines are often natural. In a few instances frequent syncope has oc-

* Edinburgh Med. Journal, vol. ix. p. 405.

curred. When the disease has continued some time, the patient becomes sallow, or of a dirty complexion, and much emaciated; and some degree of œdema appears in the lower extremities, and afterwards extends to other parts."* This is a very faithful general account; but in several of the cases which have been recorded, the febrile symptoms, and those indicative of internal affections of the congestive or inflammatory kind, have been much more considerable than we should collect from Dr. Bateman's statement. Such affections are considered by Rayer as always constituting an "accidental complication" of purpura; and he says that it is only in such cases of accidental complication that he has seen it present the characters of active hemorrhage.† On the other hand, it is to be observed that the mode of treatment which has been directed to the relief of the internal symptoms, has in several well-marked cases procured the cessation of those proper to purpura; an effect which has also not unfrequently occurred from a profuse eruption of the catamenia,‡ or from a hemorrhage which has appeared to be, in the language of the schools, critical. This subject, however, will more properly come to be considered under the heads of pathology and treatment.

4. "The purpura hemorrhagica," observes Willan, "has not any regular or stated termination. It was protracted, in the cases under my own observation, from fourteen days to twelve months and upwards. The disease did not, in any of these cases, prove fatal."§ In some cases the disease has proved fatal from internal or external hemorrhage, or the violence of the febrile symptoms, or prostration of the vital powers, in a shorter time, considerably, than the former period mentioned by Willan. In others it has assumed a completely chronic form, and either recurred periodically, or as to some of its symptoms been more or less constantly present. Several well-attested cases are recorded where it has appeared to be linked in an inexplicable manner with the mode of existence of the individual, and put on the character of what are properly called "constitutional hemorrhages." (See Hemorrhage.) In such cases, it has existed for years without impairment of the general health. A boy is mentioned by Bateman on the authority of the elder Dr. Duncan, whose skin for several years was constantly covered with petechiæ, and exhibited vibices or purple blotches on the slightest blow; yet he was in other respects in good health, and capable of active exercise. Pulmonary hemorrhage at length supervened, and carried him off.‖ A case is related by Adair, where the symptoms of purpura recurred regularly for six succeeding summers.¶

5. We have not been able to meet with any account of the chemical analysis of the blood in a case of purpura. Its sensible qualities, however, and mode of coagulation have been carefully noted in several cases. Dr. Watson asserts that "in many, perhaps in all instances of the disease, in which it can be examined, the blood is found actually to have undergone a change, and not merely a change which may be ascertained by nice or elaborate chemical research, but such an alteration of its sensible qualities as is evident to the eye, and forces itself upon our notice."* The inquiry into the state of the blood is certainly one of the highest interest, both with regard to the pathology of this disease in particular, and as it bears upon the general doctrines of pathological science. But in pursuing it we must be careful to keep in view the causes which, independently of any primitive alteration in the state of the blood existing as the cause of all the phenomena of purpura, may materially affect the condition of that fluid. The co-existence of fever or inflammation will, of course, give rise to those alterations in the blood which are proper to those morbid states; accordingly we find it stated by Dr. Parry, that in both his cases the blood was highly buffed, the crassamentum firm and cohesive, but bearing a small proportion to the serum.† In other cases where the blood has been examined, there had previously occurred either very profuse or long-continued hemorrhage, which necessarily altered the quality of the blood by diminishing the quantity of the red globules as well as of the fibrine of the blood in proportion to the serum. Our conclusions ought, if possible, to be derived from the examination of blood drawn at the height of the disease, when no excessive hemorrhage has preceded, and in cases where there are no decided marks of inflammation or other disease co-existing with purpura.

Some of the most remarkable results of the examination of the blood in purpura have been the following. In the case of a sea-captain, a plethoric subject with a full pulse, the state of the blood obtained by a *second* venesection, and when purgatives had been prescribed, and two pounds of blood previously lost by epistaxis, is described by Dr. Jeffreys as follows: "The blood drawn yesterday shews an inflammatory buff on its surface, at least an inch and a half in thickness, firm and yellow, far exceeding any thing I ever saw in rheumatism or pneumonia, but not at all cupped; in fact, the whole serum looks like a corrupted coat of coagulable lymph. The crassamentum appears in a very dissolved state, of nearly a black colour, and much less in quantity than usual."‡ This patient was again twice bled, the blood presenting the same appearances; he ultimately recovered. In a case related by Dr.

Johnston, of decidedly febrile character, and which rapidly proved fatal, the blood did not separate into serum and crassamentum; it had little consistence or tenacity, but traces of coagulable lymph were diffused through it.* In Dr. Duncan's case, which has been already quoted, the blood, while flowing slowly from the vein, was observed to be florid and semi-transparent, resembling diluted arterial blood. It slowly formed a loose coagulum, from which no serum was separated; the coagulum was like jelly, tremulous, transparent, and colourless, the few red globules having subsided to the bottom. In this case much blood had been previously lost by hemorrhage.† In Dr. Combe's case the blood was pale, coagulated slowly, separated no serum, and was not buffed.‡ In Dr. Gairdner's the blood first drawn by the lancet seemed, four hours after, to coagulate very imperfectly into a homogeneous mass. On the following day it resembled a tremulous jelly, the top of which was of a greenish buff colour with brownish spots like tadpoles. What afterwards oozed from the puncture resembled turbid lymph, or a watery fluid containing colouring matter in suspension; the cloths taken from the arm appeared as if stained with bloody water.§ In Dr. Fairbairn's case the blood first drawn resembled that described by Dr. Duncan and Dr. Combe; on a second bleeding it presented the same appearances; but on the third it shewed the buffy coat, coagulated somewhat more firmly, and separated a portion of serum.‖

The state of the urine has been less attentively noticed, or at least less frequently. We possess, however, the accounts of two cases in which the urine has been analysed. At the conclusion of Dr. Combe's case, which we have just referred to, the results of the analysis of the urine are stated, at the height, during the decline, and after the cessation of the disease. At the height of the disease, and previous to venesection, the urine was found to contain a large proportion of serosity and of the phosphates, no free acid, and but a small proportion of urea. When the force of the disease had been broken, and the hemorrhage had ceased, there was no longer any albuminous matter, but a free acid, and but a small proportion of urea. Finally, when the patient was convalescent, the analysis of the urine detected no ingredients differing from its healthy condition. In Dr. Gairdner's case, also above referred to, the urine, on analysis by Mr. Murray, shewed a deficiency of urea and an excess of albuminous matter. For the chemical details we must refer to the original cases. In Dr. Blackall's work on Dropsy, several cases are related "resembling land-scurvy," two of which, at least, are clearly cases of the hemorrhagic purpura, in which the attack was sudden and attended with febrile symptoms. In both these cases the urine was albuminous, and Dr. B. states his opinion that "venesection would have been their appropriate remedy; in the early stage, probably a successful one."

6. The appearances which are exhibited by the skin on examination after death have already been noticed. Of the morbid alterations discovered in the internal organs we possess a tolerable number of histories, recorded with various degrees of minuteness.*

The chief morbid appearances which have been noticed in the three great cavities, have been the following.

In the *head*. In a case transcribed by Rayer† from Stoll, the meninges of the brain, especially on the left side, were spotted with several large ecchymotic maculæ; some ecchymoses, resembling clots of extravasated blood, from the size of a lentil to that of a bean, were also found in the convolutions of the brain. The surface of the ventricles, and that of the cerebellum, were covered with innumerable small petechiæ; the left ventricle was distended with straw-coloured serum. The girl who was the subject of this case had died comatose, having previously suffered severely from headach (which chiefly affected the left side); she had high fever, petechiæ, and hemorrhage from the mouth. In Dr. Walsh's case‡ of a soldier previously in good health, who died apoplectic on the fourth day from the supervention of purpura hemorrhagica, besides the impression of petechial spots on the pericranium, and an ecchymosis of the right temporal muscle, a considerable coagulum (a table-spoonful) was found pressing on the brain, and the vessels of the pia mater were turgid with black blood. In Mr. Wood's case§ the pericranium and dura mater were covered with petechial spots, and "in the right temporal region a fine coagulum, floating in bloody serum, had forced its way through the broken-down brain into the ventricle." Similar effusions of blood on the brain were observed in two cases by Dr. Watson.‖

In the *chest* the following appearances are noticed by Rayer as characteristic of this disease. "The outer surface of the lungs is commonly speckled with numerous ecchymoses, which are the more distinctly visible, that the surface of the lung in the intervals retains its natural hue. Beneath each of these ecchymotic spots the tissue of the lung is of a uniform brownish-red colour, is firmer in its texture than the surrounding healthy lung, and presents a circumscribed engorgement, from which, on pressure, black blood is squeezed out—a morbid alteration quite analogous to the hemoptysical engorgements described by Laennec." Similar petechial spots are also found

on the surface of the heart, on the pleura, &c. The other morbid changes noticed in the thorax are not so characteristic, being common to other diseases. Such are the effusions of serous or sero-sanguineous fluid very commonly found in the cavities of the pleuræ or pericardium, or in the cellular tissue of the lungs. In one case (Dr. Johnston's) the heart is stated to have been small, pale, and easily lacerable. In some cases it has contained fluid blood, or pink-coloured gelatinous coagula in some of its cavities. The pericardium, in one case, and the inner membrane of the aorta in another, shewed a blush of redness. In a boy who died ten days after the supervention of purpura, Dr. Bateman found a large firm tumour occupying the situation of the thymus gland; this tumour, which must have been of slow growth, had not perceptibly affected the respiration or impaired the general health. Tubercles of the lungs were found in a case mentioned by Rayer;* and pulmonary tubercles, and the marks of chronic inflammation of the substance of the lungs, were met with in another case in a child seven years old. But this case, in which petechial spots and epistaxis supervened only on the day of the child's death, and as a symptom of impending dissolution, ought not to be taken as a fair instance of purpura.

In the *abdomen* petechial and ecchymotic spots are often found throughout a considerable tract of the mucous membrane of the alimentary canal, especially in the stomach, duodenum, and upper part of the small intestines, but sometimes also in the colon. Similar spots are also met with underneath the serous membranes, as betwixt the folds of the mesentery, and under the peritoneal covering of the viscera. Dr. Fairbairn found the cardiac extremity of the stomach emphysematous, (which did not arise from putrefaction,) the liver and spleen somewhat softened, and a bloody fluid could be squeezed from their substance; one kidney was also softened. A case is related by Dr. Bateman, where the spleen had been felt during life nearly as low as the spine of the ileum, and after death was found enormously enlarged.†

Predisposing and exciting causes.—Purpura generally may be stated to be rather a rare disease; it is especially so in its more severe forms. The purpura simplex most commonly affects children; cases resembling purpura urticans, but often presenting anomalous symptoms, occur chiefly in young women. Of seventeen cases of purpura hemorrhagica, which were all that Dr. Willan had met with, two only were men, nine women, three boys, and three infants under a year old; four of the women were above the age of fifty. The proportion of male adults is considerably greater in the cases which have been recorded subsequently to the publication of Willan's work, especially in the severe and fatal cases.

Willan, Bateman, and Rayer agree in stating that purpura chiefly occurs in individuals of delicate habit, or enfeebled by their occupations or mode of life; by confined, low, or damp habitations, scanty food, hard labour, grief, anxiety, fatigue, and watching; or who have suffered from acute or chronic disease. In a case mentioned by Willan, it ensued on excessive drinking of undiluted spirits.* In a fatal case which occurred to Bateman, it came on during a severe salivation, accidentally induced by a few grains of mercury.† A remarkable case is related in the appendix to Adair's Thesis, of a Hampshire farmer, aged 34, who was hereditarily predisposed to insanity, and becoming affected with religious melancholia, refused all food and drink except bread and water. After having some time subsisted on this diet, symptoms of purpura or scorbutus supervened; viz. petechiæ all over the body, accompanied by remarkable roughness of skin, a large ecchymosis above the right ham, gums tender, swollen, and bleeding, legs œdematous, pale dejected countenance, great debility, stiffness of the joints, (which preceded the petechial eruption,) oppressed respiration, bowels costive. This patient recovered under the use of vegetables and ripe fruits, for he could not be persuaded to take animal food.

On the other hand, purpura frequently occurs where no causes of a debilitating or depressing nature can be supposed to have existed; in persons in the prime of life, in the easy and opulent classes of society, breathing a pure air, and enjoying the necessaries and comforts of existence. "This circumstance," observes Bateman, "tends greatly to obscure the pathology of the disease; for it not only renders the operation of the alledged causes extremely questionable, but it seems to establish an essential difference in the origin and nature of this disorder from that of *scurvy*, to which the majority of writers have contented themselves with referring it. In scurvy, the tenderness of the superficial vessels appears to arise from deficiency of nutriment, and the disease is removed by having recourse to wholesome and nutritious food, especially to fresh vegetables and to acids; while in many cases of purpura the same diet and medicine have been taken abundantly without the smallest alleviation of the complaint .... In other cases, where a residence in the country, and the circumstances of the patients necessarily placed them above all privation in these respects, the disease appeared in its severest degree."‡

Pathology of purpura.—If the opinion just adverted to of the identity of purpura with true scurvy were admitted, it would not be necessary to enter into any particular inquiry respecting the pathology of the former disease, as distinct from scorbutus. Dr. Willan seems to have entirely acquiesced in that opinion. "I consider it (purpura), under all the forms described, as pertaining to the scurvy; though it is not always attended with sponginess of the gums and a discharge of blood from them, according to the definition of scorbutus in noso-

ogy."* Into the nature and causes of scorbutus we are not to enter in this place; not only because we can say nothing satisfactory of a disease which we have never seen, and which is now happily rarely to be met with even by naval practitioners, but because it will form the subject of a separate article in this work. We are, however, inclined to acquiesce in the opinion of Bateman and of most succeeding writers, that purpura (at least many cases of it) is distinct in its nature, causes, and mode of treatment, from the true scurvy described by Lind, Trotter, &c. and as we conceive there can be no doubt of the truth of Cullen's doctrine, "that there is one disease only entitled to the name of scurvy; that it is the same by land as upon the sea, depending every where upon the same causes,"† it appears to us that the name of *land-scurvy*, as a synonym for purpura,‡ is improper, and calculated to lead to an erroneous notion of the latter disease.

The late Dr. Duncan enumerates the following as the possible modes in which he conceives the phenomena of purpura might be produced:—1. increased tenuity of blood, allowing it to escape from the extremities of the capillary arteries; 2. dilatation of the mouths of these arteries, allowing natural blood to escape; 3. tenderness of the coats of the minute vessels, giving way from the ordinary impetus of the blood; 4. increased impetus of the blood, rupturing healthy vessels; 5. obstruction in the vessels causing rupture; 6. two or more of these causes acting simultaneously or successively. But he acknowledges that he cannot reconcile any of these suppositions with the phenomena of the disease.§ Other recent writers equally confess their ignorance of its true pathology. Of the intimate nature of the process by which the blood is poured out at once from the capillaries of the cutaneous surface, and of the internal organs, we must probably be content to remain ignorant, until the *physiological* action of that important part of the vascular system shall be better understood than it is at present. Many processes, both natural and morbid, are not more explicable than the occurrence of petechiæ, either as a symptom of fever, or from other causes; and especially the process of *hemorrhage by exhalation*, of the close connexion of which with the phenomena of purpura there can be no doubt.

The most striking peculiarity of purpura, considered as a hemorrhagic disease, is the *universality* of the hemorrhagic tendency, whereby the blood is poured out not only from the various mucous membranes, at least from several of these outlets, simultaneously or in succession, but is also effused into the textures of the skin and cellular membrane, forming petechial spots, and occasionally into the serous cavities or the texture of the solid viscera. It is, therefore, a very probable, if not a certain conclusion, that the immediate cause of these phenomena is one affecting the whole system; and none seems so probable, or so well accords with the phenomena, as *an alteration in the composition and vital properties of the blood.* When we take into consideration the analogy which subsists between the phenomena of purpura and those of petechial fever on the one hand, and of cachexy, passive hemorrhage, and scorbutus on the other, it is highly probable that a similar cause is in operation in all these cases. In scorbutus it is generally admitted that the composition of the blood is vitiated. That a change both in its composition and its vital properties is intimately concerned in the production of the phenomena of fever, is a conclusion the proofs of which are rapidly accumulating upon us. (See the articles Fever, and Morbid States of the Blood, in the present work.) We have, therefore, strong analogical grounds for believing that a like cause is productive, at least in some cases, of that assemblage of symptoms to which we give the name of purpura. The proofs of this opinion will be found fully and very ably developed in Dr. Watson's Lecture on Purpura,* to which we refer the reader.

The third hypothesis suggested by Dr. Duncan, viz. weakness or frangibility of the coats of the capillary vessels, has several facts to support its probability, and especially the tender state of the gums, and the readiness with which blotches and ecchymoses are produced in some cases by the slightest pressure on the skin. Such a state may co-exist with a primary diseased condition of the blood, and may be induced by the circulation of such blood through these vessels, which is not improbable; though, as Dr. Watson has suggested, the relation of cause and effect may be different from this: "It is easy to imagine that some derangement (of the nature of which, supposing it to exist at all, we know nothing) in that part of the circulating system which is strictly capillary, and in which those changes take place whereby the blood, from being scarlet or arterial, becomes purple or venous, should modify or interfere with the change itself, and so come to affect the quality of the blood."†

But to whatever conclusion the pathologist may come on these points, it cannot affect the practical fact, that purpura is not unfrequently connected with a state of the system at large, or of particular organs, which not only will bear, but requires depletory measures for its removal, and which renders the use of tonic and stimulant remedies improper and dangerous. Of this the recorded cases of the disease supply abundant evidence. "The rapidity of the attack," observes Dr. Bateman, "the acuteness of the pains in the internal cavities, the actual inflammatory symptoms that sometimes supervene, the occasional removal of the disease by spontaneous hemorrhage, the frequent relief derived from artificial discharges of blood and from purging,—all tend to excite a suspicion

that some local congestion or obstruction is the cause of the symptoms in different instances."*

Diagnosis.—The diseases with which purpura is most likely to be confounded are, typhous fever attended with petechiæ, and scorbutus. Where the symptoms denoting purpura are accompanied by febrile symptoms of some intensity, it may become a question whether the purpura or the fever be the primary disease. The origin and course of the complaint, the period at which the petechiæ appear, the extent and the variety of the accompanying hemorrhages, will enable the practitioner to judge of the nature of the case. With regard to scorbutus, that disease is now fortunately seldom if ever to be met with in its genuine form. Cases of petechial efflorescence attended with hemorrhage and signs of great general debility, without any febrile or inflammatory symptoms, may be considered by some practitioners as properly belonging to scurvy; and if they occur in patients who have been much exposed to the influence of debilitating causes, the tonic treatment appropriate to that disease, and especially pure air and an improved diet, will generally be beneficial.

Prognosis.—In the milder cases of purpura, which are unattended by hemorrhage, by any considerable febrile symptoms or organic disease; or where the hemorrhage is slight, or attended with amelioration of the symptoms; a favourable prognosis may be formed. But when much blood is lost by the profuse occurrence or long continuance of hemorrhage, or where there are symptoms of serious internal congestion or inflammation, high fever, or great depression of the vital power, the prognostic is unfavourable. Even in chronic and *constitutional* cases a guarded prognosis should be given, and the danger of the supervention of fatal hemorrhage should not be lost sight of.

Treatment.—While the older doctrines prevailed, which ascribed the symptoms of purpura solely to debility of the solids and attenuation of the blood, a tonic and invigorating treatment was universally recommended. The mineral acids, cinchona, and wine, comprehended the whole medicinal treatment; these, however, were acknowledged to be often merely palliative, and to have little effect in producing a radical cure.† The same remedies are alone mentioned by Willan, who at the same time insists strongly on the importance of pure air, exercise, good diet, and whatever may tend to produce cheerfulness and serenity of mind.‡ Willan's experience of this disease had not been extensive; and in particular its more severe and fatal forms had not occurred to him. The publication of his opinions respecting this disease and its treatment called forth the observations of Dr. Parry on the utility, in some cases, of venesection.§ Dr. Harty and Dr. Bateman subsequently called the attention of the profession to the benefit to be derived from the employment of purgative medicines. Dr. Harty having experienced a complete failure in a case of purpura hemorrhagica which he treated strictly according to the plan of Willan, with every advantage of country air, nourishing diet, and tonics, had his attention turned to the functions of the alimentary canal in this disease. In a seemingly very unfavourable case of purpura hemorrhagica, in a tedious and obstinate case of purpura simplex attended with fever and headach, and in nine others, he employed brisk purgation with decided success.*

Dr. Bateman, after admitting that in slighter degrees of purpura, occurring in women and children who have been under the influence of close air, want of exercise, and other debilitating causes, the tonic plan, as recommended by Willan, may be adequate to the cure of the disease, adds:—"But in adults, especially those already enjoying the benefits of exercise in the air of the country, and who have suffered no privation in respect to diet; or when it appears in persons previously stout, or even plethoric; when it is accompanied with a white loaded tongue, a quick and somewhat sharp, though small, pulse, occasional chills and heats, and other symptoms of feverishness, however moderate; and if at the same time there are fixed internal pains, a dry cough, and an irregular state of the bowels,—symptoms which may be presumed to indicate the existence of some local congestion,—then the administration of tonic medicines, particularly of cinchona, wine, and other warmer tonics, will be found inefficacious, if not decidedly injurious. In such cases, free and repeated evacuation of the bowels, by medicines containing some portion of calomel, will be found most beneficial. The continuance or repetition of these evacuants must, of course, be regulated by their effects on the symptoms of the complaint, or on the general constitution, and by the appearance of the excretion from the intestines. If the pains are severe and fixed, and if the marks of febrile irritation are considerable, and the spontaneous hemorrhage not profuse, local or general bloodletting may, doubtless, be employed with great benefit, especially in robust adults."† We have given Dr. Bateman's practical directions at length, because little has been added to them by subsequent writers, except in the way of illustration. We apprehend that in very few cases will tonics be requisite or admissible, at least at the commencement of the disease. We have seen them do evident mischief, even in children of delicate frame, in whom the cautious but effectual employment of laxatives and a mild antiphlogistic regimen have afterwards effected a cure. From the manifest success of purgatives, and especially calomel, in the congestive form of typhous fever attended with petechiæ, practitioners have learned not to be deterred by the symptoms of apparent debility from employing this most useful class of remedies in such fevers; and in purpura, notwithstanding similar signs of prostration of strength, they are no less efficacious.

Venesection is a more hazardous remedy, and requires greater discrimination as to the cases and period of the disease in which it may be employed with safety and advantage. In the circumstances pointed out by Bateman, and especially where there is hardness of pulse and fixed local pain, there can be no doubt of the propriety of having recourse to it, especially at an early period of the disease. But we must be very cautious not to push it too far, or employ it too late to be of benefit. Dr. Mackintosh informs us that he lost a patient some hours after she had been bled; and the subject of Dr. Fairbairn's case, though a strong man in the prime of life, never rallied after the third bleeding. Dr. Fairbairn candidly confesses that he doubts whether the bleeding was not carried too far. In other cases which have been treated by venesection, but where, from the symptoms of debility or supposed putrescent tendency, wine and other stimulants have been administered, it is much to be suspected that these have proved injurious, and that if a mild antiphlogistic regimen had been trusted to, the result might have been more satisfactory.

In conclusion, we may sum up by observing that, in the treatment of cases of purpura, we are not to be guided by the name or the external appearances of the disease, but by diligent attention to the symptoms, and especially to the state of the functions, and the habit and constitution of the patient. Where high excitement prevails, with strength of pulse and vigor of constitution, and we have reason to suspect inflammation, or an approach to it, venesection and free purging, with a suitable antiphlogistic diet, are the appropriate remedies. Where a quite opposite state exists, extreme languor and debility, pale cachectic complexion, small and weak pulse, and much hemorrhage has occurred, all active depletion must be abstained from, and the strength supported by beef-tea and other mild nutriment, while sulphuric acid, and perhaps divided doses of quinine, may be resorted to. In intermediate cases, a mixed treatment must be adapted to the exigencies of the particular case by the discrimination of the practitioner. It will be often much safer in such cases, where any doubt exists as to the proper plan of treatment, to adopt one almost purely negative, as saline diaphoretics and a mild antiphlogistic diet, (paying due attention to the bowels,) than to have recourse to any extreme measures.

Local hemorrhage, when trifling in its amount and occurring early in the disease, it may not in all cases be advisable to interfere with. It has in several well-attested cases appeared to be a salutary effort of nature, and has removed the symptoms of the disease. Where the hemorrhage is protracted, or dangerously profuse, the usual means (pointed out in the article Hemorrhage, and in those which treat of the individual hemorrhages) must be had recourse to to arrest it; and of these there is none so generally efficacious as the application of cold.

Some particular modes of treatment have been recommended in this disease, of which we cannot speak from experience, and therefore we shall merely refer to them. The oil of turpentine was employed with success by Dr. Nicholl in several cases of purpura unattended with fever, and which he conceived to depend on mere relaxation of the extreme vessels. A successful case of its employment has since been published by Dr. Magee; but it should be noticed that both these physicians employed it in combination with laxatives. Dr. Mason Good and Dr. Mackintosh recommend the vegetable acids in purpura, in preference to the mineral; the latter especially speaks in favour of "fresh lime-juice, not only taken internally, but applied externally." Spirit-lotions, or a solution of chloride of lime, or cloths dipped in vinegar and water, are advised by Rayer to be applied to those parts of the skin which are spotted with petechiæ and ecchymoses; we confess we do not understand on what principle.

Dr. Belcombe, Physician to the York County Hospital, has recently applied with success to this disease the principles of treatment which Dr. Stevens has advocated in certain diseases conceived by him to depend on a morbid deterioration of the blood, and especially in the fevers of hot climates and in epidemic cholera, namely, the administration of neutral saline remedies, not intended to act as cathartics. In a decided and severe case of purpura hemorrhagica, in which Dr. Belcombe adopted this treatment, according to the formula of Dr. Stevens, (bicarbonate of soda 3ß, muriate of soda 3i, chlorate of potass gr. vii.;) the result was the recovery of the patient; and in two other cases of petechial eruption which have since occurred to him, he has had recourse to it with the same success.

(George Goldie.)

PUS, (from πύον, *matter,*) a yellowish-white, bland, cream-like fluid, having a sweetish taste and faint smell, heavier than water, (Sp. gr. about 1.03,) found in abscesses, on the surface of ulcers, and occasionally deposited on free surfaces, or in the tissue of organs.

An account of the various opinions entertained of its formation, as well as a description of its physical and chemical properties, will be found under Abscess, Inflammation, and Suppuration.

(A. Tweedie.)

PYLORUS, DISEASES OF.—See Stomach.

PYROSIS, (Gr. πύρωσις, *burning, inflammation;* from πυρόω, *to burn;* th. πῦρ, *fire.*)—This is the generic name of a disease adopted into their nosological classifications by Sauvages, Sagar, and Cullen, and, according to the definition of the last mentioned writer, synonymous with the cardialgia *sputatoria* of Linnæus and Mason Good. Sauvages has defined it, "Sensus ardoris in ventriculo et œsophago sine febre acutâ;" and Sagar, "Ardor œsophagi ad ventriculum usque extensus sine febre, vulgo soda dicitur;" both corresponding to the character of soda in the system

of Vogel, formerly a common but now obsolete name for *heartburn*. But the peculiar combination of symptoms which the early writers on medicine had included in their general descriptions of gastric disorder, particularly under the term cardialgia, and which previous nosologists had classed as one of several species of the same genus under the generic name of pyrosis, Cullen was the first to consider as the indications of a distinct idiopathic disease, which he separated accordingly, and placed in his class Neuroses, and order Spasmi, with the following definition, "epigastrii dolor urens cum copia humoris aquei, plerumque insipidi, aliquando acris, eructata." Such has been the general and limited acceptation of the word pyrosis in this country since the time of Cullen, and the signification we attach to it in the present article.

This form of disease is known in England by the popular name of *black-water*, and in Scotland by that of *water-brash*. It is most frequently to be observed amongst the poor, but sometimes, though rarely, in persons of more fortunate condition in life. In Scotland, Lapland, and Iceland, it has been observed to be endemic, and probably is a prevailing disease in many other countries; in England it is strictly sporadic. The subjects of it are most commonly persons under middle age: it seldom appears before puberty, and very rarely in advanced life. Females are more often affected with it than males, sometimes during pregnancy, and occasionally it seems incidental to this state, subsiding when it terminates, and recurring with its repetition. It most frequently, however, occurs in the unmarried; and of the married, most frequently in those who have never been pregnant: in many instances it appears when leucorrhœa has been present. Having once taken place, it is apt to return for a long time after; and though often extremely difficult to cure, is seldom if ever directly attended with danger to life.

The causes by which it has been induced have never been satisfactorily determined; but the facts of its endemic occurrence, its almost exclusive prevalence among the lower classes of the community, even where it is only sporadic, as in this country, and regard to the functions of the particular organ which appears to be chiefly implicated, have raised a prevailing belief that the ingesta have a powerful influence on its production. It was remarked, however, by Cullen, that he had not observed its occurrence in connexion with any particular diet, and that persons using animal food were subjects of it, although he thought more frequently those whose subsistence was milk and farinaceous substances. In Scotland, however, (the field, be it remembered, of Cullen's observations,) unfermented meal forms the bulk of the diet of the poor; and up to the present time the same substance in the form of oat or barley cake has stood as an article in the diet of the great mass of the people, in the same relation as wheat-bread to the diet of the people of this country. The similar use of other articles of food defective in its nutritious quality, and difficult of digestion, has been commonly observed to precede its occurrence, and in those whose idiosyncrasy predisposes them to be so affected, (a condition of which we acknowledge our entire ignorance,) all those circumstances which obstruct the natural functions of the stomach are, more or less, conducive to the development of pyrosis.

In some instances the use of indigestible substances has appeared to us to have been an *exciting* cause of the attack; but those which are most generally considered so, are suddenly diminished temperature, particularly in the application of cold to the feet, and extraordinary emotions of the mind.

The paroxysms of pyrosis, according to Cullen, (whose description of the symptoms has been considered most faithful,) usually come on in the morning and forenoon after food has been abstained from for some hours, though in our experience the period has not uncommonly been two or three hours after dinner: its first symptom is a pain at the epigastrium, described as that of extreme heat (emphatically called by the French *fer chaud,*) with a sense of constriction, as if the stomach were drawn towards the back, the pain being greatest when the body is in the erect posture, and causing it to be bent forwards; it is often very severe, and after continuing for some time is followed by an eructation of thin fluid, varying in quantity, but in appearance always resembling water; to the taste it is often absolutely insipid, but sometimes extremely sour. Though apparently the occasion of a sense of extreme heat in the stomach and œsophagus, the ejected fluid in passing through the mouth occasionally impresses it with an opposite sensation of cold in a very remarkable degree. The eructation is frequently repeated, and the pain which preceded it does not immediately cease, but does so after a time, and terminates the paroxysm. These paroxysms vary in their duration, both in the same and in different individuals, recurring often successively every day for a considerable time, and sometimes intermitting for one or several days, but always with great irregularity. Cullen has declared that pyrosis is often unattended by any symptoms of dyspepsia, but the remark is not only inconsistent with his own definitions of the two diseases and his observations upon them, but (we presume to say) with general experience. That the symptoms vary in number and degree we doubt not, but their entire absence we conceive to be extremely rare: one which has appeared to us to have been almost invariably present has been pain at the epigastrium immediately consequent to swallowing any ordinary food. We are, moreover, without proof or reason of probability that the morbid condition of the stomach which gives rise to pyrosis differs in any essential degree from that which occasions some other forms of dyspepsia, certain variations in the phenomena of which are as much beyond our explanation, as the specific distinctions by which they are severally characterized. The distinguished writer we have so frequently had occasion to cite, seems indeed to have been unconscious of the approximation of his own ideas on this point in reference both

o dyspepsia and pyrosis, having defined the roximate cause of dyspepsia, "an imbecility, oss of tone, and weaker action in the muscular bres of the stomach," and spasm (which can e viewed in no other light than a consequent ondition, and of the same structure), as the roximate cause of pyrosis. "It seems," says e, "to begin by a spasm of the muscular bres of the stomach, which is afterwards in a ertain manner communicated to the blood-essels and exhalents, so as to increase the mpetus of the fluids in these vessels while a onstriction takes place on their extremities. While, therefore, the increased impetus deter-mines a greater quantity than usual of fluid nto these vessels, the constriction upon the xtremities allows only the pure watery parts o be poured out, analogous in every respect o what happens in diabetes hystericus." An-ther and opposite view has been suggested by Iason Good, who considers that in some in-ances pyrosis may be induced by a peculiar uresis or inactivity of the proper absorbents of e stomach,—an hypothesis founded on some xperiments of Majendie, proving the rapidity f the absorption of fluids from the stomach in state of health, even when its pyloric orifice as been encircled by a ligature; but the ab-rption of other fluids, and the regurgitation ly of the morbid product, reflects a degree f improbability on this conjecture. We are, deed, without any evidence that the latter actually secreted by the stomach, and it has een surmised, from the resemblance between e natural secretion of the pancreas and the ected fluid, that it may be derived from this urce: the writer, however, is not aware that e latter has been submitted to chemical ana-sis, but the result of this process promises eans of comparison whereby the supposition ould be further confirmed or invalidated. *priori* it appears improbable that a fluid so ncongenial to the sensibility of the stomach ould be admitted into it by an inversion of e natural action of the duodenum without ore violent efforts than are manifested, or that e fluid itself proceeding from this source ould appear entirely free from any admixture bile.

Prognosis.—Pyrosis in its simple form is ver attended with danger to life, nor does it mmonly even prevent the sufferer from pur-ng his ordinary occupation. The physician, owever, is frequently baffled in his attempts cure it, and even when there has been a asonable hope of the remedial means having en successful, a recurrence of the watery uctation has not unfrequently exposed its llacy.

Treatment.—The doubt in which our know-dge of the pathognomonic causes of pyrosis involved, obscures the indications on which e method of treating it should be grounded d pursued with a rational anticipation of ccess; nor has observation even up to the esent period in any satisfactory degree sup-ied the deficiency. Opium will certainly heve the paroxysm; and its various pre-rations, as well as other anodynes and anti-asmodics, as hyoscyamus and conium, with camphor, the compound spirit of sulphuric ether, and the aromatic spirit of ammonia, variously selected and combined according to the peculiarities of the circumstances of the patient, will all be found useful for this purpose, but relief of the paroxysm appears only to be a temporary advantage: to render it permanent, the intermediate state must be the object of our more particular consideration. We have the warrant both of reason and experience for concluding that digestion cannot be perfectly accomplished whilst the functions of an organ so important to it as the stomach are subject, whether primarily or secondarily, to the frequent interruptions occasioned by the accessions of this disease. A morbid state of the pancreas we know also will materially obstruct this process. The regulation, therefore, of the diet is a most essential point in the plan of treatment: all substances which are likely to ferment are difficultly digestible, and manifestly productive even of temporary discomfort or uneasiness, and the farinacea should as far as possible be avoided. It might be even advantageous, and especially when the disease is endemic, to effect an entire change in the articles which have constituted the general diet, so regulating the quality and limiting the quantity as if the cure of indigestion, whether evident or not, were the object to be effected. Any deviation from the natural state in the functions of the liver or alvine canal should be corrected by remedies appropriate to their particular condition; but in the special plan of the treatment of pyrosis, it will be found advantageous occasionally to produce a laxative effect on the latter, and for this purpose aperients which occasion a sense of warmth in the stomach have been found most suitable; such, for instance, as the compound decoction of aloes, combinations of the powder of rhubarb with magnesia, the compound tinctures of rhubarb and cardamoms, and peppermint-water, the powder and compound tincture of rhubarb, with carbonate of ammonia and camphor mixture, &c. It has further been the practice pursued to attempt to restore the supposed loss of tone in the muscular fibres of the stomach, and at the same time to neutralize the acid secretions which are commonly present. The particular medicines used with this view have been various combinations of the vegetable tonics with aromatics, and large doses of alkalies and the alkaline earths; of the former, particularly the carbonate of ammonia and its preparations. Tonics of the same kind with the mineral acids, particularly sulphuric, have also been recommended for this purpose. The various preparations of iron and zinc have also been had recourse to, but we believe it to be the result of general experience, as it has been of our own, that however such means may have counteracted any other co-existent symptoms resulting from dyspepsia, or have mitigated or suspended the painful accessions which constitute this affection, its recurrence has too often taken place as usual.

Cullen distinctly states that all the remedies for the cure of indigestion have been applied

to it without success, and the late Dr. Baillie has left it on record that, consistently with his experience, it had been little benefited by medicine. He added, however, that a drachm of compound tincture of benzoin rendered miscible with water by trituration with mucilage, he had found the most efficacious of any.* We know it to have been also a favourite prescription of another experienced eminent physician in the treatment of pyrosis. Astringents, such as the compound powder of kino given three times a day in doses of ten grains, have been considered serviceable in cases of dyspepsia in which pyrosis has been a prominent symptom. Linnæus, who had frequent opportunities of witnessing the disease, recommended the nux vomica for its relief, in doses of ten grains three times a day; but this has been regarded, and doubtless is, a very hazardous quantity to commence with. We are not aware that strychnine has been substituted for it; but the preceding recommendation points it out as worthy of trial, in doses of from a twelfth to a sixth of a grain every eight hours. The subnitrate of bismuth, suggested as a remedy in cases of gastrodynia and other painful affections of the stomach by Dr. Odier of Geneva, and favourably reported of by Dr. Marcet in the fifth volume of the Memoirs of the London Medical Society, in similar cases, was particularly recommended as a useful medicine in the cure of pyrosis by Dr. Bardsley of Manchester, in his "Medical Reports of Hospital Practice," published in the year 1807. His recommendation is accompanied with a detail of several cases in which its use was successful; and with the comment, that in pyrosis and disorders of the same kind it exerts a local and specific action upon the organs of digestion, restoring the stomach to a state of vigour and consequent healthy secretion, essential to the removal of the symptoms of acidity, spasm, and pain. Dr. Bardsley prescribed it in doses of five grains with from fifteen to twenty grains of compound powder of tragacanth, two or three times in the day; a mode which we have found useful in similar cases. Dr. A. T. Thomson speaks highly of it in combination with extract of hops, having found it, as he states, extremely beneficial in pyrosis, gastrodynia, and some other varieties of dyspepsia; and when there has been merely atony of the digestive organs without organic mischief, almost universally successful. Mason Good has spoken in high commendation of the internal use of soap in pyrosis, combined with opium if it should be attended with much pain; he refers the efficacy of the former to its decomposition allowing the alkali to unite with the acrid secretion, whilst the oil defends the stomach from the action of any acrimonious matter which may be present. He has not, however, mentioned the quantity or form in which he has prescribed it; but from the benefit we have known it to produce with rhubarb and extract of gentian in some of the modifications of dyspepsia, we should be inclined to adopt a similar combination in prescribing it for the cure of pyrosis. On the principle of allaying irritation, and thereby favouring a slower, and consequently more healthy gastric secretion, hydrocyanic acid has been recommended for the relief of pyrosis; but experience is yet required to determine whether it possesses any lasting power over it. The decided advantage derived from its use in cases apparently allied to pyrosis, leads us to anticipate that it will be found a valuable medicine in the treatment of the latter affection. Commencing with a dose of two minims, we may gradually increase it to five; and it will be suitably prescribed diluted with an ounce and a half of water and a dram of tincture of calomba every eight hours.

In conclusion, we refer the reader to the article INDIGESTION, in which the various disorders of the stomach commonly classed under the term dyspepsia have been fully discussed, and particularly to the third section of that article, which describes pyrosis in relation to them, under the head of *irritable gastric dyspepsia*.

(William Kerr.)

RAPE.—The high value set upon female purity, and the heavy penalty incurred by its loss, in the banishment of the delinquent from society, have led most civilized countries to inflict the severest punishments on the individual guilty of a forcible violation of the weaker sex. When we consider, on the one hand, the condition of a virtuous female thus plunged into an abyss of misery, a release from which by death has been voluntarily sought by many; and, on the other, contemplate the number of profligate persons who are found in all countries and societies, whose chief occupation seems to be the corruption and debasement of the female sex; we cannot fail to rejoice that the strong arm of the law should interpose its protecting shield, and visit with its severest judgements one of the grossest crimes that vice can perpetrate. By the law of England, rape is defined to be the carnal knowledge of a woman against her will, and death is its penalty. All classes of females are equally protected, the virgin, the married woman, and even the common prostitute is included, because she may at the very time have determined on a reformation of her former habits. In Scotland the ravisher is exempted from the pains of death, only in case of the woman's subsequent consent, or her declaration that she yielded of her own free will; and even then he is to suffer an arbitrary punishment either by imprisonment, confiscation of goods, or a pecuniary fine.* In the state of New York, death was formerly the punishment for committing a rape on a married woman or a maid; and it was also ordained at the same time, that if a woman had been ravished, and afterwards consented to her ravisher, her husband, father, or next of kin, might sue by appeal against such offender.

* Lectures and Observations on Medicine, by the late Matthew Baillie, M.D. 1825.

* Edin. Encyclop. vol. xi. p. 823.

These laws, however, have been repealed, the punishment altered, and appeals of felony abolished. The acts now in force prescribe the punishment of imprisonment for life in the state-prison, of the offender and his accomplices, if he have any, for ravishing by force any woman-child of the age of ten years and upwards, or any other woman. An assault, with an intent to commit a rape, may be punished by fine and imprisonment, or both.

In the case of adults, it is necessary, in order to constitute a rape, that the act shall have been committed against the will of the female; but in the case of children, in whom the power of judging between right and wrong is not supposed to exist, the matter of consent is of no moment, and the deed is equally criminal whether it be obtained or not. "A female infant under ten years of age is in law deemed incapable of consenting to any act, much less to her dishonour; the carnal knowledge of such infant, whether she yield or not, is therefore virtually a rape; but whether if the child be above ten years of age, it be also a felony, has been questioned. Sir Matthew Hale was of opinion that such profligate actions, either with or without consent, amount to rape and felony, as well since as before the statute of Queen Elizabeth; but in his Summary, the learned judge appears to have altered his opinion; and the present practice is, that if the child be under ten years of age then it is felony by the statute; but if she be above ten and under twelve, then it is no rape if she consented, but only a misdemeanour."* The French code extends the period to fifteen years, and punishes the crime committed on a child of that age by hard labour for a limited time.† "In New York the carnal knowledge of a woman-child under ten years of age is punished by imprisonment in the state-prison for life. In Massachusetts and Illinois, death is the punishment. In Virginia, New Hampshire, Connecticut, and New Jersey, imprisonment either for life or a long term of years is directed. All these specify the period of ten years. The law in Vermont varies from this. It directs that whenever any individual over the age of fifteen shall abuse any female under eleven with or without her will, he will suffer fine and imprisonment."‡

By the ancient law of England, the woman was required to make her accusation immediately after the commission of the outrage. At a subsequent period she was allowed forty days as the utmost limit; but by the law as it at present stands, there is no time of limitation fixed. However, although there is no limit fixed by law, public opinion demands an early discovery; and an accuser who has postponed her complaint for any unreasonable length of time, is listened to with great caution by a jury. In fact, this is a crime so easily charged, so hard to be proved, and so much harder to be rebutted, that it is of the utmost importance that no time shall be allowed for concocting a malicious tale, particularly if medical testimony is to be adduced, as a few hours are often sufficient to efface appearances that might have been evident on an early examination. Indeed, in all cases, the greatest caution is necessary in judging of the guilt of an accused party. There is generally no witness to confirm the direct testimony of the accuser as to the fact; the whole case turns upon the woman's assertion, and unless there is strong collateral evidence, such as a speedy disclosure to her friends and the authorities, and an early medical examination, we are of opinion that it should require the clearest and most unshaken testimony on the cross examination to gain credence with a jury. It is better that ten guilty should escape than that one innocent man should suffer; and however we abhor the crime, and would wish the heaviest punishment to overtake the guilty, we cannot help offering this caution to medical men and jurors, knowing as we do the depravity of the human heart, and the lengths to which it will sometimes go to accomplish the ends of malice or revenge. It is not impossible, nay, it has sometimes happened, that a woman who has freely consented to surrender her virtue will afterwards turn round on her paramour, and denounce him as her ravisher. This becomes a case of the greatest intricacy from the fact of the principal feature (that of the venereal congress having taken place) being true. It now passes out of the hands of the medical jurist, and becomes a question with the jury whether they believe the deposition of the woman as to consent or not. This, it must be confessed, is a most difficult question to solve, and it requires all the ingenuity of the bar to sift to the bottom all external circumstances which may contribute to prove the negative. Cases of a mixed kind are also sometimes met with; as when a woman will at first resist the advances of a suitor, and even continue her resistance for a time, but afterwards, from the excitement of passion or some other cause, yields to his desire. This is a case, if possible, more puzzling than the former, because marks of violence on the limbs of the female, from her previous struggling, may be evident, which would naturally lead to the supposition that the act had been accomplished by force. We confess that we should be inclined to deal harshly with a man under such circumstances, from the difficulty of understanding what constitutes consent. The act is committed in secret; there are no witnesses; the woman is bruised on the limbs and body; and her person is violated: it is not likely that a formal question of "Will you consent?" has been put, followed by an answer of yea or nay; and yet, after the employment of so much force, the man defends himself by saying the woman consented, which she denies. The jury alone can determine which is to be credited; but, as we have already said, appearances are strongly in favour of the woman, and a struggle of such violence and duration, followed by coition, amounts, in our opinion, if not to a legal, at least to a moral rape. Having spoken thus generally

* *Paris and Fonblanque*, Med. Jur. vol. i. p. 419.
† *Capuron*, p. 1.
‡ *Beck*, p. 60.

of some of the difficulties attending the investigation of accusations of rape, we proceed to consider some of the points upon which medical testimony is more particularly required.

Of the physical signs of violation.—These are the absence of the signs of virginity, marks of violence, tumefaction, or laceration of the pudenda, with effusion of blood, and bruises on other parts of the body, particularly on the breast, arms, and thighs. It must be evident that the most important of these, that is, the want of the attributes of the virgin state, together with the injuries inflicted on the genital organs, as evidenced by inflammation and tumefaction, cannot apply to all women, but only to virgins; for in married women, or those previously in the habit of sexual intercourse, the negative signs are of course of no value, and the positive are not likely to occur. And this narrows our present observations to the signs of rape committed on virgins.

The investigation of this subject must be preceded by an exposition of the signs of virginity. This is a question which has occupied the attention of anatomists and physiologists from an early period; but it does not appear that any very accurate conclusions have been agreed upon.

The existence of the hymen is the sign upon which the greatest stress has been laid by some authors, while, strange to say, its presence has been esteemed by others, among whom we find Ambrose Paré, Columbus, Dionis, and Buffon, as an unnatural formation. However, at the present day, it is generally considered as an attribute of the human virgin. The hymen is a membranous or membrano-carneous structure, which is situated at the entrance of the vagina, and serves to form a boundary between that passage and the external genitals. It is formed by duplicatures of the lining membrane of the vagina, and is usually of a crescentic form, leaving an opening into the vagina at its upper part. This opening serves as an outlet for the menses, and in the average of adult subjects is large enough to admit the index finger sufficiently high up into the vagina, to effect an examination of the os uteri, without injury to the hymen. Dr. Davis states that in breech presentations he has sometimes introduced his finger into the vagina of the infant without injuring this membrane. The shape of this membrane, however, is various and uncertain. In some cases it is more or less circular, presenting through its centre a round aperture of three or four lines in diameter. At other times only a part or exclusive portion of the orificial extremity of the vagina, sometimes the superior, at other times the inferior portion of it, is seen to be veiled over with this structure. In some rare cases the hymen is an imperforate circular membrane attached to the edge of the orifice of the vagina in every part, so as to close the canal completely. We have already alluded to some of these cases in the article IMPOTENCE. Another form of the hymen is, when there are two crescental portions attached to the more carneous structure of the external orifice laterally. The structural tissue of the hymen seems in some measure to vary in different instances. "In most fœtal subjects it seems to be distinctly membranous, whilst in some others it partakes also of a carneous character. Hence, probably, the very different descriptions given of it by different authors. By Soranus it is accordingly described as being membranous; by Avicenna as veinous and ligamentous; by Riolanus as carneous; by Berengarius as retiform, consisting of vascular and delicate ligamentous tissue; by Columbus as a thick substance; and by Spigelius as partly carneous and partly nervous."* In order to see this membrane in the living subject, it is necessary to separate the labia and even the thighs to a considerable distance from each other; for the opening into the vagina is quite closed up by the external parts in the ordinary positions of the body. The hymen is usually torn by sexual intercourse, and its rupture is attended by an effusion of blood; an appearance upon which so much reliance was placed by the Jews as a test of virginity, that the nuptial sheets were constantly exhibited to the relations on both sides, and preserved by the friends of the woman as evidences of her chastity. In case this token of virginity was not found on them, she was to be stoned to death at her father's door. After the rupture of the hymen, its remains shrivel towards their base into several small excrescences at the orifice of the vagina. These are thick, red, and obtuse at their extremities, and from their fancied resemblance to a myrtle-berry, have been called *carunculæ myrtiformes*. They generally disappear after frequent connexions or deliveries. The carunculæ which are found at the opening of the vagina are not, however, always remains of the hymen. Dr. Conquest† remarks that the carunculæ may be found when the hymen is entire. Dr. Davis‡ observes that the greater part of the circle at the basis of the hymen when that structure remains, and at the same locality when it has suffered rupture, may occasionally be seen studded with caruncles of different origin; such extra caruncles in some cases being few and small, but in others large and numerous. He alludes to one case, which was that of a young lady of unquestionably good character, who, in consequence of some irregularities imputed to a gay husband, to whom she had been recently married, became the subject of a professional examination: there presented at the orifice of the vagina on either side, and in immediate contiguity to the carunculous remains of the hymen, two large multifoliated masses of structure, disposed in parallel layers in such a manner as scarcely to fail to suggest the idea of a pair of epaulettes. These are the forms under which the hymen is usually found; but it should be borne in mind by the medical jurist that it is liable to certain malformations, with which

* Princip. and Pract. of Obstet. Med. by Dr. Davis, p. 100.

† Outlines of Midwifery, p. 17.

‡ Loc. cit. p. 101.

: should be acquainted. It is commonly a in membrane, easily ruptured by any large ody introduced into the vagina. But it some- mes occurs that it is possessed of so much nness as to resist the intromission of the enis. This unusual degree of thickness and rength may belong to a hymen composed of ne uniform membrane; or to that conforma- on of it termed cribriform, from its being ierced by a number of holes. In this latter ondition the membrane is commonly exceed- gly strong, and capable of resisting the or- inary means of rupture. It is a state, how- ver, that does not prevent impregnation, some ases of which are related by Dr. Davis; and s they relate to an important medico-legal oint we refer to them, in addition to those ready mentioned in the article Impotence. ne of these cases of cribriform hymen we anscribe in consequence of its great interest: It was usually narrated in his peculiarly terse yle by the late Dr. Haighton, in his lectures n midwifery in Guy's Hospital. The subject f it had been the lady of one of the physicians o that or to the neighbouring hospital of St. homas. It was become matter of post-mortem istory even in the time of Dr. Haighton. The ymen was perforated by many small apertures; ut it nevertheless was so strong that it had esisted all the efforts of the husband to effect s rupture. That gentleman, however, con- ealed his chagrin; nor did he take any means o accomplish artificially what he had failed to ffect by the ordinary means. Under these ircumstances the lady drooped and became nhappy; but she also, at no distant period, ecame the subject of faintings and sickness, nd eventually of great abdominal enlarge- ent, and of anasarca of her lower extremities. During the urgency of those symptoms she as advised to go to Bath for the benefit of ne waters and of the other good things to be btained at that celebrated city. No remedy as found, however, even there for the lady's ropsy, and the symptoms became more and ore urgent every day. Finding no relief at Bath, and giving up all hope of recovery any here, she determined, after a residence of ome weeks at that place, to return to London, n order that her remains might the more con- eniently be deposited in the monumental ault of her family. Whilst on this journey, hich she was performing in a post-chaise, she as seized with a severe abdominal pain, which he naturally enough ascribed to a spasm of he intestines. This colic, which was moderate nd bearable at the commencement, became so xtremely violent in its progress that she was bliged to stop suddenly at an inn on the road, here in less than an hour she was radically ured of her dropsy by becoming the mother f a well-grown living child. The hymen was hen ruptured without the assistance of art."*

We have alluded to these cases to shew that t is possible for all the moral guilt of a rape to e incurred without the conditions necessary o satisfy the law upon the point, namely, in- romission of the penis, &c. Besides these sources of difficulty presented to the medical jurist in malformation of the hymen, there are some cases, and probably not a few, in which this membrane has never existed at all; or having been at first formed of great tenuity, has been ruptured and destroyed in early life. Accidental circumstances may also serve to obliterate it, such as disease, improper practices, or acrimonious discharges; and instances are not wanting where it has been destroyed by the pressure of the confined menstrual fluid. From the cases alluded to above, it appears that impregnation may take place without rupture of this membrane, but in these instances perforation is not supposed to have occurred. It is, however, stated by Zacchias that intromission may be effected when a disproportion exists between the organs, when the hymen does not exceed the ordinary size, but is thick and hard, and when connexion has taken place during the presence of menstruation, or fluor albus, without damage to this membrane. Gavard* found it perfect in a female thirteen years of age, who was labouring under the venereal disease. Ruysch† has said, that if coitus take place during or immediately after the menstrual excretion, this membrane is often not ruptured.

From these several circumstances of variety in the original formation and appearance of the hymen, its power of resisting the natural means of rupture in some cases, and its yielding in others to the slightest force, we are inclined to think that the accuracy necessary in forming a medico-legal opinion cannot be attained by looking to this sign alone. We must, however, agree with Dr. Beck‡ that it would be difficult to support an accusation of rape where the hymen is found entire, although its presence cannot be considered as an unequivocal proof of virginity; for, as we have stated, it has been asserted by good authority that it is not always ruptured in coitu. An instance is related by Dr. Smith,§ in which an accusation of rape fell to the ground in consequence of the presence of this membrane. This occurred in the case of a man named Stewart, who was tried at the Old Bailey in 1704 for ravishing two female children. The evidence being at variance as to the fact of penetration, the children were sent out of court to be examined, and the eldest was found to have the signs of virginity.

The state of the vagina is the next point worthy of consideration. In young subjects it is extremely small; but as the female advances towards puberty, it becomes encreased in its dimensions. In a healthy adult virgin the parietes of the vagina are remarkably firm and substantial, and from the only function it has to perform, that of giving exit to the menstrual excretion, it is rigid and narrow. The internal surface is lined with a mucous membrane which is remarkable for the peculiarity of being much wrinkled or folded together into shallow irregularly transverse rugæ, the pecu-

* Op. cit. p. 104.

§ Prin. of For. Med. p. 410.

liar use of which is to qualify the passage for being indefinitely developed during parturition. These folds are removed by frequent sexual intercourse, and nearly obliterated in women who have borne one or two children. The dilatation of the vagina, and smoothness of its internal surface, are not, however, to be taken as unequivocal proofs of want of chastity, for these appearances may arise from other causes. There are disorders of which the tendency is to render it so, as fluor albus, chlorosis, or menorrhagia; and certain malpractices will also occasion the same dilatation as sexual intercourse; and, on the other hand, coitus may have taken place, and the vagina afterwards re-assume its contracted condition.

Generally speaking, in virgins the external labia are thick, firm, elastic, and internally of a bright red colour, with their edges so opposed as to occlude the entrance into the vagina; while in married women, or those accustomed to coition, they are soft, pale, and have an interval of greater or less extent between them. But these signs will be found to vary according to the age, temperament, and state of health of the individual. Thus, in persons of a sanguine temperament, although in the habit of venereal enjoyment, the colour, firmness, and thickness of these parts will be preserved; and virgins of advanced age and weak leucophlegmatic habit of body, or those afflicted with leucorrhœa or menorrhagia, may present appearances which, if the above signs were supposed to be valid, would lead to a conclusion of an opposite character. The same observations will apply to the state of the frenum labiorum, or posterior commissure of the pudenda. Some authors have esteemed the integrity and rigidity of this part as a proof of virginity, but no positive conclusion can be drawn from it, for it frequently remains untouched even after parturition.

From the observations just made, we feel ourselves compelled to acknowledge that there are no anatomical signs by which we can attest the presence of virginity. Taken singly they are all fallacious, and even viewed in connexion, they can only favour the conclusion as to the chastity of the female; but the converse is not established by the absence of these signs, as they may be all absent from causes already enumerated, although their absence may serve to corroborate the opposite opinion in suspected cases.

Signs of defloration.—In this inquiry it is necessary to take into account the age, strength, and state of mind of both persons concerned. The sexual organs of both should be examined, and this as speedily as possible after the alleged assault, for if the woman have reached the period of puberty, no satisfactory information can be obtained by a professional examination unless made immediately after the commission of the act. In children, from the great disproportion of the parts, the violence is greater, and the effects consequently remain for a longer time; but in a subject of full organic development, the appearances consequent to connexion are very fleeting. If the examination be made early, and particularly if the female have been a virgin, besides the state of mental excitement in which she may be found, there may be physical signs consisting in local marks of violence. The parts are found lacerated, tumified, and bloody or inflamed, and painful to the touch; the hymen most commonly ruptured; and sometimes the presence of semen can be detected. Besides these marks upon the genitals, there are usually bruises or ecchymoses on other parts of the body, particularly on the arms, thighs, nates, and breast. In children the local appearances are more evident, from the greater injury the parts have received; and the inflammation is sometimes so great as to incapacitate them from walking. But in married women, even a very speedy examination will fail to afford much assistance, from the previously dilated condition of the parts. It should be borne in mind that the female genitals are liable to diseases which may imitate the appearances just pointed out. Of this fact, a case related by Dr. Percival* is a striking example. A girl, four years of age, and in good health, was suddenly seized with inflammation of the pudenda, and symptoms of defloration, with pain in making water. She had slept two or three nights in the same bed with a boy fourteen years old, and had complained of being very much hurt by him during the night. The symptoms increased in violence, and the child died on the ninth day. An inquest was held on the body, and Mr. Ward, under whose care the patient had been in the Manchester Infirmary, deposed that death was caused by external injury. A verdict of murder was returned against the boy, and he was accordingly taken into custody. A very short time afterwards, however, several similar cases occurred in the same neighbourhood, in which there was no ground for supposing that violence had been offered. Fortunately for the boy his trial had not come on, and Mr. Ward now informed the authorities of the mistake he had committed, and the prisoner was discharged. This kind of disease appears to be to a certain extent epidemic, and is very fatal. Thus, out of twelve cases mentioned by Mr. Kinder Wood,† only two recovered. It is usually preceded by febrile symptoms for two or three days, and when the genitals are examined, they are found inflamed and swollen. The colour is dark, and ulceration with gangrene quickly follows. The fever assumes a typhoid character, and death shortly takes place.

The presence of the venereal disease in the female, when its invasion corresponds with the period at which the outrage is stated to have occurred, that is, in from three to eight days afterwards, is a very strong corroborative proof of defloration, if the aggressor is found on examination to be afflicted with the same disease. This is not uncommonly the case in young children, in consequence of a very prevalent notion entertained by the lower orders, that connexion with a virgin is a certain cure for the disorder. Appearances resembling gonorrhœa,

* Medical Ethics, p. 103 and 231.

† Med. Chirur. Trans. v. vii. p. 84.

however, should be looked at with a very scrupulous eye, as it is now perfectly well known that children, particularly those of strumous delicate constitutions, are liable to purulent discharges from the vagina, which very much resemble the consequences of impure connexion. These discharges take place during dentition, or from the presence of worms in the intestinal canal, and are also sometimes observed in the male sex from the same causes. We are indebted to Sir Astley Cooper* for the following energetic observations on this peculiar affection. "There is a circumstance on which I am exceedingly anxious to dwell—I allude to a discharge from young females, and I hope that there is not one here this evening but will be strongly impressed with the importance of the subject. Children from one year old, and even under, up to puberty, are frequently the subjects of a purulent discharge from the pudendum, chiefly originating beneath the prepuitium clitoridis; the nymphæ, orifice of the vagina, and the meatus urinarius, are in an inflamed state, and pour out a discharge. The bed-linen and rest of the clothes are marked by it. It now and then happens to a nervous woman to be alarmed at such an appearance, and she suspects her child of having acted in an improper manner; and perhaps not quite clear herself, she is more ready to suspect others, and says, dear me, (if she confesses,) it is something like what I have had myself. She goes to a medical man, who may unfortunately not be aware of the complaint I am speaking of, and he says, 'your child has got a clap.' I can assure you a multitude of persons have been hanged for such a mistake. I will tell you exactly what takes place in such cases; the mother goes home and says to the child, 'who is it that has been playing with you? who has taken you on his knee lately?' The child innocently replies, 'no one, mother; nobody has I declare to you.' The mother then says, 'Oh, don't tell me such stories; I will flog you if you do.' And thus the child is driven to confess what never happened, in order to save herself from being chastised; at last she says, 'Such a one has taken me on his lap.' The person is questioned, and firmly denies it; but the child, owing to the mother's threats, persists in what she has said. The man is brought into a court of justice; a surgeon who is ignorant of the nature of the discharge I am now speaking about, gives his evidence; and the man suffers for that which he never committed. The mother is persuaded, if there be a slight ulceration on the parts, that violence has been used, and a rape committed.

"If I were to tell you how often I have met with such cases, I should say that I have met with thirty in the course of my life. The last case I saw was in the city; a gentleman came to me, and asked me to see a child with him who had a gonorrhœa on her. I went, and found that she had a free discharge from the preputium clitoridis. I said that there was nothing so common as this. There was considerable inflammation, and it had even proceeded to ulceration, which I told him would soon give way to the use of the liquor calcis with calomel. 'Do you tell me so?' he replied; 'why, suspicion has fallen on one of the servants; but he will not confess. If he had appeared at the Old Bailey, I should have given my evidence against him; for I was not aware of what you have just told me.' I told him that if the man had been hanged by his evidence, he would have deserved to be hanged too. I am anxious that this complaint should be known by every one present, and that the remarks which I have made should be circulated throughout the kingdom. When a child has this discharge, there is a heat of the parts, slight inflammation; and this sometimes increases, and goes on to ulceration. This disease sometimes occurs in children at the time of cutting their teeth."

In the year 1831 a man was arrested in the city of Dublin on a charge of rape committed on a child; the only evidence of which was the presence of a purulent discharge from the pudendum. Popular opinion, as is usual in such cases, ran high against him; and it was only through the positive opinion of an intelligent surgeon that the case was explained, and the man liberated. A case of a somewhat similar nature lately came under the observation of the writer. A lady and gentleman came to his house one evening in a state of great alarm and excitement, accompanied by their child, a girl of four years old, whom they stated to be afflicted with a terrible disorder, communicated to her by some person in their employment. They had previously shewn the child to an apothecary, who confirmed their worst apprehensions, and at once declared that the girl had got a clap. On examination, the parts were found in a state resembling that just described, with a free purulent discharge; and it was with no small degree of pleasure the writer was able to console the parents by assuring them that their child was labouring under no uncommon affection, and that a few days would set all to rights. It has rarely fallen to his lot to witness a more sudden transition from grief to joy than this announcement effected.

Dr. Ryan* mentions the case of a delicate girl, aged eleven years, who had a purulent discharge from the external genitals, and accused a young man of eighteen, whose genitals were developed in an extraordinary degree, of having violated her person. Two apothecaries swore the girl had been violated, a rape committed, and gonorrhœa communicated. Dr. Gordon Smith, Mr. Whitmore, and Dr. Ryan were of a different opinion. The case was grievously mismanaged for the prisoner; the only evidence produced in his favour was Dr. Smith's, which was contrasted with that of the two medical witnesses for the prosecution, who had refused to examine the person of the prisoner, although assured that he had no discharge from the urethra, and had not had any for six months previously. The man was found guilty at

* Lectures on Surgery.

* Med. Jur. p. 185.

the Middlesex sessions, and sentenced to six months' imprisonment, and lectured by the chairman on his good fortune that he was not hanged. The mother of the child confessed to Dr. Smith that she had had the discharge since she was five years old.

From these and other similar instances, we cannot too strongly urge the necessity of an early examination of both parties. By following this course, it has happened that the man has been acquitted where marks of disease were discovered in the female, because no signs of gonorrhœa have been detected about himself. A case related by Sir Matthew Hale* furnishes an instance where an innocent man might have been saved from a malicious prosecution, to the hazard of his life, by this precaution. Foderé† mentions two cases from Zacchias, where the falsehood of an accusation was determined by a comparative inspection of both parties. Besides the presence or not of disease, there are other points to be determined by examination. Thus it may happen that the man is impotent; the penis may have been lost by sloughing, accident, design, or cancer; the female organs may be so constructed as to prevent the possibility of penetration; in all of which cases an inspection of both parties can alone give grounds for conclusive opinions. It has been remarked by a writer in a celebrated periodical work, with reference to the purulent discharge of which we have just spoken, that "we must take care not to run into the opposite error of ascribing inflammation, ulceration, and discharge in cases where violence has been alleged, to this disease without sufficient grounds; for it is extremely improbable that diseases which occur so rarely should happen to appear in a child to whom violence was offered, unless that violence had some effect in producing it."‡ On this point we think it right to observe that the laceration, tumefaction, and inflammation consequent to the violation of a child are very different from the disease under consideration, and could scarcely be confounded with it. Its great resemblance is to true gonorrhœa; and that point can be settled by a personal examination of the man accused. Dr. Dewees§ states that when this disease arises in very young subjects, it almost always proceeds from a neglect of cleanly attention to these parts, either by withholding a frequent use of lukewarm water, or permitting the child to remain too long wet. Children, however, of a more advanced age have also discharges of a purulent character, that seem to arise from a morbid action of the mucous membrane of the vagina. This frequently shews itself about the fifth year, and may continue, if neglected, to almost any period. It should be recollected that violence has been sometimes inflicted on the external genitals for the purpose of sustaining an accusation against an innocent person. A remarkable case of this sort is related by Foderé.‖ A female at Martigues, in 1808, accused eight or ten of the principal persons of the place of having violated her grand-daughter, aged about nine years and a half, at an inn. She laid her complaint before the juge de paix, and stated that she would withdraw it provided the accused would accommodate the matter with her. She had procured a daughter of the innkeeper, aged sixteen and an idiot, as a witness. As the charge was obstinately persisted in, Foderé, with two officers of health, was ordered to examine the child in presence of the judge; and suspicion was immediately excited from the delay used in admitting the visitors. On examining the parts, he found the hymen untouched, and the vagina extremely narrow. Around the pudenda, however, a red circle about the size of a crown was observed, which appeared to have been induced recently; and this was indeed the fact; for at the end of half an hour the circle had decreased in size, and the redness disappeared. Had this been the effect of great violence, it is natural to suppose that it would have increased in intensity of colour. A report was prepared, stating the above facts; and the consequence was, that the accuser was put in prison, and finally ordered out of the city.

The chief point in an accusation of rape, necessary to be proved, is the act of coition; but as considerable difference of opinion has existed as to what legally constitutes this act, it is necessary to make some observations upon it. Some authorities have maintained that simple penetration was sufficient, while others have judged that without emission the crime is not complete. In the case of Russen, the schoolmaster, who was tried for a rape committed on a girl under ten years of age, it was proved by two surgeons on behalf of the prisoner, and corroborated by four others who had examined the girl, that the hymen (which they considered an indubitable mark of virginity) was whole and unbroken, and that the passage was so narrow that a finger could not be introduced. But Mr. Justice Ashhurst, who tried the case, left it to the jury whether any penetration were proved; for if there were any, however small, the rape was complete in law. The jury found him guilty, and he received judgment of death. But before the time of execution, the matter being much discussed, the learned judge reported the case to the other judges for their opinion, whether his directions were proper; and upon a conference it was unanimously decreed that the directions of the judge were perfectly right. They held that, in such cases, the least degree of penetration was sufficient, though it may not be attended with the deprivation of the signs of virginity. It was, therefore, properly left to the jury by the judge; and accordingly, the prisoner was executed. This occurred in the year 1777. On the other hand, Lord Coke, Sir Matthew Hale, and Hawkins held that there must be both penetratio and emissio seminis, and this appears to have been the decision of Skynner, C. B. Gould, Willis, Ashhurst, Nares, Eyre, and Hotham, against Lord Loughborough, Buller, and Heath; Lord Mansfield,

though present, having given no opinion of his own. The argument is stated to have turned on the words carnal knowledge, to which the majority contended that emissio seminis was absolutely necessary.* This state of the law rendered cases of rape extremely difficult to prove; for in virgins it is not at all likely they would be conscious of any such circumstance having taken place, particularly when we consider the state of fright, pain, and weakness into which they are necessarily thrown; and even in married women it does not appear that they are always conscious of emission—indeed, we should be inclined to suppose the reverse. Judge Buller stated, in giving judgement on a case in 1787, that he recollected a case where a man had been indicted for a rape, and the woman had sworn that she did not perceive anything come from him; but she had had many children, and was never in her life sensible of emission from a man. Again, in the case of children, it is manifestly impossible that evidence of emission can be obtained; and, as has been well remarked by Dr. Paris, if it be true that certain eunuchs have the power of erection, and consequently of penetration, they may morally ravish without incurring the punishment of rape; for it is certain that they can have no emissio seminis; or a man may have perpetrated all the more atrocious parts of his crime, and yet being incorrupted in the least voluntary constituent of it, escape the well merited vengeance of the law; while it is evident, on the other hand, that the innocent victim has suffered in body, mind, and reputation, as much as if the crime had been legally completed.† It has been stated in defence of this practice of requiring proof of emission, that it is quite necessary to make the proof of the crime difficult in order to avoid false accusations, for it often happens that the only chance an innocent man has is the cross-examination of the prosecutrix; if, therefore, it be necessary to prove all the circumstances, including emission, it follows that there is a greater likelihood of the witness tripping in her evidence.

The question with respect to requiring proof of seminal emission in cases of rape has been recently settled by an act (9 Geo. IV. c. 31, passed June 1828,) which cites, "that upon trials for the crimes of buggery and of rape, and of carnally abusing girls under the respective ages hereinbefore mentioned, offenders frequently escape by reason of the difficulty of the proof which has been required of the completion of these different crimes; for remedy thereof be it enacted, that it shall not be necessary in any of these cases to prove the actual emission of seed in order to constitute a carnal knowledge, but that the carnal knowledge shall be deemed complete upon proof of penetration only." By the same act the crime of rape, or of the abuse and carnal knowledge of a girl under ten years of age, is punishable by death. Abuse and carnal knowledge of a girl between ten and twelve years of age is considered a misdemeanour only, punishable by imprisonment, with or without hard labour.

In Philadelphia, where the law is the same as with us, it has become common of late years to indict for an attempt to commit a rape, rather than for the crime itself, and chiefly from the difficulty of proof. Emission, however, is not considered essential in Pensylvania (according to Judge Cooper); and properly, he adds, for it is not the essence of the crime, and it may happen without being perceived in cases of violence. In Illinois it is expressly enacted that so much of the law regulating the evidence in case of rape as makes emission necessary is hereby repealed.*

This crime may be committed on a female at any period of life after she has passed mere infancy. We have already mentioned the law as applied to children. In this case the charge of violation requires the most accurate inquiry, because the material evidence in other cases, that of the sufferer herself, is wanting, from her being incapable as a witness in consequence of her youth. "If the rape be charged to have been committed on an infant under twelve years of age, she may still be a competent witness, if she hath sense and understanding to know the nature and obligation of an oath, or even to be sensible of the wickedness of telling a deliberate lie; nay, though she hath not, it is thought by Sir M. Hale, that she ought to be heard without oath, to give the court information; and others have held that what the child told her mother or other relations may be given in evidence, since the nature of the case admits frequently of no other proof. But it is now settled by a solemn determination of the twelve judges, that no hearsay evidence can be given of the declarations of a child who hath not capacity to be sworn; nor can such child be examined in court without oath: and there can be no determinate age at which the oath of a child ought either to be admitted or rejected; but their admissibility depends upon the sense and reason they entertain of the danger and impiety of falsehood, which is to be collected from their answers to questions propounded to them by the court."† Females, before they reach the time of life at which menstruation commences, are generally ignorant of the consequences likely to result; and this, coupled with want of physical power, may often tend to facilitate the commission of rape. But at the age of puberty it has been doubted whether a woman of ordinary strength may not successfully resist the attempts of a single man.

Farr, in speaking of this subject, expresses himself in the following terms:—"But the consummation of a rape, by which is meant a complete, full, and entire coition, which is made without any consent or permission of the woman, seems to be impossible, unless some very extraordinary circumstances occur. For a woman always possesses sufficient power by drawing back her limbs, and by the force of her hands to prevent the insertion of the penis,

† Loc. cit.

* *Beck*, p. 67.
† *Paris and Fonblanque*, vol. i. p. 421.

whilst she can keep her resolution entire."* Dr. Beck quotes the following answer given by the medical faculty of Leipsic to the question, whether a single man could ravish a woman. "Si circumstantias quæ in actu coëundi concurrunt consideramus, non credibile, nec possibile videtur, quod unus masculus nubilem virginem (excipe impubem, teneram, delicatam, aut simul ebriam puellam) absque ipsius consensu, permissione atque voluntate vitiare, aut violento modo stuprare possit; dum feminæ cuilibet facilius est si velit, penis immissionem recusare, vel multis aliis modis impedire, quàm viro eidem invitæ planè intrudere."† It is necessary, therefore, to be extremely cautious in admitting the truth of accusations, unless the bodily power of the man far exceeds that of the complainant. At the same time, however, we should not entirely agree with the positive opinions just quoted, for we think it possible that by long continued violence, intimidation, or other circumstances, the man may ultimately prevail.

The question naturally arises here, can a female be violated without her knowledge? in which case the crime would be equally great, for it would be still without her consent. There are different ways in which we may suppose this to be effected, as during natural sleep, or stupefaction caused by inebriation or narcotics, or during a fit. As to the possibility of rape being committed on a virgin during natural sleep, we are very much inclined to doubt it, notwithstanding the decision of the faculty of Leipsic, "Dormientem in sella virginem insciam defloravi posse."‡ When we consider the violence inflicted, and the pain that attends a first intercourse, we think it scarcely possible that any natural sleep could be so sound as to preserve the woman unconscious of what was going forward. The case is not exactly the same with married women, in whom from previous sexual intercourse the parts are more dilated. In such case we must admit the possibility, but not at all the probability, for even in them natural sleep, however heavy, would be most likely broken by the attempt at violation. That a female, whether virgin or not, may be ravished during the insensibility attending intoxication, the administration of narcotics, or disease, will be readily granted. As the sufferer can give no direct testimony as to the fact, the only corroboration to be obtained is from a personal examination; but as we have already mentioned, this can be of use alone in the case of her being a virgin. There is reason to think that narcotics have been not unfrequently administered for the purpose of facilitating the commission of rape, which circumstance is justly considered a great aggravation of the offence, and, when proved, is sure to draw down the heaviest punishment on the perpetrator. A case occurred in Dublin, in April 1831, in which a gentleman was tried for a rape, and convicted, chiefly in consequence of an impression made on the minds of the jury, that some soporific had been administered by him to the young lady, by means of which he was enabled to effect his purpose.* There is another mode in which this crime may be committed, wherein, although the woman is not unconscious, she makes no resistance, neither does she consent: that is, when a man obtains admission to the bedroom of a married woman, and imposes himself on her as her husband. This constitutes a case of rape, and subjects the offender to the usual penalty. The same holds good in the case of forcible abduction, where a woman is compelled to marry and is afterwards violated by force.

The fact of sexual intercourse being proved or admitted, it now remains to be ascertained whether the woman consented or not. If she be dead, which sometimes happens from the violence employed, the most material part of the evidence, her own testimony, is of course wanting, unless she have lived long enough to give information before her death. In the well known case of Abraham Thornton, who was tried some years ago, in England, for the murder of Mary Ashford, (a case remarkable for being the last in which a wager of battle was offered, such right having been immediately afterwards abolished by the statute 59 Geo. III. c. 46;) the prisoner admitted having had carnal knowledge of her, but stated that it was with her own consent; and although the general tenor of the evidence was in opposition to this assertion, the death of the unfortunate woman rendered it impossible to ascertain the truth. It was formerly imagined that the occurrence of pregnancy after violation was evidence of the consent of the woman. This opinion was maintained by Dr. Bartley† and Dr. Farr‡ on the supposition that women under the influence of the depressing passions, such as fear, terror, &c. could not conceive. It is said by Mr. Dalton, that if a woman at the time of the supposed rape do conceive with child by the ravisher, this is no rape, for (he says) a woman cannot conceive unless she doth consent. Such an opinion was founded on the idea that a certain amount of enjoyment on the part of the female is necessary towards conception. But it has been clearly ascertained that this is not the case, and the process of impregnation may go forward, totally without the will, consent, or enjoyment of the female. "That so absurd a notion as that conception evidenced consent, should in modern times have obtained amongst any whose education and intellect were superior to those of an old nurse, is indeed surprising: at this day, however, facts and theory concur to prove that the assentation of nature in this respect is no ways connected with violation of mind."§ Such is the opinion of all medical jurists of modern times; and it is supported by the many facts on record, of im-

§ Burn's Just. tit. Rape.

pregnation having taken place in consequence of connection had with females during insensibility from disease or the influence of narcotics.

It was ruled, in the case of the king against Fleming and Windham,* A.D. 1779, that if the party be dead, the deposition of the girl, taken before the committing magistrate and signed by him, may after her death be read in evidence at the trial of the prisoner, although it was not signed by her, and she was under twelve years of age; provided she was sworn and appeared competent to take an oath; and all the facts necessary to complete the crime may be collected from the testimony so given in evidence. But, as is the practice in other criminal cases, it is not necessary that the female should be sworn, if her testimony is given while she is dying, she being conscious of her state at the time; for it is considered that the awful situation in which she is placed is as sure a guarantee of the truth as any form of oath could be. At the same time it is quite necessary to have proof of the soundness of her understanding at the time, for without this the solemnity of the occasion, and the anticipation of death, may not have a sufficient impression on her mind.

(T. E. Beatty.)

REFRIGERANTS (from *refrigere*, to grow cold), may be defined, medicines which diminish the *morbid* heat of the body. Their influence is generally admitted, but the theory of their operation is not well understood; and, consequently, many and very opposite hypotheses have been advanced upon the subject. The first of these which deserve notice is that of Cullen, based upon a doctrine of Needham: it forms a remarkable instance of the obscurity into which hypothesis leads men otherwise distinguished for the perspicuity and soundness of their reasoning. This hypothesis supposes "that there is every where, in nature, an expansive and a resisting power; and that, particularly under a certain degree of heat, the expansive power appears in all the parts of organised bodies, in consequence of which they shew a singular vegetating power; while, at the same time, there is, in other bodies, a power resisting and preventing the action of this vegetating power, and, at least, of diminishing its force." And it is assumed that this power is found in those substances which are usually employed as refrigerants.† It is unnecessary to comment upon these opinions; indeed, their obscurity is such as to render them scarcely intelligible.

A later theory is that of Dr. John Murray, whose habit of reasoning upon chemical principles led him to call in the aid of these to explain the operation of refrigerants. He founds his opinion on the presumption of the truth of the theory of Dr. Crawford, that, in the process of respiration, the arteries in the lungs absorb the calorie liberated there; and, owing to the great capacity of arterial blood for caloric, they instantly render it latent, in which state it remains until the subsequent conversion of the arterial into venous blood, when it is liberated equally through the system. Now, Dr. Murray considers that the consumption of oxygen in the lungs, supplying the calorie to the arterial blood, is greatly influenced by the nature of the food and other ingesta received into the stomach. He supposes that when these substances contain a small proportion of oxygen, the demand for that component of the air, and its consumption by the lungs, are augmented; and, consequently, the animal temperature is elevated; whereas an opposite effect takes place when the ingesta contain much oxygen, more especially if it exist in a loose state of combination. According to this theory, therefore, all substances containing much oxygen capable of being extricated by the powers of the stomach, should possess a refrigerant influence. Plausible as this theory appears to be, its accuracy is very questionable; but, in order to reason correctly upon its merit, it is necessary to take a cursory view of the theory of animal heat upon which it is founded; for if the difference of capacity of arterial and venous blood for caloric be insufficient to account for the temperature of the living body, Dr. Murray's theory of the changes produced by refrigerants must necessarily fall to the ground.

Dr. Crawford's object was to prove, as already stated, that arterial blood has a greater capacity for caloric than venous blood; and this is also the case in reference to common or atmospherical air and carbonic acid gas. The latter fact explains the augmentation of temperature arising from the change which the air undergoes in the lungs when carbonic acid is present in them; but as the caloric thus evolved is absorbed by the arterial blood, and rendered latent, the sensible temperature of the blood is not augmented; and it only becomes so as the arterial blood changes to venous in the course of its circulation. By this evolution of caloric the loss of temperature which the body sustains is compensated. Respiration, therefore, and the greater capacity of the arterial than the venous blood, are, according to this theory, the true sources of the peculiar temperature of the living body.

Many facts might be mentioned as favoring the truth of Dr. Crawford's hypothesis; for example, the greater the comparative size of the lungs, and the greater the quantity of blood which passes through them, the higher is the temperature of the animal. Thus, the capacity of the lungs is greatest in birds, which have the highest temperature among animals; and it is a well known fact, that whatever lessens the free action of the lungs and diminishes the consumption of oxygen, reduces the temperature of the animal. Individuals who labour under a malformation of the heart sufficient to prevent the arterialization of the blood, are always of a temperature below the natural standard. In hybernating animals, also, the temperature falls as the respiration is suspended; and it

* Leach's C. L. p. 996, and Paris and Fonblanque, vol. i. p. 439.

† Mat. Med. ii. 121.

rises with the return and the progress of respiration: and, farther, M. Gallois ascertained, by experiment, that the temperature of the body falls exactly in the ratio of any diminished quantity of oxygen consumed in respiration. These opinions are strengthened by some experiments of Dr. Wilson Philip; and, upon the whole, it is tolerably well ascertained that the temperature of the body sinks, if it be not maintained by the chemical changes which occur in respiration.

But, notwithstanding the support thus given to Dr. Crawford's opinion, many and as strong facts have been advanced in support of that view of the subject which regards nervous energy as the source of animal heat. The most important experiments on this side of the question are those of Mr. Brodie. He found that, by maintaining the action of the heart by artificial respiration after the brain is removed, although the blood undergoes its ordinary changes, yet that the temperature of the animal thus treated is rapidly lowered. Mr. Brodie's experiments were made on rabbits, in which the functions of the brain were suspended by dividing the spinal marrow: the blood, in both systems, underwent no change different from that which occurs in natural respiration. "It may perhaps be urged," says Mr. Brodie, "that, in these experiments, the secretions had nearly, if not entirely, ceased: it is probable that the other changes which take place in the capillary vessels had ceased also, and that, although the action of the air on the blood might have been the same as under ordinary circumstances, yet there might not have been the same alteration in the specific heat of the fluid as it flowed from the arteries into the veins. But, on this supposition, if the theory of Dr. Crawford be admitted as correct, there must have been a gradual but enormous accumulation of latent heat in the blood, which we cannot suppose to have taken place without its nature having been entirely altered. If the blood undergo the usual change in the capillary system of the lungs, it is probable that it must undergo the usual change in the capillary system of the greater circulation also, since these changes are obviously dependent on and connected with each other." From the experiments of Mr. Brodie it appears that, when the functions of the brain are suspended, the power of generating animal heat is also suspended; although the same quantity of oxygen be consumed as in natural respiration under ordinary circumstances. It is, nevertheless, proper to mention here the opinion of M. Gallois, that, owing to the nature of artificial respiration, upon which Mr. Brodie's conclusions are founded, the temperature may fall, and the animal be killed by cold, although every part remain uninjured. The air in artificial respiration does not enter the pulmonary cells in the same manner as in natural respiration, but is forcibly propelled into them; a large formation of frothy mucus occurs, which both prevents the air coming in contact with the lining membrane of the air-cells, and by its evaporation tends to cool the body.

Many other facts concur, also, to prove that the temperature of the body is regulated by the nervous energy. It is true that these demonstrate its effect chiefly in maintaining the heat of parts; but if its influence on parts be admitted, it is not easy to conceive on what grounds its power over the entire system can be denied. Sir Everard Home divided the nerves going to the growing antler of a stag, and found that the temperature almost immediately fell; and although, after a few days, it rose again higher than before, yet this may have originated from the re-union of the divided nerves: at all events it does not invalidate the fact that the temperature fell on the division of the nerves, and, consequently, was regulated by their condition. In paralysed limbs the temperature sinks, although in many cases the circulation in the limb is unaffected, and the paralysis is confined to the sensibility of the member. In a case recorded by Mr. Earle, in which the axillary plexus of nerves on one side was crushed, the paralysed limb of that side was of a lower temperature than the opposite limb: indeed, in general we find that increased nervous action, whether depending on affections of the mind or on other causes, augments the heat of the body; whilst the effect of depressing passions, which diminish nervous energy, is followed by either general chilliness, or coldness of the extremities.

These facts undoubtedly go far to prove that animal heat is a vital principle closely connected with the integrity of the nervous system; but at the same time, as the stimulus of arterial blood is requisite for the excitement of the brain and nerves, and arterialization is the result of respiration, the influence of respiration in the production of animal heat must be so far admitted; for without the function of the lungs the brain would lose its energy, and the temperature of the system be necessarily greatly lowered. This opinion receives also considerable support from some experiments of Dulong to ascertain whether the quantity of caloric, developed by the consumption of oxygen in respiration, be equivalent to the quantity given out by the body. He found that in carnivorous animals the proportion is equal to forty-nine and fifty-five parts in one hundred of the heat generated by the whole body during the same interval of time; and, in phytivorous animals, to betwixt sixty-five and seventy-five parts; and that the whole quantity of caloric and water together is equivalent to sixty and eighty parts only; so that the animal heat is greater than can be accounted for by the fixation of oxygen during respiration. Upon the whole, the examination of both sides of the question leads us to conclude that both opinions are to a certain extent true; that animal heat is influenced chiefly by the state of the nervous system, but partly, also, by the chemical changes which take place in the lungs during respiration.

If this view of the sources of animal heat be correct, it presents a considerable obstacle to the admission of Dr. Murray's explanation of refrigerants, which can only be regarded in the light of an ingenious hypothesis. The subject,

therefore, remains as he found it; and the question presents itself—can no rational explanation of the operation of refrigerants be suggested? The writer of this article, although he does not venture to offer a theory likely to be generally adopted, yet conceives that some approach to a rational explanation may be attained by ascertaining how far the action of refrigerants taken into the stomach resembles that produced on the skin by similar substances.

In abstracting caloric from the surface of the body, or, in other words, cooling the skin, whatever agent be employed, whether diluted acids, salts in a state of solution, cold air, or cold water or ice, the activity of the capillaries of the part is immediately diminished; and as their action cannot be materially lessened without the whole vascular system being more or less influenced, the vigour of the heart and arteries is also materially depressed. The consequence of this diminished vascular action is immediately felt on the respiration; the blood does not undergo its necessary change; venous blood is conveyed to the brain, the function of which being impeded from defect of stimulus, a state somewhat resembling paralysis of the nervous system ensues, so that torpor of every organ, the function of which depends on the energy of the brain and nerves, must necessarily follow. The effect of the abstraction of caloric on the nerves is strikingly illustrated by the numbness and insensibility which follow the exposure of the hands, in many individuals, in cold weather; a result which is more likely to arise from the direct influence of cold on the nerves themselves, than from the diminished supply of blood to the parts. Indeed, as in this case the effect on the nerves is partial, we can scarcely imagine any other cause of the diminished action of the capillaries than the depression of the nervous energy. Now if we suppose,—and the supposition is far from being unreasonable,—that an effect resembling that produced on the surface takes place in the stomach when refrigerant agents are introduced into it, we may readily admit that the effect on the capillaries of that organ is extended by sympathy over the system. The possibility of such a result is equally probable in the one case as in the other. This opinion receives some support from the fact that nitrate of potassa operates as a powerful general refrigerant when it is swallowed at the instant of its solution; but it acts as an excitant when it is not taken into the stomach until after it have been some time dissolved. The sensation of cold which the nitre, during solution, causes in the stomach, is evidently owing to a partial abstraction of stimulus, and the effect of this being extended through the nerves to the heart and larger branches of the arterial system, a general reduction of action is produced, and this is followed by a sensation of cold over the whole body. Let us now enquire how far this theory is borne out by the known effects of refrigerants upon the functions of the stomach, the lungs, and other organs.

1. In the healthy condition of the *stomach* refrigerants exert little perceptible influence upon it; but when it is either in an irritable state, or affected with inflammation, the continued use of refrigerants, particularly cold and iced water and lemonades, allays the sensation of heat, nausea, and general uneasiness. Even when no local inflammation exists, cold water and other cold, bland fluids, received into the stomach, moderate general excitement and control febrile action; an effect which can only be explained by the influence of the refrigerants on the nervous energy. The same results follow the administration of refrigerants in enteritis.

2. Refrigerants exert no evident influence on the *circulating* and *respiratory* organs, in the state of health; although in some individuals, owing to idiosyncrasy, acidulated fluids cannot be taken without so powerfully affecting the larynx as to cause a temporary loss of voice: but in a diseased state of these organs the influence of refrigerants is well marked.

In an excited state of the vascular system, when the pulse is both quicker and stronger than natural, acidulated drinks reduce both states, both moderating the action, and relaxing the tension of the pulse; nor is their effect on the capillaries less manifest; and it is to their influence on these that we must attribute the diminished temperature which follows their administration. It is surely unnecessary to say how intimately this is connected with their impression on the nerves of the stomach. In the febrile state, the effects of refrigerants on the circulation are necessarily communicated to the lungs; but besides this sympathetic influence, some of this class of medicines, in particular, acids, seem to operate directly on the pulmonary tissue. In acute inflammation of the air-tubes, or even of the pleura, acid fluids greatly augment the cough and oppress the breathing, when administered before the excitement be subdued; and after this is effected, we still perceive the evidence of their action on the mucous membrane by the aid which they afford to expectoration.

3. But the most decisive illustration of the extent to which the nervous system is influenced by refrigerants, is observed in the effects which acidulated fluids produce on those who are labouring under diseased conditions of the spinal cord. The author had an opportunity of witnessing this in a gentleman who was labouring under subacute inflammation of the spinal theca. Whenever he swallowed a spoonful of lemonade, or even an ordinary effervescing draught, a sensation of pricking was felt over the surface, the skin became so sensitive as scarcely to admit of being touched, and the whole system restless and uneasy. Hypochondriacal and hysterical persons, not unfrequently, suffer in a similar manner from the internal use of acids; and, as this effect is not confined to particular individuals, it cannot be ascribed to idiosyncrasy.

Upon the whole, it is evident that refrigerants operate to a certain extent as sedatives; diminishing the force and rapidity of the pulse, depressing morbid temperature, and calming, generally, the disturbance which always attends acute diseases.

The substances employed as refrigerants

operate either on the organic functions or on the sensibility of the body in a state of disease.

1. The refrigerants operating on the organic functions are chiefly vegetable acids. The influence of *acetic acid*, in its diluted impure state or as vinegar, in cooling the body labouring under disease, was very early known. In its undiluted state it is a powerful stimulant; and when daily taken in large doses into the stomach in its diluted form, it produces great uneasiness, cramps, and colic, and gradually destroys so effectually the texture of the organ and its digestive function, as to cause emaciation of the body. When it is only occasionally taken, largely diluted with water and moderately sweetened, it displays decided soothing and refrigerant properties, and is employed with advantage in inflammatory and bilious fevers, for quenching thirst, calming the vascular excitement, re-establishing the perspiratory function of the skin, and restoring the action of the kidneys. In inflammatory affections of the lungs, however, it increases the cough, and augments the morbid sensibility of the mucous membrane in the same manner as all other acids; and, therefore, it is contra-indicated in such diseases, even as an expectorant, until the excitement be subdued.

The refrigerant influence of diluted vinegar on the surface is undoubted; it not only diminishes heat but allays pain. In hemorrhagic affections, the cold feeling which it produces on the skin is extended to the whole system; hence the benefit derived from it in internal hemorrhages, and in the inflammation of cavities; as, for instance, in uterine hemorrhages applied to the thighs and abdomen; and in acute meningitis applied as a lotion to the shaved scalp. In general fever, sponging the body with vinegar and water is applicable to every case in which the skin is preternaturally hot, when no idiosyncrasy stands in the way.

When diluted acetic acid is internally administered, if opium be prescribed at the same time, it should be recollected that it decomposes the meconate of morphia of the opium and forms an acetate, which is a more powerful narcotic than the meconate. The combination of this acid with ammonia, in the preparation known by the name *liquor ammoniæ acetatis*, possesses refrigerant powers nearly equal to those of the diluted acid, acting at the same time as a diaphoretic; and it is more generally employed than the acid in modern practice. The salts procured by the combination of acetic acid with the other alkalies operate chiefly on the kidneys.

The *citric acid* is more frequently employed than the acetic as a refrigerant; but chiefly in its combined state as prepared by the hand of nature, in the juice of the lemon, the orange, and other fruits. It is more grateful in its combined than in its uncombined state; a fact which is quickly perceived by patients in fever, when it is ordered to form the common effervescing draught for checking nausea and vomiting. When simply diluted with water, in the proportion of the juice of two moderately-sized lemons to a pint of water, and slightly sweetened, forming lemonade, citric acid constitutes a most serviceable and agreeable beverage in fevers; and in those of a typhoid character this is rendered more grateful and beneficial by using water impregnated with carbonic acid gas instead of common water. In the ordinary condition of the stomach, citric acid, either pure or combined, does not weaken the stomach; and in some irritable states of that organ, characterized by a sensation of heat, painful digestion, an unpleasant taste in the mouth, and a disgust of food, it removes these symptoms and proves decidedly beneficial; but on the other hand, when the stomach is highly irritable, and its nervous susceptibility great, lemon-juice, or the citric acid, even when largely diluted, causes heat, uneasiness, and pain, and not unfrequently obstinate vomiting. Nevertheless, as M. Broussais has remarked,* the citric acid is that which the stomach supports best when suffering under inflammation.

The citrates of potassa and of ammonia are also refrigerant: the citrate of soda, which is not an officinal preparation, operates as a purgative.

The above remarks are applicable to the juice of the orange, the apple, the currant, and the gooseberry, all of which owe much of their acidity to the citric acid.

The *tartaric acid*, except as it is contained in the tamarind, is much less frequently prescribed than the citric as a refrigerant, being more apt to disorder the digestive organs, to produce colic and to purge; and its morbid influence on those labouring under affections of the spine is more constant and evident than that occasionally resulting from the employment of citric acid: indeed, so obvious is this, that patients sometimes refuse to continue taking it on account of the nervous agitation which it causes. Its combination in the form of the *bitartrate* is more frequently employed; and in small doses at moderate intervals, it does not operate as a purgative, but as a simple acidulous refrigerant. It is best administered in the form of whey, or of cream-of-tartar beverage; it moderates febrile heat and softens the skin; but when its employment is followed by a red and dry tongue, it ought to be discontinued. Both the acid and the bitartrate are incompatible in mixtures with the nitrate of potassa, which it decomposes, and, uniting with its alkaline base, forms either a bitartrate or a tartrate.

The *oxalic acid* in the form of the binoxalate, as found in the oxalis *acetosella* and rumex *acetosa*, was formerly much prescribed as a refrigerant; but these plants, and, indeed, the oxalic acid in any form, are now rarely employed.

Nitrate of potassa, in small doses, is a well-known refrigerant: it produces a powerful sympathetic effect on the nervous system, depressing the strength and diminishing the frequency of the pulse, and lowering the animal heat: the skin becomes pale, and a sensation of lan-

* Phlegmas. Chron. t. iii. p. 254.

uor is felt. To obtain the full refrigerant ffect of nitre, the salt must not only be admiistered in small doses at short intervals, but should not be dissolved until the instant in hich it is to be administered. As a refrierant, the dose should not exceed a scruple, , at the utmost, half a drachm.

The *bicarbonate of soda*, although seldom prescribed as a general refrigerant in this country, et is frequently administered in inflammatory brile affections on the continent. It is, however, better calculated for operating as a local an as a general refrigerant.

2. The refrigerants operating on the sensility of the body are few; but they are more irectly refrigerant than those which have been ready noticed. *Cool air*, the first of these, so agreeable to the feelings in a heated ate of the body, that observation alone might ave led to its early employment as a remedial gent; and nothing marks more strikingly the erversity of mankind than the opposition of hysicians, at one period, to the indulgence f the instinctive desire for this remedy in fever atients. Its utility in moderating high vasular action and operating as a sedative refrierant is now generally acknowledged; and onsequently its admission to the apartments f the sick, in febrile diseases, is almost uniersal.

If cool air be beneficial in the above-mentioned conditions of the body, *cold water* and e are still more so; and their application is xtensive. For an account of the effects of old water and ice in reducing the temperaure of the body in its healthy condition, we ust refer our readers to the articles Bathing nd Cold. When cold water and ice are mployed as curative agents, their influence ay be obtained either by their internal admiistration or by their application to the surface: n both cases their effects are extended by symathy over the system; but they are modified y the manner in which these agents are used. f the body be immersed in the *cold bath*, the ost striking effect is the shock or nervous mpression which produces the vascular rection so beneficial when cold bathing is used s a tonic; an effect, however, which must be voided as much as possible when the refrierant influence only of the bath is required. o insure simple refrigeration, the water should e of a temperature not much below that of he skin; but as, even at such a degree of heat, he sudden immersion of the body is likely to ause more reaction than would be safe in ases requiring mere refrigeration, the cold bath s rarely or never employed in this country for roducing that effect. The shock and reaction aused by dashing cold water over the body, onstituting the *cold affusion* as it is termed, is s considerable as when the cold bath is used, ut it is more transitory, and therefore it is more useful refrigerant. *Sponging* the body ith cold water, as far as a simple refrigerant ffect is desired, is preferable to either the cold ath or the cold affusion: there is no shock; he fluid, being left to evaporate, merely cools he surface; and by persevering in the process, the cooling effect is fully obtained, and rendered permanent. One great advantage of sponging the surface with cold water is the facility of limiting the extent of the effect according to the feelings of the patient: in general it may be continued until the sensation of chilliness comes over the body, when the patient should be dried and placed in bed. The more simultaneously the influence of the cold water is extended over the surface, the better; the process of sponging should, therefore, be performed by several attendants with large sponges on the different parts of the body at the same time. In ordinary cases the temperature of the water may be regulated by the feelings of the patient, as the beneficial effect depends on the evaporation, which may be aided by the addition of vinegar or alcohol. *Evaporating lotions* applied to a part operate locally in the same manner as general sponging; the sedative and refrigerant influence is not confined to the part, but extends to other parts of the body, even to the interior, as, for instance, to the brain, the contents of the abdomen, and to joints. The sedative effect is still more powerful when a small stream of cold water is directed upon the part: the author of this article has seen this most strikingly exemplified in burns; the mere immersion of the part in cold water, or the application of cloths dipped in cold or even iced water, is much inferior in its effect to this method of employing cold water. It is scarcely necessary to comment on the influence of the local application of *ice*, which operates exactly in the same manner as evaporating lotions, but more effectively, owing to the steady continuation of the same low temperature to the part.

The foregoing remarks lead to this conclusion—the utility of refrigerants as curative agents is more limited than that of most other classes of remedies. They are chiefly employed to depress inordinate vascular action, and thereby to lower temperature; consequently, it is in inflammation, active hemorrhages, and febrile affections that they are found beneficial; and in such cases they are, undoubtedly, most valuable remedies.

In local inflammations on the surface of the body, cold water and evaporating lotions prove highly serviceable; whilst in those more deeply seated, as for instance, inflammation of the brain and its membranes, ice applied to the scalp is to be preferred: the steady abstraction of caloric which it effects, operates not only upon the vessels and nerves of the integuments; but, by diminishing action in the carotids and large vessels, it produces the most decisive benefit in reducing the vascular action within the cranium. These applications have been lately recommended in other internal inflammations, even those of the thorax and abdomen, and under proper circumstances have been found highly beneficial.

Hemorrhage arising from increased action, or accompanied by it, is frequently checked by the sedative influence of refrigerants. When the bleeding is internal, the degree of cold should be such as to operate sympathetically

on the whole system; and to lessen not only the action of the vessels of the part, but to restrain, to a certain degree, that of the heart. Thus in hemoptysis, not only should the patient be freely exposed to cold air, but ice and cold acidulous fluids should be freely administered; indeed, the temperature may be with safety, and even with advantage, diminished so much as to be uncomfortable to the feelings of the patient. In such a case the low degree of temperature is accompanied with an evident diminution of the irritability of the contractile fibres of the whole vascular system, and, consequently, aids greatly in checking the flow of blood. The liquids administered as drink should be cooled down to 32°, either by ice or by a freezing mixture, and slowly swallowed. The influence of nitre has long been regarded as considerable in such cases; and much of the benefit received has been attributed to a chemical change effected on the blood; but if the opinions advanced in this article be correct, it is unnecessary to assert that this explanation of the operation of nitre must fall to the ground.

In hematemesis occurring in young and vigorous persons, the same assiduous employment of refrigerants is requisite as in hemoptysis; and when the bleeding is so violent as to threaten quickly serious consequences, the other refrigerant plans may be aided by injecting iced water into the rectum, and by the local application of cold to the epigastrium. In no species of hemorrhage is the sympathetic influence of refrigerants more strikingly obvious than in epistaxis. Thus dashing cold water on the genitals has sometimes instantaneously suppressed bleeding at the nose; and on the same principle is explained, what it is scarcely necessary to notice, the popular remedy of applying a large cold key or a piece of metal between the shoulders under the clothes.

It is superfluous to say that, however useful refrigerants may prove in all cases of active hemorrhages, their employment in the passive is to be most carefully avoided.

But it is in fevers that refrigerants under every form are to be regarded as the most valuable set of therapeutical agents. In continued fever, the vegetable acids largely diluted are internally administered, especially those found in fruits; and not unfrequently nothing is more grateful to fever patients than cold water slightly acidulated with either the sulphuric or the nitric acid. It is, however, the general application of cold to the surface which proves the most useful refrigerant in continued fever. In those forms of the disease which assume a typhoid type, ventilation and the free admission of cool air into the apartments of the sick are absolutely necessary: irritation is allayed, debility obviated, and the whole complexion of the disease often changed in a few hours, by the removal of the patient into a cool and well-ventilated, from a close and filthy apartment. The most direct and effective refrigerant, however, in continued fevers is the cold affusion; but its employment requires certain cautions, without attention to which much mischief may be incurred. In the first place, the exact temperature of the body must be carefully ascertained. In this country, in the severest attacks of fever, it has rarely exceeded 108° Fah., but in tropical climates it rises sometimes to 112°; the higher the temperature of the patient, the more benefit may be anticipated from the cold affusion. The temperature of the water should vary according to the season of the year and the feelings of the patient, the average range being from 40° to 70° Fah. The effect is to diminish the morbid heat of skin, to lower the force and retard the rapidity of the pulse, and to induce perspiration and sleep; and when such results follow, the cold affusion proves beneficial in any form of fever.

The thermometer is employed to determine the temperature of the patient; but if he feel cold when that instrument indicates an augmented morbid temperature; or if he feel hot when the thermometer demonstrates that the heat of the body is below that of the natural standard; then in neither case should this form of refrigerant be resorted to. It is also improper when the skin is bedewed with perspiration; or if the patient dread greatly its use; nor is it less so during menstruation, and in the latter months of pregnancy. In the advanced stages of fever, refrigerants of any kind are injurious.

With respect to the kinds of continued fever in which refrigerants are indicated, we may enumerate six.

1. In inflammatory fever, *(synocha,)* a rare disease when unaccompanied with topical inflammation, the advantages to be derived from refrigerants are well understood. The cold affusion is admirably adapted for rapidly abstracting the stimulus of heat, diminishing general excitement, and operating as a powerful sedative. In the more advanced stages of the disease, cool sponging is often substituted for the affusion; but when the patient can bear the fatigue of the affusion, it is always to be preferred. The greater frequency of this form of fever among the ancients than the moderns explains their constant employment of cold drinks and cold bathing in continued fever.

2. In fevers of a typhoid type, the disease has been cut short by the cold affusion; but in this case more perhaps is to be attributed to the shock and the reaction which follows, than to the refrigerant influence of the affusion.

3. In synochus or inflammatory fever, gradually assuming the typhoid character, refrigerants in general, but more especially the cold affusion, are chiefly applicable to the early stages of the disease; and, indeed, no form of remedy is more advantageous when there are no local determinations; but when these exist, particularly if the lungs be affected, much caution is required.

4. In remittent fevers, especially those of warm climates, and in their more intense and excited variety, the cold affusion may be employed with great benefit. In severe attacks, also, much advantage is derived from the

application of ice or cold water to the scalp; in the remissions, however, the application of cold in any form must be suspended. In yellow fever, the safety of the patient frequently depends solely on the early application of the cold affusion.

5. If hectic be symptomatic of pulmonary affections, or determination to internal organs, the cold affusion is decidedly contra-indicated; but even in such cases much benefit is often obtained by sponging the trunk of the body with cold water mixed with vinegar, whilst the lower extremities are kept warm in bed. We must, nevertheless, bear in mind that, under any form of hectic, although general refrigerants are useful auxiliaries, yet the cold affusion can scarcely be regarded as admissible.

6. In most eruptive fevers, except measles, the body should be freely exposed to cool air; and even the cold affusion may be safely and advantageously prescribed, should the state of the surface require it, nor should the presence of the eruption operate as a reason against its employment. The Hindoo physicians plunge their patients, during the eruption of small-pox, into cold water, and with the best results. It diminishes the fever, lessens the number of the pustules, and is said to prevent pitting. The writer of this article has long been in the habit of employing the cold affusion in scarlatina during the height of the eruption, and has seen the severity of the disease instantly checked by it.

In intermittent fevers, when the skin is dry and parched, and the general heat greatly augmented, cold in every form applied to the surface, and cold acidulated fluids taken into the stomach, are of the same value as in continued fever, and greatly favour the accession of the sweating stage. The affusion should be used in the hot stage of the paroxysm, and continued until the temperature of the body of the patient be reduced to the natural standard.

It is unnecessary to discuss the nature of the various diseases, besides idiopathic fevers, in which refrigerants are indicated: in all, much depends on the degree of the attendant fever, and the existence of local affections. In one local disease, phrenitis, however, their advantageous effects are very conspicuous: the most furious delirium is quickly subdued by allowing cold water to drop on the vertex, whilst the rest of the scalp is covered with cloths moistened with vinegar and water. The degree of collapse, indeed, which is thus produced, is often so great as to require most active measures to counteract it; when such occurs, the state of sinking is to be treated exactly in the same manner as when extreme debility suddenly appears from other causes: external warmth, particularly the application of bladders of hot water to the scrobiculus cordis, friction, electricity, and sometimes artificial respiration, are the means to be employed to restore animation; and when the power of deglutition returns, the administration of excitants, especially aromatics and ammonia, is to be resorted to.

From the foregoing remarks, it is evident that, although, as we have already said, refrigerants constitute a class of medicines of limited application, yet they are of much value in a few important diseases. Like every other class of therapeutical agents, their utility will be more or less obvious as the discrimination, the judgment, and the observation of the practitioner are properly exercised, in determining the exact condition of the body which demands their employment.

(A. T. Thomson.)

RHEUMATISM, from ῥεῦμα, *a defluxion*. This term, originally adopted when diseases accompanied with swelling were usually attributed to the flow of some special humour to the part affected, has been used for ages to designate an affection which has so much of distinct character as to justify its being considered a special disease. So loosely, however, has the term been applied, that a host of ailments, with no character in common save that of pain, have been classed under it, and much both of false experience and of bad practice has thence resulted. Diseases called rheumatic have been relieved by stimulant remedies, which from the character thus acquired have been empirically resorted to in states of constitution for which they were utterly unsuited. In acute rheumatism, a disease intensely inflammatory, we have known the use of the most powerful stimulants confidently urged by well-meaning but misguided friends, who in support of their prescription have pleaded the wonderful cures which they had seen their favourite specific perform in what they assumed to have been rheumatism; thus misled by a name to recommend in active inflammation what could have benefited only in a totally opposite state of the system. As many affections really rheumatic present an equivocal character which to superficial observation too often appears to justify the use of stimulants, it is very necessary to discriminate the real disease, so as to distinguish it from those diseases with which it is liable to be confounded; and however difficult it may be to class the latter, it is better to leave their place in nosology unassigned, than, by ranging them under the head of rheumatism, to beget confusion where clearness and precision are of the first importance.

In the investigation of rheumatism, the best mode, similar to what was followed in treating of gout, is to consider, first, the simple disease in its most perfect form; and then, with the lights thus supplied, to elucidate the more complex conditions which the larger portion of rheumatic affections presents. So contradictory, and, we may add, so ineffectual are the means ordinarily used in treating the latter, that no greater benefit could be conferred both on patients and practitioners, than to divest the treatment of perplexing confusion and inconsistency by reducing it to fixed principles, and bringing it within the pale of rational and scientific practice.

In determining the diseased condition to which the name of rheumatism should be specially assigned, it is expedient to examine the representations given of it by the systematic nosologists. Sauvages describes rheumatism

as "dolor diuturnus in parte carnosa artuum," and places it in the class *Dolores*, order *Vagi*, of his nosology. According to Linnæus it is "musculorum dolor ad motum, a tunica cellulosa injecta;" class *Dolores*, order *Extrinseci*." Vogel places it in class *Dolores*, as merely "cutis et musculorum dolor." It would be difficult to recognise in these brief and meagre specifications the ordinary disease of rheumatism, such as we daily witness it.

Sagar is both more copious and more precise. He describes two diseases, a chronic one ranged in the class *Dolores*, order *Vagi;* and an acute under the specific name of myositis, in the class *Phlegmasiæ*, order *Phlegmasiæ musculosæ*, giving respectively the following definitions. "*Rheumatismus.* Dolor diuturnus in parte carnosa tendinosa artuum, vagabundus, sæpius sine coryza, rheumate, catarrho, erysipelate, et sine febre notabili; (acutus rheumatismus facit genus inter Phlegmasias, myositin a me dictum;) sanguis missus rheumatismo laborantium, est gelatinosa crusta tectus, et urina sæpe ad sulphureum colorem tendit." "*Myositis.* Febris acuta inflammatoria, dolores in diversis musculis artuum, eorundemque involucris, diu noctuque discruciantes, motum vetantes fere omnem, ad noctem exacerbantes; sanguis missus est tectus crusta inflammatoria subgelatinosa, vel pelli tenui tenaci: hic morbus vulgo audit rheumatismus acutus." It is worthy of remark that Sagar notices the blood drawn in chronic rheumatism as exhibiting a buffy crust. Cullen considers acute rheumatism alone as a special disease, regarding the chronic form as only a sequel of it. He places it in the class *Pyrexiæ*, order *Phlegmasiæ*, and gives the following definitions. "*Rheumatismus.* Morbus ab externa et plerumque evidente causa; pyrexia; dolor circa articulos musculorum tractum sequens, genua et reliquos majores, potius quam pedum vel manuum articulos infestans, calore externo auctus." "Rheumatismi sequela est, *Arthrodynia.* Post rheumatismum, nisum violentem vel subluxationem, dolores artuum vel musculorum, sub motu præsertim aucti, plus minusve fugaces, calore lecti vel alio externo levati; artus debiles rigidi, facile et sæpe sponte frigescentes; pyrexia nulla; tumor plerumque nullus. Rheumatismus chronicus auctorum."

I.—Acute rheumatism.

This disease is often designated by the trivial name of rheumatic fever, a term which implies a constitutional disturbance as well as a local. The ordinary phenomena which characterise it are so familiarly known, that a very brief account of its accession and progress will here suffice. That given by Sydenham, derived as it was from actual observation, and marked by his wonted truth and accuracy, presents in few words as clear a description of the early seizure as can well be rendered.

"This disease happens at any time, but especially in autumn, and chiefly affects such as are in the prime of life. It is generally occasioned by exposing the body to the cold air immediately after having heated it by violent exercise, or some other way. It begins with chillness and shivering, which are soon succeeded by heat, restlessness, thirst, and the other concomitants of fever. In a day or two, and sometimes sooner, there arises an acute pain in some or other of the limbs, especially in the wrists, shoulders, knees; which shifting between whiles, affects these parts alternately, leaving a redness and swelling in the part last affected. In the beginning of the illness the fever and the above mentioned symptoms do sometimes come together, but the fever goes off gradually, while the pain continues, and sometimes increases."

The latter circumstance Sydenham, in conformity with the pathology then prevalent, attributes to the "derivation of the febrile matter to the limbs," which he conceives to be sufficiently shewn "by the frequent return of fever from the repulsion of morbific matter by external remedies." The theory here propounded may be questionable as resting on hypothesis, but the facts with which it is connected are not the less valuable.

It appears, then, that acute rheumatism presents a state of active fever accompanied with local inflammation of one or more joints. And here one of the most important questions respecting rheumatism arises,—whether the local inflammation be the cause of the fever, or only its attendant? On the solution of this, much both of the pathology and treament of rheumatism must depend, and accordingly its elucidation will form a prominent part of the present article.

In the foregoing description of Sydenham, it appears that the state of febrile excitement precedes the local inflammation. In theoretic speculations this fact seems generally recognised, yet it does not appear to have been kept steadily in view either by speculative or practical writers. The term symptomatic fever, so often applied to the constitutional disturbance, implies that this was regarded rather as a contingent result of the local inflammation, than as a precursor or cause of it. To determine this point is of much importance, for by the decision must the whole course of treatment be influenced. If the local inflammation, whether seated in the *muscular*, though more frequently in the *fibrous* tissue of the affected parts, be the cause of fever, as implied by the term symptomatic, the reduction of local inflammation by the most direct means would be the best and most effectual relief; and this being duly attended to, the contingent fever might, according to the familiar axiom, *sublata causa tollitur effectus*, be little regarded. On the contrary, if the state of fever, or rather that condition of the habit which gives rise to fever, be the real source of rheumatic seizure, then should the constitutional state be chiefly attended to, and local treatment be only subsidiary to that by which the derangements of the constitution are rectified. We hope clearly to shew that the constitutional state is that which chiefly claims our regard in the treatment of rheumatism.

When acute rheumatism occurs in its most active state, so intense is the inflammatory fever

attendant, that whatever theory of the disease be entertained, the fever claims its full portion of attention, and is met by adequate activity of treatment. Bleeding, purging, and other means of reducing fever are promptly and freely employed, the more so as experience has shewn this treatment to be indispensable for abating the local inflammation. This being the case, then, it may be asked, of what importance is it to decide whether the local or constitutional affection is to be regarded as the primary disturbance, inasmuch as the same treatment relieves both? It would be sufficient to answer that truth ought always to be ascertained, for it can never be unimportant. Were acute rheumatism in its more active state to be alone considered, the importance of the decision might be less, both the local and constitutional disturbance demanding the vigorous employment of corresponding means. But when the minor degrees of the same disease, constituting what is termed chronic rheumatism, come to be investigated, it will be seen that their essential character involves the point at issue; and that unless this be determined as truth and reason dictate, the practice in a malady which is more prevalent, causes more suffering, and leads to more decrepitude than almost any other, must be vacillating, imperfect, and unsuccessful.

It will materially abridge the present article to refer to certain general principles of pathology already detailed in the articles Gout and Plethora. These principles apply directly to rheumatism, and through them alone can its pathology be adequately unfolded, or its treatment rationally explained.

Acute rheumatism principally attacks the young and vigorous. The period of life most subject is said to be from puberty to thirty-five years. Though no age is exempt, it yet more rarely occurs in the very young, or in advanced life. This circumstance alone would seem to indicate some connexion between rheumatism and fulness of habit, or that approximation to plethora which was formerly noticed as exuberance of health; and if rheumatic seizures be duly scrutinized, they will be found to take place in those who from plethora, whether absolute or relative, are prone to fever or inflammation on any exciting cause being applied. The extraordinary health so often remarked by patients as having immediately preceded the rheumatic attack is sufficiently intelligible. But direct evidence of the state of constitution in which attacks of rheumatism occur is amply shewn in those who, having had the disease, are liable to its recurrence, and on this account compelled to watch the premonitory indications of an attack. In these, constitutional disturbance of a febrile kind, marked by all the phenomena formerly detailed as denoting the transition of plethora into febrile excitement, will be invariably found to exist for a sensible time before the disease presents its full character by the establishment of a local inflammation. And to these premonitory indications should the earliest attention be given, for it is in this stage that relief can be most speedily and effectually afforded. By reducing plethora and subduing febrile action in this stage, the local inflammation may be wholly averted, and thus may be prevented not only the injury which the joints, when affected, are liable to sustain, but also the susceptibility to impression from slight causes which reiterated attacks of rheumatic inflammation never fail to leave.

The local inflammation of acute rheumatism undergoes a change during its progress which seems to have escaped observation. It exhibits at different stages two conditions, which may be conveniently distinguished as primary and secondary. The former is the immediate result of the rheumatic seizure, and must be attributed to the specific cause, whatever it may be, from which the disease derives its distinctive character. It differs from common inflammation in being more transient, for it is capable of rapid subsidence without any trace of its attack remaining. When this inflammation migrates from joint to joint, the occurrence of a fresh inflammation is oftentimes followed by a quick subsidence of that which immediately preceded. Still more signally does this rapid subsidence take place if active treatment for the relief of the constitutional inflammation be resorted to immediately on the attack occurring, and before the secondary inflammation has had time to supervene. In this respect the primary or specific inflammation of rheumatism has a close analogy with that of gout, from which it differs, however, in having a stronger tendency to pass into inflammation of a more ordinary and permanent kind. This specific inflammation is promptly relievable by constitutional treatment, no local applications being at all needed.

When from the severity of the attacks, or from neglect or delay in having recourse to suitable discipline, the specific inflammation lingers in a joint, a secondary inflammation results, more permanent in its nature, which does not immediately subside on the constitutional inflammation being subdued, and which generally leaves some traces of its existence, in effusion into the cellular membrane or bursæ mucosæ, or in more or less thickening and rigidity of the ligaments and other membranes surrounding the joints. The distinction here noticed is important, because it has a sensible influence on the local treatment of rheumatism, both acute and chronic.

Causes of acute rheumatism.—The chief, if not the only exciting cause, is the application of cold to the body when unusually heated. Cold is more liable to produce this effect when combined with moisture, whence a cold and humid atmosphere, and wet or damp clothes, are the most frequent sources to which rheumatism can be traced. Partial cold, as when parts of the body are subjected to currents of cold air, is very apt to give rise to rheumatism. When the body is predisposed, a very transitory exposure of this kind will suffice to bring on an attack; if the current be sustained for any time, few will wholly escape some contingent suffering. Of the fact that rheumatism is so excited there can be no doubt. When it

is reflected, however, that for every instance of rheumatism so induced, numbers continually endure a much or greater exposure to the alleged cause without any disease ensuing, too much importance should not be attached to it.

Of far greater moment is it to regard the predisposition, without the concurrence of which either no rheumatism will take place, or it will be slight and partial, exhibiting none of the constitutional disturbance and febrile excitement which characterise acute rheumatism. A predisposition is said to be given by many circumstances, as age, temperament, climate, season of the year. Even hereditary liability has been classed among the predisposing causes, and possibly with reason. Each of these merits attention, but the circumstance common to all of them, and that which has most influence in producing the disease, is a state of general constitution, which from the prevalence of plethora, either absolute or relative, is prone to be aroused by any excitement into febrile or inflammatory action. This subject having been fully discussed in its proper place, (see Plethora,) it will suffice on the present occasion to apply to the consideration of rheumatism the doctrines already explained. It furnishes a presumption, at least, of these doctrines having some foundation in truth, that corresponding principles have been advocated by one of the most enlightened pathologists of the present day. M. Andral, in various parts of his luminous Treatise on Pathological Anatomy, traces a variety of structural lesions, as well as the inflammatory actions which induce them, to a redundancy of nutritive matter in the blood, supporting his views with a copiousness of illustration, matured experience, clear discernment, and sound judgment, which claim the respect and confidence of every intelligent mind. These views, too, are so reiterated throughout the work as to shew that they were not a mere transient conception, but a deliberate conviction deeply impressed.

A few extracts will evince that in these assertions we do not misrepresent this acute and philosophic writer. In discussing the effects of hyperæmia, or excess of blood, on particular tissues, he says, "The hyperæmia, instead of being confined to a simple organ, may exist at the same time in every organ of the body. The general capillary system is thus overloaded with blood, and the whole system is said to be in a state of plethora or polyæmia. I shall not enter into a detail of the circumstances which characterise this state, the essential character of which seems to consist in the formation of a greater quantity of blood than is necessary for the purposes of nutrition and secretion. There are some individuals who, according to common observation, naturally make a greater quantity of blood than others. In general, those persons who live high, and make but little exertion, mental or corporeal, are most liable to this affection. It has been said, but without the slightest proof being adduced in support of the assertion, that an appearance of plethora has been produced in some individuals by an inordinate expansibility of the blood. When the bloodvessels contain a greater proportion of the nutritive fluid than is necessary to supply the demands of the different organs, the superabundant quantity becomes a permanent source of excitation to the solids, and at the same time the blood has a remarkable tendency to accumulate in different organs; so that, in such case, the whole system is in a general state of excitation, and some of the organs may become the seats of local congestions of various degrees of duration and intensity. Indeed, the phenomena which result from the plethoric diathesis cannot properly be termed morbid unless when some local congestion is formed. Sometimes the brain is the seat of the congestion, and then follow the various symptoms of cerebral disease, giddiness, headach, drowsiness, alteration of the sensorial and intellectual faculties, &c. which may be so violent as to induce death, and yet leave no trace of disease except a little more blood than usual in the cerebral vessels. Sometimes the congestion more particularly affects the pulmonary organs. The dyspnœa which accompanies this form of the disease arises from an unusual quantity of blood transmitted through the lungs, which necessarily requires a corresponding quantity of air to fit it for the purposes of the general circulation. It is this want of proportion between the blood which requires to be aerated, and the quantity of air inspired for that purpose, which produces the dyspnœa. In other cases the complication of palpitation with various degrees of dyspnœa proves that the heart has become the seat of congestion."

Corresponding effects are traced through other organs and tissues, and due notice is taken of the constitutional derangements resulting from polyæmia when no organ more especially suffers, as well as of the prostration of strength or false adynamia, as it is expressively called, which so generally attends this state. The section closes with remarks which are too apposite to our present purpose to be omitted, however reluctant we may be to indulge in lengthened quotations. "The morbid state which I have now described, and to which may be referred some of the species of continued fever described by the older nosologists, may terminate in recovery or death. When the termination is favourable, the symptoms gradually improve as the superabundant quantity of blood, the original source of all the accidents, is diminished by abstinence and bloodletting. When death ensues, the post-mortem examination generally exhibits traces of well-marked inflammation of one or more organs. This inflammation seems to have taken place subsequently to the commencement of the febrile paroxysm; at least the symptoms would lead us to this conclusion. But on other occasions no trace of inflammation can be discovered, and the only morbid appearance consists in a simple accumulation of blood in the capillaries of the different organs, their textures remaining perfectly unaltered.

These slight congestions affecting simultaneously several organs, may, by the various morbid sympathies which they excite, produce as violent and formidable symptoms as the most serious organic lesion of any individual organ. In such case, where are we to assign the origin of the disease?—Wherever the blood is distributed, there derangement of function is found. In the blood, then, indisputably resides the first cause of the disease; the lesion of the solids is only a secondary affection, but may, notwithstanding, become, during the progress of the disease, the prominent affection, and give rise to many and formidable accidents."

In noticing fevers, he particularises one class which he refers specially to excess of fibrine in the blood. "Lastly, the third class of fevers appears to be more particularly connected with alterations of the blood. On this head I can but refer to what I have already said, when treating of the diseases that may arise from that source. I shall content myself at present with repeating that the fever termed inflammatory seems to me often to arise from no other source than the blood being too rich in fibrine." Again, in considering the lesions of the blood, he refers the occurrence of inflammatory fever, not only to a general hyperæmia or excess in quantity of the circulating fluid, but more particularly to an altered condition of its quality arising from redundancy of fibrine. "I have already established the fact that, under the influence of a state of general hyperæmia, every organ becomes excited; that death may result from such excitation; and that a superabundance of blood is found all over the body, but in no part is there any serious lesion, any alteration of texture. In such cases there exists that state of pyrexia, termed by nosologists inflammatory fever. But if, instead of being simply in excess, the blood contains more fibrine than ordinary, its exciting power will be still greater, and what it did in the former case merely by its increased quantity, it will now do by its alteration of quality." In fine, he applies the doctrines thus propounded to the particular disease which is the subject of the present essay. "Now if we mark the symptoms and progress of acute rheumatism, we find that very often a well-marked febrile action with a strong reaction, but without any symptom whatever of local affection, precedes the pain. In a word, there is first an inflammatory fever, and then rheumatism. Next observe the extreme mobility of the rheumatic pains. They run along in a manner wherever the blood is distributed; the application of leeches often removes the pain from one part, but it soon shifts to another, and not unfrequently it quits the articulating tissues and fixes on different internal organs, producing, by the derangement of their functions, symptoms more or less severe. It often happens that bleeding from a large orifice puts an end to the disease, as if by diminishing the mass of blood it proportionally diminished the stimulus that promoted all these shifting irritations."

The doctrines here advanced we believe to be founded in truth, and capable of furnishing much valuable guidance in the investigation and treatment of disease. In such copious extracts we may appear to have made too free with the pages of an author whose works are so generally known, but we could not resist the temptation of fortifying, by the authority of so distinguished a pathologist, principles which we have long maintained, and which we have endeavoured already to illustrate in the articles Gout and Plethora. They will suffice, we trust, to justify the assertion lately made, that whatever importance may attach to the exciting cause of acute rheumatism, the predisposition induced by a plethoric state of constitution is far more entitled to the practitioner's attention.

Diagnosis of acute rheumatism.—This may be briefly disposed of. The only disease with which it is liable to be confounded is gout, in treating of which the distinctive character of each malady has been sufficiently noticed. Formerly discrimination in this respect was deemed of high importance, the prevailing theories of gout demanding a course of treatment very different from that to which rheumatism was subjected. In the present day a juster pathology of gout assimilates the treatment of both diseases sufficiently to render extreme accuracy of discrimination of very slight moment.

Prognosis of acute rheumatism.—The prognosis is so dependent on the promptitude with which suitable treatment is resorted to, that any remarks on the natural course or duration of the disease are of little worth. Generally speaking there is little immediate danger to life, there being no inflammatory disease of equal intensity which so little deranges the vital functions. This, most probably, is owing to the disease expending its violence on the joints and other external parts, and being little prone to attack the viscera. The peculiar character of the inflammatory action too, and the little liability which it has to pass into suppuration, or undergo the other changes consequent to phlegmonous inflammation, may account for the safety with which even the metastasis of rheumatism to internal parts is borne. It is certain that such metastasis is not attended with so much danger as the severity of the symptoms would seem to denote. In early life we were often appalled by the metastasis of rheumatism from the joints to the heart, an organ more peculiarly liable to this transition than any other. More extended experience abated such fears, by shewing that the immediate danger was by no means commensurate with the suffering experienced.

If an attack of rheumatism be treated at the onset with due activity and discrimination, it may be relieved in a very few days without the affected joints sustaining any injury. But both with respect to time and local ravages, much will depend on suitable discipline being resorted to and adequately pursued, ere the specific inflammation of the joints becomes complicated with that which we have termed

secondary. The specific inflammation we have repeatedly seen subside in twenty-four hours, leaving behind but little trace of its accession. When secondary inflammation, however, has been suffered to supervene, the case is materially altered, and greater obstinacy of local affection may be expected. It might be laid down almost as an axiom, that the severity and duration of the disease are proportionate to the degree of plethora present, the activity of inflammation, and the length of time during which the morbid actions are suffered to prevail unrestrained. If the plethora be great, inflammation high, and much delay take place in resorting to efficient means for correcting the constitutional derangements, then would it be difficult to assign limits either to the constitutional disturbance or local ravages, both of which may continue, though with abated force, for months or years, to undermine health and cripple the limbs; in other words, acute rheumatism may then pass into chronic of the most inveterate and intractable kind. Thus, though acute rheumatism rarely destroys life by its immediate seizure, however violent, this furnishes no excuse for supineness or inactivity in the treatment; for if not radically relieved in its early stage, the disease, even when of no extraordinary violence, may become so confirmed as to yield afterwards with difficulty to the most active and judicious use of remedies, while progressive disorganization of joints may entail protracted suffering and lasting decrepitude.

It is true that a slight rheumatic seizure may, like a gouty paroxysm, pass away without medical interference, the efforts of the constitution sufficing for relief. But this is not its general character; and to rely on such a contingency would be in the highest degree rash and inexcusable. Whenever an attack of acute rheumatism occurs, the constitution must need some relief, which enlightened practice will never withhold. To neglect of this principle may be ascribed a very large proportion of the decrepitude which the victims of rheumatism so continually present. There is no truth of which we are more thoroughly persuaded, than that if rheumatism were at its onset treated as its real nature demands, and if due care were afterwards taken to guard against its recurrence by prophylactic measures judiciously directed and adequately pursued, there need not from this malady be one case of disorganized and crippled joints for every hundred that are so afflicted. The effects of the earlier treatment will, therefore, in general, decide the prognosis. There is inflammatory fever to subdue, local inflammation to remove. If early bloodletting in subduing the fever make prompt impression on the local affection, so that both pain and swelling quickly subside, thus marking the local inflammation as still retaining its specific character unmixed with secondary effects, speedy and effectual relief may be confidently predicted, medical treatment judiciously conducted being fully capable of ensuring it. When febrile action is inveterate, and it is oftentimes very obstinate, though chiefly so when the earlier periods of disease have been neglected or inadequately treated, a tedious progress may be expected, for so long as fever remains unsubdued are the local inflammations incapable of removal, either keeping their ground unmitigated, or if abated by topical remedies, continually recurring. Again, when abatement of fever is not followed by quick subsidence of local swellings, in consequence of the latter having passed into the secondary stage, and especially when effusion and organic changes have already taken place in the affected joints, then is the restoration of the joints much more tedious, though great local derangements will admit both of speedy and decisive relief, provided the local mischief be not rendered inveterate, or continually renewed by unsubdued fever.

Much, too, depends on the state of constitution in which acute rheumatism occurs. In a healthy subject, capable of bearing the depletory and other treatment required for relief, great reliance may be placed on the efficacy and certainty of the curative process. When the constitution is depraved by long continued relative plethora, with its attendant febrile excitement, and especially if the feebleness, natural or acquired, be such as to render caution necessary in carrying bloodletting and other remedial processes to the requisite extent, more protracted disease and more tedious recovery must be the natural and inevitable consequence.

It is said that rheumatic inflammation does not tend to suppuration or gangrene, and the remark is generally true. Yet we have seen abscess of the cellular membrane supervene on rheumatic inflammation, and we have also witnessed sloughing ensue when leeches have been applied to a highly inflamed joint without adequate constitutional treatment being conjoined. The most frequent consequences are, gelatinous effusion into the bursæ, thickening and rigidity of the ligaments and other membranes surrounding the joints, contractions of the limbs, and wasting of the muscles, all of which will come under consideration in the latter part of this essay, where it treats of chronic rheumatism.

Treatment of acute rheumatism.—The indications are here to subdue fever and remove inflammation. It has been already shewn that the former claims the first consideration. The promptitude with which the local inflammation in its earliest stage yields to the treatment by which a plethoric state of constitution is corrected, and febrile action allayed,—and the obstinacy of the local ailments, whenever the constitutional state is overlooked or inadequately treated, furnish the best proofs of the correctness of this pathology. In its simplest form and early stage, acute rheumatism is speedily and effectually relieved by antiphlogistic treatment, properly directed and adequately pursued. Bleeding, purging, salines with antimony, diluents, and abstinence, suffice both for subduing the general fever and removing the local inflammation. It continually happens, however, that these means, how-

ever actively or perseveringly employed, will not succeed in re-establishing health; a lurking fever remaining unsubdued, the blood retaining its buffy crust even when the crassamentum is reduced far below its natural and healthful proportions, and the local inflammation maintaining its hold of the affected joints. Further means are then required, which will be noticed in their proper place. The treatment of the simpler and more manageable form must be first discussed.

One of the earliest practical writers on this complaint was Sydenham; and so direct and judicious was his practice, that we cannot do better than to make it the text on which to comment in treating this part of the subject. Sydenham's theories of disease often involved the pathological fantasies prevalent in his day; but it is his signal merit that he never suffered them to mislead him from the path which his clear discernment and practical experience enjoined him to follow. He attributed the local affection to "the derivation of the febrile matter to the limbs," which, as he observes, "the frequent return of the fever from the repulsion of the morbific matter by external remedies sufficiently shews." But we cannot perceive that he was influenced by this hypothetical principle, further than to adduce it in explanation of facts which his experience had taught him. He had witnessed the inefficacy of local treatment, and also the increase of constitutional disturbance which resulted when this alone was trusted to, and he wisely abstained from repellent applications. Having described the disease with some of its modifications, he gives the following concise instructions for its cure. "Since both kinds of this disease seem to arise from inflammation, as appears from the concomitants just mentioned, and especially by the colour of the blood taken away, which exactly resembles that of persons in pleurisy, which is universally allowed to be an inflammatory disease, so I judge that the cure ought to be attempted only by bleeding, the heat of the blood being in the mean time abated by cooling and thickening remedies along with a proper regimen. Accordingly, as soon as I am called I order ten ounces of blood to be immediately taken away from the arm of the side affected, and prescribe a cooling and incrassating julep. To ease the pain I order a cataplasm prepared of the crumb of white bread and milk tinged with saffron, or a cabbage-leaf to be applied to the part affected, and frequently renewed. With respect to diet I enjoin a total abstinence from flesh, and even from the thinnest flesh broths, substituting in the place barley-broth, water-gruel, panada, and the like. I allow only small beer for drink, or, what is more proper, a ptisan prepared of pearl-barley, liquorice, sorrel-roots, &c. boiled in a sufficient quantity of water, and I allow the patient to sit up some hours every day, because the heat which arises from lying always in bed promotes and increases the disease. The next day I repeat the bleeding to the same quantity, and in a day or two after, as the strength will allow, I bleed again. Then interposing three or four days as the strength, age, constitution of the patient, and other circumstances indicate, I bleed a fourth time, which is generally the last, unless too hot a regimen has preceded, or heating remedies have been exhibited without necessity. But the use of opiates requires more copious bleeding; and, therefore, though the pain be ever so violent during the whole course of the disease, yet when I intend to effect the cure solely by bleeding, I judge it highly necessary to refrain from opiates, because the disease is fixed thereby, and does not yield so readily to bleeding; so when such medicines are given too frequently, bleeding must in consequence be oftener repeated than is otherwise necessary. Besides, in the height of the disease, they do not answer the expectations we have conceived of them. Whilst the above mentioned remedies and regimen are carefully continued, I inject glysters made of milk and sugar, between times on the intermediate days of bleeding, earnestly recommending the exact observance of these directions for at least eight days after the last bleeding; and then I prescribe a gentle purging potion to be taken in the morning, and in the evening a large dose of the syrup of white poppies in cowslip flower-water, whereby a check is put to the tumultuary motion of the blood which might otherwise occasion a relapse. This being done, I allow the patient to return by degrees to his customary way of living in relation to diet, exercise, and air; but, at the same time, caution him to refrain for a considerable time from wine and all spirituous liquors, salt or high-seasoned flesh, and, in general, from all food of difficult digestion. After having repeated bleeding as above specified, the pain greatly abates, though it does not go quite off; but as soon as the strength returns, which bleeding had greatly impaired, the symptoms will vanish, and the patient perfectly recover."

In the simplicity, fitness, and activity of the foregoing course of treatment, there is much to admire. It comprises the more essential articles of antiphlogistic discipline, bleeding and abstinence; it discourages the premature use of narcotics, which, when employed too early, or in substitution of depletory measures, only mask the symptoms even when they allay pain, while they too often exasperate the disease, rendering it both more violent and more obstinate. It also inculcates a salutary reserve in the return to animal food and fermented liquors. That under this simple treatment many would pass safely through the disease, there can be no doubt, although recovery would certainly be slower than it might be rendered. But cases continually occur in which this treatment would be utterly inadequate, the febrile action maintaining its ground, and the local inflammation migrating from joint to joint, notwithstanding the diligent employment of all the means which Sydenham's practice in the disease comprises. In this practice one great deficiency is observable, the use of purgatives in aid of bloodletting not being at all enjoined. For regulation of the bowels clysters of milk

and sugar are trusted to, and not until eight days after the last bleeding is a gentle purging potion prescribed. In this and other respects, later experience has added much to our means of combating acute rheumatism.

When this disease occurs in its most active state, the means suited for reducing plethora, abating fever, and checking the progress of inflammation, must be promptly and adequately employed; full bloodletting and active purging, with the united powers of colchicum and antimony, being required to lower the circulation and arrest the evils which inflammatory action when unrestrained is sure to occasion. The first procedure in respect both of time and importance is bloodletting. In many instances the use of this directed by Sydenham would suffice, but in many it would fail. As a rule of practice, therefore, Sydenham's directions in this respect are defective, as not embracing conditions of disease which are of frequent occurrence, and for which the depletion directed by him would prove utterly inadequate. Indeed, no express rule in this respect could be laid down, both the amount and frequency of venesection being in every instance dependent on the degree of plethora existing, the activity of fever and inflammation present, and the natural powers of the constitution to be acted on. The pathology of inflammation, and the use of bloodletting most effectual for subduing it, have been so amply discussed in the articles Gout and Plethora, that to recapitulate what has been already advanced on these points must be needless. We shall proceed, therefore, on the presumption of the principles inculcated in those articles being clearly comprehended, and in conformity with these principles state practically how the lancet can be most successfully used. In ordinary cases the loss of twelve, sixteen, or twenty ounces of blood may suffice to check disease and prepare the way for the subsidiary treatment. But if absolute plethora be considerable, inflammatory action high, and the constitution robust, blood must be drawn to much greater extent if adequate impression is to be made on disease. In such case the rule should be not to abstract any assigned quantity, but to carry the bloodletting to the extent of making a sensible impression on the force of circulation. Thirty or forty ounces of blood may require to flow ere this is effected, and so essential is the impression alluded to, that even large bleedings, if not carried to this extent, will fail to produce their full effect in restraining inflammatory action. It continually happens in cases of active inflammation, that notwithstanding the loss of thirty or forty ounces of blood, the pulse does not yield, but maintains its hardness, while the abstraction of a few ounces more, by inducing a disposition to syncope, completely checks the inflammatory action and abates the violence of the disease. By making the constitutional powers the measure of the depletion, less bleeding on the whole is needed; thus by this mode blood is virtually saved and unnecessary exhaustion prevented, a single venesection carried to the necessary extent being far more effectual than reiterated bleedings to a far greater aggregate amount, if these be respectively of insufficient extent. Bleeding to actual syncope is not desirable, but if inflammation be high, some impression on the pulse should be manifested. If this begin to falter, while nausea is felt, the lips grow pale, and perspiration begin to bedew the forehead, such bloodletting may be relied on for accomplishing all that this remedy is capable of effecting. This use of the lancet, however, can only be required where severity of symptoms with vigorous habit demands such active treatment. In a large proportion of cases much more moderate depletion will suffice. From twelve to twenty-four ounces of blood may be regarded as the ordinary limits, and many repetitions are never advisable; for when bloodletting to such extent, assisted by purging and other febrifuge treatment, does not make sensible impression on disease, other more adequate means of arresting its progress must be resorted to. Blood may be drained away until the body is blanched and the crassamentum reduced to a tithe of its just proportions, yet febrile action will continue, inflammation be unsubdued, and the blood drawn be still buffed and cupped.

It is right to mention here, that although a full and hard pulse is generally attendant on acute rheumatism, yet the absence of hardness is no evidence of active inflammation not being present, or of bloodletting not being needed. If the general symptoms concur to indicate inflammatory action, then, though the pulse be soft and compressible, bloodletting is nevertheless essential, the blood drawn in such case being almost uniformly buffed and cupped, the pulse rising after venesections, and disease more rapidly subsiding.

The next measure is to purge freely the stomach and bowels; and here again we must refer to what was formerly advanced on this subject in illustration of the necessity of suitable and adequate purging being employed in aid of bloodletting. As soon as may be after bloodletting, a full dose of calomel combined with antimony (either James's powder or tartarized antimony) should be given, and in a few hours after a cathartic draught. The bowels being well evacuated, diaphoretic salines with antimony and colchicum contribute much to allay fever, quieting the pulse, and promoting the several excretions.

One of the best forms of saline for this purpose is a combination of acetate of ammonia, camphor mixture, antimonial wine, and wine of the colchicum seeds, as in the following formula:

℞. Liquor. ammon. acet.
Mist. camphoræ, *aa* ℥ß.
Vin. sem. colch.
Vin. ant. tart. *aa m.* xx.
Syrup. aurant. ℥i. *m.* fiat haustus quartis vel sextis horis sumendus.

The properties of colchicum and the best modes of administering it have already been so fully discussed in the article Gout, that to avoid needless repetition, we shall refer to

what is there stated. It is only necessary to remark that the effect of colchicum on the bowels requires to be watched, for when it irritates them so as to excite active purging, its use must be discontinued. In our early trials of colchicum in gout and rheumatism, we were accustomed to give it in full doses, but, for reasons already explained, we have for many years discontinued them, the salutary effect of the remedy being fully attainable from the more moderate exhibition of it which has just been prescribed. When the use of it irritates the bowels, producing frequent watery stools, discontinuing the colchicum suffices in general for the relief of this disturbance; but should it continue troublesome, moderate doses of Dover's powder are sure to allay it. It has been surmised that the use of colchicum has through irritation of bowels led to ulceration of their mucous membrane, but this effect we altogether distrust. It must be a very rash use of the remedy which could produce any such effect, and where it has appeared to result, our persuasion is, that the membrane was in an advanced stage of sub-acute inflammation ere the colchicum was exhibited. We have given colchicum freely and extensively for many years, with caution certainly, though not greater than is required in the administration of every active drug, yet a single instance has never occurred to us in which we could trace any injury to its use, while its medicinal properties have rendered valuable aid, not only in gout and rheumatism, but in many other inflammatory diseases.

As the extent and repetition of bloodletting must depend on the activity of disease and vigour of constitution, so must the use of purgatives be regulated by the condition of the bowels, and the necessity for purging which the stools may evince. So long as these are dark, slimy, fetid, and otherwise unhealthy, must purgatives be used; and the most effectual are those by which the morbid secretions of the alimentary canal are evacuated. Pills of colocynth, calomel, and tartarized antimony should be given at intervals, and, if necessary, cathartic draughts should be interposed. When fever declines, and the stools present a more healthy appearance, milder aperients will suffice. Under such treatment low diet and a cooling regimen are indispensable. Barley-water or toast-water is quite sufficient during the inflammatory stage. Animal food and fermented liquors of every kind are prejudicial, and should be carefully withheld.

The several means now pointed out will in many instances suffice to allay fevers, remove inflammation, and restore health. But cases occur in which neither fever nor inflammation can be thus subdued. If active treatment be not resorted to on the first accession of disease, or if it be not urged to the requisite extent, inflammatory action acquires an inveteracy which simple antiphlogistic treatment is quite unable to correct. In such circumstances bloodletting may be pursued until the patient become nearly exanguious, yet the blood will still be buffed and cupped, febrile action will remain unsubdued, and local inflammation continue to disorganize and cripple the joints.

Even in milder cases of this kind, although permanent injury may be averted, and perfect recovery ultimately ensue, yet the successive migrations of local inflammations prove harassing to both patient and practitioner. We have seen such inflammation traverse almost every joint of the body, attacking several a second and a third time before the disease yielded. When the progress is favourable, each successive inflammation becomes slighter, until towards the close a mere blush of redness marks the morbid effort.

But this course of proceeding is at best tedious and unsatisfactory, even where an issue so favourable as has just been mentioned is attained. Such result, however, is not to be relied on; for in the form of disease now considered, it will more frequently happen that unsubdued fever will exhaust the general powers, and inflammation inflict its ravages on the joints, producing effusion, thickening of ligaments, with enlargement, rigidity, or contraction. When, therefore, one or two full bloodlettings, assisted by purging, abstinence, and other means, fail to make adequate impression on the disease, it becomes necessary to call in other aids in order to prevent the exhaustion and other ills which repeated bloodletting would occasion. And fortunately one exists which is worthy of our fullest confidence. This is mercury, which, when judiciously administered and made subsidiary to bleeding and purging, is capable of subduing rheumatic inflammation with as much certainty as attaches to the operation of any remedy in any disease. The practice of arresting the progress of rheumatism by means of mercury has been before the public sufficiently to have made it more generally known and more justly appreciated than it appears to have been. It originated with Dr. Robert Hamilton of Lynn Regis, who published, in the Medical Commentaries of the year 1783, an interesting account of the success with which he had administered calomel and opium in the treatment of several inflammatory diseases. So far back as the year 1764 he had been induced to employ calomel for the cure of hepatitis. Its efficacy in the disease and in several other inflammatory affections led him to extend his views of its applicability, and to conceive that it was a suitable remedy for inflammation in whatever viscus or tissue this might be situated. He accordingly employed its aid with the best effects in inflammations of every part, and particularly in acute rheumatism. His practice in the latter was to take blood in proportion to the violence of the inflammatory symptoms and to the age and constitution of the patient; after which he exhibited calomel and opium at suitable intervals until the disease yielded, or until the influence of the remedy on the constitution was evinced by increased secretions from the salivary glands, bowels, or skin. If in twenty-four hours after the use of mercury was commenced, relief did not ensue, or if inflammatory symptoms continued unabated, he bled again, and gave the

calomel more frequently. Salines, antimony, camphor, and other auxiliaries were combined with bleeding and mercury, and through their united agency he found disease subside with a promptitude which no other mode of treatment could command. When this treatment was employed early in the disease, recovery was soon accomplished; if postponed to a later period, its effects were more tedious and uncertain. His experience also taught him that the curative process was most favourable when the salivary glands became affected by the medicine. This brief account of Dr. Hamilton's rational and effective practice in rheumatism embraces so many essential points of the treatment of this disease, that we shall have little to add save the detailed instructions which the young practitioner may need for conducting that treatment with discrimination and effect. In confirmation of the truth and accuracy of Dr. Hamilton's views, we may here remark, that having for five-and-twenty years pursued the practice and applied the principles which he inculcates, our faith in them has never wavered, and that with ample opportunities for subjecting them to the test of experience, we can truly say that we know of no fact in medicine better established than the power which mercury possesses of subduing inflammations, when used as subsidiary to bleeding and purging.

Every case of acute rheumatism does not require mercury for its cure. Bleeding, purging, abstinence, and salines, with antimony and colchicum, will frequently suffice. But if, after twenty-four hours, the early discipline has not produced sensible effect on the disease; if after this period fever continues unabated, inflammation unallayed, and further bloodletting be required; as obstinacy of disease is here sufficiently announced, it is expedient to lose no more time, but to resort to the only means by which an adequate check can be given to the malady.

Profuse use of mercury is not needed; both the amount of dose and frequency of exhibition must be determined by the circumstances of the particular case. Although it is desirable to obtain evidence of the constitution being affected by the remedy, so far as tenderness of gums indicates, it is not expedient to produce this effect very speedily, and there are many reasons for enjoining caution in the administration of this medicine. It is not necessary to urge on its full operation, for the curative effect commences ere the specific action on the salivary glands appears. Unless the plethoric state of constitution, too, be adequately relieved by depletion, there is considerable risk of pressing the use of mercury. On this subject we must once more refer to what has been already advanced respecting it in the article Plethora. The susceptibility of impression from mercury, too, varies greatly in different persons, so much so, that while some cannot be salivated by any quantity, a few grains of calomel will in others induce severe ptyalism, with inordinate swelling of the jaws and extensive sloughing. On every account, then, it is advisable to incline to the minimum quantity capable of acting on the disease. The expediency of combining opium with calomel, when exhibited for this purpose, admits not of question. When thus conjoined, it allays pain, abates irritability, prevents the calomel passing off too quickly by the bowels, and promotes its more certain absorption. In general, two grains of calomel and a quarter of a grain of opium is a sufficient dose, and the frequency of its exhibition will be best guided by the severity and threatened obstinacy of the attack to be combated. In severe cases it is beneficial to commence with five grains of calomel, one of opium, and one of tartarised antimony at bedtime, and to pursue the course the next day with the smaller dose. In mild cases it may suffice to give this night and morning; to administer it thrice a day is no inactive practice, and by this use the gums will in general soon become affected. Given every six hours, so that, in the four-and-twenty, four doses are taken, is perhaps the frequency that will most commonly be needed. We have never had occasion to enlarge the dose, nor to exhibit it oftener than every four hours; but to this extent we have been occasionally compelled to employ it. The cases, however, requiring this active use of it are rare. The circumstances to guide its use are the curative effects on the constitutional and local symptoms, and its specific effects on the salivary glands, bowels, and skin: if any of these be signally induced, the use of it should abate, and the intervals of its exhibition be lengthened. Unless active salivation take place suddenly and unexpectedly, it is never expedient to withdraw it wholly so long as fever lurks or inflammation keeps its ground. The best practice is to lengthen the interval, and to do this progressively by reducing the employment from four times a day to three, then to twice, and finally to continue a single dose daily for a short time. By this cautious proceeding, if bloodletting be adequately practised, the bowels freely purged, and no error in diet committed, the beneficial effects of mercury may be ensured without any risk of injury and scarcely of inconvenience. Should salivation chance to advance beyond what would be wished, the evil is but a slight counterbalance to the benefit which mercury confers in the case of this most painful and disorganizing malady. When the mouth becomes painfully affected, we may here remark that saline purges abate the distress, and that gargles of chloride of soda or of nitrate of silver have considerable power in allaying the morbid sensibility of the gums and tongue which is sometimes experienced. There are constitutions on which mercury acts so unfavourably, producing great derangement of the nervous system, that its use cannot be borne. When such sinister effects occur, its use must of course be abandoned; but such instances are not common, and when they do occur, we strongly suspect that neglect of early depletion is more in fault than any idiosyncrasy inimical to the remedy.

While mercury is exhibited in the way directed, the salines formerly prescribed should

be continued, and occasional purges should be interposed. The use of the latter should be regulated by the degree of fever and the state of the stools. If fever continues high, with a dry tongue and costive bowels, or if the stools be very dark and slimy, purgatives must be the more freely used. When the bowels are unusually torpid, it is often expedient to substitute for the diaphoretic saline a solution of sulphate of magnesia in rose infusion, giving this at such intervals as shall keep the bowels free. It is generally conceived that purgatives impede the constitutional operation of mercury, and in consequence, when this operation is the object in view, purgatives are usually withheld. Without discussing this point, we shall merely observe that if the degree of fever or the foulness of bowels demands purging, it should be carried to the full extent required, without regard to its supposed interference with the effects of mercury. Under such circumstances greater injury would result from the neglect of purging, than even the unimpeded action of mercury would compensate.

There are cases in which it is not expedient to combine opium with the calomel, but they are rare. If headach prevail,—if the tongue, instead of becoming moist and clean, grow parched and dark, and the skin be hot and dry,—opium should be withheld, and the calomel given either alone or conjoined with James's powder.

The progress of recovery and the experience of a few cases thus treated will readily guide the practitioner in that adaptation of remedies to the exigencies of each case which no specific rules could prescribe. He who possesses himself of the principles on which the treatment here directed is founded, will commit no error in the extent or duration to which he may carry it.

There is a period, however, in the progress of rheumatism, even when actively and judiciously treated, which calls for something more than has yet been enjoined. In a large proportion of cases, the treatment now prescribed will fully suffice. It will subdue fever, remove local inflammation, prevent disorganization of joints, and restore the patient in moderate time to health and the free exercise of limbs. But it occasionally happens that notwithstanding the full employment of all the means directed, a certain degree of fever lingers, the skin continues dry with some morbid heat, the tongue too white, and pains of acute character are still felt in the joints. When this state first met our view, so completely did the assemblage of symptoms simulate active inflammation, that we hesitated whether there was not an actual relapse of disease, and a necessity for reverting to active remedies. But the indecision was of short duration; for assured by the treatment already pursued, and the effects produced by it, that inflammation had been successfully combated, we could not regard the supervening state as corresponding in its nature to that which we had already corrected, and instead of recurring to bleeding and mercury, we made trial of bark as a preferable agent, and with such benefit, that we have seen it remove, in twenty-four hours, the whole train of symptoms which we have just mentioned. Half a drachm of bark with ten grains of nitre is the combination on which we most rely, giving this twice or thrice a day; and so effectually does it answer the purpose that we are slow to change it. What we have now stated may serve to explain the confidence with which some writers have advocated the use of bark as almost a specific in rheumatism. There is undoubtedly a stage of the disease in which it may be beneficially given, but in the acute stage, to which we have hitherto chiefly referred, we at least would not compromise the patient's safety by trusting to bark, while bleeding, purging, and mercury were applicable; and even in what is called chronic rheumatism we would as little rely on it so long as plethora was unrelieved, the pulse high, the bowels loaded, and active fever predominant. When the general state of constitution is restored to the proper balance of its several functions, should some febrile indications linger, and pains continue to infest the joints or muscles, bark furnishes then a valuable and unexceptionable means of correcting the slight remnant of disease, but not before.

The cure of rheumatism by profuse perspiration has fallen so much into disuse that it can hardly be necessary to notice it. Yet it was held in high estimation not many years back, and very generally deemed the most effectual mode of treatment. The late Dr. Gregory, in his lectures, used to represent sweating as the evacuation most to be relied on for the cure of rheumatism, and to bear his testimony to its efficacy. He gave a caution, however, against resorting to it until the pyrexia had been abated by bloodletting, and stated that his test was, never to employ it until the pulse was reduced to 100. The chief agent was Dover's powder, given in doses of ten grains every two or three hours, assisted by warm covering and copious diluents, the latter to be used only when the perspiration commenced. To be effectual, this required to be kept up for forty-eight hours. This practice has, we believe, been very generally, and, as we think, judiciously, laid aside, the treatment recommended in the foregoing pages being far more certain and effectual, producing less exhaustion, and leaving less susceptibility to recurrence of disease.

We have hitherto treated chiefly of constitutional disorder, and have considered the local inflammation only so far as it was connected with or dependent on the constitutional state. It is necessary, however, to scrutinize the local affections still further. So directly is the local disturbance dependent on the constitutional in the incipient stage, that if the latter be promptly and vigorously treated, the former will very speedily subside without any local treatment being needed. We have seen the local inflammation thus subside in rheumatism equally as in a first attack of mild gout, leaving as little trace of its visitation. It must be admitted, however, that such speedy decline is not the

general character of this local affection. Notwithstanding the abatement of fever, some pain, heat, and swelling will continue to affect the joint for a longer or shorter time, and in order to understand the treatment which this requires, it is necessary to bear in mind what was formerly stated respecting the change of character in the local inflammation. If on fever becoming subdued by the means directed, the local inflammation declines, no topical treatment whatever is needed, nor is it expedient that any should be resorted to. Decline of inflammation thus obtained affords conclusive evidence of disease being arrested at its source, and relapse need not here be apprehended; while, if the local inflammation be checked by topical remedies, its abatement affords no such assurance, and if the constitutional derangement be not thoroughly rectified, repeated renewal of the local inflammation with successive migrations from joint to joint will most probably ensue. But independently of this consideration, there are other objections to the early use of topical remedies which ought not to be overlooked. Repellent applications may remove inflammation from any particular part; but only to transfer it to some other, if not to the heart, stomach, or other internal organ. Local bloodletting would beget less danger of this kind, but neither is it free from objection. The inflamed part is ill suited to sustain the operations by which blood can be abstracted. We have seen leeches when applied to a rheumatic joint prematurely and without sufficient regard to the constitutional state, exasperate every symptom, and cause increase of inflammation both in the skin and cellular membrane, ending in extensive sloughing, with troublesome ulceration, and followed by thickening of the ligaments with rigidity and contractions of unusually obstinate kind. So long as it is possible, therefore, to procure decline of local inflammation by the constitutional treatment, we consider it the better practice to abstain from topical remedies.

When inflammation continues in the joint, however, after fever has been sufficiently subdued, thus manifesting its having passed into what we have distinguished as the secondary state, it then becomes necessary to regard it as a local disease, and by appropriate topical treatment to avert those ravages which its continuance would occasion. The means are cupping, leeches, warm fomentations, poultices, cold lotions, modified according to the degree of inflammation, the sensations of the patient, and the effects produced. By such means, the local inflammation in this its secondary state may be so corrected as to prevent organic lesion, and preserve unimpaired the mobility of the joint.

We would here impress, as we formerly did when treating of gout, the importance of an early renewal of motion in the affected joints, as indispensable for re-establishing their health and preserving their flexibility and power. From neglect of this, much protracted confinement and ultimate decrepitude continually result. On the subsidence of inflammation, the parts so lately disturbed are indisposed to motion, and some pain attends the early attempts at its removal. Yet leaving them at rest is not the means by which the power of motion is best restored. Exercise of the parts is necessary not only to restore those which have been morbidly affected to their healthy functions, but to preserve in due energy and activity the muscular apparatus by which they are moved. By exercise healthy circulation is maintained, effusion prevented, absorption promoted, and flexibility preserved. By it, too, the muscles subservient to the motions of the joint are kept in a healthy and efficient condition. When, from too great apprehension of exciting pain or renewing inflammation, quiescence is too long continued, the ligaments and other parts surrounding the joints become rigid; if these be kept bent, contractions take place, and the mobility of the part becomes permanently impaired; while the several muscles, from want of exercise essential to the maintenance of their nutritive and healthy actions, progressively waste and lose power. This latter contingency is, we are persuaded, much more frequently owing to the continued inactivity to which the muscles are consigned than to any morbid action induced in them by the disease; and as we before observed, so satisfied are we of the mischiefs resulting from long-continued rest after rheumatic inflammation, that we would in our own person much rather hazard any renewal of inflammatory attack, than suffer those derangements to proceed which spring from a state of inaction too long continued.

What remains to be said respecting acute rheumatism, and the sequelæ occasionally left by it, will be more properly noticed in the division of the subject which treats of the chronic form of the disease, to the consideration of which we shall now proceed.

II. Chronic Rheumatism.

It would simplify the consideration of this form of the disease, if it were limited to that morbid condition to which analogy with the acute affection discussed in the foregoing pages would justify the name of rheumatism being applied. So many and various, however, are the derangements loosely classed under this generic term, that to give any history of the disease which should comprise the whole, would present a mass of confusion, if indeed it were not utterly impracticable. It has been too much the practice to pronounce as rheumatic every chronic pain of which the nature is obscure, or to which no other specific character is assigned. Practical writers have not overlooked this tendency; it is noticed by Heberden in the following very expressive passage: "Multi dolores quibus nomina nondum propria imposita sunt, quamquam inter se distent, ex causis longe diversis orti, tamen ad rheumatismum pariter referuntur." In order to ensure as much clearness as possible in the following observations, it will be expedient to commence with that modification of disease which, presenting all the essential characters of rheumatism, differs from the acute affection already

treated of only in being less violent in its symptoms, and of longer duration. The distinctive characters of this malady are a febrile state of the general system, with more or less of pain and swelling in certain tissues and joints. And in this, precisely as in acute rheumatism, the continuance of febrile action undermines the general health, while the local inflammation, however indolent, disorganises the joints, occasioning eventual decrepitude. The pain and swelling of joints with progressive thickening of the ligaments, and effusion in the several bursæ, sufficiently evince the morbid actions from which such effects result. But, coincident with these will generally be found in the instances now referred to, evidences of constitutional derangement sufficiently marked to denote that a plethoric and febrile state of the circulation is also present. A quickened pulse, some increased heat of skin, and a furred tongue, are in greater or less degree the invariable attendants of chronic rheumatism of the joints so long as the disease in them continues to advance. It, no doubt, occasionally happens that in the course of time all febrile symptoms disappear, and the morbid action in the joints ceases to make further ravage. In such cases there is no longer rheumatism, but only the disorganization produced by it; and the distinction is important, for where such ravages alone remain, so far as they are concerned, constitutional remedies can be of no avail, and any treatment, to be effectual, must have special reference to the local lesions by which the free motion of the limbs is impeded. In the larger proportion of cases, however, the disease is strictly rheumatic, that is, it consists of a constitutional derangement having a febrile character, and of a local inflammation seated in the joints. This condition may be, and frequently is, the sequela of acute rheumatism; but it may be fully formed without any particularly acute attack having preceded. Cullen regarded it in the former light, as appears from his definition of arthrodynia being introduced as "rheumatismi sequela." In the definition itself he somewhat incongruously represents this as ensuing to violent sprains and luxations, though why the pains resulting from such accidents should be deemed rheumatic it is difficult to imagine. In this definition, too, which ought to embrace every form in which chronic rheumatism presents itself, he states somewhat too positively the absence of fever and of swelling,—"pyrexia nulla, tumor plerumque nullus;" characters which do not apply generally to the disease, and which seem to have been introduced as an antithesis to the definition of acute rheumatism. This imperfection obliged him, when treating of chronic rheumatism, to enter into explanations rather at variance with his own definition, and in the following passage he describes more correctly and intelligibly the transition of the acute into the chronic stage. "The limits between the acute and chronic rheumatism are not always exactly marked. When the pains are still ready to shift their place,—when they are especially severe in the night time,—when at the same time they are attended with some degree of pyrexia, and with some swelling, and especially with some redness of the joints, the disease is to be considered as still partaking the nature of acute rheumatism. But when there is no degree of pyrexia remaining,—when the pained joints are without redness, when they are cold and stiff,—when they cannot easily be made to sweat, or when, while a free and warm sweat is brought out on the rest of the body, it is only clammy and cold on the joints,—and when especially the pains of these joints are increased by cold and relieved by heat applied to them, the case is to be considered as that of purely chronic rheumatism." If the character of chronic rheumatism is to be derived from the most numerous and predominant instances, then we would say that the former of these descriptions is far more applicable to the disease, as generally met with, than the latter; for though all the phenomena recited as indicating the continuance of febrile and inflammatory action may not attend, it rarely happens that some or other of them are not present. As the former condition is capable of indefinite duration,—for it may endure for years, and is hence strictly entitled to be called chronic,—it could not, where any distinction were made, be classed with the acute disease lately treated of; while, if it constitute any part of the chronic malady, a definition professing to characterise this ought assuredly to embrace it. Perhaps the more perfect representation of the disease, if it be necessary or beneficial to make any such distinction, would be to include both descriptions under arthrodynia, subdividing this into sthenic and asthenic. In this view the sthenic arthrodynia is by far the most frequent form in which the disease presents itself; and, what is no less important, it is that which, if unrelieved or improperly treated, is productive of the greatest mischief and of most distressing results; for under it the disease both local and constitutional, however indolent it may appear, is yet sufficiently active to continue and extend its peculiar ravages, deranging the general health, enfeebling and crippling the body through progressive disorganization of joints, and consequent wasting of muscles. In the asthenic form, the mischief is already done, and, however the body may suffer under the ravages sustained, there is no longer the active constitutional derangement inflicting further injury, which forms so essential a part of rheumatism. In the latter form there is little to do but support the general health, and remedy, as far as may be, the local lesions. But sthenic arthrodynia both admits of and demands more corrective treatment, the judicious, discriminating, and persevering use of suitable remedies being capable of accomplishing much, both in renovating health, and restoring power of motion to the still inflamed though rigid and contracted joints. With the consideration of this form we shall now proceed.

It is a prevailing impression that a chronic disease cannot be inflammatory. How this originated it is needless to conjecture; but,

however the misconception arose, it is a familiar truth that the term chronic conveys to most minds not the simple idea of duration, which alone it expresses, but something the opposite of inflammatory; some state to which the treatment proper for inflammation cannot be applicable. The pure chronic rheumatism of Cullen, as described in the foregoing extract, is unquestionably of this latter character; but as the disease comprises, in addition to this, the subacute or sthenic condition also noticed by him, it is necessary to understand the term chronic, when its application is thus extended, in that restricted sense alone which rightly belongs to it.

Practitioners who are accustomed to regard chronic rheumatism as asthenic, and to treat it accordingly, are little aware of how long a decidedly inflammatory character may attach to it. Years may elapse, yet a distinctly febrile state, indicated by its appropriate phenomena, prevail, accompanied with evidences of disorganizing inflammatory action on the joints. And so long as this state endures, is there progressive deterioration of general health, and increasing structural derangement of joints. It gratifies the writer of this article to see this fact unequivocally stated by Dr. Elliotson, in his excellent clinical lectures delivered at St. Thomas's Hospital. He acknowledges the inflammatory character, and also the great length of time for which this may be retained, specifying this form of rheumatism as active in contradistinction to the term acute, which in its strict sense could not apply to it. The same character was long ago indirectly recognised by Sagar, when, in his definition of chronic rheumatism, he stated the blood drawn to exhibit a buffy crust. In this form, however subdued the symptoms may be, the characteristics of rheumatism, as they have been exhibited in the acute disease, are distinctly traceable. There is a febrile state of the general constitution, and more or less of inflammatory action in the joints; and the principles of treatment are precisely similar, though they require to be modified in their application so as to adapt this to the derangements, both constitutional and local, which need relief. It will assist in comprehending the real nature of this form of the disease to bear in mind what was formerly stated in treating of relative plethora. Certain delusive appearances were then noticed, as misleading practitioners from a right conception of the state of circulation or condition of health existing; and to similar delusions has it been owing that the febrile character of active or sthenic arthrodynia has been so frequently overlooked. An apparently feeble and compressible pulse induces the persuasion of debility; the enfeebled powers of the body sanction the conclusion; and relief is sought from a class of remedies which, in such case, cannot give other than transient relief, if, indeed, they do not aggravate every symptom. Were we sure that the doctrines of plethora formerly illustrated were rightly understood, we could at once close the discussion of the constitutional state prevailing in sthenic arthrodynia, by representing it briefly as that of relative plethora. It differs from the condition formerly described as relative plethora, only in having the local inflammations with their consequences superadded. In order to determine accurately this state of constitution, it is necessary to judge, not from any one indication, but from that assemblage of evidences which, when collectively present, cannot mislead. The pulse, if alone trusted to, may deceive, at least where the practitioner is not on his guard against the delusive lowness of pulse which belongs to incipient plethora, or is unacquainted with the peculiar changes which the pulse undergoes when the congestive state is passing into that of febrile action. Though apparently low in force, it yet evinces some resistance to pressure, and is more or less quickened; the skin, too, is hotter than natural, and the tongue is white and furred. The gastro-intestinal membrane will also be found charged with redundant mucus, such as it generally secretes under febrile action. When all these phenomena are present, and especially when they are accompanied by evidences of local inflammation in the joints, no doubt need be entertained either of the nature of the disease, or of the principles of treatment. In this form of disease, then, it is obvious that the indications of cure are in no respect different from those which have been already shewn as applying to acute rheumatism, namely, to subdue fever, and remove local inflammation. And the rationale of the practice suited for fulfilling these indications will be clearly perceived by those who have taken the trouble to comprehend the doctrines respecting the pathology of the circulation advanced in the article Plethora.

The constitutional state of sthenic arthrodynia bears the same relation to relative plethora that the acute form does to absolute; and in the principles of treatment laid down for the correction of relative plethora, with its concomitant disturbances, will be found the best guidance for conducting with precision and effect that of active chronic rheumatism. On the same principle as in acute rheumatism, it is the constitutional state which demands the first attention; for, unless this be radically corrected, all efforts to cure permanently the local ailments must fail, or be only of transient effect. In treating the constitutional disturbance, it is necessary to bear in mind that it is connected with relative rather than absolute plethora; that, consequently, the derangements existing are more complex, and that the practice must hence embrace considerations which it was not necessary to insist on particularly in discussing the acute disease. In acute rheumatism, active bloodletting was directed; the object being not only to reduce plethora, but to make speedy impression on febrile action, in order to arrest promptly the injuries which unrestrained continuance of this would occasion. In the more chronic form it is necessary to diminish plethora, but not equally so to make so speedy impression on

febrile action. This latter requires to be regulated, but not extinguished; for some increased energies of circulation are absolutely necessary for correcting the concomitant derangements of function produced by defective capillary circulation. To restore the impeded circulation of the capillaries, and renew the secretory and excretory processes of which they are the agents, seems to be the final cause for which febrile action is instituted; it is assuredly the end which it often attains, and hence, when natural fever fails to accomplish it, we are accustomed to institute an artificial fever through the operation of mercury to effect the purpose. This, however, is not to be forced; it requires time for safe and salutary progress: minute vessels long obstructed cannot be all at once rendered pervious and efficient for the discharge of functions long disused; and hence, in treating the febrile state of chronic rheumatism, the practice, though corresponding in principle with that of acute, must be much less energetic. Bleedings must be of smaller amount and at longer intervals; a free state of excretion must be moderately but steadily maintained; and mercury must be employed for that renewal of function in the capillary vessels and their secerning extremities, which the powers of the constitution, unaided by mercury, are inadequate to accomplish.

It will be recollected that in relative plethora the redundancy of blood results more from its imperfect appropriation than from absolute excess; and that correction of this state requires, not only that the larger vessels be relieved from the load which oppresses them, but that the aggregate capacity of vessels be enlarged by renewal of the suspended activity of the capillaries, and also by promoting the natural expenditure of blood through the several secretions and excretions. These are the curative effects of febrile action; they constitute also the beneficial operation of mercury on the system, and on regulating them conformably with the views here displayed will the success of medical practice in a great measure depend, not only in this but in many other diseases. In the diseased state now under consideration, the first object should be to relieve the oppressed circulation, and thus arouse the energies of the system by taking away some blood; and in conducting this part of the treatment, judgement and discrimination are so requisite, that, even at the hazard of being deemed unnecessarily minute, we must dwell on the several circumstances from which any guidance can be derived.

If, with the general evidences of plethoric oppression and febrile action, the powers of the constitution be very low, and the pulse very feeble, it may be advisable to suspend for a while direct depletion, and to trust to purgatives. It may, in such case, be even expedient to employ gentle stimulants in order to arouse the dormant energies, and enable them to bear direct bloodletting; this being the end to which the use of stimulants should in this stage be directed. The necessity for this degree of caution, however, is not of most frequent occurrence. Much more generally may the curative treatment commence with small bleedings; and in these it should never be forgotten that the object is not to make impression on the moving powers, but to withdraw a portion of the circulating mass, and this with a view of arousing the natural powers to the discharge of functions required for the re-establishment of health. Small bleedings here suffice; and the extent of six or eight ounces will best answer the end designed. According as power increases, larger bleedings will be borne; but beyond twelve ounces it is rarely necessary to carry them. In general, even the first portions of blood drawn will be buffed, if not cupped; and under such circumstances the pulse, if previously low, will be found to rise under bleeding. As was before remarked, a soft pulse is no contra-indication of bloodletting; for we continually find buffy blood and increase of power after venesection, where the previous softness and feebleness of pulse would, to unreflecting observers, appear to prohibit all direct depletion. This deceptive character of pulse is too often allowed to influence the practice even in acute rheumatism; yet it has been so often the subject of remark, that practitioners ought to be fully aware of it. Dr. Gregory, who in the treatment of acute rheumatism did not employ bloodletting indiscriminately, nor deem it essentially necessary, but who trusted rather to sweating as the preferable evacuation, used to acknowledge that he had been obliged to have recourse to bleeding after several weeks duration of disease, where he had at first been apprehensive of employing it from the smallness and apparent debility of the pulse; and that after bleeding the pulse rose and disease subsided. This is not peculiar to rheumatism, but a general fact connected with derangement of circulation, and worthy of attention in many diseases. The explanation of it has been fully and clearly given in the article PLETHORA; and if the principles there inculcated be duly regarded and discriminately applied, there will be little hazard either of bloodletting being withheld where it is needed, or of its being carried to any injurious extent.

Next to bloodletting, the most important evacuation is purging, which requires to be regulated both according to the degree of febrile action present, and to the state of the bowels as manifested by the stools. In proportion as fever is active will the free use of purgatives be required, and saline cathartics be needed in aid of those which more peculiarly deterge the mucous membrane of its morbid secretions; but so long as these continue dark, slimy, and unnatural, must suitable purgatives be assiduously employed. Pills of calomel, colocynth, and antimony, with occasional doses of sulphate of magnesia and senna, are the most effectual means of adequate purgation. According as active fever prevails, as evinced by a quick pulse, hot skin, and white or

furred tongue, salines with antimony and colchicum, assisted by antiphlogistic regimen, should also be conjoined.

If under this treatment febrile action does not speedily abate, and local inflammation subside, mercury will be required, and for purposes similar to those for which its use was directed in acute rheumatism. According as fever is active will calomel and opium be necessary, for the proper administration of which no further instruction can be here needed, it being only necessary to observe, that as the morbid actions requiring correction yield more slowly than in acute rheumatism, a more slow and cautious administration of the remedy is here expedient. The direct agency of the medicine is to excite freer circulation in the capillary vessels, by which the larger vessels become relieved, both through the increased capacity thus given to the vessels through which the mass of blood circulates, and the increased expenditure of blood in the several secretions and excretions thus promoted. Whoever bears these facts and principles in mind, will experience no difficulty in regulating the administration of mercury in this or any other disease.

In many cases, however, febrile action, though sufficiently manifested by its appropriate phenomena, is less developed than in those just referred to. The pulse is feeble and irregular, the several secretory and excretory functions are inactive, and the whole frame displays a deficiency of power. Here stimulants are needed, and the most effectual for arousing the dormant energies is mercury. The milder preparations in small doses, repeated at intervals, are what should here be employed. The compound calomel pill, blue pill, hydrargyrum cum creta, are the remedies chiefly in use where a slowly alterative effect is desired. In old and obstinate cases minute doses of the oxymuriate have effect when other preparations fail. When the latter is resorted to, decoction of sarsaparilla is beneficially combined. Whenever mercury is employed for such purposes, it is highly necessary to watch closely the state both of the circulation and of the bowels. If under its use the arterial system becomes excited, and the pulse rises, becoming full, hard, or resisting, blood should be taken; and as mercury, when so administered, promotes the intestinal excretions, these should be assiduously evacuated by suitable purges, which in such case serve the double purposes of removing from the intestines a source of irritation, and of maintaining the excretories in an active exercise of those functions which so materially assist the curative process.

Under the foregoing treatment part of the local inflammation will subside without any topical remedies being applied. But as these inflammations have long reached the secondary stage, and as local derangements, such as were formerly noticed, have become more or less established, the local treatment suited to the special circumstances of each case is here indispensable. According as the local inflammation presents an active character, cupping or leeches will be required; and by these, with fomentations, or with cooling and sedative lotions, much impression may be made. Blisters, too, in time, are of much effect, especially where the bursæ are loaded with glairy effusion, the ligaments thickened and rigid, and the whole joint enlarged. To these changes all the joints are liable; they peculiarly occur in the wrists, where they materially impede the motions of the hands, rendering the patients very helpless. These swellings, when accompanied with heat and redness, require leeching and cold lotions; otherwise, repeated blisters are the means by which the enlargement can be best reduced, the effusions absorbed, the ligaments attenuated, and the flexibility of the articulations restored. In the intervals of blistering, stimulant embrocations are very serviceable; and frictions, especially the kind of manipulation termed shampooing, are of much avail.

In the inveterate cases which continually occur in practice, it is not any one remedy that can be relied on. The combined agency of all is required, and they should be assiduously employed in such succession and alternation as enlightened judgement may direct. By a judicious and steady use of them many a case, apparently hopeless, may be restored to the enjoyment of good general health, and to considerable freedom of the affected limbs. Throughout the whole course of treatment warm bathing is signally beneficial, as is largely attested by the records and daily experience of the noble institution to which the writer of this essay is indebted for much practical knowledge—the Bath Hospital. It cooperates with the constitutional treatment to improve general health, promoting a free circulation in all the capillary vessels, and calling into renewed activity the highly important excretory functions of the skin, while its special effect on the pained and crippled joints is eminently salutary. For the latter purpose, pumping on the limbs, as it is termed, that is, directing against those affected a stream of tepid water, impelled with such force as to exert a mechanical influence on the part, is oftentimes a very powerful auxiliary. Even when general warm bathing is not admissible, this partial application of warm water may be used with much advantage for the relief of local ailments.

Subsidiary to these several means, one of the most effectual aids for restoring motion to rigid or contracted joints is the persevering endeavour to render them flexible by assiduous exercise; and the more this can be promoted through the appropriate muscles of the affected joints, the greater will be the benefit resulting; for the muscles previously wasted will thus recover bulk and strength, and through renewal of exertion will prove a most valuable instrument both in preserving and extending any power of motion that may be gained. Frictions and shampooing are a sort of passive exercise, and through this, as well as by promoting absorption and inducing a freer circulation in

the extreme vessels, their effect on enlarged or rigid joints is considerable.

But even where, from great rigidity and extreme muscular feebleness, the joints are incapable of being exercised by their own proper muscles, the advantage derivable from passive exercise is not to be despised. Frictions and shampooing may lessen rigidity, so as to give more effect to the feeble muscles in their languid efforts. When the wrist and finger joints are affected, the parties may materially benefit themselves by moderate but continually renewed attempts to move the joints of each hand by means of the other. The joints may resist for a long time, but this should not discourage, and the slightest renewal of mobility should be hailed as the sure harbinger of further improvement. It is needless to urge this further. The principles are obvious, the effects proved by ample experience; and at all events perseverance in such endeavours, however little it may in extreme cases accomplish, holds out to the rheumatic cripple the only hope of recovering mobility in joints rendered inflexible by the effects of rheumatic inflammation. Attempts to restore mobility in such cases by internal medicines alone, is worse than fruitless. They may correct constitutional derangements where these coexist, and, by restoring general health, prevent further mischief; but they can have no effect in renewing either mobility or power to limbs so affected.

It has been shewn that the secondary inflammation of acute rheumatism may survive the cause in which it originated. In like manner the local inflammation of chronic rheumatism may continue, although the febrile state which nurtured and aggravated it may have wholly subsided; and, further, the ravages of rheumatism in the joints may remain when all fever, as well as local inflammation, whether primary or secondary, has ceased to exist. Chronic rheumatism, therefore, may be said to present three conditions which deserve to be practically distinguished;—active fever with local inflammation;—inflammation unaccompanied with fever;—and structural derangements of joints unattended by either fever or local inflammation. Each of these conditions requires to be treated on principles applicable to its peculiar state; and any treatment adopted merely on account of its being specifically suited for rheumatism, must, if indiscriminately applied, be productive of much mischief.

There is another diseased condition often consequent to rheumatism, namely, a loss of nervous energy, which constitutes a modification of paralysis; but this demands a separate consideration, which belongs rather to paralysis than to the present subject.

The first condition of chronic rheumatism, or that which comprises both active fever and local inflammation, has been sufficiently discussed. The next in order is where the local inflammation, with the attendant pains and other derangements, endures after fever has subsided. This form also is of frequent occurrence, and it differs from the former in not requiring general bloodletting for its cure. Local depletion and occasional blisters constitute the principal topical treatment; and mercury with sarsaparilla and other such auxiliaries, is the chief agent for inciting the constitutional energies to cooperate in the cure. It is this form of the disease that has misled even intelligent practitioners into pronouncing that general bloodletting is not necessary in chronic rheumatism. Dr. Elliotson in his admirable clinical lectures has expressed himself of this opinion, and declared that he has relinquished general bleeding in active rheumatism, unless when some internal inflammation coexists. That in many such cases the treatment recommended by him, namely, local bleeding, colchicum, and mercury, will succeed without general bleeding, we are well aware; but we are no less assured that in very many it would prove very tedious, if not wholly fail. We consider, therefore, that Dr. Elliotson has stated this opinion somewhat too broadly; and that on reconsideration he will himself admit that the criterion for employing the lancet should be, not the presence of an internal inflammation, but such degree of plethora and febrile excitement as in itself demands direct depletion, independently of all coexisting local derangements. Topical bleeding, low diet, colchicum, and mercury, form a combination of influences which has great power in subduing febrile and inflammatory action; but if plethora exist to a certain extent, even their united agency will be insufficient, unless direct depletion be conjoined. And in such case it requires to be borne in mind, that, as has been already explained, the operation of mercury is not devoid of danger. When there is local inflammation without plethora or fever, the treatment recommended by Dr. Elliotson cannot be improved. Even where plethora and fever exist only in slight degree, it may also succeed, although the progress will be slower than when venesection is conjoined. But when plethora and fever exist to any extent, then, even though there be no internal inflammation, general bleeding ought unquestionably to form part of the treatment.

Chronic rheumatism has been sometimes distinguished into hot and cold,—the hot being the active rheumatism of Elliotson, the cold the arthrodynia of Cullen. In the last, various stimulants are of much avail, and for the relief of such disease they should undoubtedly be resorted to. It is to be hoped, however, that their misapplication to acute or to any active rheumatism as the appropriate remedies, has passed away, or is confined only to ignorant empirics. It illustrates the difficulty of adapting treatment explicitly to the name of a disease, or even to special degrees of it, that there are modifications of active rheumatism in which even stimulants, cautiously administered, are not only safe but beneficial; and this circumstance confirms the necessity of all medical treatment being regulated, not by express rules, but by those principles from which all rules ought to emanate, and to which they ought to be subservient.

It would be vain to enumerate the various

stimulants which have obtained character for the cure of cold rheumatism. The principal are essential oils drawn from resinous substances, such as turpentine; various balsams and gum-resins; the latter either in substance or in simple or ammoniated tinctures; sudorific decoctions; electricity. Any of these may benefit according as the general constitution is prepared for their operation, or as the special ailments may require. If there be no plethoric or febrile state present, their use will at least be harmless, if not beneficial; but should the case be such as to need depletory treatment and the operation of mercury, then must the use of such stimulants as are now named be watched with great caution.

Warm bathing and active exercise are among the unexceptionable and most powerful means of relieving chronic rheumatism. The local treatment formerly directed for the sequelæ of acute rheumatism also requires to be assiduously employed.

There are some affections generally regarded as rheumatism, which, however connected with rheumatic, seem to depend chiefly on a morbid condition of particular nerves. Of this kind are *sciatica* and *lumbago*, both of which differ so much in their symptoms from acute rheumatism, as scarcely to admit of their being classed under it. A mere error of arrangement, however, is of little consequence, as the same principles of treatment apply to all. If the state of constitution be such as to require for its correction bleeding, purging, colchicum, and mercury, these remedies must be employed, else the local affection will not readily yield. That sciatica arises from some lesion of the sciatic nerve or its investments, most practitioners are agreed. That this lesion results from a primary congestion or inflammatory action, seems evidenced both by the whole train of symptoms, and by the treatment most successful in giving relief.

When there is only the local affection to treat, repeated cupping or leeching, and blistering, with the warm bath, and a cautious return to exercise, will do much to effect restoration. Stimulant and sedative embrocations too, are occasionally of service.

In lumbago, though the spinal nerves affected are less distinctly indicated, yet the character of the pain marks it as more neuralgic than rheumatic. Free cupping and the general treatment of acute rheumatism will best succeed in relieving this disease.

But there is a form of neuralgia occasionally attendant on rheumatism which causes much suffering, and which does not seem to be generally understood. It occurs in paroxysms of great intensity, attended with a severity of pain which few can patiently endure. This may arise ere the febrile state has thoroughly subsided; and this circumstance is apt to mislead, for a continuance or removal of inflammation is thus apprehended, and depletory treatment is pursued, under which the disease is aggravated instead of relieved. The character of this affection is best denoted by the suddenness of the painful accessions. The nature of the pain, too, so different from that which attends inflammation, seems to distinguish it. For this affection the most certain and effectual remedy is iron; but it must be largely used, and assisted, if necessary, by full doses of opium. The carbonate is the best preparation, and this should be given in doses of two drachms three or four times a day. By administering it with equal parts of treacle, as directed by Dr. Elliotson, its constipating effects are obviated. Should opium be required, it should be given in full doses, and the best preparation for the purpose is Battley's sedative solution, of which from thirty to ninety minims may be given at bed-time without any sinister effect resulting. Under this treatment it may be necessary to purge occasionally with the common senna draught, which is sensibly improved by the addition of half a drachm of spirit of ammonia.

In the progress of rheumatism the chest is apt to become affected with pain and great dyspnœa, the distress being referred to the lower part of the chest, and described as if the point of the sternum were drawn back to the spine. This arises from the extension or translation of rheumatism to the diaphragm. The means of relief are bleeding, purging, and colchicum, with calomel and opium. So soon as the gums are touched the distress finally ceases.

One of the most important affections connected with rheumatism is that in which the heart or its investments becomes the seat of rheumatic inflammation. This inflammation may be of the most acute kind, constituting complete carditis or pericarditis; or it may be only such increased action of bloodvessels as ultimately leads to hypertrophy. For the acute attack the most active treatment is required; full bloodletting, purging, antimony and colchicum, but above all the early and decisive operation of calomel and opium. If the latter be not speedily and effectually obtained in subserviency to bloodletting, this will be required to such extent as to render recovery extremely doubtful, sink greatly the powers of life, and occasion a very tedious convalescence. Some interesting cases of rheumatic pericarditis have been recently published by Dr. Davis, the senior physician of the Bath hospital. He seems, however, to have trusted to general antiphlogistic regimen, without calling in the aid of mercury. The principles advocated in this article display the merits of mercury as an adjuvant; and the experience of the writer fully confirms their truth and practical utility. But independently of this acute seizure there is continually found in connexion with rheumatism inordinate action of the heart, with evidences of actual enlargement or hypertrophy of that organ. The treatment of this affection, we can from much experience say, is best conducted on the principles inculcated in this article. Moderate bleedings are indispensable, the blood being almost invariably buffed and cupped. In judging of the state of circulation, the pulse at the wrist would mislead, for it may be soft and compressible even when the action of the heart is tumultuous. The carotid should here be examined as furnishing a more certain criterion.

Free bowels and antiphlogistic discipline are indicated by the same necessity which calls for abstraction of blood. Mercury with opium is also required to produce its specific effects, by which alone the morbid action can be effectually or permanently subdued. The use of this requires to be cautiously conducted, for its slowest operation is that which is here most beneficial. The morbid condition is generally of slow formation; the changes wrought are not of a nature to be suddenly rectified; and attempts to accelerate the case beyond what nature permits, would beget mischief and lead only to disappointment. Cupping and leeching over the heart are valuable auxiliaries, and blisters are occasionally needed.

In fine, when inflammation both general and local is allayed, and the action of the heart still continues inordinate, or is too easily excited, the application of belladonna to the side, in the form of plaster, affords a valuable means of quieting the heart's motions, and of procuring rest from a disturbance which is always distressing.

By the cautious adaptation of such means, and steady perseverance in their use, the disturbance of heart here treated of may in time be effectually relieved. Time, however, is required, for the disease yields slowly; and though impression be made on it by the early procedures, months may elapse ere perfect tranquillity of circulation can be restored. The patience, however, which can await this result, and pursue steadily the means of accomplishing it, will be amply rewarded.

There is one more form of rheumatism which requires to be noticed, namely, that which is called *rheumatic gout*; and so far as a name is concerned, this appellation, though only a popular term, is not misapplied. So much has this disease in common both with gout and with rheumatism, that it is scarcely possible to regard it otherwise than as a hybrid malady, in which the elements of both these diseases coexist. Its accession corresponds most with rheumatism; its ravages have a greater resemblance to those of gout. The enlargement of joints to which it is so prone presents much more of the character of gout than of rheumatism. Dr. Haygarth has described this disease, and proposed to denominate it *nodosity of the joints*. Of its history and treatment there is little to be said beyond what has been already advanced under the heads of gout and of rheumatism. It is more frequent in women than in men. Its commencement is often marked by active fever, and in proportion as this is disregarded or inadequately treated, are its ravages more severe and inveterate. But in many it advances by a slow and insidious progress, disorganizing the joints without materially deranging the general health. The local swellings long retain the character of active inflammation, being hot, red, and painful. They in general surround the whole joint, and, so far as mere touch can determine, they seem to arise from a general enlargement of all the structures constituting the joint. It seems strange that the structures actually enlarged have not been long since ascertained by actual dissection; yet we are not aware of any account of them, founded on anatomical examination, having been published. In 1805 Dr. Haygarth had not met with any such account, as appears from the following paragraph of his treatise: "In this disease the ends of the bones, the periosteum, capsules, or ligaments which form the joint, gradually increase. These nodes are not separate tumours, but feel as if they were an enlargement of the bones themselves. *This point might be anatomically ascertained without any difficulty or doubt.*" The disease, according to Dr. Haygarth, does not appear to shorten life; the first patient whom he saw so affected reached the age of ninety-three.

As to treatment, this must be regulated according to the state of constitution and local symptoms, and on the principles inculcated in this article. By local treatment much relief may be rendered. Frequent leeching has much effect in abating heat, swelling, and pain. In the purely chronic stage, successive blisters contribute much to reduce swelling and restore flexibility. As the hands particularly suffer from this malady, it becomes necessary to blister each finger separately, and even each joint; a process which, however irksome, is yet ultimately recompensed by the increased power of using the hands which may be thus obtained.

(E. Barlow.)

RICKETS—Rhachitis, Rachitis. The term *rhachitis* was derived by Glisson from the Greek ῥάχις (spine), because this disease affects, in an especial manner, the spinal column; but he acknowledges that he was induced to adopt this term from its near resemblance to *ricketts*, a word by which the malady was commonly known in England even before his time.* The work of Whistler, and the remarkably clear and full account of rickets afterwards given by Glisson and his associates Bate and Regemorter, have procured a currency for their opinion that the disease made its first appearance in the western parts of England towards the middle of the seventeenth century, and have obtained for rickets among continental writers the designation of the *English malady*, (Morbus Anglicus, Maladie Anglaise, Englische Krankheit.) That rickets was never distinctly described by any medical author before the times of Whistler and Glisson, we readily admit; but that it was of such recent origin as the period stated above, we conceive to be quite inconsistent with the several terms in the Greek and Latin languages denoting deformity and decrepitude of the human body, and with the instances recorded in ancient history of persons so afflicted who were distinguished in various departments of letters and even in arms.

The essential characteristic of rickets is a softening of the bones; but the exact change

* *David Whistler*, Dissertat. Inaugur. de Morbo Puerili Anglor. dicto "The Rickets." Lugdun. Batavor. 1645. This work, which preceded that of Glisson, is now exceedingly rare: a copy still exists in the Bodleian Library.

which takes place in their structure, and the general symptoms by which this alteration is attended, are considerably different at different periods of life. Taking the term rhachitis in this extended sense, to which perhaps *osteomalakia* would be more properly applied, the disease may be divided into two species:—1st, softening of the bones of children, or common rickets; 2d, that of adults, mollities ossium, or osteo-sarcosis. Softening of the bones, like scrofula, is not unfrequently met with among the inferior animals. Thus Lordat dissected a ricketty monkey; Bicherod found softening of the ribs of an ox;* Dupuy describes the skeleton of a ricketty horse;† Mason Good‡ asserts that rickets occurs in the lion; and Comber has written a dissertation on the disease as it appears in sheep.§ But to descend from the researches of the learned to the information of those who are observant of the manners and diseases of our domestic animals, curvature of the bones and swelling at the joints are not unfrequently seen in whole broods of young geese and ducks, when they have been continually exposed to cold and wet. The same affection is met with in young pointers, and more frequently in greyhound puppies, when kept in confined and cold damp kennels. In pigs, the same disease is in some places named krinckets; its causes are cold and moisture, and bad nourishment; and for its cure baths of hot grains are used, oily frictions, nutritious food, and removal to a warm and dry place.

I. RICKETS OF CHILDREN.

1. *History.*—This disease rarely appears before the seventh month, and most commonly does not declare itself until the child first begins his attempts to walk, or until he suffers from the severity of the first dentition. Rickets has also been observed at birth, and in the fœtus: of the former Glisson,‖ Henckel,¶ Klein, and Lepelletier,** have given examples; and of the latter Bordenave,†† and Pinel.‡‡

When a child is about to be affected with rickets, he becomes dull and languid, the appetite is variable and capricious, the bowels are irregular, the stools unhealthy and usually pale. Constitutional disturbance now arises, and a febrile state is soon established: the limbs become emaciated, the belly tumid, the face full, and the head disproportionately large, the forehead projecting, and the sutures of the cranium remaining open or perhaps expanding slightly. The extremities of the long bones which are least concealed by muscle, as those of the wrists and ankles, and the sternal ends of the ribs, particularly these last, are swelled out into knobs. Some have doubted the tumefaction of the extremities of the bones in rickets, ascribing the appearance of swelling to the emaciation of the limbs; but an attentive examination of ricketty cases has convinced us of the correctness of the former opinion. The firm texture of the bony framework of the body now begins to yield, and its increasing softness becomes apparent by the change of form which takes place. The sides of the chest are approximated by the combined operation of the pressure of the child's arms, the weight of the body when laid on its side, and the mode in which children are usually carried; and thus the sternum is made to project like that of a bird, or like the keel of a boat. The lower extremities bend under the weight of the body, while they yield at the same time to the action of the most powerful muscles: the knees are usually bent inwards and the feet thrown out, so that the patient when he walks rests on the inside rather than on the sole of the foot. At other times the whole of each lower extremity forms an irregular curve with its convexity looking outwards, and thus the knees, instead of knocking against each other, stand far apart. Among some of the native tribes of North America, this particular form of the limbs is esteemed handsome; and the utmost care is taken in early infancy to mould them by continued pressure into the admired shape, which, therefore, must not be regarded as any proof of the previous existence of rickets. In this disease the natural convexity of the thigh-bone is often so much increased as to form an elbow; and the angle between the neck and the shaft is converted from an obtuse to a right angle, or even to an acute one. The pelvis is usually deformed in the reverse direction of the chest, the pubes approaching to the sacrum; but in all cases where the pelvis suffers, its cavity is diminished, which to the female in after-life is necessarily attended with more or less dangerous consequences in the event of pregnancy. The vertebral column exhibits in a remarkable manner the effects of rickets in retarding the completion of the bones, and softening their texture: the spinous processes of the last dorsal and of the lumbar vertebræ are sometimes deficient, and the natural form of the spine is variously changed; its uppermost portion is often bent backwards, while the dorsal part projects into a hump, the loins fall in, and the extremity of the sacrum is unnaturally protruded: thus the gait of the hunchback, who has survived the severity of

the disease, is stiff and formal, and the face directed upwards. The distortion of the arms of ricketty children is usually outwards at the upper part of the humerus from the action of the deltoid, and in other parts also it is chiefly determined by the operation of the most powerful muscles; but much will depend on the positions in which the limbs may chance to be placed at the time when the bones are recovering their strength and firmness. Rickets is considered by some to produce little or no change on the bones of the cranium, face, hands, and feet. Those of the two last, we believe, are little affected; but the vertex in ricketty children is, with few exceptions, unnaturally flattened, the centres of the parietals are expanded, and the forehead is prominent from an enlargement of the frontal sinuses: the bones of the face also appear in most cases to undergo some change of form, indicated by the shortness of visage and elongated under-jaw usually observed in those who have suffered from general rickets. In such children the process of dentition is protracted, and the teeth soon decay: the enamel of the permanent teeth is often craggy and worm-eaten, shewing its imperfect formation, though sufficiently hard; but the fang during the progress of the disease has been found somewhat softer than natural.*

The rapidity with which the bones are softened by rickets is sometimes altogether extraordinary. Brunninghausen observed the whole of the bones in one instance become soft in the short space of six weeks, and the case proving fatal, he preserved the skeleton.

As the disease proceeds, the bones are readily fractured when even a slight force is applied, and it is remarkable that, softened as they are, they usually re-unite; at length they become completely pliant. We have seen those of the forearm of a child of four years as flexible as a piece of soft gristle, bending with the weight of the hand whichever way it was turned. The muscles grow more and more flabby, the abdomen more tumid, the appetite becomes keen, and the bowels sluggish. The urine in rickets is rarely healthy, sometimes clear, but more frequently turbid, depositing a copious whitish or light brown sediment, indicating the very disordered condition of the digestive organs, and consisting in all probability of lithate of ammonia, with a large admixture of the phosphates. During the continued progress of rickets, the febrile excitement abates until its latter stages, when at length a regular hectic is established, and contributes by its perspirations and diarrhœa to exhaust and destroy the patient.

The intellect of the subjects of rickets generally possesses a degree of development far beyond what is usual in healthy children of the same age; the children exhibiting a quickness of perception and a fluency of language sometimes astonishing. In other instances, though much more rarely, they are taciturn and stupid, or even verge to a state of idiotey. The frequent precocity of understanding has been ascribed to the expansion of the skull, and the earlier development of the brain consequent on that determination of blood to the head which appears always to exist at least in the first stages of rickets; but when this disease does not occur until the sutures of the cranium have closed, the same circumstance of an increased flow of blood acting on a part no longer capable of yielding has been assigned as the cause of the mental torpor or fatuity occasionally met with.

Almost all those who become ricketty soon after birth perish, but many in whom the disease has appeared later recover before their fifth or sixth year; the general health gradually improving, the tumefaction of the abdomen subsiding, and the bones acquiring firmness, though retaining, with scarcely an exception, a certain degree of deformity. The head remains disproportionately large, the child preserving its acuteness and vivacity. At other times recovery takes place after smart febrile re-action, which is occasionally accompanied by the appearance of a cutaneous eruption. Sometimes the child at the approach of convalescence exhibits an extraordinary liking to particular articles of food. We have known the desire for common salt so strong that the little patient would devour it as others do sweetmeats. The quantity taken in one instance was very great, and to the parents it seemed as if the salt had proved the means of cure.

After the cessation of the disease, the bones acquire a degree of solidity and strength even greater than natural, and many persons whose form proves that they were ricketty in early years, are in after-life distinguished for robustness and activity. The deficiency of earthy salts in the bones, which existed during rickets, is succeeded by their excessive deposition; and that state is induced which has been named hyperostosis: the long bones become more rounded and massy; and the sutures of the cranium are often obliterated, and the lines of junction raised into flattened ridges. In some instances rickets has been followed after some interval by a remarkable tendency to the production of bony growths. There is related by the Bishop of Cork in the Philosophical Transactions for 1740, 1741, the case of a man who had been so ricketty in his youth that almost every bone in his body was distorted. At the age of eighteen he began to grow stiff, and at length, having lost all use of his limbs, he became like a statue: he survived till his sixty-first year, and at his death his skeleton was found to be one continuous bone from the top of his head to his knees. Many osseous growths, some of them of the most grotesque forms, branched from his head, back, and haunches; and a portion of fully-formed bone was also found imbedded within one of the large muscles.

Should the disease not yield before the seventh or eighth year, the individuals, if they

* *Wilson*, Lectures on the Human Skeleton.

survive, are condemned to a life of infirmity, which is seldom prolonged beyond middle age. Such persons suffer exceedingly from the unnatural pressure and displacement to which the organs of the chest, and even the most important of those of the abdomen, are more or less subjected. The stomach in these cases is frequently pushed as low as the umbilicus, and even the urinary functions have been disordered by a projecting vertebra pressing upon the kidney. These unfortunate individuals are remarkable for their shrill voice, dilated nostrils, and panting respiration; and life is generally cut short by one of those attacks of pulmonary inflammation to which they are peculiarly prone; at other times they are destroyed by the development of tubercular disease, and occasionally by dropsy.

In rickets, as in most chronic disorders, the change which takes place at puberty is productive of amendment, or of an increase of the disease. Ravaton has detailed a remarkable case, which serves well to illustrate this influence. A girl, whose legs were so deformed that at thirteen years she was only three feet high, was seized with continued fever; the catamenia appeared, the limbs then gradually straightened, and in less than three months her height was five feet one inch.

The progress of rickets is accelerated by confinement and exposure to cold and damp, by bad clothing, imperfect nourishment, and careless nursing; and retarded by circumstances the reverse of these: hence it may be that the disease is now of less frequent occurrence than in former times, and that it has been observed to make less progress in spring and summer, and to advance most quickly in winter and autumn. But the progress of rickets often varies without any obvious cause; it sometimes appears to be arrested as if recovery were at hand, then revive, and proceed with more rapidity than before. As the disease advances to a fatal termination, the little sufferer cannot bear even to be moved in bed, and the attempt is often productive of the fracture of some bone: hectic fever is now established, with its attendant colliquative perspirations and diarrhœa. At this period also, a variety of nervous symptoms sometimes present themselves; such as temporary deafness, or blindness, irritation of the bladder or inability to expel the urine, or paroxyms of epilepsy, or convulsions. Should these last not prove the cause of death, the patient at length sinks under debility, and dies exhausted.

On examining the bodies of those who have died while still labouring under rickets, the brain is found disproportionately large, but often in other respects quite natural; in some instances the ventricles are filled, or perhaps considerably dilated with a limpid fluid; and a similar fluid is also found in the basis of the skull and within the canal of the vertebræ. The cavities of the thorax and abdomen likewise sometimes contain serous or bloody liquid; the lungs are compressed and occasionally displaced by the alteration in the form of the thorax; marks of inflammation are often apparent in the pleura and pulmonary substance, which last is sometimes hepatized, and at other times contains numerous tubercles in various stages of advancement. It is remarkable that in some cases of ricketty children from one to ten years old, the thymus gland has been found much enlarged, and the upper part of the sternum bulging out, so as to form a concavity, within which the overgrown organ was lodged.* The heart is not found diseased where death occurs during the active progress of rickets; but in those who have survived with deformity of the chest, the obstacle thus occasioned to the circulation, especially through the lungs, rarely fails to produce in the end hypertrophy of that organ.† The liver and spleen of ricketty subjects are almost in every case enlarged, the former in particular. The mesenteric glands are usually enlarged, and often filled with tuberculous matter; and the other absorbent glands, both within the abdomen and externally, present similar alterations.

In the soft parts little or no adipose substance is found; the muscles are pale, flabby, and wasted; and the rigidity of death is rarely met with in such subjects. The bones, during the active stage of rickets, are found to resemble very vascular cartilage; the medullary cavities are filled with a bloody gelatinous-like substance in place of marrow; and the osseous texture presents every where, even in the cortex, numerous minute cells, from which a thin bloody fluid can be pressed. The appearance of ricketty bones has been well compared to that of a healthy bone deprived of its earthy materials by immersion in a weak acid; but there is this difference, that the ricketty bone is much more vascular, and that the cartilage of which it consists is of so loose a texture, that it is soluble in the same acid which will deprive common bone of its earthy constituents. We are not acquainted with any analysis of recent bone affected with infantile rickets; and the examination of those which have been dried cannot afford much accurate information respecting the constituents of parts which obviously contain so unnaturally large a proportion of fluid and easily destructible ingredients. Nothing, indeed, has tended so much to obscure the pathology of the bones as the almost exclusive practice of macerating and preserving them in a dry state. When the bones of those who have recovered from rickets are examined, their texture is found to be more dense, in consequence of a morbidly increased deposition of the earthy salts; even small exostoses and bony spiculæ are sometimes observed; and in cases where the spine is deformed, the bodies of many of the vertebræ are found united by new osseous substance. The bones of the cranium are observed to be much heavier and thicker than natural, the sutures often obliterated, and the grooves

* *Lobstein*, Anatomie Patholog. t. i. p. 54.
† *Hope*, on Diseases of the Heart, p. 194.

formed by the meningeal arteries greatly deeper than common. Wherever the bones have been bent during their yielding state, a larger deposition of earthy salts is observed in the interior of the curve where its weakness had been the greatest; and to such an extent does the deposit of osseous matter sometimes take place, that the bone at the point of curvature has been converted into a solid substance, the medullary cavity being wholly obliterated.* Perhaps to some it may appear sufficient to say that the earthy salts are thus deposited, because they are most wanted at the weakest point of the bony shaft; but the real cause of this arrangement seems to be that the bending of the bone has compressed into the interior of the curve a larger quantity of cartilaginous substance, which is afterwards filled with an earthy deposit; while it stretches and attenuates that on the exterior of the arch, and so diminishes there the matrix for the reception of earthy materials. It may be observed also, that the effect of bending the pliant bone is to bring its opposite sides into closer approximation, and thus to prepare the way for that ossification throughout its whole diameter to which allusion has already been made. Bones which are distorted are commonly named ricketty, whether in the active stage of that disease or after its cure, when they have acquired an unnatural density from hyperostosis: hence some confusion has arisen in stating the composition of ricketty bones; and the assertion has even been hazarded that a deficiency of phosphate of lime is not an essential, but merely an adventitious circumstance in rickets. Dr. John Davy found 100 parts of the dry tibia of a healthy subject of fifteen to yield 46·4 of animal matter, and 53·6 of earthy; while the same quantity of the dry tibia of a ricketty child contained 74 parts of animal and 26 of earthy substance.†

2. *Causes.*—Rickets appears under very different circumstances, and therefore may be supposed to derive its origin from a diversity of causes. It is met with among the children of the affluent, enjoying every advantage of careful nursing, warm clothing, nutritious food, and airy apartments; and it is found likewise in the damp unwholesome dwellings of the artizan and labourer, where the child is neglected, scantily clothed, and poorly fed. In the former of these classes it is almost always a hereditary disease, or if not, it exists in connexion with a scrofulous habit transmitted from the parent: in the latter it may also arise from hereditary influence; but it seems more generally to originate from those unfavourable circumstances in the rearing of the child which have just been enumerated. Some writers have endeavoured to trace a connexion between rickets and gout, syphilis, and scurvy; but it has not been satisfactorily shewn that any of these diseases, either in parent or child, can operate as causes of rickets excepting by the debility which they may induce, and the predisposition to the malady which may thus be occasioned. Of scrofula, on the other hand, we would speak in very different terms; for the connexion of this disease with rickets appears to be very intimate; although we are far from agreeing with Dr. Thomas Young in the propriety of classing rickets as a mere species of scrofula (*scrofula rhachitis*).*

Rickets rarely occurs excepting in delicate and sickly children: instances are occasionally met with where robust children, born of healthy parents, have been attacked with the disease; but it may be questioned whether such cases were truly ricketty, or if the yielding of the bones had not rather arisen from the great weight of the infant's body, and from too early endeavours to make him walk.

Many cases have occurred which prove the close connection which exists between rhachitic disease and affections of the encephalon, such as hydrocephalus and convulsions. Büchner† relates that he saw almost the whole of a family of eleven brothers affected with rickets. Most of them died of the disease in an advanced stage, while the rest were carried off by convulsions.

Rickets has been observed to prevail in particular localities, probably from their unhealthiness, and the indigence and misery of their inhabitants. Hence it may be regarded as occasionally an endemic disease: it is so described by Glisson in reference to England,‡ and instances are recorded where it assumed the same character in different parts of Germany.§

3. *Treatment.*—During the existence of the acute febrile symptoms of rickets, it will be proper to administer moderate doses of antimonials, to employ the tepid bath, and in some instances even to apply leeches to the forehead or nape of the neck, according to the urgency of the case and the strength of the little patient. The impaired appetite, morbid stools, and disordered urine require the use of small doses of calomel or hydrargyrum cum creta; followed by magnesia and rhubarb, or rhubarb and soda, with an occasional dose of a more active aperient, such as castor-oil or senna. If the disease have occurred at a very early age, it may be advisable to try the effect of changing the wet nurse; and in general it will be proper to wean the child about the end of the ninth month, for protracted suckling is certainly one of the debilitating causes which dispose to rickets. While the child continues at the breast, the diet of the nurse ought to be carefully attended to, in order that her milk may prove nutritious and easy of digestion; or its powers may be assisted by allowing the infant, in addition, small quantities of isinglass jelly, beef tea, or yolk of egg, provided the absence of febrile excitement will

permit. After the child has been weaned, the diet must be suited to the degree of constitutional irritation which exists; but one leading principle should be to support the strength as much as possible without quickening the circulation or oppressing the stomach. Farinaceous food has been condemned by many writers as injurious to ricketty patients from its inferior nutrient properties; yet it will not be denied that, during the existence of febrile symptoms, the various preparations of starch will be found to yield a mild and appropriate nourishment. Whenever the state of irritation has so far subsided that a more substantial diet can be borne, it ought to be given freely, and even a little wine or sound ale may be allowed as long as it causes no morbid excitement.

In the second stage of the disease our principal objects in selecting the means of cure are, to give tone to the system, and improve its nutrient and reparative powers; and for these purposes the cold plunge bath, the affusion of cold water with salt, careful friction of the whole body, and the employment of tonic medicines, will be found very useful. Among the tonics best adapted for cases of rickets may be enumerated sulphate of quinia, gentian, calumba, oxide of zinc, and various preparations of iron, of which, perhaps, the wine and carbonate are to be preferred. With many of these it will be found highly advantageous to combine the alkalies and alkaline earths, the choice of some of them being determined by the state of the bowels and the rapidity or languor of the circulation; carbonate of soda being preferable when the bowels are relaxed, and carbonate of ammonia when the action of the heart is languid. In ricketty cases, where the nervous energy appears defective, it may be proper, in addition to the means of invigorating the frame already enumerated, to employ electricity or galvanism, but in a very cautious manner.

The clothing of the child ought to be warm, and great care should be taken to preserve it free from damp. The apartment in which he sleeps should be dry and well ventilated, and his residence should be in a pure temperate atmosphere, either in the country or on the seacoast; and when the weather permits, he should be carried about in the open air as much as possible. When the ricketty child is carried, it should be alternately in either arm; and when placed in a chair or laid in bed, his position should be such in regard to the various objects of attraction around him, that he shall not incline continually to one side only; or so varied from day to day, that the formation of any fixed deformity may if possible be prevented. His bed should be smooth and comfortably firm, and the head but little elevated; the bedclothes light, yet sufficiently warm. As soon as the constitution appears to be rallying, and the bones acquiring renewed strength and firmness, attempts should be made to restore them to their natural shape by well directed manipulations, and the employment of such mechanical contrivances as will give support without injurious confinement. Considerable success is known to have attended the treatment practised by the Baron Dupuytren* in deformity of the chest. His plan is to place the child with his back against the knee or a wall, and make moderate and gradually increasing pressure with the palm of the hand on the sternum, so as to diminish the antero-posterior diameter of the chest, and force out the ribs towards their natural convexity. This practice is repeated day after day very frequently, and at suitable intervals, with increasing force and for a longer time, augmenting and relaxing the pressure so as to suit the movements of respiration; until at length, after long and careful perseverance, the natural shape of the thorax is to a certain extent restored.

II. Rickets of adults.—*Mollities ossium.*

1. *History.*—The softening of the bones which is met with in persons of adult or advanced age, presents itself in various degrees of severity. Sometimes it is merely a protracted form of infantile rickets, which has continued with numerous checks and interruptions, and successive revivals and increase of symptoms, even to advanced life. On other occasions, and these are not rare, softening of the bones occurs during pregnancy or follows parturition, and increases in severity during each successive gestation. The parts of the osseous system chiefly affected in these cases are the spine and the pelvis; hence the difficulties of childbirth are usually augmented at every succeeding confinement. But the disease has been observed in its most aggravated form among males as well as females, although certainly more often among the latter. Several notices of this intense form of mollities ossium are to be met with among the early historians and biographers of modern times: thus Abbon, the monk, who lived in the ninth century, relates an extraordinary instance where a very large man was reduced by it to the diminutive size of a child.† And Abulfedda asserts that the body of the prophet Gatleb was without bones, so that his limbs could be folded up like a garment.‡ Perhaps the first medical writer who has made mention of mollities ossium is Hollerius:§ he states briefly that there was a woman in Paris whose whole body was soft and flexible, and without solid bones. The next case on record, and it is a well marked and interesting one, is that detailed by Abraham Bauda, which occurred at Sedan in 1650.‖ Since that period many instances of mollities ossium have been published in different countries, references to the most important of which will be found in the present article.

The softening of the bones in this disease is preceded by severe and long-continued pains, which are usually confounded with rheumatism, and have sometimes been supposed to arise from syphilis: a gradually increasing debility seizes the limbs, the nervous system acquires

‖ Microcosmus Mirabilis. Sedan, 1665.

an excessive morbid irritability, the patient walks with the utmost fearfulness, and the slightest jar or concussion of the body causes agony.* Some bone now suffers fracture, which all the efforts of the surgeon are perhaps unable to unite; the patient being constantly confined to bed, the bones soften more and more, assume the most strangely distorted forms, and before death have in some cases been so completely disorganized that the extremities were as limber as a rag.† The patient lies coiled up in bed, sometimes scarcely preserving, except in countenance, the semblance of a human being; the limbs appearing more deformed, and the stature much more shortened than they are actually found to be after death. Every attempt to alter the position of the patient produces agonizing pain, and perhaps new fractures, if the bones be not already too much softened to snap asunder. In such circumstances it is truly astonishing to observe how little the general health suffers, the appetite, digestion, and excretions remaining unimpaired till within a few weeks of death, and the mind continuing calm and intelligent, almost to the last. The urine in such cases is frequently turbid, depositing a copious white sediment; and in some instances small urinary calculi have been voided. But this morbid state of the urine is not constant, for it becomes clear and then again turbid, and occasionally clear for weeks before death. At length hectic fever comes on, sometimes with a feeling of intense burning heat, such that the patient can bear with difficulty the thinnest covering, and requires the windows to be kept open even in the middle of winter.‡ Diarrhœa and perspirations now exhaust the patient, and death at length, after years of protracted suffering, comes to his relief.

The appearances on inspection after death from mollities ossium differ considerably from those which are observed in the bodies of ricketty children. The bones, instead of presenting the appearance of cartilage, as in rickets, are reduced to a mere shell resembling the rind of cheese, and are sometimes described as soft and membranous, and of the thickness of the peritoneum; in one instance the form of some of the bones seems to have been preserved merely by the periosteum;§ and in the case related by Saviard,‖ the remnants of the bones are described as crumbling between the fingers like the rotten bark of a tree. The cavity within the changed and wasted bone has been found filled with a soft red or liver-coloured substance, which in the living body has been ascertained to be devoid of sensibility;* at other times the contents have been a reddish fluid of the consistence of thick honey, and free from any disagreeable odour.† In Mr. Howship's case‡ the contents of the wasted bony shell were various in their appearance: one mass resembled coagulated blood, another gorged liver, a third light fibrinous matter, and a fourth was like compact fleshy substance. The last portions of the long bones which undergo these remarkable transformations are the extremities; and the remnants of osseous substance which they present are found softened and honey-combed with numerous irregular apertures, appearing, when macerated, like a thin piece of ice when partly melted; thus affording unequivocal evidence of the powerful action of the absorbent vessels to which the osseous tissue had been subjected. The cartilaginous coverings of the articular extremities of the bones have sometimes been found entire, at other times attenuated, but the surface polished and raised into eminences; the cavities of the joints sound; and even when unused for six years, filled with healthy synovia.§

Although fractures of the bones have not appeared during the life of the patient to have united, yet after death a callus has occasionally been found to have formed, sometimes only within the cavity of the disorganized bone, occupying it completely at the point of fracture; at others it has appeared externally as a prominent ring, and formed within a solid osseous partition;‖ thus proving that the solution of continuity had served to restore to the part its ossific powers while they were everywhere else deficient. The muscles, in cases of mollities ossium, are found pale, and in general totally altered in their appearance, so that it would be quite impossible from their adhesions and displacement to unfold them by dissection. The viscera of those who have died of this disease have sometimes been found quite healthy,¶ and in most of the cases they are not stated to have suffered much serious alteration; in one instance indeed the liver was enlarged,** in another the gall-bladder was contracted, and contained no bile, but many minute black calculi.†† It is obvious, however, from the histories of other cases, that the lungs and mucous membrane of the bowels must in these instances, if carefully examined, have presented abundant traces of active disease.

2. The *causes* of mollities ossium are exceedingly obscure: syphilis, gout, rheumatism, and scurvy, have all been accused as the sources of this singular disorganization of the solid framework of the body. The sagacious Saviard observes that syphilis produces caries; but this is a softening and melting down of a totally different nature: as to the other diseases named above, they possess nothing in common with that now under consideration, excepting pain, langnor, and debility. In well-marked and extreme cases of syphilis, gout, rheumatism, and scurvy, where death has been the result, we do not meet with mollities ossium as a concomitant, yet authors gravely tell us that softening of the bones arises from the diseases now enumerated lying hid in the constitution and tainting the habit. This affection appears to be closely connected with an enfeebled and relaxed state of the system. Long confinement to bed, after acute diseases in young persons, is often productive of some degree of softening of the ligaments and bones, and consequent deformity; we have seen the pelvis in a delicate boy, after tedious convalescence from measles, elongated diagonally, producing great deformity and lameness; in old age, we have known a lady, who was long bed-ridden, fracture her clavicle by the mere effort of attempting to raise herself in bed by the help of a cord. Indeed, the progressive alteration which the bones naturally undergo in advanced life is itself an approximation to decay, the cortical part becoming thin, and the medullary cavity enlarging; but the former still preserves its hardness of texture. A careful examination of the bones, after a long period of inaction, shews that their healthy state is almost as much dependent on the due exercise of the muscles as that of the muscles themselves. In the vegetable kingdom we see the effect of exercise remarkably exemplified by the increase which it occasions in the bulk and density of the woody fibre. The wood of forest-trees which have stood alone, and exposed to the full force of the blast, is much closer in its texture and more durable than timber raised in natural groves or crowded plantations; and the size and strength of the roots of trees is always much greater in the side which stands exposed to the prevailing wind.

Females are much more liable to mollities ossium than males; and pregnancy and parturition favour in a remarkable manner the progress of the disease. Under such circumstances, the weight to be supported, the drain of nourishment for the supply of the fœtus, and the distending throes and exhausting consequences of labour, must all prove powerful causes of relaxing the connexions of the bones and lowering the strength of the system. Softening of the bones is observed to occur most frequently in persons of a strumous habit; and this peculiarity of constitution may be fairly regarded as forming at least a strong auxiliary cause in the development of the disease.

3. *Treatment.*—Mollities ossium, unlike the rickets of children, occurs at a period of life when the reparative powers of the system have lost their early vigour, or perhaps when they are already in a state of decay: hence a cure of this disease very rarely or never takes place; but it may proceed with greater or less rapidity, and may be checked in its progress by judicious management. We have been unable to discover any case of mollities ossium in which a satisfactory cure has resulted, either from the unassisted efforts of nature or from medical treatment; but instances of the milder form are known to us, where the disease has proceeded slowly for years, and some of the individuals have attained even an advanced age. The influence which pregnancy has been observed to exert in accelerating the progress of mollities ossium, renders it necessary that the patient should live as in a state of celibacy; and every thing which tends in any degree to weaken the frame ought to be carefully avoided. Frictions of the whole body, gestation in the open air, nutritious diet, mild tonics, great attention to the state of the digestive organs, and removal to a dry, warm, and pure atmosphere, are the principal points to be attended to in our endeavours to arrest the progress of this disease. Benefit is likely to be derived, also, from sponging the body with sea-water, or the strong acetic acid obtained from wood; and if the strength be not too far reduced, the cold shower-bath, or sudden immersion in sea-water, may be tried with caution.

Before concluding our account of the several species of softening of the bones, it is proper that we should say a few words on the subject of lateral curvature of the spine, which of late years has engaged so large a share of the attention of medical men of both branches of the profession. In rickets, the curve assumed by the spine is, with few exceptions, confined nearly to the mesial line; and in mollities it is sometimes so, and sometimes lateral; but a very large proportion of the cases of lateral curvature of the spine are wholly independent of both rickets and mollities ossium, and arise from debility or habitual malposition of the body, such as are too often induced by the restraints and fatigue to which young persons are subjected in the course of education.* Hence arise sinking of the spinal column into the flexures naturally assumed under feelings of languor and exhaustion, and twisting of a part of the vertebræ upon their axes: after a time they remain stationary in their new situations, both the ligaments and muscles being so changed that the latter are no longer capable of restoring the bones to their proper positions. Thus, lateral curvature becomes established, and the figure of the patient is permanently deformed.

On examining after death the individual bones of the spine in such cases, we often find them quite healthy and natural in their form, but more or less twisted upon their axes: in some instances we have seen traces of inflammation, and new bone formed uniting them to each other; and, more rarely, we have ob-

* *Shaw*, Essay on the Nature and Treatment of Distortions of the Spine and Chest.

served the bodies of the distorted vertebræ somewhat attenuated and expanded in the interior of the curve where they were most exposed to pressure—a change which was probably the effect rather than the original cause of the deformity.

The treatment of lateral curvature of the spine falls chiefly within the province of the surgeon, but it will be the business of the physician to direct the application of those means which tend to restore the general health of the patient, and thus render effectual the exercises and training, the manual efforts and mechanical contrivances of the surgeon, which would otherwise prove unavailing or injurious. A carefully regulated diet, strict attention to the bowels, mild alteratives and tonics, relief from the restraints of education, and removal to a pure air, friction of the body, gentle exercise in a carriage or on foot, sea-bathing, or the cold shower or plunge bath, or tepid or warm bathing according to the circumstances of the case, constitute the principal remedies by which the physician is enabled to lend effectual assistance in the treatment of lateral curvature of the spine.

(W. Cumin.)

ROSEOLA.—This term is applied to a cutaneous efflorescence of a rose colour, not sensibly prominent, usually preceded and accompanied by mild febrile symptoms. In some cases the rash is diffused generally over the skin, but frequently it is partial or limited to certain regions of the body, as the face, neck, trunk, or extremities; in which situations it occurs in patches variously figured, and of more or less extent. It has not unfrequently, especially by the older writers, been mistaken for measles or scarlatina; hence, probably, originated the notion, which many entertain, that scarlatina, unlike other exanthematous fevers, may occur more than once in the same individual.

Roseola is generally preceded by smart feverish symptoms—irregular chills alternating with heat of skin—pain in the head and limbs—languor and lassitude—and sensation of faintness. After these symptoms have continued for a few days, the rash appears first on the face and neck, spreading in a day or two afterwards over the whole body, and is generally attended by tingling or itching. When it first comes out, the eruption is of a bright red, but it soon assumes its characteristic rose colour. It begins to decline about the third day, and on the fourth, a few dark red specks are only perceptible, which wholly disappear on the fifth, at which period the whole disorder in general terminates.

From the redness and sensation of roughness in the throat, it would appear that the efflorescence extends over the mucous membrane of the mouth and fauces; and this circumstance tends to render the diagnosis between roseola and scarlatina more obscure.

The efflorescence is not always so generally diffused over the skin; in many cases it is partial, appearing only in patches on the face, neck, breasts, or shoulders: it frequently recedes and comes out again, its recession being followed by symptoms of gastric disturbance, which cease when the rash reappears. The recession and reappearance of the rash cannot often be traced to any evident cause, though in many instances irregularities in diet and other indiscretions have been supposed to be powerful agents.

Though roseola may occur at any season of the year, it is more frequently observed in summer, *(Roseola Æstiva,)* and is usually attended by smart feverish symptoms. On the first day the eruption is very liable to be mistaken for measles; but the peculiar character of the eruptive fever, the absence of the catarrhal symptoms, and the form, colour, progress, and duration of the rash, are sufficient to distinguish the two diseases. The rash, which is accompanied by sensation of itching or tingling, is observed first on the face and neck, and in the course of twenty-four to forty-eight hours spreads over the whole body. The spots are distinct and scarcely prominent, of a circular or oval form and deep rose-colour, the intervening portions of the skin preserving their natural appearance. The patches are at first very small, but gradually increase in size. The duration of this form of roseola is from three to four days, unless, as sometimes happens, the rash reappears at irregular intervals, and then its course may be protracted indefinitely. It generally disappears without sensible desquamation of the cuticle.

A similar form of roseola is occasionally observed in autumn *(Roseola Autumnalis)*. It differs from the preceding in being unattended by itching or tingling, or feverish indisposition, and in the eruption appearing chiefly if not exclusively on the arms.

Another variety of roseola has been described by Willan *(Roseola Annulata)*, in which rose-coloured rings, with central areas of the natural colour of the skin, appear on almost every part of the body, attended with sensation of heat, pricking, and tingling, especially during the night. The eruption, which is preceded by symptoms of acute fever, rigors, headach, flushing of the face, nausea, and pain of limbs, may last four or five days, and disappear as the feverishness abates; or, as now and then happens, it may be unattended with fever, and be of much longer duration. In these latter instances the eruption generally appears most vivid in the evening, or when the individual becomes warm in bed, and continues till morning, when it fades. It is sometimes also sensibly elevated, and very often, more especially when the eruption suddenly recedes, attended with considerable gastric disturbance.

Though roseola is not confined to any period of life, it is a frequent cutaneous disorder of infants, more especially during dentition, derangement of the bowels, and various infantile diseases attended with fever *(Roseola Infantilis)*. Dr. Willan states that this efflorescence continues in some instances for a night; in other cases

it appears and disappears for several successive days, being attended with symptoms of violent irritation. He has seen, even in infants but a few days old, an efflorescence on different parts, in numerous coalescing patches, rounded, though not exactly circular, of about the size of sixpence, and of a strong red colour. These continue five, six, or eight days, with a slight elevation of the cuticle, and terminate by desquamation, but are not always attended with constitutional disorder. Occasionally during the first stage of dentition, a single patch of efflorescence appears on one arm, or on the neck: it remains three or four days, then disappears, and is in a short time succeeded by another, perhaps on the opposite arm. This fades and disappears in about the same period, when a fresh patch rises in another place, and thus the eruption may be continued two or three weeks.

Roseola occasionally occurs also previous to the eruption of both the natural and inoculated small-pox, but seldom in the former; and when it does occur in connexion with the natural small-pox, it always indicates a severe and often fatal disease, though some inoculators deemed it an indication of a favourable variolous eruption. The early writers on small-pox observed this roseolous efflorescence, which they regarded as measles converted into small-pox. Dr. Willan, who applied the term *Roseola Variolosa* to the rash when it occurred in connexion with small-pox, states that it appears in about one case of fifteen in the inoculated small-pox, on the second day of the eruptive fever, which is generally the ninth or tenth after inoculation. The rash is first observed on the face, breast, and arms, and on the following day spreads over the trunk and lower extremities. It sometimes assumes the form of oblong irregular patches: in other cases it is diffused with numerous interstices; and occasionally it extends over the whole body, so that the skin presents a continuous redness, with slight elevation in some places. The rash continues about three days, on the second or last day of which the small-pox pustules make their appearance, and may be distinguished in the general redness by their prominence and hardness.

A similar efflorescence, but appearing generally in a congeries of dots and small patches, and slightly elevated, takes place in some children about the ninth or tenth day of vaccination, and about the same time that the areola forms around the vesicle. To this rash, which spreads irregularly over the surface of the body, Dr. Willan gave the name *Roseola Vaccina*. It is generally attended with slight febrile indisposition, though from the statement of Dr. Jenner it would appear to be seldom observed, as his notes did not furnish him with a single instance of it, nor did he recollect in any case more than one or two slight patches of redness, which very soon disappeared.

Lastly, roseola sometimes appears in connexion with various acute disorders—miliaria, various forms of continued fever, acute rheumatism, and with gout. When it occurs under such circumstances, it is to be regarded merely as an accidental complication or concomitant.

Though attention to the appearance of the efflorescence and the constitutional symptoms by which roseola is accompanied will seldom leave any doubt as to its nature, there are some acute eruptive disorders which it resembles in some particulars, and from which it must be distinguished.

Measles may be discriminated by the catarrhal symptoms which precede and accompany the eruption, which generally appears on the fourth day of the eruptive fever, and declines about the seventh or eighth; by the crescentic form and vivid red colour of the rash; by the tendency to bronchial or pulmonary inflammation during the course of the disease, and by its being propagated by contagion. In roseola, the patches are larger, more irregular, and more varied in their form; the eruption disappears after four or five days' febrile indisposition, is not preceded nor followed by any peculiar local inflammation, and is never communicated by contagion.

In scarlatina, the bright-red or scarlet colour of the eruption, which is more generally diffused, and more evident about the flexure of the joints; its appearing on the second day of the eruptive fever; the peculiar appearance of the tongue; the affection of the throat when it exists; the desquamation of the skin at the decline of the rash, and its propagation by contagion, will seldom fail to distinguish it from roseola.

It is scarcely possible to mistake roseola for erythema, in which the diffused or continuous redness of the skin without any distinguishable efflorescence, the trifling amount or total absence of constitutional disturbance, and its being generally symptomatic of some other affection, render the discrimination sufficiently easy. (See Erythema.)

The treatment of roseola includes the adoption of an antiphlogistic regimen modified according to circumstances. The little constitutional disturbance with which it is usually accompanied, and the comparatively slight irritation which it in general induces, render any active measures unnecessary. All that in the majority of instances is required, is to keep the patient cool, to prescribe light diet and acidulated drinks, to administer from time to time a mild aperient; and as the mineral acids have been found useful, they may be ordered according to the feelings of the practitioner. Dr. Bateman was of opinion that the decline of roseola was expedited by the use of sulphuric acid in the infusion of roses, or the infusion of gentian, in combination with small doses of sulphate of magnesia. The occasional employment of the warm or tepid bath may be conjoined with these measures.

When roseola occurs as a complication of some internal disorder, the treatment must be directed to the removal of the disease of which it is merely symptomatic.

(A. Tweedie.)

RUBEOLA, (Measles,) derived from rubio, *red*. This word appears to be of Spanish origin, and probably emanated from the school of Cordova: it was formerly written *rubiola*, or *rubiolo*. Another term by which this affection has been designated is *morbilli*, or the minor plague, being the diminutive of *il morbo*, as the Italians called the plague. The restriction now adopted in the application of the term rubeola is of rather modern date, and owes its establishment to Sauvages, before whose time great confusion prevailed in the naming of several of the exanthemata: rubeola, in particular, was used to signify equally scarlet fever and measles. A similar inaccuracy was to be found among the French writers also, for the word *rougeole*, their common name for measles, meant at one time *scarlatina*, and that so decidedly, that when it was thought necessary to apply distinct names to the two diseases, in consequence of the difference between them becoming fully understood, Chevenau informs us that the Marsellois used the word rougeole to signify scarlatina, and distinguished measles by the name of scnapion.* In our own country, Morton maintained the identity of these two exanthemata, and considered the relation existing between them the same as that between distinct and confluent small-pox.† Even so recently as 1769, Sir William Watson confounded these two diseases,‡ the correct diagnosis between which ought probably to be referred to the time of publishing the second edition of Dr. Withering's Essay on Scarlet Fever in 1793. But this was by no means the only or the most remarkable inaccuracy which in former days prevailed on this subject, since we find Sennertus, in the middle of the seventeenth century, discussing the question "why the disease in some constitutions assumed the form of small-pox, and in others that of measles;"§ and in a posthumous work of Diemerbroeck, published in 1687, it is laid down that small-pox and measles are only different degrees of the same affection: "Differunt (morbilli) a variolis accidentaliter, vel quoad magis et minus."‖ The same doctrine was still more recently maintained by Lange, a professor at Leipsic: "Præterea tam morbilli quam variolæ sunt eruptiones in eo duntaxat discrepantes, quod vel minus vel magis appareant," &c.¶

Later and more accurate investigations have very clearly shewn the distinction that exists between these diseases, not only in their essential characters, but also in the treatment which they require; so that we no longer hesitate in separating them, or feel doubtful as to the elements of a correct diagnosis between them.

By the term rubeola, or measles, in modern times, is understood a contagious inflammatory disease, affecting at once the skin and gastro-pulmonary mucous membrane, in which, after catarrhal fever has continued about three days, a rash appears on the skin, at first in small stigmatized dots, not unlike flea-bites, which, presently coalescing, form patches of a crescentic or semilunar figure, first on the face, and thence spreading gradually downwards over the whole of the body and limbs, at the end of four days disappear by desquamation of the cuticle.

Rubeola occurs at every period of life, but infants and persons of advanced age are less frequently affected by it than those of the intermediate stage. In childhood and adolescence, however, the disease is most common. It is asserted by Rosen, Vogel, and others, that infants have been born with the traces of measles. Guersent mentions* having seen an infant born with measles on it, having taken the disease from the mother; but we presume such instances must be of exceedingly rare occurrence.

Measles are not unfrequently epidemic; they generally prevail from the beginning of spring to the vernal equinox, and decline about the summer solstice, though this is only a general observation to which numerous exceptions occur. It has been frequently observed that whenever measles rage as an epidemic, small-pox prevails at the same time; and, generally speaking, the rubeolous contagion, if received into the system previously to that of variola, has the power of suspending the variolous action till the measles have run their course. This has not, however, been invariably the case, for instances have occurred in which both diseases proceeded together; "this," we are informed by Dr. M'Bride, "was observed particularly in the Foundling Hospital of Dublin in 1769. A number of the children having been inoculated for small-pox, in the mean while were seized with the measles, and both species of eruption were perfectly distinct; they nevertheless all recovered:"† and Mr. Russell has described two cases in which the two eruptions ran their course together in the same individuals, when these diseases were epidemic at Aleppo in 1765.‡

The general law with regard to measles, in common with others of the exanthemata, is, that they affect the system but once, and this peculiarity is maintained with much greater strictness and fewer exceptions than the statements we are accustomed to hear in society would lead us to believe; very many indeed of the cases of secondary measles so reported, originating merely in the parties having confounded roseola or some other cutaneous efflorescence with rubeola. Of this we have detected several instances, and almost invariably it has been acknowledged that the former disease had not been seen by any competent judge: that exceptions have occurred, however, in this disease, as in scarlatina and small-pox, cannot be

denied, but that they have been very rare is proved by the few instances which have been recorded. Guersent mentions having seen children affected with the disease twice in the course of the same year; in one child he observed two very regular eruptions of measles in six weeks, and in the interval between their first and second appearance the child had a variety of small-pox.* The cases of this kind related by Dr. Baillie† are not only the most decisive of which we are aware, but also the most remarkable, as shewing not merely an individual but a family susceptibility. In the first instance five brothers and sisters had it in succession a second time, four of them after an interval of six months, and the fifth after a lapse of twenty-one years. In the other instance two sisters had a return of the disease after four months. An observation of Dr. Burns‡ deserves to be noticed here: he observed that "when the measles were epidemic, it was not uncommon to find those who had formerly had the disease affected sometimes with catarrh without any eruption, sometimes with an eruption preceded by little or no fever and without any catarrh: this was very distinctly observed during every season when the measles were prevalent;" but he is doubtful as to the exact nature of the eruption. Frank§ says that a second attack of measles is more common than of variola, an opinion which appears to be at variance with general experience, and decidedly with our own. It is also a well ascertained fact that the imperfect form of measles, generally denominated *rubeola sine catarrho*, does not afford any protection against a recurrence of the disease.

The contagious nature of measles is, we believe, universally acknowledged, and there is even reason to believe that it is infectious before the appearance of the eruption;‖ but, as in other contagious diseases, there is a great difference in the susceptibility of different individuals equally exposed. We very lately attended a young lady with this complaint, whose younger sister slept with her during the whole of the eruptive fever and for two nights after the eruption made its appearance, and yet escaped the disorder. Heberden mentions that an infant who sucked a nurse till the measles appeared on her was not affected.

With regard to the latent period of measles, our own observation would lead us to fix it at about nine or ten days, but this is a point difficult to determine: after inoculation the symptoms of fever appeared about the seventh day. Dr. Burns¶ states the latent period to be about twelve or fourteen days; Heberden** from ten to fourteen days; Dr. Gregory†† from eight to fourteen days; Dr. Elliotson‡‡ from five days to a fortnight. Dr. Willan says he knew a person who passed through the measles and became convalescent, whose clothes infected a child in the country; this child had the eruption sixteen days after being exposed to the fomites.

Progress of the disease.—The symptoms of the antecedent fever are not usually such as to excite much attention. The child appears at first not so well as usual, is less active, and out of spirits; the appetite is impaired, and the sleep is disturbed: this derangement of the system is presently explained by the patient exhibiting symptoms of catarrh, — frequent cough, sneezing, running from the nose and eyes, which are tender and generally itchy, so that the child frequently rubs the eyes, and picks the nose: the skin is hot and dry, with occasional chills; and the pulse is quickened. When these symptoms have continued about three days, the child feels on the fourth still more decidedly sick, and is unwilling to leave its bed. Sometimes the precursory symptoms are so slight as scarcely to be felt by the patient or noticed by others. We had lately under our care a young lady of seventeen who was in constant attendance on her sister in measles, and the first notice we had of her having caught the disease was the appearance of the rash on her face.* In other instances the precursory symptoms are very severe: there is high fever, with violent catarrhal symptoms, rigors, total loss of appetite, intense thirst, burning headach, suffused eyes, intolerance of light, constant somnolence, but little or no sleep, or if the patient happens to fall asleep he starts from it as if frightened; the pulse is rapid and sharp, the throat sore, and the cough incessant, with pain or soreness in the chest. There is an evident exacerbation of these symptoms towards evening, accompanied often by difficulty of breathing, and not unfrequently by nocturnal delirium.

When the rash appears, which it usually does on the fourth day, it is not in general productive of much relief of the precursory symptoms, which are indeed more frequently somewhat increased: it is first perceived in general about the roots of the hair, on the upper parts of the forehead, and on the chin, in the form of small red spots somewhat resembling flea-bites, which are at first distinct, but soon coalesce and form patches of an irregularly crescentic or semicircular figure, of a dull red colour, slightly elevated, and having between them portions of the skin retaining its natural appearance. If the finger be passed over the surface, the patches of eruption are felt slightly prominent and rough;† this roughness is frequently stated to be perceptible only on the face, but we have repeatedly found it most remarkable on the arms. In a case which we very lately attended, the elevation of the

† It appears very singular that Rayer should describe the patches of eruption as not rising above the surface; his words are "ces taches ne donnent pas sous le doigt la sensation d'une surface inegale et prominente."—Maladies de la Peau, tom i. p. 18.

patches on the latter parts attracted our particular attention. In the course of the fourth day the eruption spreads over the face; spots also may be observed on the palate and fauces, of a dark red colour, which are still more distinct after another day, the inflammation attending which causes a sensation of dryness and roughness in the pharynx, and increases the hoarseness. On the next day (the fifth) the eruption extends over the neck, breast, and upper parts of the trunk; it is now very vivid on the face, which is not unfrequently so much swelled, especially the eyelids, that the eyes are quite closed up as in small-pox, while the other features are from the same cause greatly altered. Towards the close of the same day, the eruption begins to appear on the arms, and spreads over the lower part of the trunk. On the sixth day the eruption is vivid on the trunk and arms, and appears on the lower extremities about as far as the knees, while it is declining or nearly faded on the face. On the seventh day it is fully out on the legs and feet and on the hands, while on the body it is fading, which it does in the same order as to parts as it appeared on them. On the eighth day the rash is fading from the parts last invaded, so that on the ninth it is hardly perceptible, and by the tenth it has in general entirely disappeared. While the fading proceeds, the elevations of the cuticle drop off in the form of little scales, so that the surface of the body appears as if it had been sprinkled over with fine bran.

Such is the usual course of the disease in its simple and regular form; but we occasionally meet with deviations or peculiarities requiring to be noticed. Thus the eruption, sometimes anticipating the usual time of its appearance, comes out on the third or even the second day of the eruptive fever, while in other instances it has been delayed many days beyond the ordinary period. Buchobz gives an instance of its not appearing till the twenty-first day, and Dr. Elliotson in his description of the disease says, "these catarrhal symptoms will sometimes last two days, sometimes twenty before the appearance of the eruption: in some instances the disease is ushered in by severe vomiting, and occasionally, though rarely, free salivation takes place." Heberden* tells us of a patient who on the first day of the eruption "was seized with a spitting which continued to tease him for forty-eight hours, without suffering him to rest at all by day, or to sleep by night; the cough in the mean time almost ceased, and all the other symptoms were as mild as in a favorable sort of the measles." Convulsions also have occasionally preceded the attack, as happens sometimes in small-pox; and one person is mentioned by Heberden, who had a most excruciating pain in the back, which continued for a day or two after the eruption. In some instances the spots have appeared first on the body instead of the face, and in a few rare cases the rash has not spread to the arms during the whole course of the disease. Sometimes the eruption is not followed by desquamation. In many the rash is accompanied and intermixed with a very full crop of miliary vesicles of such size and distinctness as to lead to a suspicion of the approaching disease being small-pox. The production of these vesicles has been ascribed by some writers to an unusual intensity in the inflammatory action attending the disease, but this is certainly incorrect, as we have seen them very numerous in perfectly mild cases. It has happened, but we believe very rarely, that the eruption has broken out anew: Dr. Conolly* relates the case of a young lady at school, who became the subject of a very singular hysterical affection, a few months after having had rubeola in an unusual form; the eruption came out and seemed to be disappearing at the usual period, when it suddenly broke out afresh, and to such an excessive degree as to make it impossible to recognize the features of her face: very nearly the same thing was observed in a case detailed by Frank.†

Treatment.—The treatment of measles in its ordinary and simple form may be comprised in very few directions. The patient should be kept in bed, with so much covering only as will secure comfort, avoiding equally too much heat or exposure to cold; on these points we almost always have to contend against one or other of two prejudices, the most common of which is, that a breath of cool air is most pernicious to a patient in measles, and in consequence of this belief the individual is kept constantly enveloped in a smothering heap of bed-clothes with drawn curtains, and the room well heated by fire, by which means the fever and all its concomitant dangers are greatly augmented; others again, who have had children in the small-pox, insist upon the advantages of cold, not being able to discriminate between the widely different natures of the fevers accompanying the two diseases. The patient should be kept free from disturbance or noise, and, on account of the tenderness of the eyes, a subdued light only admitted into the chamber; he should be liberally supplied with mild mucilaginous drinks, and little or no food, and whatever is taken should be of the simplest kind; he should be solicited to inhale watery vapour by inclining the face over a basin of warm water or of chamomile infusion, by which means the tender eyes have at the same time the advantage of the soothing effect of the vapour; sponging the face, chest, arms, and hands with the same infusion, or with vinegar and warm water, is productive of great comfort by removing the heat, dryness, and itching of the skin, which are often distressing; for a similar reason mild diaphoretics should be given, which may be advantageously combined with gentle aperients in such quantity as the state of the bowels absolutely requires, active purgation being neither useful nor safe. In the opinion of some the administration of an emetic should form part

* See article HYSTERIA in this work, vol. ii. p. 564.

† Tom. ii. p. 377.

of the treatment, but the propriety of such a remedy has always appeared to us doubtful, and we think we have had reason to be satisfied that its effects were often decidedly injurious by exciting disorder of the alimentary canal.

However favourable may be the condition of the case, we should guard against being lulled into security as to the event. There is no disease in which a change of symptoms occurs more suddenly, or danger more quickly takes the place of safety; we must therefore at every visit carefully ascertain the state of the head, chest, and abdomen; since from these, and especially the two latter, are likely to arise those dangers which may compromise the life of the patient. Thus the discovery, at any period of the disease, of severe headach, with pain piercing through the temples, and perhaps accompanied by delirium and suffused eyes, to which the least ray of light is torture, with a rapid hard pulse, is calculated to excite great apprehension, and demands the immediate adoption of very active measures. The state of the lungs should most particularly engage our attention, as being the organs most constantly and most severely affected in this disease. The period at which danger may generally be apprehended from this source is about the decline of the eruption, that is, from the seventh to the ninth day; but we should be equally on the watch at all times to detect the first symptom of inflammation within the chest, and for this purpose we would strongly inculcate the necessity, where there can be the slightest doubt, of always determining the point by auscultation, instead of trusting to the ordinary symptoms to be collected from the state of the pulse and respiration, or the expression of the countenance, all of which, under the peculiar circumstances of this disease, are but little likely to afford satisfactory information. When once we have satisfied ourselves of the presence of inflammation, our sheet-anchor is bloodletting. We should bleed at once; and if the symptoms are not subdued, bleed again:* we would even say, if there be doubt, bleed, but of course very cautiously,—carefully watching the effect, which, in ninety-nine cases out of a hundred, will be decidedly beneficial. Heberden,† Cullen,‡ and others of our most celebrated physicians, appear to have considered bloodletting as an essential part of the treatment in almost all cases, and to have practised it in every stage of the disease. Mead§ makes no exception, but directs it in every instance. We should, however, be very far from recommending an indiscriminate adoption of such a practice, which under the ordinary circumstances of the disease is not required, and might often be injurious. Bloodletting is seldom necessary during the eruptive fever; and when the rash has appeared, we must take care not to fall into the error of mistaking the hurried and labouring respiration and quick pulse which accompany the disease during the height of the eruption, for proofs of pulmonary inflammation, these conditions being merely symptomatic, and subsiding after a day or two, without any morbid condition of the lungs coexisting, as may be ascertained by the careful application of the stethoscope. Should the character of a prevailing epidemic or of a particular case be low, typhoid, or putrescent, the abstraction of blood would be altogether inadmissible; we must also bear in mind that a great majority of our patients are of tender years and must be treated accordingly. In most cases all we desire may be accomplished by the application of a few leeches, which should always be applied over a part where there is a solid resistance to pressure, should it become necessary to restrain the bleeding; in general the back of the foot is preferred for this purpose in most of the diseases of children. If the object be to relieve the head, the leeches may be applied to the temples, or still more advantageously behind the ears. Whenever we find the patient harassed with an incessant hacking cough, complaining of pain or soreness within the chest, with a sensation of tightness or constriction across that cavity, increased by a full respiration, and with a full hard pulse, we should not hesitate to bleed, even though we may not be able fully to satisfy ourselves of the absolute existence of thoracic inflammation, the effects of which we shall too probably have to lament if we postpone the application of the most effectual remedy for its control.

We do not propose to enter here into the details of the treatment of pneumonia, bronchitis, or pleuritis, which may be consulted in full under their respective titles in other parts of this work: we will only here observe, that the remedial agents on which our reliance must be placed for subduing the inflammations incident to this disease are—bloodletting, leeches, blisters, or vesicating liniments, calomel, ipecacuan, tartar emetic, and the warm bath. Vesicating liniments will often be found preferable to the common blister in treating this and other diseases of children, from the much greater quickness with which they may be made to act, and their not being nearly so apt to produce ugly sloughing sores,—an effect which is too often found to follow the action of the common blister, especially in measles; besides we can very conveniently regulate the degree of their activity by altering the relative proportion of their components. A very eligible formula for such an application, the efficacy of which we have repeatedly proved, is three or four parts of linim. camph. comp. or linim. ammoniæ with one part of ol. terebinth. If this liniment be applied warm to

* "I have with great success ordered even the tenderest infants to be blooded in the arm, in such quantity as their age and strength indicated. And sometimes, also, when the disease (pneumonia) has been urgent, I have not feared to repeat the operation; and in reality, by bleeding, I have snatched abundance of children from imminent death. This disorder attacks children upon the departure of the measles, and proves so fatal, that it may justly be esteemed one of the principal ministers of death, destroying greater numbers than the small-pox."—*Sydenham*, p. 177-8.

† See Commentaries, p. 321.

‡ Practice of Physic, vol. ii. p. 180 and 181.

§ Medical Works, p. 261. Edit. 1767.

the skin, by sopping in it a fold or two of lint of whatever size and shape may be thought necessary, it will produce vesication generally within twenty minutes. M. Luroth has recently recommended frictions with strong tartar emetic ointment over the chest and epigastrium in this disease; but when we consider the extreme irritability of the skin in children, it would require a strong conviction of the indispensable necessity for such an application before we should venture to resort to it. Cold affusion has been recommended,* and in a few instances adopted in the treatment of measles, and it is said successfully. Kœmpfer assures us that at Java the children die of measles if they are not washed with cold water; and Guersent says he would not hesitate to use it where there was pure debility free from disease in the chest.† We have never witnessed the adoption of this practice, and we confess that it appears to us so hazardous and so unnecessary, that it would be difficult to induce us to venture on the experiment.

It sometimes happens that the rash comes out imperfectly, or having appeared properly, suddenly retrocedes and disappears: under such circumstances the nurse will almost certainly, if not well watched, give the child a good dose of sulphur in diluted spirit, or a glass of punch containing saffron, which are considered specifics for helping to bring out the eruption. The pernicious results of such remedies it is unnecessary to point out, especially when we consider that in almost every such instance the retrocession is the effect of some internal disorder which is generally inflammatory, or of too high a degree of fever, the reduction of which should be the primary object of our treatment. If the retrocession have been caused by exposure to cold, the use of the warm bath, diaphoretics, and warm or perhaps slightly stimulating drinks, are all that will be required. Should debility appear to have been the cause, a stimulating plan must be adopted, not only because the rash has receded, but because it has done so in consequence of a condition of the system which, if allowed to continue, might place the patient in danger. The improper use of active cathartics may have been the source of the evil, or it may have arisen from a spontaneous diarrhœa setting in from the commencement; if so, the state of the alimentary canal claims our particular care. Should there be tenderness and other evidence of inflammation, we must bleed, or apply leeches, and use the warm bath; if the discharges are ill-coloured and of very foul odour, we should give calomel, or mercury with chalk and rhubarb; afterwards an anodyne injection may be advisable. These observations apply to the treatment of diarrhœa when it comes on at the termination of the disease: Sydenham says, "Bleeding, also, cures the looseness which succeeds the measles;"‡ but we must observe that we cannot always venture to bleed when there is tenderness present, which may exist without any other evidence of inflammation. On the contrary, there may be much debility; and here we must have recourse to blisters, irritating liniments, the warm bath, opiates, astringents, and a rice diet, with removal into the country to complete the cure.

Varieties of rubeola.—1. *Rubeola sine catarrho* is a form of the affection in which the eruption appears unaccompanied by the usual symptoms of fever and catarrh, and its invasion does not protect the individual against a second attack. This variety has been called by the German writers *rubeola spuria*, and by Dr. Good *rubeola incocta*. Rayer denies the existence of this form of measles, and maintains that such cases are merely roseola mistaken for measles; but the descriptions of Willan, Heberden, and many other very accurate observers, leave no room for doubt on the subject. The most satisfactory example the writer ever saw of it was in one of his own children; the rash was perfect, but the catarrhal symptoms were entirely absent. There is nothing peculiar in the management of this variety, but we should warn the parents that they may expect the occurrence of the disease in its usual form. Frank, in his general observations* on the exanthemata, maintains that as "there is no exanthem which does not occasionally exist without its peculiar fever, so on the other hand there is not one of the exanthematous fevers which does not in certain cases pursue its course without any cutaneous eruption, and *with the same consequences as in other cases.*" This appears in some measure supported by the observation of Dr. Burns already quoted, but we confess that our own experience has made us very sceptical on the point. Rayer is of opinion that the cases which have been supposed *rougeole sans eruption* were neither more nor less than *catarrhus sans rougeole*; and it is to be remarked that Frank himself, speaking of measles, declares "he never met with the fever of measles without the eruption (febris morbillosa sine morbillis), and doubts its existence, until it shall have been proved by inoculation that persons who have had such a fever are not susceptible of taking measles."†

2. *Rubeola nigra.*—This designation is applied to a peculiar appearance which the rash occasionally assumes about the seventh or eighth day, the spots becoming of a livid colour; or, more properly, of a brownish hue, inclining to yellow. It is generally accompanied by languor and a quick pulse, but seldom lasts more than a week or two. Guersent,‡ however, met with a case in which it continued for more than five weeks; he thinks it ought to be distinguished from measles. Practically it is not a matter of much importance, as it is not productive of any bad consequence, the patient recovering quickly under the use of tonics, of which Dr. Willan preferred the mineral acids, which may be very conveniently and advan-

taneously given in combination with sulphate of quinine. It is to be recollected that this is a condition totally distinct from the presence of petechiæ, which mark a debilitated and broken-down state of the system, likely to occasion great danger.

3. *Rubeola putrida vel maligna.*—This distinction has been made to designate a class of cases in which the concomitant symptoms are such as accompany the low form of typhous fever, with a tendency to putrescency throughout the system. The form of disease described by Sir William Watson* as prevailing in the Foundling Hospital in 1769, which proved very fatal, was evidently scarlatina in its malignant form, and not measles. At that time the two diseases were confounded, and Dr. Watson was one of those who even thought that the term scarlatina might be altogether dispensed with.

This variety of the disease is said to have prevailed at Plymouth at 1745, in London in 1763, and at Edinburgh in 1816.† In these epidemics the symptoms of the eruptive stage were particularly violent: the patients were early seized with extreme debility, restlessness, sometimes with coma; the tongue became dry, hard, and black; the fauces were of a deep red colour, accompanied with great irritability of the stomach; the eruption did not exhibit its usual characters; it frequently receded very soon after it made its appearance, was less elevated than it ought to be, and of a dark or livid colour. A large majority of these cases died, and on examination there were found well-marked evidences of inflammation within the thorax. In Edinburgh the retrocession of the eruption was almost always a fatal symptom. Such a form of the disease we believe to be extremely rare in this country, at least we have never met with it. At the same time, however, it is not to be doubted that in particular constitutions, or under certain contingencies, the complaint may assume these characters. Thus Dr. Perceval mentions that in a charity-school where measles prevailed, typhous infection was introduced, and a corresponding change was immediately observed in the character of the measles. Dr. Thomson saw a case in which the languor and state of the pulse were alarming, and the skin rubbed off like a moist cobweb, but the patient recovered by the use of wine and cordials, the administration of which, with the addition of some of the preparations of bark and ammonia, with the warm bath, constitute the chief remedial agents suited to such a condition of the system.

4. *Morbilli variolosi* is a variety mentioned by Dr. M'Bride,‡ in which he says "the eruption is prominent, the face swells greatly, and many pustules actually suppurate like those in the small-pox;" and he adds, "the cough and other catarrhal symptoms are the things which distinguish this from the small-pox." Such a disease as that here described we have never seen, except it should be merely what we have already alluded to,—measles accompanied by a great number of miliary vesicles, some of which occasionally suppurate, but bear no resemblance whatever to small-pox: the occasional conjunction of the two diseases has been already spoken of.

Inoculation.—Some time about the middle of the last century it was proposed to adopt inoculation of measles for the purpose of rendering the disease milder; and Dr. Home* of Edinburgh performed several experiments on the subject, inoculating with a little blood drawn from one of the exanthematous patches. The result does not appear to have been either very decisive or satisfactory; nor has the eligibility of the practice been at all proved by subsequent trials, many of which failed altogether; and even where they succeeded in producing the disease, the operation did not always ensure a mild form of the complaint; on the contrary, many of the cases so produced were as severe as those arising naturally. On this point we have no evidence to offer from our own experience, never having seen the practice put to the test; and we can only find that authorities of equal weight are completely at variance on the subject. Theurmen and Tellegen, as we learn from Rayer, inoculated five infants without any other result than the production of slightly inflamed spots where the punctures were made. The same want of success attended the trials made by Dewees and Chapman at the Philadelphia Dispensary in 1801. The most recent trials of which we are aware are those made by Professor Speranza of Mantua: he inoculated in the first instance six individuals, and afterwards himself, with blood taken from a vivid patch of the eruption: in a few days the measles appeared, and proceeded mildly and regularly; in consequence of this he made further experiments, and he says they were all successful. Dr. Elliotson thinks "it likely that the vesicles which occasionally accompany the eruption may contain the contagion itself in a concentrated form."

Prognosis.—The prognosis in simple measles is almost always favourable; but nothing is more certain than that the mildest form may be speedily converted into the most dangerous; a sudden change taking place in the symptoms which could not have been foreseen, or produced by improper treatment, such as the administration of stimulants, by too much heat, or by exposure to cold. It is to be recollected that it is not the eruption or the mere disease which endangers the safety of the patient, but the internal inflammation which may accompany or follow it; and hence the great necessity for ascertaining exactly the degree of their developement by a most careful examination of the organs of respiration and digestion, to enable us to form a correct opinion as to the probable result. There is a very general impression that adults are in greater danger from measles than younger subjects; but as far as our experience enables us to judge, we should pronounce exactly a contrary opinion, sup-

* Med. Obs. and Enq. vol. iv. p. 132.

‡ Practice of Physic, vol. ii. p. 116.

* Clinical Facts and Experiments, 1758.

posing each to be in an equally good state of health at the time of being attacked. Of course, if an adult encounters the disease with a constitution naturally delicate or previously broken up by intemperate habits, or with some old pulmonary complaint, such a patient would be in great danger; but as a general rule, young children are most likely to suffer severely, because they are most disposed to severe attacks of pulmonary inflammation; so that, in our opinion, the younger the subject the greater the danger. Pregnant women are known to bear all the exanthematous diseases badly, and especially small-pox; this might, *à priori*, be expected, because their system is already in a state very unfavourable for the reception of an inflammatory disease. Rayer considers measles under such circumstances peculiarly dangerous. The cases which the writer has seen have done well; and Heberden* expressly mentions that he "attended several who were greatly harassed by the violence of all the usual symptoms in this illness, but never knew it make one woman miscarry, or be in more danger on account of the pregnancy."

The character of a prevailing epidemic should always be taken into account: thus that of 1670, described by Sydenham, was particularly mild, while that of 1674 was remarkable for the frequency of pneumonia.† The season of the year also has no inconsiderable influence on the progress and issue of the complaint, which is likely to proceed more favourably and safely in mildly warm and temperate weather than when there prevails either extreme of heat or cold. When measles and some other disease are conjoined, as for instance variola or pertussis, or when measles follow close upon the subsidence of some other ailment, especially if that has affected the lungs, the danger to be apprehended will be greatly increased: the same may be said when this disease attacks persons of a scrofulous or a plethoric habit. The following may be considered as the general circumstances which should forewarn us of danger:—great violence in the symptoms of the eruptive fever; the eruption appearing too soon or too late; the approach of pulmonary or abdominal inflammation; severe headach with delirium, suffused eyes, or coma; a hacking cough, with a hard pulse; extreme dyspnœa; retrocession of the eruption, which is generally owing to some serious internal derangement; the accession of typhoid symptoms; the appearance of petechiæ; profuse hemorrhages, inducing prostration of strength:‡ while, on the other hand, a favourable case may be known by the regularity with which the eruption appears and proceeds, and its equal distribution on the different parts of the body successively; by the absence or slightness of the symptoms of thoracic or abdominal inflammation; freedom from headach; the soft state of the pulse; the naturally moist condition of the skin; and the patient obtaining a sufficiency of refreshing sleep. From the London bills of mortality, it appears that there died, from December to October 1831, of measles 532, of small-pox 436, and during the same period in 1832 the number of deaths were, of measles 508, of small-pox 532; making a total of measles 1040, of small-pox 968. Morton has given a very highly exaggerated account* of the mortality during the epidemic of 1672, when he says the deaths from measles were *three hundred every week;* whereas it appears, from the public bills of mortality, that the whole number of deaths for that year by measles amounted only to 118.†

Sequelæ.—Measles are very frequently followed by a train of symptoms indicative of serious pulmonary lesions, very generally by a distressing and tedious cough, by chronic bronchitis, chronic pleuritis, pneumonia,‡ tubercles and phthisis; chronic diarrhœa, generally of an inflammatory character, sometimes harasses and exhausts the patient; ophthalmia, ear-ach, and running of the ears, occasionally also supervene. There are several cutaneous affections apt to appear after measles; amongst them is a very troublesome eruption of inflamed pustules, sometimes terminating in ulceration. In a few instances gangrene of the inside of the cheeks, gums, and lips, in the horrid form of *cancrum oris*, has been observed: in other instances the mortification has affected the vulva. Anasarca has been known to appear after measles, as it very often does after scarlatina; but this is so rare an occurrence, that where anasarca is found, and said to have been preceded by measles, there is much reason to suspect that the previous disease was scarlatina.§ Dr. Harty, who has had extensive opportunities of observing this disease, informed the writer that he has very frequently found during convalescence from measles that the pulse became unusually slow, about forty or fifty beats in a minute; but it did not appear to be connected with any thing unfavourable in the condition of the patients, whose recovery was uninterrupted.

(William F. Montgomery.)

* Commentaries, p. 322.

† The number of deaths from measles that year amounted to 795; while for the three preceding years, taken together, they amounted only to 141.

‡ When females, especially girls, are the subjects of measles, it very frequently happens that during the eruptive stage of the disease the catamenia make their appearance perhaps a week or two before their natural period, and sometimes much more profusely than is natural: this we have repeatedly observed to happen, not only without injury, but we have thought with advantage.

* Append. ad Exer. de Morb. Acutis, p. 427.

† See paper by Dr. Dickson in Med. Obs. and Enq. vol. iv. p. 256.

‡ Laennec thinks that the suffocating orthopnœa which sometimes very suddenly carries off young children after measles is produced by an idiopathic œdema of the lungs. In the greater number of cases examined after death by the writer, the morbid alteration existing was the condensation of the pulmonary structure ordinarily found as the effect of pneumonia.

§ Frank, tom. ii. p. 372, op. cit. Guersent, Dict. de Méd. art. *Rougeole.*

RUPIA, from ῥύπος, *sordes*, may be characterized as an eruption of flattened and scattered bullæ, each surrounded with an inflamed areola; the bullæ filled with serous, purulent, sanious or dark bloody fluid, and succeeded by thick dark-coloured scabs covering unhealthy ulcerations. Bateman and Biett describe the varieties of rupia under three species or heads, viz. rupia *simplex*, rupia *prominens*, and rupia *escharotica*. The last of these, rupia escharotica, being the same disease as gangrenous or infantile *pemphigus*, and as such already fully described in the article Pemphigus; the other two species, rupia simplex and rupia prominens, alone demand a place here: moreover, as these differ from one another merely in degree of severity, they may be comprised under one general description.

The bullæ of rupia are observed most often on the lower extremities, but are also frequently seen on the loins, the upper extremities, and about the shoulders. They are always few in number, and are generally scattered at some distance from one another. In the mild form, (rupia simplex,) one or more oval bullæ arise with little or no premonitory redness of the skin. These bullæ are flattened, and are filled with a sero-purulent fluid, and seldom exceed a sixpence in size. After the lapse of a few hours from their formation, they become partially flaccid; the contained fluid grows muddy and puriform, and dries into a dark-brown scab, thick in the centre, and thin towards the circumference. Around the scab there is a dusky red areola, the cuticle covering which is slightly raised or separated from the true skin, and continuous all round with the thin edges of the scab. The latter is in general easily removed, or falls after a few days, leaving an unhealthy-looking ulceration of the skin, which either becomes crusted with a fresh succession of scabs, or heals, leaving a dark purple mark. In the aggravated degree of the disease, (rupia prominens,) a circumscribed inflammatory redness precedes the formation of the bullæ. The bullæ rise slowly, and, instead of serous fluid, contain purulent matter or a mixture of purulent matter and blood, which constitutes the blackish fluid already mentioned as sometimes found in the bullæ. The contained fluid dries into a very dark-coloured scab, which covers a deeper ulceration, and is surrounded by a wider inflammatory areola than in rupia simplex, and as the ulcerated surface is continually secreting pus, and at the same time enlarging in circumference, the scab is increased by successive layers, each wider than the preceding, and at length, at the termination of ten or twelve days, acquires a conical shape similar to a limpet-shell, sometimes extending at the base to the size of a dollar in area, and protruding in the centre an inch above the surface of the skin: hence the name of this variety of the disease—rupia prominens. This scab is superficial, and if removed is either replaced by a fresh scab, or leaves exposed a pale unhealthy spreading ulcer, bleeding on the slightest touch, of a depth proportionate to the duration of the scab, with livid swollen borders, and in old persons often very difficult to heal, and even when healed leaving a dark-coloured cicatrix.

Diagnosis.—Rupia may be confounded with pemphigus, ecthyma, and venereal pustular eruption, but the bullæ of pemphigus are large, full, and very prominent, and generally contain a serous fluid, while the bullæ of rupia are small, flattened, quickly become flaccid, and contain a fluid, which, if not sanious or purulent from the commencement, very quickly becomes so. Gangrenous pemphigus pours out a sanious fluid, but does not form scales like rupia. The ulcerations of rupia are deep and indented, while those of pemphigus are superficial, resembling excoriations. The shape of the scab in rupia prominens at once distinguishes this variety from pemphigus. Rupia is frequently found in conjunction with ecthyma luridum and cachecticum, and Plumbe has classed rupia and ecthyma together. The two diseases are, however, very distinct in their pathology and appearance. Ecthyma commences as a pustule, rupia as a bulla. The scab of rupia is generally easily removed; the scab of ecthyma is strongly adherent. Around the circumference of the scab of ecthyma there is deep-seated inflammatory hardness, extending into the subcutaneous cellular tissue; around the scab of rupia there is only a superficial red areola, the cuticle over which can be traced in continuation with the surface of the scab. The scab formed on some of the pustular venereal eruptions bears a very close resemblance to the scab of rupia; and as both diseases are likely to occur in the same broken-down constitutions, there is risk of confounding them. The venereal scab and pustule are, however, found to proceed from pustules with hardened bases, not from bullæ as in rupia, and they are generally surrounded with the peculiar syphilitic copper-coloured areolæ. These characters, with the presence of some of the usual constitutional symptoms of syphilis, will suffice to distinguish the two diseases. Plumbe speaks of having seen evil result from mercury being administered for rupia, under the mistaken supposition of its being a venereal affection. Few practitioners, however, in the present day, after the clear and lucid views laid down for the treatment of venereal affections by Mr. Carmichael,* would push mercury to any extent for such appearances, even admitting them to be of venereal origin.

Prognosis.—The duration of rupia is very uncertain, running through its course in a few days, or extending to months. The disease is severe in proportion to the age of the patient, or weakness of the constitution. The slowly-healing ulcerations often keep up a low fever in the system, and thus injure the health, but rupia is scarcely if ever a fatal disease.

Causes.—Rupia may be considered as altogether a constitutional affection, being only

* An Essay on Venereal Diseases, and the Use and Abuse of Mercury in their Treatment, by Richard Carmichael, M.R.I.A. &c.

seen in the aged, or in the debilitated from any cause, but particularly from intemperance, abuse of mercury, or want. Acute diseases affecting the skin, and leaving much debility after them, predispose to it; thus it appears as a sequela of small-pox and scarlatina. The scrofulous are peculiarly subject to it, and it is most prevalent during the winter season among the poor who are badly fed and clothed.

Treatment.—From what has been just stated relative to the causes of rupia, its treatment is easily anticipated. The remedies are a light nutritious diet, cleanliness, the warm bath, attention to the state of the bowels, and sarsaparilla or cinchona, with the mineral acids. Dr. A. T. Thomson, in his edition of Bateman says that slight mercurial courses carried so far as to affect the mouth are sometimes necessary. Mercury, when used in this disease, should according to the best observers be used only as an alterative, and in its mildest forms, as in Plummer's pill. As to local applications, the scabs should be removed by a poultice, and the raw surfaces, if painful, are to be stuped with decoction of bran and poppy-heads. Relaxing or emollient applications, however, should be used only for a short time; the surfaces of the ulcers very soon require stimulating applications, and the strength of these must vary, according to the relaxed state of the ulcers, from a weak solution of nitrate of silver to the application of the solid nitrate, the strong nitric or muriatic acid, or ointment of red precipitate of mercury. Rayer recommends the ulcers to be dressed with saturnine cerate, pledgets of lint to be placed over this dressing, and all to be confined with a bandage which shall keep up a moderate compression. He recommends the ulcers when indolent to be dusted with powdered supertartrate of potass, or a solution of it to be used as a lotion. In this, as in all skin diseases where there is ulceration attended with low irritative fever, internal opiates given at bed-time to procure sleep form an essential requisite in the treatment.

(D. J. Corrigan.)

SCABIES.—This is the classical word now universally used to designate the well-known contagious vesicular disease of the skin, called popularly, in English, *itch*, French, *gale*, German, *krätze*, Italian, *rogna*, &c. These vulgar appellations, except the French, (the etymology of which is doubtful,) are derived from the property which our English expresses, the intense itching and irresistible scratching which it excites. Scabies is the word by which the Latins rendered the ψώρα of the Greeks, a term under which the latter comprehended a number of papular and squamous affections, although they at length appropriated it to the disease which we now denominate psoriasis. The confusion which for a long time attached to ψώρα necessarily involved its synonym scabies, and prevented it from becoming definite in its signification, until they were divorced by Celsus, who restricted the Greek term to scaly diseases, and excluded these from the comprehension of the Latin scabies. The Roman physician and his successors did not, however, confine its signification within its present limits, but included under it other pustular and pruriginous affections, and so caused an inaccurate latitude in its acceptation, which prevailed to a comparatively recent period. The advance of cutaneous pathology at length isolated the disease, but the verbal confusion was revived by Cullen and others, who, when scabies had been definitely fixed, chose for the designation of the itch the term anciently used in so indefinite a sense by the Greeks, *psora*, which (with a prolonged termination) Willan, with a greater regard to its old signification, appropriated to the scaly disease. No imputation of inexactness in this instance attaches to the old medical writers, for words must ever be varying and inconstant in their signification until the state of science permits the diseases which they represent to be investigated upon enlightened principles, and discriminated by a true nosology; but authors are to blame, who, after this period arrives, embarrass the received nomenclature by arbitrarily multiplying names, or changing them from their general acceptation.

Scabies is one of the cutaneous diseases the distinct identity of which is best confirmed by peculiar characters, yet in the description of which such a variety exists as to render it extremely difficult to give a comprehensive account of its history and symptoms. An artificial arrangement would be very desirable for this purpose, but in seeking for such we find how difficult it is to fix arbitrary bounds within which natural phenomena may be circumscribed. "This troublesome disease," says Bateman, "from its affinity with three orders of eruptive appearances, pustules, vesicles, and papulæ, almost bids defiance to any attempt to reduce it to an artificial classification."* A ready illustration of this statement is found in the fact that while Willan has placed it in his order "pustulæ," Biett and Rayer, who have adopted his system, classify it among the vesicles; and again, Dr. Paget, the author of a late ingenious essay on the classification of cutaneous diseases,† coincides with others who consider it as appertaining to the papulæ. It does not belong to our object to maintain the credit of the artificial arrangement, but we may remark that this discrepancy, which shows its defectiveness in this particular as a system, by no means detracts from its practical advantages; on the contrary, the purposes of study and description demand more urgently the aid of arbitrary methods of arrangement when the natural appearances are diversified.

It is admitted by the majority of observers that by far the greatest part of the eruption of scabies is composed of vesicles, so that we unhesitatingly agree with the French authors above cited in regarding its type as essentially vesicular. The transparent apex of the elevation is often so minute or so fugitive as to give the idea of a papula, if not observed atten-

* Synopsis, 7th edition, 1829. p. 278.

† Edin. Med. and Surg. Journal, vol. xxxix. p. 270.

tively and at the seasonable period of its course. With respect to the true papulæ, which are often interspersed amongst the vesicles, it is to be observed that in all eruptions of the skin (whether their real type be vesicle or pustule) there is a period at which the elevation is merely a papula, and it frequently happens that in a vesicular or pustular eruption some pimples proceed no farther in their development than the state of papulæ. Nothing is more common than to see among the pustules of porrigo several which have no purulent apex, having never advanced beyond the papular stage; but on this account their genuine character is not the less established, being properly regarded as *undeveloped* pustules. The papulæ which complicate the vesicles of scabies bear a larger proportion to the true type than in the example of porrigo, but they appear to possess a similar relation to it, being as it were *abortive* vesicles. The occurrence of pustules in scabies forms, indeed, a more decided variety, as one species of it seems to be truly pustular in its nature. Yet it is not to be overlooked that some of these apparent pustules are also primitively vesicles, in which an inflammation of more than ordinary acuteness has produced a purulent secretion instead of transparent serum. According, then, to the opinion here stated, we embrace the vesicular as the true type of the eruption, and regard the deviations of papulæ, and in part those of pustules, as caused by casual variations in the intensity of the inflammatory action. On the one hand, papulæ occur where the inflammation stops short of maturing vesicles; and on the other, pustules are met with when, proceeding to an immoderate degree, it fills the vesicles with pus in place of serum.

The contagious nature of this eruptive disease is the most essential character of its history. Its vesicles are minute and slightly acuminated, with a pearly semitransparency at their summit. They may arise at any part of the body, and spread until it cover every part except the face, which appears to possess a singular immunity from their invasion. The hands and arms are always principally affected, and are often so when no other part of the body partakes of the eruption, which is sufficiently accounted for by the fact that infectious contact usually occurs in this situation. The vesicles are mostly distinct, but have a disposition to accumulate at the flexures of the joints; being almost invariably found confluent on the soft fold of skin between the fingers and at the joint of the phalanges and wrist, and often at the larger articulations, if the eruption be more extensively spread. The intense itching which is the characteristic feature of this troublesome disease accompanies the first appearance of the eruption, and, indeed, seems generally to precede it, as the inflammatory elevation which generates the vesicle is much promoted by the scratching, which the pruritus irresistibly induces. It increases from the commencement until each vesicle attains a certain degree of maturation, when it decreases. The annoyance which it produces is in proportion to the extent of the eruption; if the vesicles be few in number, are developed slowly, and confined to a circumscribed locality, it may cause little attention; but when they are numerous and extensive, and come out with rapidity, the pruritus rises to an intolerable height, and produces inexpressible irritation. The patient then seeks to assuage it by scratching, from which, howsoever he may be cautioned against it, he feels it impossible to refrain. Temporary relief may be obtained from this by changing the itching sensation into the pain of laceration, but he only lays up in store a future visitation of greater intensity. The action of the nails increases the inflammation, which causes new crops of vesicles to spring up, and aggravates the pruritus in the old. More or less of the same consequences flow from any other circumstances which give rise to even a transitory excitement of the cutaneous circulation, as the warmth of bed, the digestion of a stimulating meal, or the use of spirituous potations.

Several days elapse between the time of infectious contact and the manifestation of the pruritus, which period is called in this as in other eruptive diseases the incubation. Its length is much modified by the age of the individual, as connected with the susceptibility of the cutaneous surface to impressions. In childhood, when the skin is soft and active in its functions, the incubation has generally three or four days' duration; in adults it averages ten to fifteen, and in old age, when the skin is rigid and has lost its vascularity, this period is still more prolonged. In the bilious temperament, in which the skin's function is less energetic than in the lymphatic and sanguine, it is also comparatively protracted. The relations of climate and seasons, moreover, have a sensible effect on it, cold and heat respectively retarding and accelerating the first appearance of the disease. The existence of an inflammatory affection of any internal organ is another condition which appears to diminish the susceptibility of the skin to its infection, and to add to the period of incubation. The circumstances connected with this latent period are worthy of attention, not only on account of their intrinsic interest as pathological facts, but because they afford an important practical deduction, which is as follows: the duration of this period has a relation to the actual course of the disease, and the facility with which it may be removed; when the eruption appears promptly after infection has been contracted, it may be inferred that the disease can be speedily conquered by the appropriate remedial applications; but if, on the contrary, the skin has exhibited a tardy inactivity in producing the eruption, when fully developed, the latter will be proportionately inveterate and less amenable to therapeutic means.

When scabies has fully appeared, although it may be modified as to its intensity by circumstances, it always assumes a progressive course, until arrested by treatment; it has no tendency like the exanthematous eruptions to a spontaneous cure. From its original seat it

spreads until the whole surface is affected, but collects especially where the skin is disposed in loose folds, subject to friction, as the axilla, the internal part of the thighs, and fold of the buttock, as well as the flexures of the articulations. The situation where it may first shew itself appears to be entirely dependent on the liability of different parts to contact with infected persons. This is demonstrable from the consideration of it in different individuals, whose conditions in life expose one part of the body more than the rest: for example, in tailors, sempstresses, and shoemakers, it commences on the hands; in infants in the nurses' arms, the nates are frequently found to be the part first affected; and if, on the contrary, the nurse receive it from the child, it breaks out on the hands, and sometimes (which is more in point) on the breast. An exception to this rule would seem to exist in the case of dyers, smiths, and sawyers, whose hands and wrists are rarely primitively affected, and often escape, while it infests other parts: this is to be ascribed to the rough hardened state which the hands of these tradesmen contract from labour, and doubtless in the first two their immunity must be in some part owing to the chemical agents with which their employments bring their hands in contact. Sulphuric acid and other powerful astringents form a main ingredient in the dyers' liquors, and the iron and embers of the forge constantly impregnate the smiths' hands with sulphureous vapours, which are at once its best prophylactic and cure. Redi asserts that he knew an instance in which the face became the first part affected, from the contact of the collar of an infected mantle; but its appearance on the face at all is so contrary to experience deduced from innumerable observations, that this has been denied to be a genuine case of scabies by later writers.

Willan and Bateman divided scabies into four species, derived purely from the variety of form which the disease assumes. They have not been followed in this by the recent authors who have borrowed their arrangement. As the framer of a system, Willan was disposed to attach too much nosological importance to his divisions, and his followers, conceiving that they imply theoretic error, have in many instances relinquished them. It does not appear, however, that by so doing they have attained either to more simplicity of arrangement or fidelity of description, but rather the contrary. In our opinion, the specific distinctions which Willan employed are as valuable as the grander divisions of his system, and to those who are jealous about natural arrangement they are less objectionable, as being the mere expressions of facts, which may be received without reference to any theory of classification. Artificial subdivisions of cutaneous diseases founded on real differences in external characters, if they have no other advantages, greatly facilitate their study, and without the aid derived from this source their description becomes necessarily either vague or defective. In scabies, these practical means of discrimination are particularly requisite, as its diagnosis, which is of great importance, is chiefly to be arrived at (where contagion cannot be proved) by an accurate knowledge of its external characters.

We now proceed further with its description, and in addition to the general remarks with which we commenced it, we recommend attention to the following divisions, which are the same as those proposed by Willan. Far from being the mere offspring of theory, they were suggested to him by their common use amongst the lower order, whose familiarity with it forces them to be intimately acquainted with the various forms in which it appears. Of these they distinguish four, designated the *rank*, *watery*, *pocky*, and *scorbutic* itch, which Willan adapted to his nomenclature under the following titles, viz.:—

Scabies papuliformis.
——— lymphatica.
——— purulenta.
——— cachectica.

Scabies papuliformis, or rank itch.—In this form of scabies the eruption is generally extensive, and accompanied with slight inflammation in the vesicles, and intense itching. It is found chiefly to infest the fingers and wrists, but also spreads extensively upon the trunk, particularly the front part of the chest and abdomen. The elevations resemble papulæ, and thus seem to evince an affinity between this form and prurigo and some varieties of lichen; but where they are fully developed and unbroken by scratching, a close inspection may always detect the transparent apex which indicates its vesicular character. The itching is so troublesome that frequent scratching is resorted to, and the abrasion of the vesicles and even of the skin which ensues, changes the primitive appearance of the eruption; "long red lines are here and there left, and the blood and humour concrete upon the vesicles into little brown or blackish scabs." When it occurs in a sanguine habit, or if it be inordinately exasperated by scratching or other circumstances, some scattered pustules sometimes make their appearance, filled with thick yellow purulent matter.

Scabies lymphatica, or watery itch.—The difference between this and the former is inconsiderable. The separate vesicles are larger and do not partake of the papular character, being full of serum to the base, which besides exhibits no inflammatory redness. The pruritus is extremely troublesome, and when the vesicles are ruptured, moist excoriations are apt to form, upon which after a certain time dark scabs concrete. The most ordinary appearance which this variety presents is a compound of the three stages just referred to, viz. the entire vesicle, the excoriation succeeding its laceration, and the scab which covers this ulcerated part when it begins to heal. It seldom extends like the former variety to the trunk, but is chiefly found collected at the lower parts of the extremities, on the fingers, wrists, back of the hands, and on the feet and toes.

Scabies purulenta, or pocky itch.—This possesses more the characters of a distinct species than any of the other forms, and evinces the

necessity of marking these varieties. As Bateman well remarks, "it is often mistaken by those who confine their notion of scabies to the ichorous vesicles of the varieties already noticed." Heberden had divided the disease into two species, comprehending in the first two former varieties under the name of "pustulæ exiguæ, aquâ plenæ."* The other he describes as "majusculæ enm fundamento rubro, et pure impleantur, fere tanquam variolæ." This resemblance of the round pustules which constitute this species to small-pox, caused the vulgar to denominate it pocky itch. They arise distinct, upon an inflamed base, above which they are considerably elevated; after a few days they maturate and break, having attained frequently to a diameter of two or three lines. The pruritus which they occasion is mixed with a painful tension of the part, different from that which occurs in the vesicular forms. After their breaking they leave a cracked ulceration behind, the heat and stiffness of which causes considerable pain. The pustules may spread like the vesicular form over the body, but seldom extend far from their original seat, which is usually the hands or feet In these situations they are largest, and two or three of them sometimes coalesce between the knuckles, especially between the index finger and thumb. The scabby concretions which at length form upon the ulcerations adhere for a considerable time during the healing process. The pustular scabies occurs usually in children before the age of ten years.

Scabies cachectica, or scorbutic itch.—This is not distinguished from the forementioned varieties by difference in external character; for it appears under the form of the other varieties, at one time indiscriminately mixed, at another exhibiting them separately in different parts of the body. It mostly occurs in persons of debilitated constitution brought on by indigence and intemperance, and is the most intractable form of scabies. It is not unfrequently combined in such individuals with other cutaneous maladies, as lichen, prurigo, ecthyma, and impetigo, and Bateman asserts that when the latter disease is superadded, it as well as the scabies possesses a contagious character. He also remarks that the most severe degree of it which his experience made him acquainted with, exhibited itself in persons who came from India, and he had often observed it in children brought from that country. It is there denominated "courap," a term which is equivalent to itch, and is the same which Bontius† describes under the name of herpes, seu impetigo Indica, and Sauvages under that of scabies Indica.

It was, perhaps, superfluous to make a separate species of this, inasmuch as it possesses no particular form which distinguishes it from the others; yet, as it is so disposed in Willan's divisions, it might be invidious in such a matter to use an arbitrary power in altering an established arrangement, which we have taken advantage of for greater facility of description.

In whatsoever form scabies manifests itself, it is to be regarded entirely as a local affection, being never like other vesicular eruptions connected with disorder of the internal organs. It gives rise to no disturbance of the circulation, except in severe cases of the pustular scabies, which, from the inflammation sometimes attending it, causes slight febrile action in children. Some authors recount a list of the most formidable diseases as liable to be produced by its retrocession and the metastatic transport of the cutaneous irritation to the vital organs. These notions, however, are now disregarded, being justly considered as the imaginary fabrications of an exploded theory, which pretended that a specific virus residing in the serum of the blood was the cause of scabies We conceive that the observations of others which assert that important diseases of the internal organs have been cured by its eruption are to be equally unheeded. Unprejudiced experience demonstrates that it exerts little or no pathological sympathy upon the internal organs, and therefore such cases as those narrated by Beer* and others can be only regarded as coincidences.

The disease chiefly shews itself amongst children, yet on this account it is not to be inferred that it shews a preference for youth more than age. This is to be attributed solely to the fact that children are more brought in contact with infection than adults, from their heedlessness of exposure and inattention to cleanliness. It depends upon the same cause that amongst the working classes males are more generally affected with it than females. Climate does not appear to have much effect in modifying its prevalence,—although it is certainly more common in the northern parts of Europe than the southern, an observation which we think must be connected with the fact that individuals of sanguine and lymphatic are much more liable to it than those of bilious temperaments. Habits of uncleanliness, however, are more powerful than this predisposition arising from the temperaments, of which its great prevalence amongst the Polish Jews and Spaniards affords examples; for amongst these people, as is well known, the bilious preponderates beyond comparison over the opposite temperaments.

It prevails in so general and constant a manner in some countries that it may be said to be endemic. In Poland and Hungary the mass of the population are constantly more or less infected, and it is equally rife in Galicia and Asturias in Spain, in Lower Brittany in France, and in certain parts of the highlands of Scotland. It is, however, no stranger amongst the indigent classes of every country,

* Comment. de Morb. Histor. et Curat. Frankf. ad Mœn. 1804. p. 102.

† De Medicinâ Indorum, lib. iii. cap. 17.

* Geschichte eines geheilten volkommenen, von zurückgetretener Krätze enstandenen schwarzen Staars, (Account of an Amaurosis caused by Retrocession of Itch, which was perfectly cured.) 8vo. Vienna, 1798.

and where it is found to infest one region with peculiar pertinacity, this is not to be attributed to any special influence of the atmosphere or the soil, which alone would properly entitle it to be called endemic, but to the habits of the poor population. It has been suggested that salt diet and the neighbourhood of the sea were concerned in maintaining it in some districts, but these circumstances have no influence in producing it, although they are frequent concomitants of that which is its true promoting cause,—inattention to cleanliness of the person, and particularly of the habiliments. Change of linen is the surest protection from it in a family or in a country, and we may with certainty predict its prevalence amongst every people where custom or necessity has precluded this best preservative of the health of the skin.

This malady inspires, as might be supposed, no friendly feeling in communities, and it is curious in this respect to remark the difference between it and those contagious eruptions which put life in jeopardy, as small-pox, measles, &c. With whatsoever dread the latter may be contemplated, they do not produce disgust; but the itch, being free from danger, may be treated more disrespectfully, and is very generally regarded as contemptible. However, different nations have different opinions on this subject; it is reported of the inhabitants of the Spanish provinces before mentioned that they retain it often from the cradle to the tomb, and that they are not only careless of its concealment, but regard it as a kind of hereditary possession: they even refuse to use means to be freed from it, alledging that they are not willing to change the customs of their ancestors.* But in countries where civilization is more diffused, its residence is less tolerated. Here even the imputation of the itch becomes almost injurious, and sometimes engages philosophers in its refutation, of which the following is an example. "Laennec was a true Breton, fond of his country and jealous of its honour. It is amusing to observe the high tone he assumes in refuting a charge brought by a certain writer against his native country, for being infamous for an epidemic itch. He solemnly assures us, that if in very truth 'la gale s'observe quelquefois en Bretagne, on en doit moins accuser les localités, que le passage et le sejour des matelots.'"† Equally patriotic renunciations of it have been made in our own islands.

Diagnosis.—There is scarcely any disease compromising the general health in so trivial a degree in which it may be more important to the reputation of the practitioner to be able to deliver a categorical diagnosis than in scabies. He is in fact frequently consulted for no other purpose than to decide whether an individual has not brought this contagious affection into his circle; and as the physician's opinion on the one hand sets him free from this suspicion, and on the other sentences him to a temporary banishment from society or even from his employment, it is obvious how much it behoves him to be able to distinguish it without error. In forming his opinion, he should learn to be as much as possible independent of the criterion furnished by its contagious quality, for it will be generally where this point is yet undecided that his judgment will be sought for. When some evidence of exposure to infection exists in addition to the proper characters of the eruption, there is no difficulty; but if such be unattainable, it will often require all the resources which an accurate acquaintance with it and other affections which resemble it supplies, to distinguish between them. The eruptions with which it is liable to be confounded are some forms of lichen, prurigo, and eczema. The papular elevations of lichen are attended with considerable itching, and are frequently abraded by scratching, so that considerable resemblance may exist between them and scabies, particularly the first variety of it above noted, (*s. papuliformis.*) If the latter be present, the apparent papulæ, examined in an unbroken state, will be found to be topped by a vesicular apex, and where they have broken spontaneously, a dark scab remains; but in lichen the papula is solid, even to the summit, and it passes away in a scurfy exfoliation. Lichen occupies the back of the hand, and the external surface of the limbs, and is seldom or never developed in the intervals of the fingers. Moreover the itching is not nearly so intense as in scabies, and is of a more remitting nature, and the papular eruption is commonly attended by some constitutional disturbance which is foreign to scabies. In the lichen *urticatus* the eruption is of a more acute nature, and has occasionally a few vesicles interspersed amongst the papulæ, which might confound an observer who relied on any single characteristic; but the diagnosis in this case is still easier than in the simple lichen—the inflamed wheal-like papulæ, causing rather a deep tingling than an intense itching, sufficiently distinguish this eruption. Finally, the suspicion of contagion will seldom attach to any form of lichen.

The itching of prurigo is of a still more vehement character than that of scabies; they were of old frequently confounded, insomuch that the former was sometimes erroneously denominated scabies *sicca*. (See Prurigo.) The diagnosis between them is not difficult if these points be held in memory. Prurigo occurs chiefly in elderly individuals, its papulæ are flat, and when abraded by the nails no serous fluid is effused, but a dark spot of blood concretes upon their surface. The situation also of the pruriginous eruption (as that of lichen) is distinguished from scabies by its preference to the surfaces of extension on the extremities, instead of those of flexion, which the latter particularly affects. Prurigo, moreover, is not contagious.

In eczema we have a vesicular eruption, which often bears a striking resemblance to scabies in the second variety, (*s. lymphatica.*) Its vesicles, however, are more flattened and

* Dict. des Sciences Méd. t. xvii. p. 183.

† Forbes's Translation of Laennec, Author's Life, p. xxviii.

confluent than those of scabies, which are acuminated and distinct. But when the disease is passed to an ulcerated and scabby state, such distinguishing characters may be wanting, and then other circumstances must be sought out. Eczema is for the most part a local affection, and when the itch has in any place assumed the ulcerations and soft scabs which resemble it, the eruption has proceeded to a considerable extent, and will doubtless shew its proper form in the parts which it has most recently invaded. The irritation of eczema is a stinging or tingling sensation very different from the pruritus of the itch, and its origin may be often traced to the action of irritating causes upon the skin, as sugar, lime, and other acrid substances, or to exposure to the solar rays or great heats.

Very lately a female presented herself to the writer with an eruption at the root of the right middle finger, which from its situation and appearance was difficult to distinguish from scabies. She ascribed its origin to milking cows, whose teats were in a diseased state. The pruritus was not that of scabies, and after a careful examination it was concluded to be a vesicular form of impetigo. Bateman calls attention to the possibility of confounding the pustular form of scabies with impetigo, and even with ecthyma; and although this seems remote, it is yet only a prudent caution to keep in mind every form of cutaneous disease which bears any affinity to it.

A circumstance in the history of scabies of the greatest moment, is the simultaneous presence of the diseases which we have just contrasted with it for the sake of diagnosis. This is indeed rare in ordinary cases of itch, but the fact of its occasional occurrence forcibly impresses the necessity of cautious examination, and adds much practical importance to the diagnosis, because those complications require a line of treatment quite distinct from that of scabies. They are met with in the cases in which much inflammation has attended the scabid eruption, and (which serves to illustrate what we have said as to their different treatment) they are very frequently produced by improper applications for its cure, such as powerfully irritant lotions or frictions. The actual complication which may be present will be much influenced by the constitution and age of the subject; in young and vigorous habits, the excess of irritation will mostly take the form of eczema or of impetigo, while in those of an opposite condition pustules of ecthyma may appear, or the inflammation may seize on the cellular tissue, and an eruption of boils be the consequence. Cazenave and Schedel remark that the same subject may present at once "vesicles of itch, pustules of impetigo, pustules of ecthyma, and boils,"* a case which would exercise the diagnostic tact of the physician to discover the primary contagious disease amongst so many complications.

Causes.—The universally diffused cause of scabies is contagion, and it appears to be the disease which of all is most readily communicated by contact. When it once gains admission into a family the greatest caution often fails in preventing it from infecting every individual. A question exists undecided amongst pathologists as to whether it ever originates from any other source than contagion. It was observed by Sir John Pringle, that in military hospitals the patients often became the subjects of itch after the crisis of fevers;* but there remains little doubt in our mind that this excellent physician in these instances mistook some of the papular eruptions, as lichen or prurigo, for scabies, for those are not uncommonly observed to occur when the skin recovers its tone in the convalescence from fever. We would make the same remark with respect to a kind of it which Heberden describes as primarily contracted by contagion, but which being cured by the customary remedies, "tamen non cessat redire semel vel bis quotannis.†" This is rather the description of the lichen simplex, occurring periodically in a person who has been once affected with scabies; for this faithful observer adds, that after its first attack it is no longer communicable by contagion, even to those who lie in the same bed, and that it as often terminated spontaneously as was removed by any remedy. Bateman thought that it might originate without contagion in crowded, close, and uncleanly houses, and wherever the means of cleanliness were not obtainable.‡ These are, however, just the circumstances which facilitate the propagation of contagion. On the whole, there are no facts which contravene the opinion of those who assert that the latter is its sole origin, and it appears to us that it agrees best with every analogy.

We have reserved to this head the notice of a very remarkable circumstance connected with the etiology of scabies, the existence of the insect called by Linnæus and by preceding naturalists "*acarus scabiei*." First in the writings of Avenzoar, the Arabian physician, and subsequently in those of Ingrassias, Gabucinus, and Joubert, notices of a minute insect occurring in a certain disease of the skin attracted the attention of the English entomologist Thomas Moufet, who examined and described them with considerable accuracy. They are, according to him, minute animalcules similar to the acari of decayed cheese or old wax, which burrow under the cuticle, and excite intense itching, with an eruption of vesicles. His observations were repeated by various naturalists in different parts of Europe, and Hyacinth Cestoni, at the end of the seventeenth century, investigated the characters of this insect with much exactness, and was the first proposer of the theory which regards it as the proximate cause of the itch.§

† Op. cit. p. 102.

‡ Synopsis, p. 289.

§ This was communicated by Cestoni's coadjutor, G. Bonomi, in a letter to an eminent physician, Francisco Redi, in whose works it was first published, an. 1685. (Dict. des Sc. Méd.)

This doctrine gave rise to a controversy which has continued ever since, and seems at the present day to be as far from being settled as ever. In the order of time, two questions are involved in this subject. By the first the acarus, or (as Latreille denominated it generically) *sarcoptes* scabiei, was universally received; but issue was joined on the opinion, first mooted as a conjecture by Cestoni, that scabies is nothing else than the bite of these small insects, which produces the itching and an extravasation of serum collecting into vesicles; moreover, that the contagion is effected by the transfer of those insects from one individual to another. Experiments were made, and opinions were contested negatively and affirmatively, by many eminent medical men in different countries. Redi, Wichmann, Osiander, Pringle, and many others, considered the contact of the insect as the only exciting cause of the itch; while as great a number insisted that the acarus was produced by the disease. Again, a middle opinion was embraced by the majority, to which Morgagni attached himself. They held that in most cases the insect was the product of the disease, but admitted that in some instances the latter owed its origin to the insect. M. Galés, apothecary to the Hôpital St. Louis in 1812, undertook a series of investigations, which he conducted with the greatest variety and perseverance, and which finally seemed to leave nothing undecided as to the whole subject. He observed with the microscope upwards of three hundred of the insects taken from the scabious vesicles.* He confined the insect upon his hand with a watch-glass, and observed it penetrating the cuticle, upon which, after a few hours, three vesicles appeared, the intense itching of which left no doubt of their identity with scabies. He inoculated in the same manner three children with the insect, who became covered with the itch. These experiments were testified to by many of the first naturalists in Paris; and as they appeared to have the force of demonstration, after their publication the opinion that the itch was produced by the insect was ratified by the assent of almost all. They doubtless proved the presence of the acarus, and moreover that its penetration of the skin is an occasional cause of scabies; but with all, this may be a very secondary matter in the production of the disease. In fact, it seems to us somewhat singular that these observations were permitted to prove more than that the insect taken from a scabious vesicle, *being charged with the virus, the fluid of the vesicle*, by penetration of the cuticle, inserted this virus, and produced the disease, like the inoculation of cow-pox.

At a later period, however, the opinion supposed to be thus incontestibly fixed by M. Galés' experiments was not only called in question, but, singular to relate, the existence of the acarus was again doubted. M. Suriray of Havre, and afterwards MM. Lugol and Mouronval, revived the discussion of the subject, and, as the result of their researches, denied that any insect could be found. This extraordinary revulsion of opinion was confirmed by M. Biett, who, even with the use of microscopes of high power, was unable, in a great number of trials, to discover it in a single instance. Cazenave and Schedel state that many others have made an equally unsuccessful search for the insect; and rejecting for themselves the idea of its existence, they announce a kind of challenge to M. Galés to transport himself again to the Hôpital St. Louis, and demonstrate it anew.

It would follow from these negative researches, that while at one period the disease is attended by the acarus, at other times it exists without it. In these countries it is a notorious fact that the insect is frequently found. Moufet originally stated that the common people were in the habit of extracting it from the vesicles with the point of a pin; but that more usually it may be found in a small channel, which it frets from the vesicle in the adjoining cuticle. We have conversed with those who have frequently seen them, and whose description of their being found not in the vesicle, but in the red streak adjoining it, exactly coincides with Moufet. Bateman and Mr. Plumbe bear the same testimony; and the latter adopts an hypothesis proposed by Galés and Fournier,* by which it is conjecturally affirmed, that when the elevation becomes large and full of lymph, it being no longer possible for the insect to exist in it, in obedience to a preservative instinct it makes its way laterally, and is then found beside, and not within the maturated vesicle. He supposes, also, that it is sufficient to account for the ill success of those who have not found it, to presume that they happened to select for their researches vesicles which had been evacuated by the acari. This does not occur to us as by any means satisfactory; but the opinion of Sauvages, adopted by Bateman, seems more plausible, that the insect is generated only in some instances of scabies, of which cases Sauvages proposes to make a particular species under the title of "scabies *vermicularis*." This is not irrational; yet we deem it more consonant with the varying history of the researches to suppose that there is a variation in the *disease itself* in this respect at *different epochs*. This view is more consistent with analogy, as we know how often the type of diseases changes at different epochs in the same locality, without therefore losing their identity. Of this fever is a familiar example, which it is unnecessary to do more than mention in respect to its change of type; but an occasional phenomenon which it presents (as was remarked by M. Ranque of Orleans) may be adduced,

* His descriptions of the insect agree with those of Linnæus and Latreille, but are much more extended and exact. It has six legs, with a few filaments besides projecting from the body, and is not unlike the minute pulix sometimes accompanying prurigo. It lies in the centre of the vesicle, round the margin of which it deposits its ova.

* Dict. des Sc. Méd. art. *Gale*, tom. xvii. p. 199.

and reflected on in connection with the generation of the acarus scabiei. We allude to what is occasionally observed when a favourable crisis takes place at the last extremity of typhus; the head is sometimes swarmed by a sudden production of lice, so unaccountably numerous as only to permit the supposition that they are secreted by the skin.

According to the view here propounded, and in agreement with the analogy just mentioned, the animalcule of scabies is regarded as a secretory product of the disease, which at certain periods is endemic; but ignorance is professed as to the circumstances which give rise to it at one time more than another; and at the same time we agree with Bateman that the contagious property of scabies exists in the fluid, and not in the insect, which, however, may be the occasional means of transport of the latter. We would finally remark, with regard to the whole controversy, that it includes a lesson at least to medical theorists: here many ingenious men oppose each other in a matter of fact and observation; with what sobriety, then, should dogmatic opinions be entertained, when it is often so difficult even to lay their foundation in certain facts!

Treatment.—The cure of scabies appears to have been considered a matter of no slight medical interest. Treatises have been written upon it, and a vast variety of means discussed with so much earnestness, that we are led to the conclusion, (which we believe coincides with general tradition,) that it was formerly a scourge to the community of greater extent and virulence than at the present day. It is now regarded as of trivial importance. Never in itself dangerous, it gives much annoyance to the individual by its unappeasable itching; but the fear and restraint which it puts upon him of infecting others often causes as much discomfort to him as its action upon himself. Neglect of the appropriate means may indeed protract it to an indefinite length; but by their use its treatment is conducted with so much certainty that we have scarcely any other care in the choice of remedies than to select that which experience has approved of as effecting a riddance of the disease in the most secure and speediest manner. A multitude of such has been vaunted, but modern practice has contracted the most useful within a small circle; and it is unnecessary to enumerate here any of minor efficacy, as we are in possession of some whose virtues are almost infallible.

Sulphur is considered in the light of a specific remedy in the cure of itch. It is the basis of the applications which by universal consent are considered its most effectual antagonists. In the ordinary forms of the disease the common people have long used it as an ointment, mixed with equal parts of hog's-lard or butter, with which they smear the parts on which the eruption exists once or twice a day. They administer it internally at the same time, in doses of from ten grains to half a drachm given in milk at bedtime. By this treatment they scarcely ever fail to cure it expeditiously. The internal use of sulphur is adapted for it in children, and is occasionally combined with magnesia; in adults, however, it is unnecessary to have recourse to any but the external use of the sulphur ointment. The assiduous use of it for a fortnight is sufficient to cure the common forms of it, if they be attacked with it speedily after its first appearance, as the duration of the treatment will be longer if long neglect has permitted it to gain a certain inveteracy.

A great improvement was made in the application of the sulphur ointment by the combination of an alkali with it. This adds to the specific effect of the sulphur the advantage of a detergent action, which loosens and dissolves crusts or scabs, and permits the skin to be well penetrated by the ointment. M. Helmerich, a French army surgeon, became famous for a method of using sulphur which cured the itch more promptly, and also permitted the greasy stain of the ointment to be removed from the linen by washing, obviating an objection to the use of unguents which was very generally felt. He kept it a mystery, but it was analyzed by M. Burdin, and found to consist of the following ointment:—

Sublimed sulphur, two parts,
Sub-carbonate of potass, one part,
Axunge, eight parts, intimately mixed.*

This deserves a preference over all other methods of applying the sulphur externally. It has the most constant and prompt success, and is seldom attended by the cutaneous affections which sometimes result from the use of other stronger but more irritating sulphureous applications. It is the ointment which Biett has exclusively employed at the Hôpital St. Louis for several years. He orders half an ounce of it to be rubbed, morning and evening, over all the parts occupied by the vesicles. The action of this ointment is favourably promoted by the use of a tepid bath every second day during its application, which will rarely have to be continued beyond ten or twelve days. Another sulphureous friction which, in the Paris hospitals, rivals the reputation of the above-mentioned ointment, is made with the sulphuret of lime. A scruple or half a drachm of this powder is to be triturated with a small proportion of olive oil, so as to render it sufficiently fluid for using as a friction, and this quantity is to be rubbed upon the affected parts twice a day. This is a very effectual cure, but it is not so applicable as the former, when the itch has already spread to any considerable extent.

The use of ointments over an extensive surface of the skin may be considered unadvisable in some cases, as interfering with the cutaneous transpiration. When these objections exist, substitutes of no less efficacy are found in the proper use of lotions. None of these is preferable with regard to activity to the solutions

* For the sake of depriving this ointment of the smell and appearance of sulphur, it would be agreeable to add to each ounce of the axunge a few drops of oil of lavender or bergamotte, and ten grains of the hydrargyri sulphuretum rubrum (vermilion).

of sulphuret of potash, or of lime. These have been long known and extensively used in scabies, and a saturated solution of the latter is an excellent remedy in the mange of sheep or dogs. The following formula of a lotion was prescribed by M. Dupuytren, and highly extolled in France for the promptitude with which it effects the removal of the disease:—

R.—Sulphureti potassæ ℥iv.

Aquæ puræ lb. iſs.

Acidi sulphurici ℥iß, dissolve ut fiat lotio.

Whatsoever part the eruption has invaded is to be moistened by a gentle friction with this lotion twice a day. It has the advantage of not injuring the linen of the patient, nor does it compel him to renounce his employment during its use. However, it produces a smarting of the skin, which will sometimes require it to be used in much weaker proportions, and renders it not so appropriate in some irritable habits.

If the individual entertain insuperable objections to the use of sulphur from disgust to its odour, many other external remedies of approved efficacy are at hand. The ointment of white hellebore in the proportion of a drachm of the powder to an ounce of lard, is both a safe and expeditious application. Solutions of the chloride of lime or of soda have been extolled as highly beneficial by some practitioners; they are used as a lotion in the proportion of an ounce to a pint of water. The aqua chlorinii applied in the same manner is also mentioned with applause. Heberden strongly recommended a lotion composed of a solution of the muriate of mercury, made with one drachm, or two, (according to the inveteracy of the disease,) to a pint of water. This is acknowledged to be a remedy of great power in curing scabies, but it is objected to by some as liable to produce the constitutional effects of mercury. We have, however, been assured that these fears are vain, by an esteemed practitioner, who has had a very favourable experience of this lotion, and has used it on his own person with success; and in our own more limited sphere of observation, we never saw any such effects from it.

Sulphureous baths are an excellent auxiliary means in many cases of scabies. In cases of very irritable skin they are frequently the only form in which general applications of this remedy can be made to the surface; in young children, therefore, they are a very valuable resource. The artificial are found to answer the purpose equally well with the water of sulphureous springs, and their employment possesses the advantage of being proportioned according to circumstances. They may be prepared by simply adding to an ordinary sized warm bath six ounces of the sulphuret of potash in powder, and agitating it until it be dissolved, and the water be reduced to a lukewarm temperature.

Sulphureous vapour baths are another means which possess great power in this as well as in some other diseases of the skin. This is evident from the testimony of all who have used them, from M. Galés, who was the first to construct an apparatus for their convenient administration, to Mr. Wallace, who has also ably illustrated their use. Dr. Bardsley informs us, that he has "always seen the most obstinate and neglected cases of it yield very speedily to a few fumigations."* It is happily to such inveterate cases that they are mainly applicable; for even if they did possess the superior advantages over ordinary methods of treatment which are claimed for them, they are too stimulating to be employed in any cases except where the disease has become chronic through neglect, and has induced an unhealthy torpid condition of the skin. They are particularly contra-indicated where there exists any tendency to congestion in the gastric or pulmonary mucous membranes, and in females with complaints depending on morbid conditions of the uterine functions.

In the conduct of the treatment the practitioner has but little to be solicitous about; but, having used his discrimination in the adoption of the most appropriate remedy, he perseveres until the cure is complete. He should inculcate great attention to cleanliness and change of linen, especially during the convalescence. A vigilant inspection must be made for the purpose of detecting any of the complications previously noticed as apt to coexist with certain forms of the disease, or to spring up under improper treatment. If any of those be present, it will be necessary to modify his plan accordingly, and often to suspend the use of the stimulating remedies, with which he had commenced to combat the scabies. The state of the alimentary canal now demands particular attention; cooling laxatives and alteratives will be proper; and for topical applications recourse should be had to emollient fomentations, and the other soothing means specially adapted to the individual complication, for which we refer to Ecthyma, Eczema, Impetigo, Lichen, &c.

(James Houghton.)

SCARLATINA.—*Syn.* Morbilli Confluentes, *Morton*: Rubeola Rossalia, *Hoffman*: Febris Scarlatina, *Sydenham*: Febris Rubra, *Heberden*: Scarlatina, *Sauvages*, *Vogel*, and *Cullen*: Purpura, *Schultz*, *Juncker*: Enathesis Rosalia, *Good*: Fièvre Rouge, Scarlatine, *Fr.*: Der Scharlachaufschlag, *Germ.*: Scarlet Fever. Scarlatina designates a contagious febrile disease, the distinguishing characters of which are, a scarlet efflorescence of the skin and of the mucous membrane of the mouth and pharynx, appearing on the second day (though often later) of a febrile disorder, and terminating about the fifth; accompanied, in the majority of instances, with inflammation of the throat, either of a phlegmonous or gangrenous character; and occasionally with tumefaction of the cervical absorbents and subcutaneous cellular membrane. Other organs become also sometimes involved in the progress of the disease, giving rise to lesions of greater or less severity. The type of the accompanying fever is various, and modifies remarkably

* Hosp. Facts and Observations, p. 198.

the whole aspect of the malady. In some cases, the constitutional disturbance is so trivial as scarcely to attract notice; in others, the febrile symptoms are those of strong inflammatory excitement; while in individual instances, or during the prevalence of an entire epidemic, the fever is of a low typhoid form, the local inflammation, with which it is associated, partaking very much of the same character.

The origin of scarlatina is involved in great obscurity. It was evidently unknown to the ancients; no allusion to it can be discovered in the writings of Hippocrates, or in the early Greek and Roman writers; and, notwithstanding the opinion of some modern authors of the French school, that it was described about the middle of the sixteenth century, it is generally admitted that Prosper Martianus, an Italian physician, who gave a description of the disease as it prevailed in Rome about the middle of the seventeenth century, if not the first, is among the earliest writers on scarlatina. It made its appearance in London in 1689, and was described by Sydenham and afterwards by Morton, though it is evident, by comparing the description given by these two writers, that they had observed different epidemics; the one described by Sydenham being a very mild disease compared with that of which Morton has given an account. From the various names, however, given to scarlatina on its first appearance, it is evident, that about the period to which we refer, the notions entertained with regard to it were vague and unsatisfactory; indeed, it was scarcely distinguished from measles, roseola, or purpura. For example, it was named by Morton *morbilli confluentes;* by Hoffman *rubeola rossalia;* by Heberden, *febris rubra;* and even till within a little more than half a century, both these diseases (measles and scarlatina) appear to have been considered by medical writers as the same, or at least as so closely allied, as only varieties of a common species. Morton, indeed, maintained their identity, and considered their relative connexion to be nearly the same as that existing between the distinct and confluent small-pox.* The description of the epidemic given by Huxham under the name malignant ulcerated sore-throat, which prevailed in the year 1734, resembles in almost every particular one form of scarlatina—that form in which the eruption is accompanied with affection of the throat. The treatise on this subject is a valuable record of the characters of this epidemic, the description being evidently taken from what he had observed in his intercourse with the sick. Dr. Fothergill also has given the history of a "sore throat attended with ulcers," which appeared in London in 1747-8, which there can be little doubt was an epidemic scarlatina, and from the remarks he has made, it is evident, that he had observed various forms of the disease, from the mildest to the more malignant. Dr. Withering published an essay on scarlet fever in 1778, a second edition of which appeared in 1793; to this author is due the merit of having first accurately described scarlatina as a distinct disease; since that period, various treatises have appeared both in this and other countries.

* De Morbillis et Scarlatina, Exercit. iii.

Causes.—Nothing satisfactory is known as to the exciting causes of scarlatina. It appears to be induced, like the other eruptive fevers, by exposure to the influence of a specific poison. Attempts have been made to induce the disease by inoculation, by inserting the thin scales, which are thrown off at the period of desquamation, under the skin of individuals who have never had scarlet-fever, but hitherto without success. How far inoculation with the blood might be followed by different results is a question which can only be determined by experiment.

That scarlatina may be propagated by contagion is, we presume, admitted even by those who profess themselves sceptical on the question of contagion in general. Instances of the disease spreading in a manner which can only be explained by admitting its contagious origin are so numerous, that practitioners of the most limited observation must have had repeated opportunities of determining the question. We have known, in several instances, convalescents from scarlet-fever, on their removal to a considerable distance from the situation in which they had passed through the disease, infect individuals with whom they came in immediate contact, though several weeks had elapsed from the period of desquamation. The period of invasion after exposure to sources of contagion is exceedingly various. Some individuals are seized within a few hours; others do not exhibit any of the peculiar symptoms for several days; and in some more rare cases, five or six weeks have intervened between the period of exposure and the accession of the disease. The poison also appears to affect individuals very differently. Of a number of persons exposed to the same source of infection, some may escape altogether; others have a mild form of the disease; or it may happen, perhaps, that in several, the disease proves severe. Even in the same family the various forms which scarlatina presents may occasionally be observed. One or more may have both the efflorescence and the sore throat; in others there may be fever with the characteristic rash, but without any affection of the throat; another case may present the characters of the malignant disease; while, again, those who have been in constant attendance on the sick become indisposed with smart inflammation of the throat and a considerable degree of fever, which lasts for some days, and then subsides with the local affection. In these latter cases, (though there have been no efflorescence) desquamation of the cuticle occasionally occurs. Dr. Rush, in an account of an epidemic scarlatina which prevailed at Philadelphia, remarks, that such was the prevalence of the contagion which produced the scarlatina anginosa, that many hundred people complained of sore throat without any other symptoms of indisposition. The slightest occasional exciting cause, particularly cold, seldom failed of producing the

disease.* The same thing has been repeatedly observed in this country.

Although sporadic cases of scarlet-fever are met with at all seasons, it is more prevalent at the end of summer, and in the autumn, than at other periods of the year. Epidemic visitations have been most frequently observed after a warm summer, especially when the heat has been accompanied with continued rains; and when the succeeding winter has been open and mild, the disease has continued till it has been checked by frost. It generally disappears in the spring months, though it has been observed to continue uninterruptedly for one or more years.

It is necessary to advert in this place to the difference in the characters of epidemic scarlatina, though the causes of such remarkable variation are unknown. For a whole season, the disease may assume a mild aspect, so that a fatal case is rarely met with; in such instances, the danger is generally produced by some local inflammation which has supervened in the progress of the disease, or during the period of convalescence. On the other hand, it should be remembered, that during a comparatively mild epidemic, one or more cases may assume a malignant character and resist the best directed curative efforts. Sometimes, an epidemic of a malignant, or, as it is popularly termed, a *putrid* form of scarlet-fever suddenly breaks out and proves extremely fatal. From its commencement the symptoms often denote a severe form; at other times on its first irruption the disease is mild, but suddenly, without any apparent cause, the symptoms assume an unfavourable appearance, which continues so long as the epidemic lasts. It is therefore of great practical importance to ascertain the prevailing type of the disease, as the character which it assumes must regulate the treatment to be adopted.

Dr. Willan observed,† that when the scarlatina spread widely, it exhibited in the different persons affected every gradation of appearances, from the slightest to the most malignant form of the disease; yet during its diffusion through some large families and schools, he had seen it uniformly retain the series of symptoms which occurred in the first patient, with nearly the same degree of fever. In the autumn of 1786, and occasionally since that period, the scarlatina maligna above described affected the inhabitants of several districts in London, comprising narrow courts, alleys, and close crowded streets, and afterwards extended to some adjoining villages, in low, damp, or cold situations. It is, however, more frequently intermixed with the other varieties of scarlatina, and it sometimes unexpectedly supersedes the milder forms of the disease on the fourth, fifth, sixth, or seventh day of their course.

"It is truly singular," he adds, "that the slightest of all eruptive fevers, and the most violent, the most fatal disease known in this country, should rank together and spring from the same origin. Experience, however, decides that the simple scarlet-fever, the scarlatina anginosa, the scarlatina (or angina) maligna, and the scarlet ulcerating sore-throat, without the efflorescence on the skin, are merely varieties of the one disease. That all of them proceed from the same source of contagion is evident, because under the same roof in large families some individuals have the disease in one form, some in another, about the same period."

Scarlatina occurs more frequently in the early than in the advanced periods of life, and in our own experience females are more liable to the disease than males. Dr. Withering states, that the epidemic which appeared at Birmingham in the year 1778, affected children more than adults, but seldom occurred in the former under two years of age. In children, the number of boys and girls that suffered from it was nearly equal; but in the adults, the number of female patients considerably exceeded that of the male.

In order to determine its relative frequency in the sexes at different ages, we selected from the register of patients admitted into the London Fever Hospital, two hundred cases in the order of their admission. The following table gives the general results:—

Age.	Males.	Females.	Total.
From 6 to 10	7	8	15
10 to 15	8	15	23
15 to 20	17	40	57
20 to 25	14	39	53
25 to 30	8	21	29
30 to 35	6	10	16
35 to 40	1	2	3
40	1	0	1
42	0	1	1
48	0	1	1
57	0	1	1
	62	138	200

It is proper, however, to state that this table cannot be considered quite complete, the number of children under six years of age who take the disease not being ascertained, in consequence of the regulations of this hospital precluding the admission of children under six years of age. The table shews the great majority of females at every age, and also disproves the assertion of Sir Gilbert Blane* and others, that the majority of those who are seized with scarlatina are under puberty.

Scarlatina in general affects the same individual only once during his life, and in this respect obeys the general law of exanthematous fevers. Occasional exceptions have certainly been observed by practitioners, though, from the testimony of Dr. Willan, a second attack of scarlatina in the same individual is extremely rare; he states that he had never seen such a repetition among two thousand patients whom he had visited in scarlatina. We certainly have met with several well authenticated instances

* Medical Enquiries and Observations.
† On Cutaneous Diseases, p. 277 and 281.

* Select Dissertations, p. 213.

of a second attack of scarlatina in the same person.

It is proper to notice the discovery of the supposed efficacy of the extract of belladonna as a preventive of the infection of scarlatina. This was first suggested by Hahnemann, of Leipsic, in 1807. The belief that this narcotic possesses such a preventive power is gaining ground in some parts of the continent, and lately even in our own country. The following abstract will explain the views of Hahnemann on this subject. A favourite doctrine of this writer is, that diseases are to be combated by remedies, the effects of which are similar to the diseases for which they are given. This is the doctrine to which the term *homœopathia* has been given, and which has of late years gained many proselytes in Germany, France, and Italy. Hahnemann observed, that belladonna given in small doses produced heat and dryness in the throat, swelling of the submaxillary glands, and a cutaneous eruption, sometimes an efflorescence only, at other times a papular rash, like miliaria; he therefore inferred that this medicine, from its producing symptoms analogous to those of scarlatina, might prove a preservative against its infection. About ten years after Hahnemann had entertained this notion of the anti-scarlatinous power of belladonna, a severe and fatal epidemic appeared in several cities of Germany, and consequently the physicians were naturally desirous of adopting measures calculated to arrest its progress. From the result of the trials made by Berndt, of Custrin, who was the first who made a series of experiments, we find, that in an epidemic scarlatina which prevailed in Custrin in 1818 and 1819, he employed the belladonna as a preservative in one hundred and ninety-five children under fifteen years of age; though they were freely and constantly exposed to the contagion of scarlatina, only fourteen took the disease, and that after employing a stronger preparation of this drug, every individual escaped. A still stronger testimony in favour of its efficacy is given by Dusterberg, a physician of Warberg; he states, that every child who took the belladonna for a sufficient length of time before exposure to infection escaped; that when a child was left in an infected family to nature, (the belladonna not having been administered with the object of determining its efficacy), it was invariably attacked with scarlatina, while the others who took the remedy escaped. Behr, of Bernberg, also affirms that of forty-seven persons who took the belladonna as a preservative, only six were attacked. Professor Koreff, of Berlin, after extensive and long-continued trials, asserts, that if the belladonna be taken in proper doses for eight or nine days before exposure, and be continued till the period of desquamation, there is little danger to be apprehended from free intercourse with persons affected with scarlatina. Similar testimony has been given as to the efficacy of this narcotic by Hufeland, Kunzman, of Berlin, and others.*

The quantity administered is very minute. Three grains of the extract of belladonna are to be dissolved in one ounce of distilled water; of this solution two or three drops are to be given twice a day to a child under twelve months old, and one drop more for every year above that age. In general, no sensible effect is produced by it, but in some instances, it brings out an eruption similar to scarlatina. It is also asserted by those who have tried this remedy, that even when it does not prove a preventive of the infection of scarlatina, which may be in consequence of its not having been administered for a sufficient length of time before exposure, it renders the disease more mild, and even that if it be taken for four or five days before exposure, the disease never proves fatal. As we have never employed the belladonna as an anti-scarlatinous remedy, we can offer no opinion of its merits, though we certainly profess ourselves sceptical as to the powers ascribed to this drug. The subject is, however, worthy of further experimental inquiry. It has one advantage, that of being perfectly harmless, if it do not act as a preservative.

Varieties.—Scarlatina occurs under several forms, to which it is necessary to advert. In the first, the efflorescence is attended with mild febrile symptoms, but there is no inflammation of the throat *(scarlatina simplex)*. In the second, the fever is of a more severe character, and the efflorescence is accompanied with inflammation of the throat *(scarlatina anginosa)*. In the third, the whole character of the disease is more severe than in either of the preceding varieties: the fever is of a low or typhoid type; the throat is affected with gangrenous inflammation, accompanied with tumefaction of the cellular tissue and absorbents of the neck, and in general with an acrid discharge from the nostrils and ears *(scarlatina maligna)*. In other instances, the efflorescence is confined to the mouth and throat, and does not affect the skin. This form (to which no name has been given) is often observed during the prevalence of epidemic scarlatina; not unfrequently in adults, when some other form of the disease is prevailing in the family. It may be designated by the name *scarlatina faucium*.

1. *Scarlatina simplex.*—In this form of the disease there is only the efflorescence with a moderate degree of fever. The rash is preceded by slight symptoms of fever—irregular shivering, nausea, sometimes vomiting, thirst, and heat of skin. The degree of fever is by no means uniform; the symptoms are sometimes so moderate as scarcely to attract attention, though there is often smart constitutional disturbance, indicated by pungent heat of skin, flushing of the face, suffusion of the eyes, pain of head, restlessness, and occasionally delirium. The efflorescence or rash generally comes out on the second day of the

* Vide Arch. Gén. de Méd. Juin, 1824.—Journ. Complément. Juin, 1824.—Hufeland Journ. der practischen Heilkunde, Nov. 1825.—Rust, Magazin für die gesammte Heilkunde, xx. I. 182.

eruptive fever, but in some instances it does not shew itself till the third, and accordingly we find authors differing as to the precise period at which it appears. Sauvages and Cullen state that it does not come out till the fourth day after the accession of the febrile symptoms. Plenciz* does not limit the period, but affirms that the rash makes its appearance on the second or third day, or sometimes later. Heberden restricts it to the first or second day. It is, however, probable that in the majority of instances, the rash comes out on the second day of the fever, and that in cases in which it appears sooner or later, there is some peculiarity in the individual or in the disease to account for the variation.

The efflorescence, which is first perceptible on the face, neck, and chest, becomes gradually diffused over the body; in twenty-four hours or less from its first appearance the trunk is covered with the eruption; on the following day (the third) it extends to the upper and lower extremities, at which period the whole body is of a bright red colour, and pungently hot and dry. On the extremities, particularly the hands and fingers, the rash is diffuse and continuous, but on the trunk it is distributed in irregular patches, the colour being most deep on the loins, buttocks, flexure of the joints, and on those parts of the body which are subjected to pressure; it is generally more vivid in the evening, gradually becoming paler towards the morning.

This is the ordinary progress of the efflorescence in the skin: it is not, however, confined to the cutaneous tissue; the mucous membrane which lines the nostrils, mouth, and fauces being covered with the eruption, so that the lips, the tongue, the pharynx, the velum palati, the nostrils, and even the internal surface of the eyelids are of a bright red colour. The papillæ of the tongue become considerably elongated, the red points shooting through the white fur, and from which it derives its characteristic appearance. In cases where the tongue is clean, it has nevertheless a bright red colour, and the scarlet points may be seen shining through its polished surface.

The rash of scarlatina consists of innumerable red points or dots, which are at first of a pale red colour, but afterwards acquire a deeper hue, giving the affected portions of skin not only a uniform red appearance, but a perceptible roughness, which is most evident on the breast and extremities, in consequence of the greater determination of blood to the papillæ of the skin in those situations.

The efflorescence on its first appearance sometimes closely resembles a papular eruption, and occasionally small miliary vesicles make their appearance, though this latter phenomenon is rarely observed, except when the individual has been subjected to a heating stimulating regimen, or confined in a small crowded and ill-ventilated apartment. These papular or vesicular spots, however, are now and then observed when the disease occurs under the most favourable circumstances. Dr. Mason Good* supposes that they arise from the great determination of blood to the cutaneous vessels producing an effusion of coagulable lymph, which is not entirely absorbed by the time the efflorescence subsides, hence there is occasionally, though not often, an appearance of vesicles, sometimes nearly empty, and sometimes nearly filled with a pellucid fluid, according as the effused fluid has been more or less carried off. The occasional appearance of these vesicles during the progress of scarlatina has been noticed by Rush, Withering, Plenciz, and other writers; Sauvages, indeed, under a mistaken view of their importance, has constituted a distinct species, under the name *scarlatina variolodes*.

In ordinary cases of scarlatina, the eruption may be regarded at its height on the fourth day; it begins to decline on the fifth, disappearing in irregular patches; on the following day it is still more indistinct, and on the eighth day no trace of the rash is discernible. The various symptoms with which the eruption is accompanied gradually disappear with the efflorescence, but the tongue still remains morbidly red and clean. The desquamation of the cuticle, which begins about the end of the fifth day on the parts on which the eruption first appeared, proceeds, so that about the eighth or ninth, portions of cuticle are thrown off, the thickest and largest being those detached from the skin of the hands and feet.

2. *Scarlatina anginosa.*—In this form, the fever and efflorescence are accompanied with inflammation of the throat. The anginose inflammation sometimes precedes the fever, but most frequently appears at the same time with the febrile symptoms, though, in some cases, not until the rash or efflorescence is at its height: in the majority of instances, however, it is felt when the eruption appears, and goes through its progress of increase and decline with the cutaneous eruption.

The precursory symptoms of scarlatina anginosa indicate a more acute disorder than the scarlatina simplex. The headach is often accompanied with slight delirium; the heat of skin is more pungent, and the prostration more marked from the beginning. In the course of the second day, the patient complains of a sensation of stiffness or pain about the muscles of the neck, extending to the angles of the jaw and under the ears, with feeling of roughness in the throat, painful deglutition, and some degree of hoarseness. The viscid secretion from the mucous crypts of the tonsils and pharynx, which takes place in the more severe cases, aggravates the patient's sufferings, from the frequent and often ineffectual efforts made to expel it. On examining the fauces, the palate, uvula, and tonsils are red and swollen, and when the local inflammation is severe, coagulable lymph is effused in small irregular masses on the inflamed surfaces. These exudations are very liable, on a superficial examination, to be mistaken for ulcers, or, when the

* Tractatus de Scarlatina, 1776.

* Study of Medicine, vol. iii. p. 13.

subjacent surface is tender and disposed to bleed, the admixture of blood imparts to them a brown or almost black colour, and thus, more especially if there be fetor of the breath, they may be mistaken for gangrenous inflammation of the fauces. On attentive inspection, however, after cleansing the throat by acidulated gargles, the entire continuity of the membrane from which the crusts have been detached, at once distinguishes this form of acute symptomatic angina, from the gangrenous inflammation and subsequent ulceration observed in scarlatina maligna.

These exudations of lymph often extend to the lateral parts of the pharynx, and occasionally as far as the œsophagus, though, according to Rayer, they are never observed after death in the larynx or trachea. This coincides with our own experience, as in the dissections of scarlatina with anginose inflammation which we have made, we have not seen an instance of membranous exudation extending to the larynx.

As the anginose inflammation becomes developed, the febrile symptoms increase, the pulse rises, the respiration becomes oppressed, the skin more pungently hot and dry, (sometimes rising to 106°, 108°, or even as high as 112° of Fahrenheit,) and the thirst urgent. The mucous lining of the mouth as well as the tongue, especially at its point and edges, assumes a florid red colour, the papillæ being much elongated and protruding their inflamed points over its surface. All these symptoms are increased towards evening, at which period, the febrile restlessness is often succeeded by delirium.

The rash does not appear so early as in the simple form of the disease. It is sometimes perceptible on the second, but more generally on the third day, and comes out in irregular patches on various parts of the body, particularly about the elbows and wrists. It has been occasionally observed that when the attack is severe, the eruption is sooner thrown out, a circumstance which was noticed by Dr. Clark, who informs us that in an epidemic which broke out in Newcastle-upon-Tyne, in the year 1778, when it began with great vehemence the eruption was often observed on the first day, though commonly it did not make its appearance till the second or third, and sometimes not until the fourth. It evinces also a great tendency to recede, or entirely vanish the day after it first comes out, and in these cases, it re-appears partially and at uncertain times, but without any perceptible change in the other symptoms, only that the duration of the disorder is protracted. About the fifth or sixth day of the disease, the fever and inflammation of the throat begin to abate; at the same time the rash declines, becoming faint first on those parts on which it first came out, its disappearance being generally followed by desquamation of the cuticle. This process is, however, uncertain. When the rash is slight, or recedes soon after it comes out, desquamation does not take place: in the more severe cases, the cuticle begins to separate after the eruption and febrile symptoms decline, and continues to desquamate to the end of the second or third week, or sometimes later, during which large portions are thrown off: sometimes the cuticle of the whole hand and fingers is completely detached, resembling precisely a glove in shape.

Though this is the usual progress of scarlatina anginosa, the disease frequently assumes a still more severe character. Thus we observe, in some instances, acrid discharge from the nostrils or ears, often accompanied with deafness: enlargement of the parotid or cervical glands, appearing sometimes at the commencement of the disease, at other times about the fifth or sixth day, but occasionally not till the decline of the eruption, and followed in some cases by abscess of the surrounding cellular tissue: and towards the decline of the disease, ulceration at the corners of the mouth, or of the tongue. Though these local affections are painful, and keep up or even increase for a time the constitutional excitement, they are seldom attended with danger; and in general, after continuing a short time after the prominent symptoms of the disease have disappeared, they subside under judicious treatment.

In scarlatina, as in all febrile disorders, the condition of the several internal organs demands attention. We have often remarked, in investigating the complications of scarlatina, the great disposition to inflammation of serous membranes; therefore, when an organ becomes inflamed during its progress, the investing membrane is much more generally the seat of inflammation, than the substance or parenchyma.

In some cases, the general symptoms are accompanied with evidence of gastro-enteritis. The tongue is morbidly red and clean, and the patient is harassed with sickness, vomiting, and diarrhœa. These symptoms are not uncommon when scarlatina prevails in the autumn, at which season, bowel-affections generally prevail, and constitute a leading feature of an epidemic.

As we have already, in the article Fever, detailed the various complications which arise, and the symptoms by which they may be detected, it is unnecessary in the present article to enter into more minute details, especially as the exanthemata bear so close a resemblance to the other forms of fever. We deem it, therefore, sufficient earnestly to impress the necessity for minute inquiry into the condition of the several organs in scarlatina, and more particularly for watching the convalescence. Cases, apparently mild, are often rendered alarming from an attack of inflammation in some organ: the suddenness of the seizure and the rapidity with which it often proceeds, prove the necessity for vigilance, however mild the symptoms of the disease may be at its commencement. Dr. Armstrong has well observed, "that scarlatina anginosa is sometimes attended with moderate, and at other times with severe symptoms; and it is of great consequence to bear this in mind, more especially as the severe may follow the moderate symptoms at any period of its progress. In those cases where

the symptoms are moderate, the inflammation is chiefly limited to the throat and mucous membrane of the nose, and the excitement of the arterial system subsides without inducing actual inflammation of the viscera; yet where the symptoms are comparatively severe, the inflammation is not limited to the throat and nasal lining, but attacks some of the viscera commonly under a sub-acute character."*

3. *Scarlatina maligna.*—This variety has been described by some writers by the name of *angina gangrænosa* or *cynanche maligna*. Thus Cullen, in his nosology, places it as a variety of cynanche, and likewise makes it one of the species of scarlatina, from which circumstance much unnecessary confusion has arisen. He was, however, candid enough to remark, that the scarlet eruption appears on the skin under the same form in both diseases, adding, that he had five or six times seen the angina maligna united with the common scarlatina; and that in different epidemic constitutions, sometimes one disease predominated, and sometimes the other.

In fact, two names have been given to one disease, which has almost invariably the same characters, and requires nearly the same treatment, making due allowance for the variation observed in epidemics, and the ever varying circumstances under which it occurs. Indeed, we are inclined, from our own experience, to affirm that the scarlatina simplex, scarlatina anginosa, and the scarlatina or angina maligna, and the sore throat without efflorescence on the skin, are merely varieties of one and the same disease.

Though several Spanish and Italian physicians had described the angina maligna, which raged with great violence and mortality in Spain and Italy in the beginning of the last century, Dr. Fothergill was the first writer in this country who described this malignant form of scarlatina as it prevailed in London in the years 1747-8.† From the description he has given, it is evident, that he witnessed during this epidemic the various forms of the disease, and consequently the malignant variety. This is apparent from the following passage. "Thus much, however, seems to be true in fact, that, in some cases, the disease appears to be of so mild a nature, and so benign, as to require but little assistance from art. Persons even recover from it under the disadvantages of unskilful and injurious management, whilst in others the progress of the symptoms is so rapid, and the tendency to corruption so strong, that nothing seems able to oppose it. Just as it happens in the small-pox: the benign and the distinct sort bears ill treatment without injury; in the malignant flux kind, the utmost art and experience are too often insufficient to conduct the distemper to a happy issue. Whether this diversity in the sore-throat we are speaking of is owing to difference of constitution or of seasons, to the different quality or quantity of the contagion, or the manner of receiving it, or whether there are in reality distinct species, may perhaps hereafter be more certainly determined."

A few years afterwards Dr. Huxham gave a faithful account of a similar epidemic, as it appeared in London from the end of the year 1751 to May 1753, and was very mortal. It is evident, however, that in this epidemic, as well as in others which have been subsequently described, the malignant form was only occasionally observed.

In this form of the disease, the symptoms assume very early a malignant or typhoid character; to the affection of the throat and skin are superadded great cerebral disorder, and often inflammation of the pulmonary and gastric mucous membranes. On the first appearance of the disease, the symptoms may differ little from those of the other forms of scarlatina. The pulse is at first soft and frequent, but soon becomes small, rapid, and often irregular: the patient is restless, and at times delirious, the delirium being sometimes so violent as to require restraint, though more generally it is of the low muttering kind. The rash comes out later and is very uncertain in its duration, often suddenly disappearing a few hours after it is first perceptible; and, five or six days afterwards, coming out again for a period of perhaps two or three days. It may thus suddenly recede and re-appear several times. The colour of the rash is at first faint, except in a few irregular patches, which assume a deep rose hue, but the whole efflorescence is speedily changed to a dark livid red, and in the worst forms, is interspersed with petechiæ. The temperature of the skin is generally cool on the trunk of the body, and cold on the extremities: the eyes are suffused and often covered with a film of mucus: the countenance is pale and dejected, while the cheeks are of a dusky red colour; the tongue is covered with dry brown, or almost black fur; in other cases, it is smooth, red, and glossy, and often so tender and fissured that it easily bleeds; the odour from the skin and breath is extremely fetid.

The throat is not much swollen, but appears of a dark red hue, and covered with small ash-coloured sloughs surrounded by a livid base; the gangrene often extends with alarming rapidity, destroying the uvula and arch of the palate. A viscid secretion with which the fauces are covered aggravates materially the sufferings of the patient by increasing the difficulty of swallowing, as well as by the obstruction which it offers to the breathing, so that when symptomatic bronchitis occurs during the progress of the disease, there is great danger of fatal asphyxia. The inflammation generally spreads from the throat to the cervical glands, giving rise to enlargement and sometimes abscess; and when the inflammatory action extends to the nostrils, as it almost invariably

* Practical Illustrations of the Scarlet Fever, &c. by John Armstrong, M.D.

† An Account of the Sore-Throat, attended with Ulcers, by John Fothergill, M.D. 4th edit. London, 1754.

does, there is an acrimonious discharge, at first thin, but afterwards thick and yellow, which produces excoriation of the nostrils, lips, and angles of the mouth, which are generally in these instances covered with black crusts.

In the more severe cases of malignant scarlatina, the symptoms are more alarming from the first appearance of the disease: the pulse is small, rapid, and indistinct: there is more marked cerebral disturbance,—stupor, coma, or violent delirium; the ulcerations of the throat are more extensive, and covered with dark sloughs, and the colour of the rash becomes livid. We frequently also observe pulmonary disease in the form of latent bronchitis, which is often combined with inflammation of the gastro-intestinal mucous membrane, giving rise to diarrhœa and its pathognomonic signs. Some writers mention that hemorrhage from different surfaces,—from the mouth and throat, lungs, intestines, or bladder, takes place, under which the patient in general rapidly sinks, unless the constitutional powers have been unusually vigorous.

In a severe epidemic described by Dr. Withering, after detailing the ordinary progress of the disease, he gives the following outline of a fatal form which it frequently assumes:—"In children, the delirium commenced within a few hours after the first seizure. The flesh was intensely hot; the scarlet colour appeared on the first or second day, and they died very early on the third. In others who escaped this rapid termination, when the scarlet colour turned to brown, and their recovery might have been expected, the pulse still remained feeble and quick, the skin became dry and harsh, the mouth parched, the lips chapped and black, the tongue hard, dry, and dark brown; the eyes heavy and sunk; they expressed an aversion to all food, and extreme uneasiness upon the least motion or disturbance. Thus they laid for several days, nothing seeming to afford them any relief. At length a clear amber-coloured matter discharged in great quantities from the nostrils, or the ears, or both, and continued so to discharge for many days. Sometimes this discharge had more the appearance of pus mixed with mucus. Under these circumstances, when the patients did recover, it was very slowly: but they generally lingered for a month or six weeks from the first attack, and died at length of extreme debility. In adults, the rapidity of the fever, the delirium, &c. was such that they died upon the fourth or fifth day, especially if purging supervened. Some survived to the eighth, or to the eleventh day: in all these the throat was but little affected: the eyes had an uncommon red appearance, not that streaky redness which is evidently occasioned by the vessels of the cornea being injected with red blood, but an equable shining redness, resembling that which we remark in the eye of a ferret. But notwithstanding this morbid appearance in the eye, the strongest light was not offensive. This redness might often be discovered, by lifting up the upper eyelid some hours before it shewed itself in the part of the eye that is usually visible: and it was of some consequence to attend to this circumstance, as it greatly influenced the event of the case. These patients were extremely restless, clamorous, and desirous to drink; but after swallowing one or two mouthfuls, upon taking another they seemed to forget to swallow, and let it run out at the corners of the mouth; whilst others spurted it out with considerable force, and were very angry if urged to drink again. In these cases, the scarlet colour appeared very soon after the attack, but in an unsettled irregular manner, large blotches of red intermixing with others of white, and these often changing places. Besides the full scarlet colour described as above, there were frequently small circular spots of a livid colour, about the breast, knees, and elbows. The pulse from the very beginning was so quick, so feeble, and so irregular, that it was hardly possible to count it for half a minute at a time. It is needless to add, that the greater part of those who laboured under these dreadful symptoms died. A few recovered, and others fell into a state of debility bordering upon idiotism, from which they were rescued by time and generous living. In one patient, a man, the jaw was so perfectly locked upon the third day, that it was impossible to get any thing down his throat, and he died early upon the fifth day."*

In a few instances, we have seen the large joints suddenly become extremely painful, to which swelling with evidence of fluctuation succeeded, and the patient was destroyed in a very short time.

In many instances this malignant form of scarlatina proves fatal on the third or fourth day, though the patient often lingers till the second or third week: it is not uncommon for the patient to die suddenly on the second, third, or fourth day, without the practitioner being able to assign any satisfactory reason, or discover any lesion on the most careful examination of the body. Sometimes, on the other hand, recovery takes place under the most unfavourable circumstances, but the convalescence is exceedingly tedious, and often retarded by the recurrence of some local inflammation, which had arisen during the progress of the disease.

It should not be overlooked that, when the early symptoms have been comparatively mild, the disease may suddenly assume the malignant character. Indeed this form (scarlatina maligna) is more frequently intermixed with the other varieties of scarlatina, and it sometimes unexpectedly supersedes the milder forms of the disease, on the fourth, fifth, sixth, or seventh day of their course. (Willan.)

4. *Scarlatina faucium.*—It has been frequently observed, that when scarlatina prevails epidemically, cases occur in which there is no appearance of rash on the skin, the efflorescence being confined to the throat and mouth. In some cases, the characteristic red ap-

* Account of the Scarlet Fever and Sore Throat, p. 18.

pearance in the throat is unattended with swelling; in others, the efflorescence in the throat is accompanied with swelling of the tonsils, and consequent painful deglutition. Dr. Willan states, that this complaint seems peculiar to adults, and is evidently a species of scarlatina, because it affects some individuals of large families, while the rest are labouring under other forms, and because it is capable of communicating by infection all the varieties of that disease. It is sometimes succeeded by an enlargement of the parotid glands, but not by dropsical swellings. Persons who have previously gone through the scarlatina anginosa, experience, while conversant with the sick, very uneasy sensations in the throat: in some there is a swelling and inflammation, or ulceration of the tonsils, producing considerable pain and irritation, but without the specific fever and efflorescence.* Similar instances have been related by Dr. Johnstone, in the description of the epidemic scarlatina which prevailed at Worcester in 1778. Some individuals, at the first seizure, were more or less severely attacked with the scarlet eruption, with swelling, redness, and ulcers in the throat; yet others in the same family, infected from them, and by them, often had the ulcerated sore-throat, without any efflorescence or eruption on the skin. Again, the first seized sometimes had the simple ulcerated sore-throat only, and yet the others infected by them had the more severe attack of the disease, of fever, and scarlet eruption, as well as sore throat.†

In a paper by Dr. Lettsom, entitled Cursory Remarks on the Appearance of the Angina Scarlatina in the spring of 1793, several cases are given of this form of scarlatina. In one case the disease assumed the characters of scarlatina maligna, but without efflorescence. The sister of this patient, a day or two after, became also the subject of the disease; but in this case, the affection of the throat and fever of the malignant kind were accompanied by general florid efflorescence. In another family, one of the children had ulceration of the throat, but no eruption: a second, about a year older, caught the disease, but had both the affection of the throat and the efflorescence. In another family, some had the sore-throat without any eruption, others had the eruption with a very moderate degree of sore-throat; and this was observed not only among the children, but also among the servants.‡

These statements accord exactly with our own experience of epidemic scarlatina. We had very lately an opportunity of observing in one family the simultaneous appearance of the various forms of the disease. In one of the children, who was the first subject of it, the symptoms early assumed a most malignant aspect; the velum and uvula were destroyed by gangrenous inflammation, and death took place about the fifteenth day. Some days after the disease had appeared in this child, one of the servants became ill, and passed through a mild form of scarlatina anginosa without any untoward symptom. No sooner had this servant recovered than the father of the child began to be indisposed, and in a day or two, considerable fever, with efflorescence of the mouth and throat, and inflammation of the tonsils, came on. The fever and anginose inflammation lasted for several days, and terminated in desquamation of the cuticle.

It appears, then, that the various forms of scarlatina may be produced by exposure to the same exciting causes, and that the differences observed depend on some individual peculiarity or idiosyncrasy, which cannot, a priori, be ascertained.

Sequelæ.—Scarlatina is occasionally followed by troublesome local affections—ophthalmia—enlargement and frequently suppuration of the cervical glands—abscess in the pharynx—laryngitis—chronic bronchitis—inflammation of the ear, ending in purulent discharge from the meatus externus, or suppuration and consequently destruction of the internal ear.

In some instances, dropsical effusion comes on during the convalescence from scarlatina, and always proves an alarming affection.

Anasarca is the form in which the dropsy more generally appears, and though the fluid may be confined to the subcutaneous cellular tissue, it sometimes accumulates in the different cavities; when this is the case, the patient may be considered in great danger. It is singular, that the dropsy has been remarked to succeed as often to mild as to the more severe forms of the disease; but it has never been observed to supervene in cases of malignant scarlatina: it would, therefore, appear to be connected with the acute or subacute forms of scarlatina only. It is almost entirely confined to children, rarely occurring after puberty; Dr. Wells, however, had occasion to treat one case which occurred at the age of seventeen. It seems peculiar to some epidemics. We have seen it occur in several children of the same family, who had passed through scarlatina at the same time. Some writers seem to view this secondary affection as of trivial importance; others regard it as more serious than the primary disease. Plenciz, indeed, affirms that more persons die of it than of scarlatina. This, however, is not the result of the cases which we have witnessed, though in this country it occasionally proves fatal. It generally comes on ten or twelve days after the period of desquamation, and often without any evident cause: sometimes it does not come on for two or three weeks after the disappearance of the rash; and in one case which came under our care, the dropsical symptoms did not appear till five weeks after the desquamation. Previous to its appearance, the patient, after perhaps satisfactorily proceeding in his convalescence to a certain point, finds he does

* On Cutaneous Diseases, p. 274.

† Memoirs of the Medical Society of London, vol. iii.

‡ Ibid, vol. iv.

not advance, but rather retrogrades: he complains of unaccountable languor and lassitude, loses his appetite and strength, his sleep is disturbed, his pulse becomes quick, the bowels costive, and the urine scanty: sometimes there is considerable gastric disorder, indicated by sickness, vomiting, and purging. The swelling is first observed in the face and upper parts of the body, to which it is sometimes confined, though more generally it extends over the whole body, and occasionally effusion takes place in the brain, cavity of the chest, or belly. In fatal cases, fluid has been effused in these three cavities in a very short time. In an epidemic scarlatina, described by Dr. Hamilton, which occurred among the boys in Heriot's Hospital, in three cases the disease proceeded with a rapidity which afforded little opportunity for deliberation or action. The stomach gave way; all food, cordials, and medicines were rejected by vomiting. The watery effusion rapidly filled the cellular membrane, and inundated every cavity. Within less than six-and-thirty hours from the occurrence of the ailment, the boys died, labouring under symptoms denoting ascites, hydrothorax, and hydrocephalus.

In this form of dropsy, the urine generally coagulates by exposure to heat or the addition of nitric or muriatic acid, alcohol, or a solution of the chloride of mercury. Sometimes it deposits a dark-red or brown sediment, which seems to arise from the admixture of the red globules of the blood.

As dropsical effusion is to be regarded only as a secondary affection, it is of importance to ascertain its source. We have always regarded the dropsy succeeding to scarlatina as of an acute or subacute kind, arising from increased action in the sanguiferous system; the consequence of this increased action is the effusion of serous fluid into the external tissues of the body, or when there is a still greater degree of vascular excitement, into one or other of the cavities. That this is the cause of the effusion, if not invariably, at least in the majority of instances, and certainly in all those which have come under our observation, was evident from the character of the pulse as to frequency and power, the coagulable urine, the rapidity with which the fluid accumulated if not arrested by prompt treatment, and from the efficacy of bloodletting, purging, and other antiphlogistic measures, which were generally necessary to remove the dropsical effusion.

Burserius,* in the account he has given of an epidemic scarlatina which prevailed at Florence in the year 1717, mentions that on opening the bodies of several persons who had died of this disease, the lungs, pleura, intercostal muscles, diaphragm, kidneys, and intestines, were more or less inflamed: that peripneumony having been considered as the primary disease, and the dropsical swelling only a consequence, blood was taken from the arm in the succeeding cases, once or oftener, as the occasion required; and that no one afterwards died of the dropsy who was thus treated.

Morbid anatomy. — In scarlatina the appearances on dissection are by no means uniform; indeed, we have frequently been surprised, in examining rapidly fatal cases, to find no morbid appearances that could explain the cause of death: in such instances, it is more than probable, that the diseased condition of the blood and fluids has had an important share in the fatal issue. The skin runs rapidly into putrefaction: it is generally of a dark red colour, the redness being of a deeper colour in different parts, and frequently interspersed with livid spots. When there have been violent delirium and other symptoms of cerebral excitement, the arachnoid membrane is vascular or even opaque, with effusion of a serous or sometimes milky fluid underneath. In such cases, the substance of the brain is also unusually vascular. The mucous membrane of the mouth, cavity of the nose, pharynx, and sometimes even of the trachea and bronchi, is often red from sanguineous injection; and when there has been considerable acute anginose inflammation, there is swelling of the tonsils with exudation of lymph. In the malignant scarlatina, there is little or no swelling, but the membrane of the pharynx is sometimes of a dark livid colour, and occasionally in a sloughing state. In some cases, there is a small quantity of puriform fluid in the sacculi of the larynx, and in two or three instances we have seen ulceration of the cartilages. These appearances in the throat are, however, by no means uniform or frequently observed, and the state of the throat after death very often presents no appreciable morbid appearance, even when there has been considerable anginose affection during the disease. In the chest, redness and thickening of the bronchial membrane, the smaller bronchial tubes and air-cells being filled with a viscid secretion, and a gorged state, with extreme softening and tendency to rapid decomposition of the pulmonary tissue, are the principal morbid appearances. In the abdomen, there are seldom any appearances that can be called morbid; in some cases, the mucous membrane of the stomach or of some portions of the alimentary canal has been slightly injected, though more frequently this membrane throughout the whole tract of the intestines retains its natural colour. When purulent deposits take place in the joints — a complication or sequela which we have occasionally observed — there are not always marks of inflammation of the synovial membrane. In the last case of this kind, however, which we examined, in which pus was deposited in the left wrist and in both ankle joints, there was deposition of pus exterior to the wrist joint, among the carpal bones. The synovial membrane of the wrist and ankles was evidently redder than natural, but there was no abrasion. We are therefore inclined to think, that these purulent

* Instit. Med. Pract. vol. ii.

formations in the joints may occur without antecedent inflammation; and even in the case alluded to we doubt the co-existence of inflammation: it is more probable that the pus which was deposited was not the consequence of the inflammatory action, but that the purulent fluid was deposited from the blood, in the same way as it is sometimes deposited in other parts of the body.

Diagnosis.—It is seldom difficult to distinguish scarlatina from other acute eruptive diseases. There is some resemblance, in the cutaneous efflorescence, to *measles* and *roscola*.

It may be distinguished from measles, 1st, by the period at which the eruption appears; 2d, by the accompanying symptoms; 3d, by the character of the eruption; and 4th, by symptoms which are frequently observed after the disappearance of the rash. In scarlatina, the efflorescence generally appears about the second day of the fever, attended (with the exceptions stated) by affection of the throat, and the characteristic appearance of the tongue: in rubeola the rash does not come out till the fourth day, its appearance being preceded by sneezing, coryza, inflamed and watery eyes, cough, and other catarrhal symptoms, which continue during its progress. The eruption in scarlatina consists of innumerable minute dots or points, diffused in patches with uneven edges, of various sizes and forms, and gives to those portions of the skin on which it appears a diffused bright red colour. In measles, the efflorescence comes out in irregular semilunar or crescent-shaped patches, distinctly elevated, the spots being of a deeper red in the centre than in the circumference, and leaving intervening spaces in which the skin retains its natural pale colour. The desquamation of the cuticle is besides more general and more considerable in scarlatina than in measles. The sequelæ of measles are principally affections of the organs of respiration, croup, bronchitis, or pneumonia, which are more liable to come on towards the decline of the eruption. In scarlatina, there is more frequent affection of the glandular system, and liability to inflammation of the joints and serous membranes, and to anasarcous and dropsical effusion into the cavities.

Roscola is always a much milder disease than even the simple form of scarlatina: the efflorescence is more continuous, of a deeper rose colour, and does not terminate by desquamation. Besides, in roscola, the anginose inflammation and appearance of the tongue peculiar to scarlatina are awanting. The whole duration of roseola too is short, seldom exceeding five or six days, and it cannot be propagated by contagion. It is also often symptomatic of other disorders.

Prognosis and mortality.—It has been generally observed, that scarlatina proves more severe to adults than to children, and that when it attacks pregnant or puerperal women it is often fatal. It has been also noticed, that it is generally mild in spring and summer, but severe during the winter months.

Simple scarlatina is in general a very mild disease, and seldom proves dangerous unless some local inflammation supervene during its progress; but thus a form of scarlatina, mild in the beginning, may be rendered suddenly and unexpectedly dangerous.

Scarlatina anginosa is always a more severe disease than the scarlatina simplex, since to the more acute form of fever there is superadded inflammation of the throat. The anginose inflammation, however, seldom of itself renders the disease dangerous, especially if proper measures be adopted at the beginning. There is in general a manifest disposition in the affection of the throat to terminate in resolution, and it is often surprising how readily it yields to general or local depletion. A moderate degree of swelling, with bright red efflorescence in the throat, is a more favorable indication than when there is little or no swelling, and the redness assumes a dark or livid appearance. It was stated in the description of this variety of scarlatina, that the inflammation sometimes extended from the throat to the larynx: when this takes place, the danger is imminent; since if œdematous swelling of the glottis ensue, death almost inevitably ensues. Danger may also arise from inflammation in some of the cavities —cerebral, pulmonary, or abdominal disease being thus superadded to the anginose and cutaneous inflammations.

A favorable or unfavorable prognosis may be often, in some measure, inferred from the cutaneous efflorescence. In the scarlatina anginosa, the rash appears late in the disease, and though in most instances, it is diffused generally over the surface, it is often only partial, coming out in small irregular patches on different parts of the body. In these latter cases, it is more apt to disappear suddenly, which is a less favorable circumstance than when the rash is general and remains out for several days. The colour of the eruption seems also connected with the general character of the disease. A bright red or scarlet efflorescence is more favorable than the dark red, crimson, or brownish colour which it sometimes assumes. A very pale rash, more especially if it be partial and evanescent, is also unfavorable; and when the eruption, whatever be its colour or the extent of its diffusion, disappears suddenly, and afterwards reappears, or if it do not again come out, more especially if it have receded at the beginning of the disease, the danger is considerable. The more perfectly the desquamation takes place, the case is to be regarded as the more favorable, as secondary disorders are less likely to arise.

From the description which has been given of the scarlatina maligna, the danger in almost every case must be apparent, though it does not appear to arise from the visceral complications which occasionally supervene, as in fatal cases there is seldom discovered in the internal organs satisfactory evidence of the cause of death. In estimating the amount of danger and probable issue of the case, however, it should be kept in view, that though this form of scarlatina proves fatal in a much larger pro-

portion of cases than any of the other varieties, there is every intermediate shade or gradation between the less severe and most malignant cases. In this more severe form of scarlatina, some particular symptoms or appearances however modify the prognosis. Children are observed to struggle better against it than adults, though in some epidemics no age seems to be exempt from its ravages. The existence or non-existence of local inflammation in any organ must also be taken into account, in estimating the degree of danger, and it should be kept in mind how little such topical inflammations are under the control of the treatment, which it is necessary to modify according to the general powers of the patient; if active measures be resorted to in cases of malignancy, with the hope of subduing the low forms of visceral inflammation, the powers of the patient would be endangered, if not irrecoverably sunk.

With regard to the prognosis of malignant scarlatina to be deduced from particular symptoms, a favorable result may be predicted from the following circumstances—mild fever and moderate affection of the throat—early and copious eruption succeeded about the third or fourth day by gentle moderate perspiration, and general desquamation of the cuticle—the throat assuming a florid red colour, and if there have been sloughing, the ulceration looking clean and healthy—diminution in the frequency, with firmness and equality of the pulse—the breathing becoming soft and free, while the eye resumes its brilliancy, and the countenance its natural expression. On the other hand, the prognosis may be deemed unfavourable, when the following symptoms occur—a partial eruption disappearing suddenly—or assuming a dusky or livid colour, more especially if accompanied with petechiæ—smallness and great rapidity of the pulse—frequent sighing, with sensation of great faintness—hot dry skin—hurried breathing not depending on disease of the lungs—acrid discharge from the nose and ears—ulceration of the lips and angles of the mouth—paleness or shrinking of the features—sunken eyes—partial cold sweats—coldness of the extremities—low muttering delirium—coma—hiccup—subsultus tendinum—involuntary stools—gangrenous inflammation of those parts subjected to pressure, as the sacrum and hips—swelling and purulent deposits in the larger joints. Huxham observed in some individuals previous to the fatal issue, the face bloated and shining, and the neck swollen and of a cadaverous appearance, the whole body even became in some degree œdematous, so that the impression of the finger remained.

The *mortality* of scarlatina varies much in different epidemics, although nothing has been satisfactorily established as to the causes which influence the fatality of the disease. The difference observed in epidemics is not confined to scarlatina, but occurs in every variety of fever, whether of the continued, periodic, or eruptive form. In some epidemics scarlatina is a very mild disease throughout; and when it does prove fatal, the cause may often be traced to the supervention of some accidental inflammation; or it may happen, that in particular instances, the symptoms may assume a malignant character, though the general aspect of the epidemic be very mild. It is unnecessary to pass under review the histories which have been recorded of epidemic scarlatina which have at various times appeared; they are alluded to, principally with the object of directing attention to the influence which certain though unknown circumstances exert over the character and symptoms of this disease. It is often sufficient for the practical inquirer to be a diligent and faithful observer of nature, without attempting to discover the hidden causes, and invent explanations of her secret operations. The extreme mildness of some epidemics has induced many to assert, that the mortality of scarlatina has been overrated, and even Sydenham from his observance of the disease (its milder forms only having evidently been presented to his notice), came to the conclusion that it scarcely required medical aid, and when it did prove fatal, this result was to be traced to the *numia medici diligentia*. Had the attention of this illustrious physician been directed to the epidemic described by Morton, a very short time after this opinion was delivered to the world, his candour would have compelled him to acknowledge, that the views he entertained and promulgated of the nature of scarlatina had been formed on too limited experience of the disease. The rapidity with which patients are hurried off is often striking. In an epidemic scarlatina which prevailed in Paris in 1743, we are told that every individual who was attacked perished—many indeed within nine hours from its first invasion. That which raged at Bromley, near Bow, in Middlesex, in the year 1746, it is stated by Dr. Fothergill, seemed to yield to no remedies or applications; several of the inhabitants were greatly alarmed by it, some losing the greater part of their children after a few days' indisposition. These are by no means solitary examples of the great fatality of scarlatina, as similar epidemic visitations have been recorded by Huxham,* Cotton,† De Haen‡, Johnstone,§ Rush,‖ Lettsom,¶ Sims,** Willan,†† Bateman,‡‡ Blane,§§ Macgregor,‖‖ Tweedie,¶¶ Carbutt,*** Sandwith,††† and others.

*** North of England Med. and Surg. Journ., vol. i.

††† Edin. Med. and Surg. Journ., No. cxvii., [a most excellent practical paper.]

Dr. Willan has given the result of his experience of an epidemic scarlatina, from cases which occurred in his own practice in the year 1786. Of 251 cases, there were 152 of scarlatina anginosa, 42 of sore throats without eruption on the skin, and 39 of scarlatina maligna. Dr. Clark, in the description he has given of an epidemic scarlatina which prevailed at Newcastle in 1778, observed, that of 131 patients, 75 had the emption with sore throat; in 33 the disease occurred with every distinguishing symptom of scarlatina maligna; and that in 23 cases it was succeeded by dropsy. He adds, when it is considered that great numbers had the distemper in such a mild manner as to require no medical assistance, and that application was only made for the advice of a physician when the patients were severely attacked, perhaps the malignant cases ought not to be estimated higher than as one to twenty in all who took the disease.

No deductions however can be drawn from these averages, as they have reference only to solitary epidemics, and it is well known that in one or several epidemics, a large proportion of the cases assume the characters of a malignant disease, while, as was formerly stated, a few malignant cases may only occur out of a large number of individuals affected.

We find from the register of cases kept at the London Fever Hospital, that the mortality of scarlatina shews great variation. In the years 1822 and 1823, the disease appears to have been extremely mild, as none of the patients died during these years. In 1824, the mortality was one in twenty-one; in 1825, one in thirteen; in 1826, one in twenty-nine; in 1827, one in forty-one; in 1828, one in ten; in 1829, one in six; in 1830, one in six; in 1831, the disease was not prevalent, and none of the cases proved fatal; in 1832, the mortality was one in forty; and during the last year, the average has been about one in twenty-two. Of 644 cases treated at this hospital, the gross mortality was thirty-eight; of these there were thirteen males and twenty-five females. The following table exhibits the comparative ages of the fatal cases:—

Treatment. From the description which has been given of the various forms of scarlatina, it is obvious that the measures to be adopted for its treatment must have reference to each individual case, as well as to the various circumstances with which it may be associated.

It is also indispensably necessary that the treatment should have reference to the prevailing type or character of the fever, an indication which it is of the utmost importance to bear in mind in the management of this disease. We have already endeavoured to impress this circumstance strongly in a former part of this article, so that it is sufficient merely to advert to it again.

1. In the *scarlatina simplex*, the symptoms are generally so mild, that it is only necessary to confine the patient to bed, to keep the apartment cool, to prescribe occasional aperients, cooling drinks, and abstinence from animal food, so long as there is any febrile indisposition. Should the skin feel hot at intervals, it is advisable to sponge the surface with cold water, by which the morbid heat is rapidly dissipated, and the feelings of the patient are rendered more comfortable. It is seldom necessary in this form of scarlatina to abstract blood, unless it be deemed expedient in cases where the fever runs high. In those cases, it may be prudent to take away a moderate quantity of blood, with the view of subduing the vascular excitement, and preventing the local inflammations which frequently arise in scarlatina. Whether bloodletting be deemed expedient or not, an emetic is often attended with good effects; after which the bowels should be freely opened by brisk aperients, and the various saline remedies, in combination with antimony, administered as circumstances require. It is necessary to watch every case of scarlatina, however mild at the beginning, as the character of the disease is often materially altered by the sudden accession of inflammation in some internal organ, by which a mild disease may in the space of a few hours be converted into one of severity and danger.

2. We have pointed out the more active nature of the symptoms in *scarlatina anginosa*. In adults of a plethoric tendency, more especially if the patient be young, bloodletting is sometimes necessary, and even in children, a moderate bleeding from the arm, when there is much excitement at the beginning, is often useful in moderating the fever, and diminishing the tendency to visceral inflammation. General bloodletting has been strongly recommended by several continental physicians in this form of scarlatina, more especially when there is much cerebral disturbance. Morton employed it with success in the epidemic he has described; and in the scarlatina which prevailed at Edinburgh in 1733, we find it stated, that few died who were timely and plentifully blooded, which weakened the fever, relieved the throat, and was the only medicine that removed the vomiting and

diarrhœa.* Huxham advocates this practice at the commencement of the fever, when the blood was often sizy, but recommends one moderate bleeding only, as patients did not bear a large bleeding, and scarcely any a second.

On the other hand, in some epidemics, evacuations of blood are less efficacious, or wholly inadmissible, either from the form of fever being of a less acute character, or from the tendency of the general powers to decline, when active depletion has been adopted. The successful treatment of the disease by bloodletting and other antiphlogistic measures at one season, does not warrant the practitioner in employing the same plan in another epidemic; the type of the fever, the pulse, and the general aspect of the symptoms must be his guide. In the epidemic described by Dr. Withering, such was the state of the pulse, that bloodletting was inadmissible, unless in the autumn, when the colour of the rash was not intense, or did not appear at all, the swelling of the throat great, and the pulse firm. Dr. Willan, also states, that during the years 1785, 1786, 1787, and since, when the scarlatina anginosa was epidemic in the metropolis, he never saw a case in which bloodletting appeared to be indicated. Whenever it had been employed, great depression and faintness were the immediate consequences, the pulse becoming more weak and frequent, and often irregular. Of two adults who had been bled largely, one died before the period of desquamation, the other lingered in a very precarious state upwards of twenty days, but at length recovered.

It is therefore almost impossible to lay down general rules for the treatment of a disease which varies so much in its character at different times. At one season, or in one epidemic, bleeding may be required—at another, the lancet is to be employed with the greatest caution, and not unless some urgent circumstance arise to require its use. We have seldom had occasion to bleed from the arm, unless in particular instances of unusual febrile excitement, or when some important organ was threatened with inflammation. We generally prefer the free topical abstraction of blood by cupping behind the neck, which is the most effectual mode of relieving the inflammation of the throat, or by the application of leeches under the jaw, or behind the ears. We have seen great benefit also from the free scarification of the tonsils when skilfully performed, though many patients object to this mode of topical bleeding, which is also often not easily performed in timid persons.

We have seldom observed any decided benefit from the use of gargles, indeed the inconvenience felt by the patient in their employment often precludes their adoption. The inhalation of the vapour arising from warm water gives much more decided relief.

The exhibition of emetics in the commencement of scarlatina anginosa as well as of the other forms, has been strenuously recommended by some physicians. Dr. Withering prescribed them not only in the beginning, but even in the later stages of the disease. Their employment, however, should be restricted to the period of invasion, as it has been observed that they are much more beneficial at this stage than when the symptoms are more advanced. The shock which is given to the system by the action of vomiting in the early stage of eruptive fevers is often followed by most decided improvement in the general symptoms and feelings of the patient. Dr. Rush exhibited an emetic, combined with calomel, in every case he was called to, which, besides inducing vomiting, seldom failed to produce two or three stools: in several cases he was obliged, by the continuance of the nausea, to repeat the emetic, and always with obvious and manifest advantage.

The abatement in the symptoms which is generally observed after the bowels have been freely evacuated has induced physicians to purge freely in the early stages of scarlatina anginosa, and certainly no class of remedies is more entitled to confidence than purgatives, when administered with discernment. Many writers have expressed their doubts of the safety of this practice, from the fear of inducing debility and repelling the efflorescence. Dr. Hamilton, however, has adduced powerful arguments in support of it, and has illustrated his views by an appeal to the result of cases treated in public and private practice. No variety of the disease, as appearing in different epidemics, or in the course of the same epidemic, has hitherto prevented this distinguished physician from following out this practice to the necessary extent. The pungent heat of surface, violent headach, turgescence of features, and full and quick pulse, the earliest symptoms in some epidemics of scarlatina, and which may have suggested and warranted the practice of bloodletting, are often quickly subdued by one or two brisk purgatives. Dr. Hamilton states, that full purging is not required in the subsequent periods of the disease, in which the sole object is to remedy the impaired action of the intestines; to secure the complete and regular expulsion of their contents; and thus to prevent the accumulation of fæces, which never fails to aggravate the symptoms and to prove the source of further suffering to the patient. He has added some very useful hints as to the same activity not being required in the exhibition of purgative medicines in every case of scarlatina, acknowledging, that he had not ascertained to what this different state of the bowels in scarlatina is to be ascribed, and observing that on whatever cause the difference depends, it is necessary to adapt our practice in the use of purgatives to the nature of the prevailing epidemic.

In the early stages, when there is nothing to contra-indicate the use of purgatives, a brisk aperient may be exhibited daily. We generally prescribe a combination of calomel and rhubarb

* Edinburgh Medical Essays, vol. iii. p. 27.

at bed-time, and on the following morning a moderate dose of castor oil, or infusion of senna with manna and sulphate of magnesia. When the cuticle begins to desquamate, and the febrile symptoms decline, active cathartics are improper: at this stage of the disease, it is necessary only to ensure the regular evacuation of the bowels, for which purpose the mildest aperients are best adapted.

Though we have advocated the employment of purgatives in the more severe cases of scarlatina, they are to be prescribed with the greatest caution, if not altogether withheld, when the mucous membrane of the intestines betrays signs of irritation or of inflammation. In such cases, the bowels are generally purged, and the dejections of an unhealthy appearance. Under such circumstances, the gastric irritation must be allayed by leeches applied to the abdomen, counter-irritation, and bland nourishment. Aperients, even of the mildest class, must be withheld, until the intestinal derangement is allayed; and should it become necessary to administer an aperient occasionally, the least irritating should be selected; none is preferable to castor-oil suspended in mucilage, with the addition of a few drops of laudanum.

The free application of cold is decidedly beneficial in the acute stage of scarlatina, and more especially, in the anginose form. The bed-chamber should always be properly ventilated by frequently renewing the air, and allowing a current of cool fresh air to pass round the patient. If the skin be hot, the body should be occasionally sponged with cold water, by which the morbid heat is rapidly abstracted, and the patient refreshed. The sponging should be repeated when the skin feels pungently hot. The testimony of Dr. Bateman, as to the efficacy of this practice, is very strong:—"We are possessed," he says, "of no physical agent, as far as my experience has taught me, (not excepting even the use of bloodletting in acute inflammation,) by which the functions of the animal economy are controlled with so much certainty, safety, and promptitude, as by the application of cold water to the skin, under the augmented heat of scarlatina, and of some other fevers. This expedient combines in itself all the medicinal properties which are indicated in this state of disease, and which we should scarcely *à priori* expect it to possess: for it is not only the most effectual febrifuge, (the "febrifugum magnum," as a reverend author long ago called it,) but is, in fact, the only sudorific and anodyne which will not disappoint the expectation of the practitioner under these circumstances. I have had the satisfaction in numerous instances of witnessing the immediate improvement of the symptoms, and the rapid change in the countenance of the patient produced by washing the skin. Invariably, in the course of a few minutes, the pulse has been diminished in frequency, the thirst has abated, the tongue has become moist, a general free perspiration has broken forth, the skin has become soft and cool, and the eyes have brightened; and these indications of relief have been speedily followed by a calm and refreshing sleep. In all these respects, the condition of the patient presented a complete contrast to that which preceded the cold washing; and his languor was exchanged for a considerable share of vigour. The morbid heat, it is true, when thus removed, is liable to return, and with it the distressing symptoms, but a repetition of the remedy is followed by the same beneficial effects as at first."*

Little confidence should be reposed in any of the ordinary saline remedies. We prefer the mineral acids, more especially the saturated solution of chlorine, prepared according to the directions given in the Dublin Pharmacopœia, which contains about twice its volume of chlorine. Of this remedy a fluid dram and a half, mixed with eight ounces of water, and two drams of syrup of lemons, may be taken in divided portions during the day. For children, ten or twelve drops every six or eight hours is a sufficient dose.

The solution of chlorine is readily decomposed by exposure to light and air, and in this state it is very apt to disorder the stomach and bowels, producing sickness, griping pain of the bowels, or diarrhœa. It is therefore necessary, that the remedy should have been recently prepared before it is exhibited. If recently prepared chlorine cannot be readily procured, (though it is obtained by a very simple chemical process,) the diluted sulphuric acid may be substituted.

In the advanced stages of scarlatina anginosa, when the general fever has declined, and the efflorescence has disappeared, it is often necessary to give, with due caution, a little support. Mild nourishment is often sufficient, but should the pulse be soft and rather weak, with a cool skin, small doses of quinine in acidulated infusion of roses are generally very beneficial. It is seldom necessary to administer wine, except under circumstances of unusual debility after a protracted illness. The moderate use of it in such cases tends much to assist the convalescence.

When visceral inflammation arises in the progress of scarlatina anginosa, no time should be lost in endeavouring to arrest it. In such cases, the judgment of the practitioner must direct him as to the extent to which it is necessary to carry the antiphlogistic treatment. We have already entered so fully into the management of the various local lesions which arise in the progress of fever, (and the indications to be observed in scarlatina are precisely similar,) that we deem it unnecessary to repeat what has been already advanced, (see Fever,) though the necessity of watching narrowly the state of the several organs, and of adopting suitable measures on the first evidence of local inflammation, cannot be too forcibly impressed on those, who may not have had much experience in the treatment of this disease.

* Practical Synopsis of Cutaneous Diseases.

3. In *scarlatina maligna*, the acute stage, in which only antiphlogistic measures can with safety be employed, soon passes off, and is succeeded by a low depressed state of the general powers, which renders any form of depletion not only doubtful but hazardous. If the practitioner be called on to treat this form of scarlatina at its very commencement, and before it is fully formed, an antimonial emetic is generally very beneficial, more particularly when the bowels are afterwards evacuated either by the antimony, or by an active aperient. If, however, those means be insufficient to subdue the excitement, moreover if the pulse be rapid and firm, the skin hot, and there be much pain in the head, or delirium, a moderate quantity of blood should be taken from the arm, and another aperient given. This treatment, if adopted at the onset of the symptoms, will generally not only moderate the fever, but shorten the duration and violence of the disease. In many cases, however, such is the violence of the symptoms, more especially if they have been neglected in the beginning, that the acute stage is speedily followed by symptoms of a low typhoid character, which require a cordial tonic plan of treatment. It then becomes necessary to support the sinking powers by animal broths, quinine, and a moderate allowance of wine.

The volatile alkali has been strongly recommended in cases of malignant scarlatina; it was considered by Dr. Peart to be endowed with a specific power over the malignant scarlet fever and sore throat. He directed two drams of the carbonate of ammonia to be dissolved in five ounces of water, of which the dose was two teaspoonfuls every two, three, or four hours, according to the urgency of the symptoms. This remedy was administered in every form and stage of the disease, and were we to judge from the result of the cases in which this remedy was given, it would appear never to have failed even in the worst. We certainly have tried this remedy repeatedly, but our experience of it does not warrant such an inference; nor do we deem it preferable to other diffusible stimulants. Capsicum is a remedy which appears to have been employed with much success by Dr. Stephens, in an epidemic scarlatina which prevailed at St. Christopher's in 1787, and of which an account was published in the second volume of the Medical Communications, and also in Duncan's Medical Commentaries for the year 1787. This remedy was used in the form of infusion prepared according to the following formula: two tablespoonfuls of small red pepper, or three of the common Cayenne pepper, and two teaspoonfuls of fine salt are to be beat into a paste, to which half a pint of boiling water is to be added. When cold, the liquor is to be strained off, to which half a pint of very sharp vinegar is to be added. Of this mixture, the dose for an adult is one tablespoonful every four hours, the quantity being diminished in proportion for children. This remedy has been commended by several writers who have employed it successfully; but having never employed it, we cannot offer an opinion on it.

When topical inflammations arise in scarlatina maligna, general bleeding is seldom admissible, unless they supervene in the beginning of the disease: the application of leeches, in numbers proportioned to the age and powers of the patient, is better adapted to the low forms of local inflammation which arise in this malignant disease.

With regard to the local treatment in scarlatina maligna, we may observe, that in the very beginning of the disease, the inflammation in the throat is best managed by the application of leeches under the jaw or behind the ears; but this treatment must be confined to the very onset of the anginose affection, since the inflammation in most cases very speedily passes into gangrene. The vapour arising from warm water may be frequently inhaled. Some physicians recommend the occasional exhibition of an emetic with the view of dislodging the viscid secretion with which the fauces are clogged, and unless the powers be so feeble as to render the shock of an emetic hazardous, benefit is often derived from their employment.

Acidulated bitter infusions, as of cinchona, cusparia, serpentaria, contrayerva, or an infusion of capsicum prepared as recommended by Dr. Stephens, may be used as a gargle.

A weak solution of the nitrate of silver, or of sulphate of copper, applied by means of a proper syringe, after the throat has been well cleansed by warm water, often improves the aspect of the ulceration.

Dr. A. T. Thomson recommends the chlorosodaic solution of Labarraque, in the proportion of ʃ3xii of the solution to ʃ℥vi℥ of water and ℥iv of honey, as an excellent gargle. The same solution, in the proportion of ℥vi to ℥v of water, without the addition of honey, if frequently thrown into the nostrils by means of an elastic bottle mounted with a tube, soon removes the coryza.*

Fumigations by the nitrous acid gas, (separated from pulverized nitre by the strong sulphuric acid,) or the nitro-muriatic acid gas, (chlorine,) (separated from a mixture of equal parts of pulverized nitre and of sea-salt, by the strong sulphuric acid,) have been strongly recommended by Willan.

It is almost superfluous to state, that proper ventilation is most essentially necessary in this, as in the other forms of scarlatina. The admission of fresh air around the patient generally invigorates his powers, and often proves a most excellent tonic. Warm sponging, a tepid bath, or, if there be much cerebral disturbance, fomentations to the extremities, may be employed in addition to the other measures.

The treatment of the dropsical effusion which we have described as an occasional occurrence towards the termination of scarlatina, is to be regulated by the condition of the system, and

* Bateman's Practical Synopsis of Cutaneous Diseases, edited by Anthony Todd Thomson, M.D.

more especially of the several internal organs. The effusion in general speedily disappears under judicious treatment; in all the cases which have fallen under our notice, the dropsy has been evidently dependent on general or local excitement, which it was necessary to subdue by bloodletting and purging, after the adoption of which measures the effusion quickly vanished. In some instances, when the state of the pulse did not require the abstraction of blood, a few doses of brisk purgatives have carried off the fluid: in others, the activity of the circulation, the heat of skin, scanty urine, and oppressed breathing, at once suggested the necessity of bloodletting, from which the most decided relief was immediately obtained, after purgatives and diuretics had completely failed. The efficacy of the antiphlogistic treatment of dropsy succeeding to scarlatina has been corroborated by many practical writers in other countries as well as our own; and though some still hesitate to adopt the practice, we are satisfied that in cases accompanied with phlogistic symptoms, it is the only safe and rational mode of treatment. Besides, when we consider the condition in which the internal organs have been occasionally found in fatal cases of scarlatina complicated with dropsy, the propriety of vigorous antiphlogistic treatment is apparent. We admit that in some instances, in which the symptoms are of a less acute character, bloodletting may be dispensed with: we allude more particularly to those in which, though the general powers be feeble, there is congestion or chronic insidious inflammation in some organ. Under such circumstances, topical bleeding, mild purgatives, and diuretics, with a bland diet, will be found more appropriate measures. As to the employment of tonics, on the supposition that the dropsical effusion depends on loss of power or tone in the exhalents, we confess we are sceptical as to this being the pathological state of the vessels in any case of dropsy succeeding to scarlatina, and therefore we are disposed to place little or no confidence in this class of remedies. When the effusion has been removed by suitable measures, pure air, mild nourishment, and attention to the bowels will be found the best mode of invigorating the general powers.

(A. Tweedie.)

SCIRRHUS.—The term σκίῤῥος, from σκίρος, marble, was given by the Greek physicians to certain tumours characterized chiefly by a great degree of hardness; but the application of the term scirrhus has for a considerable length of time been limited to tumours or portions of organs or tissues which present not only this character, but which terminate in the disease called cancer. Hence the state of induration to which the appellation of scirrhus is given is regarded as the first stage of cancer. We shall overlook for the present the propriety of this distinction, and instead of confining ourselves to the consideration of scirrhus, shall in the present article give a general view of those morbid conditions which have been denominated scirrhus, cancer, fungus hæmatodes, and the several kinds of sarcoma, under the generic term of *Carcinoma*. The reasons for our grouping together under the term carcinoma so many diseases which have generally been described as differing widely from that which is commonly known by this designation, will be fully exposed as we proceed. In the meantime, however, the following may be regarded as the more remarkable phenomena which these diseases, considered in a general and anatomical point of view, present in common with one another, and which we conceive, while they express in a concise and conspicuous manner those characters by which they are distinguished, justify our having brought them together under the same general denomination: —1. They are essentially composed of a solid or fluid substance, different from any of the solids or fluids which enter into the healthy composition of the body. 2. They often present in the early periods of their formation certain characters common to all of them, however much they may differ from each other in the subsequent periods. 3. They all terminate in the gradual destruction or transformation of the tissues which they affect. 4. They have all a tendency to affect, successively or simultaneously, several organs in the same individual. 5. They all possess, although in various degrees, the same reproductive character.

Specific divisions of carcinoma.—When we examine the several morbid conditions which we have included under the genus *carcinoma*, we find that they present differences, some of which are of considerable importance, others less so; and therefore it becomes necessary to separate them into distinct groups, and to arrange them into species and varieties. The differences to which we allude are referable to two states of the carcinomatous substance to which the diseases in question owe their origin. The first is that in which this substance has little or no tendency to become organized: its form and arrangement appear to be determined chiefly by external circumstances, and its formation and subsequent increase are entirely dependent on the nutritive function of the organ in which it is contained. In the second state this substance exhibits, on the contrary, a greater or less tendency to become organized: although it may at first assume a determinate form and arrangement, in consequence of the influence of external circumstances, it possesses in itself properties by means of which its subsequent arrangement and developement are effected, independent of the nutritive function of the organ in which it is formed, except in so far as the materials of its growth may be derived from this source.

On account, therefore, of these two opposite states of this particular substance, carcinoma may be divided into two species, the first of which we have called *scirrhoma*, the second *cephaloma*. Although neither of these terms expresses the essential characters of the respective states to which they are applied, we have not been able to find or devise others better calculated to accomplish this object; it is

therefore necessary to bear in mind that they indicate only one of the characters of these states, viz., a certain degree of consistence, and which, it may be observed, is far from being constant in either, because of various circumstances, which we shall afterwards endeavour to explain.

In these two species, scirrhoma and cephaloma, the carcinomatous substance presents itself under various forms, which may be regarded as constituting so many varieties of each species.

Varieties of scirrhoma.—The varieties of scirrhoma are determined chiefly by the relative quantity of the carcinomatous substance, the manner in which it is distributed, and the difference of colour and consistence which it presents. Thus it may be collected in numerous points in the form of a hard, grey, semi-transparent substance, intersected by a dull white or pale straw-coloured fibrous or condensed cellular tissue, and, as such, is commonly denominated *scirrhus*. When it assumes a regular lobulated arrangement, so as to present an appearance similar to a section of the pancreas, it forms what was called by Mr. Abernethy the *pancreatic sarcoma*.* Again, it may be disseminated uniformly throughout the texture of an organ, which it converts into a solid substance, resembling a slice of raw or boiled pork, and is then called by the French *tissu lardacé*. Lastly, when it presents the appearance of firm jelly, and is collected into masses of greater or less bulk in a multitude of cells, it is the *matière colloïd* of Laennec, the *cancer gelatiniforme* or *aréolaire* of M. Cruveilhier.†

Varieties of cephaloma.—The principal varieties of cephaloma are derived from the appearances which the carcinomatous substance presents either in different organs or at different stages of its developement. When it presents the appearance of firm coagulable lymph, or fibrine deprived of the red colouring-matter of the blood, possessing a uniform, fibriform, or lobuliform arrangement, with a certain degree of transparency and vascularity, Mr. Abernethy gave to it the name of *common vascular* or *organized sarcoma*. In this state the carcinomatous substance is generally collected into a mass of greater or less bulk, in which few or no traces of the proper tissue of the organ in which it is contained are observable. If, on the contrary, it be uniformly disseminated throughout the texture of an organ, so as to transform it into a substance resembling a section of the mammary gland, or the udder of the cow when boiled, the appellation of *mammary sarcoma* was given to it by Mr. Abernethy. When it presents an appearance similar in colour and consistence to the substance of the brain, it was called *medullary sarcoma* by the same distinguished surgeon; *matière cérébriforme* or *encéphaloïde* by Laennec,‡ and *spongoid inflammation* by Mr. Burns.* The *milk-like* tumour of Dr. Monro,† the *soft cancer* of various authors, and the *pulpy* testicle of Dr. Baillie,‡ are names which have been given to the same state.

Of all the varieties of cephaloma, the last is that in which a vascular organization is most conspicuous, and as the coats of the vessels with which it is supplied are remarkably delicate, the circulation of the blood through them is readily interrupted; hemorrhage from congestive rupture takes place, and the effused blood is mixed in greater or less quantity with the brain-like matter. From this accidental circumstance, together with the protrusion of this substance through the ulcerated integuments for example, in the form of a bleeding fungus, it has been described by Mr. Hey§ and also by Mr. Wardrop,‖ under the appellation of *fungus hæmatodes*. Sir Astley Cooper calls it *fungoid disease*.

Such are, we conceive, the principal varieties of scirrhoma and cephaloma, and the general characters by means of which they may be recognized. But although we have said that the essential difference between the two species of carcinoma consists in the former having little or no tendency, the latter a greater or less tendency, to become organized, it is by no means always easy, nay, it is sometimes impossible, to draw a distinct line of separation between them; for the carcinomatous deposit when first formed, and, indeed, frequently for a considerable length of time after its formation, does not furnish us with any signs which shew that it will or will not become organized. We cannot determine what those properties are by means of which it is afterwards to assume a definite arrangement, or to possess within itself the powers of contributing to its subsequent developement. These facts may be illustrated by the two following circumstances: 1. the carcinomatous deposit may exist as we have described it in the form of scirrhus, pancreatic sarcoma, or the lardaceous tissue, without its presenting any trace of organization; the textures which it invades being gradually destroyed by its presence, and both ultimately converted into a soft, granular, pulpy, or liquid mass, of the colour and consistence of cream or milk. 2. The same deposit may exist under the same forms as those we have just named, but it undergoes changes of an entirely opposite kind; that is to say, it assumes the characters of the mammary or medullary sarcoma, becoming more or less soft and vascular, and frequently terminating in hemorrhage by the rupture of its vessels, or in that state called fungus hæmatodes. Numerous examples might be given of scirrhus, medullary sarcoma, and fungus hæmatodes, as they are commonly called, originating in the same morbid state, and

passing successively from the one into the other in the order in which we have named them. Indeed, we often meet with all the varieties which we have enumerated of both species, not only in different organs of the same individual, but even in a single organ.

If such are the successive changes observed to take place in carcinoma, the distinction of the disease into species and varieties may be considered by some to be of little importance. Such, however, cannot be the case, for we know that the curability of a disease often depends on the time at which a remedy is employed, or varies with the state or period of the disease; and therefore it is obvious that whatever means may be adopted for the cure of carcinoma, we can form no precise opinion as to their relative efficacy, unless the particular condition or variety of the disease be kept in view. And it is far from being an unimportant fact that several of the varieties of both species of carcinoma differ materially from one another as regards the comparative rapidity of their developement, as well as their reproductive tendency. Thus in both these respects the pancreatic differs from the lardaceous, the lardaceous from the mammary, and the mammary from the medullary sarcoma; the first often remaining stationary for a long space of time, months or years; the last frequently acquiring its maximum of bulk in a few weeks, and when removed being sometimes reproduced with a degree of rapidity which is never observed in any of the other varieties. It may be said that the more the varieties of both species of carcinoma partake of the characters of those accidental formations which resemble the healthy tissues of the body, as the cellular, cellulo-fibrous, and fibrous, they are, *cæteris paribus*, the less rapid in their developement, and have less tendency to be reproduced.

Before proceeding to the description of the physical, anatomical, chemical, and physiological characters of carcinoma, we shall endeavour to establish on the evidence with which our anatomico-pathological investigations have furnished us, the seat, origin, and mode of formation of this disease; for unless we possess clear and accurate notions on these important points, we should meet with numerous difficulties besides those which are inseparably connected with our subject, under the several points of view in which it is necessary to consider it.

Seat, origin, and mode of formation of carcinoma.—Various opinions have been entertained regarding the seat, origin, and mode of formation of carcinoma, some of which have attracted notice merely from their novelty, others from their possessing much higher claims to our consideration, and to these we shall more particularly allude.

There are several organs subject to carcinoma which, from the peculiarity of their structure or other circumstances, afford us the means of ascertaining the precise seat of this disease, its origin, and mode of formation. But to derive all the advantages which these circumstances are capable of affording, it is necessary to catch, as it were, the disease at its earliest period, that is to say, when the peculiar substance of which it consists has just been deposited, and has not effaced the texture or structure of the part in which it is contained. Investigated in this its first stage, we ascertain with greater or less facility that this substance becomes manifest to our senses either as a product of nutrition or of secretion. In the former case it is deposited in the same manner as the nutritive element of the blood, enters into the molecular structure, and assumes the form and arrangement of the tissue or organ into which it is thus introduced. In the latter it makes its appearance on a free surface, after the manner of natural secretions, as on serous surfaces in general.

Such are two of the modes in which the formation of carcinoma takes place, and also two of the principal differences in regard to the seat of the disease. Proceeding, however, still farther in our researches, we arrive at the important discovery that the carcinomatous matter exists in the blood under circumstances which can leave no doubt as to this fluid being the primary seat of its formation. As, in our opinion, too much importance cannot be attached to these three positions, viz., the formation of carcinoma in the molecular structure of organs, on free surfaces, and in the blood, we shall endeavour to demonstrate the truth of them by a statement of the evidence derived from our own researches on the subject.

1. The liver and stomach, organs in which carcinoma is of frequent occurrence, afford us the most striking examples of the formation of carcinoma in the molecular structure of organs. If we make a section of a liver containing what are commonly denominated carcinomatous tumours, that is to say, round or irregular masses of a substance resembling one or more of the varieties of scirrhoma or cephaloma, we shall often be able to detect the first stage of these tumours, and discover the manner in which they are formed. Thus, the first thing which we have frequently been able to perceive in those portions of the liver in which the carcinomatous matter was just making its appearance was a slight change of colour, observable only in a very limited and well defined space, and which could be distinctly seen to exist in those minute divisions of the organ denominated *acini*. This change of colour may take place in a single acinus, or in several of these bodies successively or simultaneously. The red or yellow colour which they naturally present gradually disappears, and is succeeded by a pale milk-white or straw-colour, accompanied by an increase of the consistence. But the most important circumstance is, that while these changes of colour and consistence are taking place, the *form* and *bulk* of the acini remain *unaltered*. Now it need hardly be remarked that the form and bulk of the acini could not remain unaltered unless the foreign substance, to which their change of colour and consistence must be ascribed, were introduced into them in the *same order* as the normal element of nutrition, unless it were deposited in the *molecular struc-*

ture of the acini in a manner precisely similar to that in which their *nutritive function* is carried on. Otherwise, along with the change of colour and consistence which they present, we should have a simultaneous increase of *bulk*. The more we examine the acini in this state, the more shall we be persuaded that they are thus *transformed* by the molecular deposition of that peculiar substance which constitutes the essential anatomical character of the disease in question.

By tracing the transformation of the acini from a lesser to a greater degree, we can perceive them forming groups, for example, of three, four, ten, or twenty, the re-union of which constitutes tumours varying from the size of a hemp-seed to that of a cherry, in all of which the structure of the liver as characterized by the form, bulk, and arrangement of the acini, is more or less conspicuously marked, but becoming gradually less so with the increasing bulk of the tumours, until it entirely disappears, being transformed into a uniform lardaceous mass, or into some one or other of the tissues or substances which belong to either of the species of carcinoma.

We have said that a similar mode of formation of carcinoma is observed in the stomach. It is, however, chiefly in the muscular coat of this organ that it is most conspicuously seen, on account of the difference between the natural colour of the muscular fibres of this coat and that of the cellular tissue which enters into its composition. The change of colour which accompanies the presence of the carcinomatous deposit is, therefore, hardly perceptible except in the muscular fibres. These, however, become pale and acquire an increase of consistence; but their bulk does not appear to be increased at first, and they retain their form and distribution. Such, also, is the state of the intermuscular cellular tissue at the same period, except as to colour, which is not sensibly changed on account of its being naturally pale. By-and-bye both acquire a greater or less increase of bulk, become remarkably distinct, and present that fibriform arrangement, hardness, and transparency which are regarded as so characteristic of scirrhus. At a more advanced period of the disease we no longer trace this nutritive process of transformation, the muscular and cellular tissues being converted into a homogeneous mass, which is afterwards softened down, or assumes the mammary, medullary, or hæmatoid forms of carcinoma.

2. The fact of carcinoma forming on the free surface of serous membranes is strongly corroborative of the accuracy of the preceding remarks; for although in the former case we refer the presence of the carcinomatous deposit to a modification of nutrition, and in the present to a modification of secretion, the difference is merely nominal. The distinction, however, between nutrition and secretion is valuable as regards the formation of carcinoma; for considered as a modification of the latter, we possess ourselves of the advantage of studying the disease where it presents itself under, perhaps, the most simple of its forms, viz., on extensive serous surfaces, such as that of the pleura or peritoneum. Here the carcinomatous substance is found to be effused on the free surface of these membranes, without our being able to perceive that they have undergone any previous change whatever. Multitudes of tumours are sometimes found on these two surfaces, varying in bulk, consistence, and colour. Some of them are as large as a plum or an orange; others of the size of cherries, peas, hemp, or millet-seed, and composed of a substance resembling pork, the mammary gland, brain, or a mixture of the latter, fibrine, and blood. We may, in fact, have almost all the varieties of carcinoma formed in these membranes, and, as we have said, without their having undergone any previous change. Under such circumstances we must refer the presence of these tumours to the separation of the carcinomatous matter from the blood, which, being effused in the form of a secretion, afterwards undergoes changes peculiar to itself.

3. The presence of carcinomatous formations in the blood is a circumstance of great importance, and unless it be clearly demonstrated that their presence is the consequence of a modification of the blood itself, in whatever manner produced, we should find it impossible to explain many of the phenomena which the disease presents, and more especially those which accompany its formation in the molecular structure and on the free surface of membranes.

The following facts may be adduced as furnishing strong evidence that the formation of the carcinomatous substance takes place in the blood, whether it be found in this fluid alone or in other parts of the body at the same time: 1. the presence of this substance in the vessels which ramify in carcinomatous tumours or in their immediate vicinity; 2. in the vessels of a portion or of the whole of an organ, to the former of which the carcinomatous substance is exclusively confined, and can be traced from the trunks into the branches and capillaries; 3. in vessels having no direct communication with an organ affected with the same disease, as, for example, when it is confined to a small extent of the vena portæ; and, lastly, in blood which has been effused into the cellular tissue and on the surface of organs.

The appearances which the carcinomatous matter presents in the blood are very various: sometimes they are perfectly similar to those which mark its presence in the substance or on the surface of organs. When contained in large veins, such as the vena portæ and its branches, the emulgent vein, &c. it may present the lardaceous, mammary, medullary, or hæmatoid characters, all in the same venous trunks. These varieties of the disease may be found mixed together in minute quantities, or isolated into masses so conspicuous that we can readily distinguish them from one another. Sometimes they lie merely in contact with the internal parietes of the vein: at other times

they are united with these by means of a thin layer of colourless fibrine; or minute blood-vessels pass from the one into the other, and are often very numerous and remarkably conspicuous in the cerebriform matter.

The divisions of the vascular system in which the carcinomatous substance has been observed, are the venous and capillary,—a circumstance which may be ascribed to the contractile power of the arteries preventing, under ordinary circumstances, the blood from accumulating, and consequently this substance from forming within them, and not to any peculiarity of function exercised by the former. The presence of the carcinomatous matter in the veins might be, and indeed is, in general, supposed to be owing to its having been absorbed by these vessels; but without entering into minute anatomical details which disprove such to be the case, we shall again repeat the fact that there are cases of carcinoma in which the venous blood alone is found to be the seat of the disease. There is no accumulation of the carcinomatous matter either in the vicinity of the veins in which the blood is thus affected, or in any other part of the body; and in those cases in which this complication exists, as well might we refer the presence of this matter in the veins to the exercise of the function of venous absorption, as that of cellular, fibrous, osseous, and cretaceous formations in the same vessels to a similar process, which we know not to be the case.

From this view of the origin of carcinoma in the blood, its formation in the intimate structure and in the free surface of organs, after the manner of nutrition and secretion, follows as a natural consequence. The material element of the disease is separated from the blood and deposited under a variety of circumstances which modify in a greater or less degree the form, bulk, colour, and consistence which it afterwards presents, in the several periods of its developement. We cannot therefore limit the seat of the disease to any one tissue, or ascribe its origin to any modification of structure or special organization, as has been done by several pathologists.

Perhaps the most ingenious attempt that has been made to explain the local origin of carcinoma is that of Dr. Hodgkin, published in the fifteenth volume of the Medico-Chirurgical Transactions. Dr. Hodgkin has endeavoured to shew that the presence of a serous membrane, having a cystiform arrangement, is necessary for the production of carcinoma and some other diseases of a malignant character. The existence of the former precedes, he believes, the formation of the latter, and consequently is at once the seat and origin of the disease. That such is the manner in which carcinomatous formations are sometimes formed, we can have no doubt, inasmuch as we have had occasion to see them as they have been described by Dr. Hodgkin. But we have here no new law in operation, nor even an exception established to that the prineiples of which we have several times alluded to. Cysts are a very simple modification of a serous membrane; they partake of the structure and functions of the latter, and, consequently, are subject to similar diseases. If, therefore, such cysts should exist in an individual having the cancerous diathesis, they may, in the same manner as a natural serous membrane, become the seat of any variety of carcinoma. But although carcinomatous tumours, such as those described by Dr. Hodgkin, are found in cysts, attached, single, or in groups, and covered by a reflected serous membrane, these tumours may, and frequently do, not originate in the cysts. They form in the cellular tissue external to the cysts, and during their developement project inwards, carrying before them as their common envelope the internal and serous lining of the latter. Such, in fact, is seen to be the origin of these tumours in most of the cysts represented by Dr. Hodgkin in the work referred to. They are situated external to the cyst, are supplied with vessels which do not belong to the cyst, and are placed in the same circumstances as tumours formed in the cellular tissue where no cyst is present.

As an objection to the general application of the cystic origin of tumours, it may be observed that there are numerous organs in which the presence of cysts is not to be detected at any period of the developement of carcinoma, and therefore, when they do occur in other organs, they must be looked upon as a mere coincidence, or as a consequence of the disease, and not as a cause or necessary condition of it.

After what we have just said on the cystic origin of carcinoma, it will not be expected that we shall do more than notice the theory which maintained that the formation of this disease depended on the previous existence of an accidental organization, which received the name of *hydatid*: how far such was the appellation it should have received must now be a matter of indifference.

Mr. Abernethy referred all adventitious formations to the coagulable part of the blood as their origin, and fixed their seat in the cellular tissue, in the parenchyma, and on the surface of organs. This plastic substance was supposed by him to be effused in one or other of these situations, to become organized, and to derive the materials of its subsequent growth from the vascular system of the surrounding parts.

According to Andral, the cellular tissue is in general the seat of carcinomatous formations; but, that as they depend on a modification of of secretion, they may form wherever this function is accomplished; the speciality of each being determined by a previous modification of the economy in general, or of the functions of nutrition, innervation, or hematosis in particular.

The only other opinion to which we shall allude regarding the seat and origin of these formations, considered in an anatomico-pathological point of view, is that of Cruveilhier. This pathologist regards all organic transformations and degenerations (as he calls them) as exclusively the result of the deposition of morbid products in the *cellular element* of organs. He believes that the *tissus propres* of organs are incapable of undergoing any organic lesion except hypertrophy and atrophy. Both these statements we have shewn to be

discordant with facts. The source whence these products are derived is, according to the same author, the venous capillary system, to which we formerly alluded, and we assigned a reason for their being found in these vessels, and especially in the venous trunks and their larger branches.

Physical characters of carcinoma.—The physical characters of this disease comprehend the form, bulk, colour, and consistence which it presents in the different tissues and organs of the body, and in the several periods of its developement.

Form.—Carcinoma presents considerable variety of form. In its first stage, and when the material of which it is composed is deposited after the manner of nutrition, carcinoma assumes the particular form or structure of the organ which it affects, as that of the liver and stomach, the acini of the former, and the muscular, cellular, and mucous tissues of the latter, determining in these organs respectively the primary form of the disease. In the brain, lymphatic glands, testes, we cannot, however, perceive any particular arrangement of the carcinomatous matter at this early stage, either on account of the colour, homogeneous aspect, or minute structure of these organs, preventing us from detecting its presence, and the manner in which it is deposited.

At a more advanced stage of the disease, the forms which the carcinomatous matter derives from the structure of the parts in which it is deposited disappear, and those which it afterwards presents are determined chiefly by external circumstances. The most important of these forms are the *tuberiform*, *stratiform*, and *ramiform*.

1. *Tuberiform* carcinomatous matter is by far the most frequent, and presents considerable variety. When this matter is deposited in organs possessing a uniform density, and in parts submitted on all sides to an equal degree of pressure, it assumes a globular form. Although at first globular, it becomes pyriform on natural and accidental serous surfaces, either on account of the mode of its attachment, or of less resistance being opposed to its growth in one direction than in another. It assumes a fungiform shape when placed in circumstances which facilitate its lateral, and retard its peripheric developement, as when it passes from a dense into a soft tissue, or escapes from beneath the skin to the surface of the body. It often presents a lobulated appearance when accumulated in separate portions of the cellular tissue into rounded masses, grouped together and included within a common capsule; and in the submucous tissue in particular it frequently exhibits the external arrangement of the cauliflower or mulberry. That appearance of carcinoma which resembles the structure of the pancreas depends generally on the agglomeration of very small globular or pyriform tumours, separated from one another by cellular or cellulo-fibrous tissue, but inclosed in a common capsule.

2. *Stratiform* carcinomatous matter is chiefly met with in the subserous cellular tissue. Although it may be deposited in layers of various extent, which present no definite arrangement, it more frequently assumes the form of thin circular patches, varying from the breadth of a pin's head to an inch or more in diameter, and presenting an appearance similar to what might be imagined to follow the infusion of a small quantity of milk into a number of isolated points of the subserous cellular tissue. Patches of this kind, which are composed of a substance having the colour and consistence of cream or milk, are most frequently met with beneath the pia mater and pleura pulmonalis, and are remarkably conspicuous in the latter situation, on account of their white pearly aspect contrasting so strongly with the surrounding dark colour of the lungs. These patches may occur in the situations we have named without the substance of the brain or lungs presenting any trace of carcinoma; but we have never met them unless when the disease existed in some other organ, as the breast, eye, liver, stomach, kidney, or uterus. In some cases, lymphatics filled with fluid carcinomatous matter are observed to communicate with the patches; in other cases no such vessels are observed.

3. We formerly alluded to the *ramiform* arrangement, when treating of the seat and mode of formation of carcinoma in the molecular structure of organs and in the blood. This arrangement, as well as the seat of the carcinomatous matter in the veins on which it depends, may readily be detected in the liver, where this matter is collected in the form of tumours of various sizes. When such tumours are divided and submitted to pressure, we can often perceive the carcinomatous matter issuing from a number of small circular orifices in the state of a creamy fluid; and if these orifices are attentively examined by a careful dissection of the tumour from its cut surface towards its circumference, we find that they are the cut extremities of veins filled with this matter to a greater or less extent beyond the tumour. But there is no organ in which the ramiform arrangement of the carcinomatous matter is so conspicuously seen as the kidney. The whole of the venous system of this organ, including the emulgent vein to its termination in the vena cava, is sometimes found completely distended with this matter, either in a fluid state, of the consistence of brain, or as firm as the pancreas. When the kidney thus affected is divided, it appears as if it were formed of a multitude of encysted tumours of various sizes, on account of the carcinomatous matter being contained within, and bounded by, the walls of the cut extremities of the veins. This form of carcinoma of the kidney is easily ascertained by dissection, or by the introduction of a probe from the emulgent vein into its branches.

A similar arrangement is also remarkably conspicuous in carcinoma of the stomach. Not only are the minute veins, which ramify beneath the mucous membrane in the vicinity of the disease, filled with the carcinomatous matter, but also the larger branches seen on the external surface of the stomach, and the coronary veins in which they terminate. The abdominal divi-

sion of the vena portæ furnishes us with a remarkable example of the ramiform arrangement of carcinoma, isolated from any organ affected with the disease.

There is another variety of form of the carcinomatous matter which may be noticed in this place, as it may be regarded as a modification of the preceding. It is that which is observed when this matter is contained in the lymphatics and lacteals, and which is derived from the particular form of these vessels. The lacteals, more frequently perhaps than the lymphatics, contain this matter, and are sometimes seen in great numbers quite filled with it on the surface of the stomach and intestines, and between the folds of the mesentery, in carcinoma of these organs.

Such are the principal forms of carcinoma, whether we consider the disease in a general or special point of view. They are certainly not equally prevalent, nor precisely the same in both species, viz. in scirrhoma and cephaloma, nor in the several varieties of each; but they are found to occur in all of them; and as the modifications which they present in this respect are very unimportant, it is not necessary to allude to them more particularly.

Bulk.—The quantity of the carcinomatous matter deposited in the molecular structure or on the free surface of organs is extremely various, but it is perhaps never so great in the former as in the latter. In the liver it may vary from the size of a pin's head to that of an orange. In softer or more yielding organs, as the lungs, testes, and even the mamma, it may equal in bulk the head of an infant or of an adult; and in the intermuscular and subcutaneous cellular tissue its bulk is sometimes still more considerable. We now speak of individual tumours, and not of those masses formed by the aggregation of tumours, during their progressive developement, as occurs in the liver, lungs, &c. nor of those produced in a similar manner in the abdominal cavity, posterior to the peritoneum, in carcinoma of the mesenteric glands.

The influence of pressure in favouring or retarding the developement of carcinomatous tumours, and consequently in modifying their bulk, is most conspicuously seen when they are situated near the external surface of the body. So long as their progress outwards is obstructed by an unyielding fibrous membrane, they often remain for a considerable time nearly stationary; but so soon as this obstacle is removed, they acquire a rapid increase of bulk. This rapid increase of bulk on the removal of all pressure is still more remarkable when these tumours project through the ulcerated integuments in the frightful form of bleeding fungi. But the best illustration of the influence of pressure on the developement of these tumours is met with in carcinoma of the eye. A tumour which may have required several months before it reached the external surface of this organ, will, after it has been removed, together with the whole contents of the orbit, reappear, and in the course of one or two weeks acquire a much greater bulk than before the operation.

Independently, however, of this physical circumstance, which modifies so conspicuously the bulk of these tumours, there is another of an opposite nature which requires to be particularly noticed on account of its constituting the distinctive character of the second species of carcinoma. We allude to the physiological properties of the cephalomatous tumours, by means of which they possess within themselves the power of increasing their developement to an almost unlimited extent. It is to the vascular organization, which we shall afterwards describe, of the tumours of this species that the rapidity of their growth and the great bulk which they attain are to be attributed, and which renders them less subject to the influence of pressure than those of the species scirrhoma. However, unless we were aware of the modifying influence of pressure, we should often be unable to explain why tumours possessing the same characters are subject to differences both as regards the rapidity of their developement and the bulk which they acquire.

Colour.—The colour of carcinoma differs greatly from that of any of the other adventitious formations. It is, therefore, a character of considerable importance, inasmuch as it frequently enables us to distinguish this disease from others of the same class; and we have already seen that it is chiefly by the same means that we are led to a knowledge of the seat and forms of carcinoma in the early stages of its formation. It is most frequently white, with a shade of grey or blue; sometimes it inclines to yellow, brown, or red, in consequence of the colour of the organs affected with the disease, of the presence of blood, bile, pus, or other fluids in various proportions, or of some other accidental circumstance. But the principal modifications of colour of carcinoma are seen in the several varieties of both species of the disease, these varieties, as we have already stated, resembling more or less in colour that of the organ or tissue whence have been derived their respective appellations; as that of cartilage, of the pancreas, of fresh boiled pork, of coagulated albumen or fibrine, of the mammary gland, of the substance of the brain, or a mixture of the latter and blood.

Consistence.—To none of the physical characters of carcinoma has so much importance been attached as to that of consistence, but more especially to an increased degree of this property when considered in relation either to the disease itself or the tissues of the affected organ. Hence the term *scirrhus*, which implies a state of induration, in consequence of its being frequently not only one of the first, but likewise one of the most marked changes which we are capable of perceiving in the affected organ, has been employed to characterize the early or occult stage of carcinoma. The opposite condition of carcinoma, that in which this disease presents a degree of consistence less than that of the organ which it affects, has been considered as a change succeeding to the state of induration or scirrhus, and the result of a process of softening; consequently, as indicating a more advanced period of the disease,

But the degree of consistence of the carcinomatous formations is not an invariable character of a particular stage of their development, for these formations may, when first perceivable, be as hard as cartilage, soft as brain, or fluid as cream; or they may become soft or fluid after having remained for a greater or less length of time in a state of hardness. This variety in the consistence of the carcinomatous formations depends on the following circumstances:—1st. the nature of the organ in which the carcinomatous deposit is contained; 2d. the elementary composition of the deposit; 3d. the subsequent changes occurring either in the deposit itself, or in the tissues with which it is in contact.

1st. The structure, situation, connexion, and greater or less density of organs and tissues, greatly modify the consistence of the carcinomatous deposit, either in consequence of a difference between the quantity of this substance relative to that of the tissues in which it is contained, or of a difference in the degree of resistance opposed by the latter to its accumulation or developement. Thus it is more consistent in the liver than in the lungs or brain; in the skin than in the cellular tissue or a mucous membrane; in a tumour situated beneath a dense covering than on a free surface.

2d. Modifications in the composition of the carcinomatous deposit exercise a considerable influence over the degree of consistence which it presents, for we often meet with it possessing various degrees of consistence, when examined at the same stage of its developement, and in the same or in different organs. Examples of this kind, although common in almost every organ of the body, are best seen where the deposit is collected into isolated masses containing little or none of the natural tissues, and where consequently its consistence must depend on the nature of the elements of which it is composed. It is found in this state in cellular tissue and in serous membranes, and more especially on accidental surfaces, such as those of sores formed by the destruction of the protruded portion of tumours, or after the removal of an external organ affected with carcinoma. In these situations this substance may, at the same stage of its formation, present the opposite extremes of consistence, being in one case as hard as cartilage and more or less transparent, and in another as soft as brain, or quite fluid and opaque. But these opposite extremes of consistence are most strikingly manifested in those fungiform tumours which arise from the bottom of the orbit after the extirpation of the eye, or from the cicatrix of the integuments after the removal of the breast in consequence of carcinoma. In these two instances it is obvious that the stage of developement of the tumours is the same in both; and that the difference of consistence which they present is no evidence of their being different in their nature is equally obvious, inasmuch as the hardest of them often assume, after a certain length of time, the consistence of the softest, a part or the whole of the dense transparent substance of which they are composed being gradually transformed into a soft, brain-like, pulpy mass. This process of transformation is also most conspicuous in those tumours which constitute the *vascular* or *organized* sarcoma of Mr. Abernethy. They are at first more or less transparent, presenting the appearance of a solid mass of albumen, coagulable lymph, or fibrine, but become gradually opaque, soft, and pulpy, resembling fœtal brain, and are then not to be distinguished from those carcinomatous tumours which, from their commencement, possess the cerebriform character. These examples will suffice to shew that the carcinomatous deposit, besides being modified in its consistence by the tissues in which it is contained, is equally so in consequence of a difference in its composition; that its consistence may or may not be the same when first formed; that it may be either hard or soft at this period; and, consequently, that the latter state is not necessarily preceded by the former, as was maintained by Laennec and the greater number of pathologists who have published on this subject since his time.

3d. The last modification of consistence of the carcinomatous formations is that to which the attention of pathologists has almost exclusively been directed. It depends on a series of changes taking place either in the carcinomatous matter itself, the tissues with which it is in contact, or in both at the same time. But in order that these changes may be more fully understood, we shall first describe the chemical and anatomical characters of carcinoma.

Chemical characters of carcinoma.—In order to ascertain the chemical composition of the several varieties of scirrhoma and cephaloma, it would be necessary to procure a sufficient quantity of the carcinomatous matter isolated from the tissues with which it is so frequently more or less intimately united or combined. The difficulty, and in many cases the impossibility of obtaining it in several of these varieties in a separate state, has prevented the pathologist from determining accurately its chemical composition. Indeed, the results of the analyses that have been published may be regarded as indicating the chemical composition of particular organs and tissues affected with carcinoma, rather than of the carcinomatous matter itself. The most recent analysis of carcinoma in the scirrhomatous and cephalomatous states, is that published by Lobstein in his "Traité d'Anatomie Pathologique." Seventy-two grains of scirrhous breast were found to contain—

Albumen	2 grains.
Gelatine	20
Fibrine	20
Fluid fatty matter	10
Water	20
	72

Seventy grains of the uterus in a state of scirrhus contained:—

Gelatine	15 grains.
Fibrine	10
Fatty matter	10
Water	35
	70

According to the same author, it would appear that the chemical composition of cephaloma is not the same at different periods of its developement. Thus in the first stage of the disease, or that of *crudity*, it was found to contain a greater proportion of gelatine than of albumen; and in the second stage, or that of softening, that is to say, when the carcinomatous matter is of the consistence of soft brain, the albumen is in much greater quantity than the gelatine.

For the reasons already stated, it must be obvious that no great importance can be attached to these results of the chemical analysis of the carcinomatous matter, and, independent of the difference of composition which it must present from its admixture, in various proportions, with the same or different tissues, it is highly probable that it is likewise modified, in this respect, by the physiological influence of the organ in which it is formed, and the constitution of the individual in whom it exists.

Anatomical characters of carcinoma.—We have already pointed out the most important circumstances illustrative of the anatomical characters of carcinoma, when treating of the specific divisions of the disease, its varieties of form, bulk, and consistence; its seat and mode of formation. We shall, therefore, now examine more especially the structure or anatomical arrangement of the carcinomatous matter itself.

We formerly stated that the carcinomatous matter may exist in two states; that in the first state it has little or no tendency to become organized, its form and arrangement being determined chiefly by external circumstances; and that in the second it exhibits a greater or less tendency to become organized, possessing in itself properties by means of which its form, arrangement, and developement are effected. The carcinomatous matter may, as we have seen, exist in three situations, viz. in the molecular structure of organs, on free surfaces, and in the blood. It is, perhaps, only in the two latter situations that we can submit it to minute anatomical investigation. When, therefore, we examine anatomically a mass of carcinomatous matter contained in a large vein, or situated on the surface of a serous membrane, in loose cellular tissue, on the surface of a sore or cicatrix after the removal of an organ affected with carcinoma, we find it composed of the following elements in various proportions, viz. carcinomatous matter; cellular, fibrous, and serous tissues; and bloodvessels.

The *carcinomatous matter*, whatever may be its consistence, almost always forms by far the greater bulk of the disease. If, however, its consistence be considerable, it generally presents a uniform, granular, or radiated, and, when soft, a lobulated arrangement. These three varieties are sometimes met with in the same tumour, and indicate the progressive developement of the disease, the radiated arrangement being seen at the basis, the uniform and the lobulated towards the circumference.

The *cellular tissue* is often small in quantity, and sometimes so fine and loose, as not to be perceptible till after the carcinomatous matter has been separated from it by pressure and maceration. It encloses that matter, separates it into granules, bundles, or lobules, intersects these in various directions, and serves to conduct the vessels which administer to the nutrition and growth of the disease.

The *fibrous tissue* is not often met with as an anatomical element of carcinoma in the situations in which we are now considering this disease. The *serous tissue*, on the contrary, is frequently present, and may form either a capsule to the carcinomatous substance, which is then said to be *encysted*, or give rise to the formation of cysts of various sizes, containing gelatinous, albuminous, or other fluids.

When the carcinomatous matter is deposited in the molecular structure instead of on the surface of organs, as we have just been considering it, the quantity of the cellular and fibrous tissues which intersect it in various directions is sometimes very considerable. In carcinoma of dense organs, such as the breast, uterus, ovaries, liver, walls of the stomach, &c., these tissues are also often very abundant. Indeed, in the early stage of carcinoma of these organs, a firm, pale, compact, cellulo-fibrous-looking tissue is not unfrequently the only anatomical element discoverable, and which on this account, and from the increase of bulk with which it is accompanied, has been described by Andral as *hypertrophy* of the cellular tissue, an appellation which does not appear to us to be warranted by analogy or by the changes which this tissue subsequently undergoes. For, hypertrophiated cellular tissue, such as we find in *elephantiasis Arabum* or *Barbadoes leg*, has no tendency to terminate in carcinoma; nor does hypertrophy of the heart from disease, or of the muscles of voluntary motion from frequent exercise, ever present any other change than that implied by this term, except a certain increase of consistence, generally in proportion to the increase of bulk which has taken place. Besides, admitting that a certain degree of hypertrophy may precede the presence of carcinoma, the facts which we have already brought forward in illustration of the mode of formation of the disease, its seat and origin, clearly show that no such change is necessary, inasmuch as all the varieties of carcinoma may form in situations in which the cellular tissue is either extremely small in quantity or does not at all exist. What, therefore, appears to be hypertrophiated cellular tissue must be regarded a tissue *sui generis*, produced by the uniform distribution and molecular deposition of the carcinomatous matter, either in the cellular tissue of an organ, or in an accidental tissue of a similar kind, formed at the same time, and deposited along with the carcinomatous matter. Such is, in fact, the manner in which the cellular and fibrous tissues which enter into the composition of the carcinomatous matter are generally formed. These tissues are most conspicuous in the early stage of the disease,

becoming gradually less apparent as it advances, and ultimately disappearing in consequence of their undergoing the carcinomatous transformation, or other changes which we shall afterwards describe.

The *bloodvessels* which enter into the composition of the carcinomatous matter vary greatly in number, and sometimes also in bulk. They are rarely perceptible in any of the varieties of scirrhoma; are generally few in number in the first and second varieties of cephaloma, or in the organized and mammary sarcoma of Abernethy; but in the last variety, or medullary sarcoma, they are often so numerous as to form the greater portion of the brain-like tumour in which they ramify. When these vessels are examined in cephaloma, they are found to vary in diameter from the breadth of a hair to a line, and present that peculiarity of distribution always more or less conspicuous in newly formed bloodvessels; that is to say, the ramifications of which they are composed communicate with a common trunk at its opposite extremities in the same manner as the hepatic and abdominal divisions of the vena portæ do with this vessel. They are frequently varicose, their walls are remarkably delicate, and they have altogether much more a venous than arterial character. They appear to be formed apart from the vascular system of the surrounding tissues, as they can be seen forming from small specks of blood situated at the centre or at the circumference of the carcinomatous mass, in the form of striæ, or slender streaks of blood, and gradually assuming a cylindrical arrangement and ramiform distribution, and thereby constituting what may be called the *proper circulation* of cephaloma. The communication which exists between these vessels and those of the organ in which the carcinomatous substance is contained, is frequently very imperfect,—a circumstance which, together with the delicacy of their structure, renders them extremely liable to congestion and rupture. The most minute divisions of these vessels terminate by penicillated extremities in the carcinomatous matter, where they communicate with veins and arteries belonging to the affected organ. The latter vessels, which may be said to form the *collateral circulation* of cephaloma, are seldom so numerous as the former, but there are cases in which they appear to constitute the greater part of the vascular structure of the disease. They proceed in a radiating direction, from the pedunculated attachment of a tumour for example, or arise along its circumference in the cellular tissue which separates it from the neighbouring parts. It is by means of these vessels that the materials required for the nutrition and growth of such tumours are supplied; and, as we shall afterwards see, the partial or even complete destruction of these and other tumours similarly situated, is occasioned by causes which interrupt this their collateral circulation.

The bloodvessels which are seen in scirrhoma appear to be no other than branches of those which belong to the neighbouring tissues, and which have become inclosed within the substance of which its several varieties are composed.

Physiological characters of carcinoma.—The anatomical characters just described are the most unequivocal circumstances by means of which we are enabled to perceive the existence and estimate the degree of those properties termed vital or physiological which manifest themselves during the developement of carcinoma. But it is more especially the formation of cellular tissue and bloodvessels in the carcinomatous matter which shows it to be in possession of these properties. We have already seen that the functions of circulation and nutrition are actively carried on in the carcinomatous matter. Of these functions that of circulation is far the most important, inasmuch as many of the more remarkable phenomena which present themselves during the progress of carcinomatous formations depend on changes which take place either in the proper or collateral circulation which we have described. Thus, the quantity of blood contained in a carcinomatous tumour, and consequently various shades of colour of the substance of which it is composed, will depend much on the degree of facility with which the circulation is performed in either or both systems of vessels. An imperfect communication between these vessels, owing to the manner in which they are connected, or the presence of a mechanical obstacle in the situation of the collateral veins preventing the return of the venous blood, frequently gives rise to congestion of the whole or a portion of a carcinomatous tumour, the colour of which becomes more or less red, purple, brown, or black. The congestion thus produced may be such as to give rise to rupture of the vessels, and internal or external hemorrhage. In the former case the carcinomatous substance, when situated externally in the form of a tumour, is seen to acquire a rapid increase of bulk, proportioned to the extent of the effusion, and, when examined afterwards, is found to be infiltrated with blood, or broken down and mixed with clots of this fluid, and irregular masses or layers of fibrine, thereby producing, when the tumour possesses the cerebriform character, appearances very similar to those observed in cerebral apoplexy from sanguineous effusion. If the obstacle interrupt entirely the circulation in the tumour, nutrition ceases, and death ensues in all those parts of it from which the obstructed vessels proceeded. The termination of carcinoma in mortification from obliteration of veins is far from being a rare occurrence. It sometimes occurs in whole tumours, but is most frequently observed in portions of them, or in some of the small tumours of which larger ones are frequently composed, that are attached by narrow pedunculated extremities. The unequal developement of one of these small tumours may give rise to compression of a neighbouring one; or the tissue to which they are attached may, from its unyielding nature, act as a ligature on their pedunculated extremities, and intercept the return of the venous blood through them. The same thing

sometimes happens to tumours that have perforated fasciæ or even the skin. The protruding portion, now relieved from the pressure to which it was before subjected, increases rapidly in bulk; but the dimensions of the opening remaining the same, very soon exercise a degree of constriction which arrests the circulation through the vessels of the neck of the tumour, and it dies and sloughs.

Changes of a similar kind result likewise from the presence of the carcinomatous matter acting as a stimulus, and exciting various degrees of congestion. In consequence of the congestion thus produced, and the modification of nutrition which necessarily follows, softening takes place, not only of the carcinomatous substance, but likewise of the tissues which enter into its composition. Softening of this kind is sometimes effected with great rapidity, and tumours which before felt firm or even hard, acquire a soft, pulpy feel, and, when laid open, are found to contain a fluid of the consistence of cream intermixed with shreds of cellular tissue, detached bloodvessels, blood, and sometimes pus. This process of softening is frequently seen taking place in carcinomatous tumours that have perforated the skin, and, when considered in connexion with the state of the circulation which has given rise to it, enables us to explain the peculiar appearance of those frightful solutions of continuity by which it is followed, such as their projecting everted edges, and rugged central excavation. It is well known that it is the most projecting part of a tumour situated beneath the skin in which a solution of continuity commences, and the reason of this is, that it is here the circulation is first arrested from the greater degree of compression to which the bloodvessels are subjected, together with the increased influx of blood caused by a greater degree of excitement. The most elevated portion of the skin becomes atrophiated during the first stage of compression and irritation, that is, when the circulation of the blood through it is only impeded; but so soon as this all-important function has ceased, which is announced by a change of colour from bright to dark-red, purple or black, and a diminution of sensibility and temperature, it begins to soften, soon sloughs, and exposes the subjacent portion of the tumour whose circulation had been similarly modified, softened, and deprived of its vitality to a greater or less depth. The edges of the solution of continuity of the skin when first formed are sharp and irregular; they are not *everted;* they are, on the contrary, sometimes *inverted;* and their thickness is in proportion to the depth of the slough. The peculiarity of form assigned to them is produced by the subsequent development of the carcinomatous substance situated beneath them, which, being entirely freed from pressure all round their internal margin, necessarily projects forward, as it grows, towards the centre of the tumour hollowed out by the softening and sloughing process, and, consequently, carries them gradually upwards and backwards. They acquire at the same time a great accession of bulk, and form a rounded undulating border beneath which the skin is found doubled upon itself, encircling the carcinomatous excavation.

All these changes, viz. congestion, hemorrhage, softening and sloughing, which we have described, take place in both species of carcinoma. In scirrhoma, however, they originate in the vascular system of the tissues included within the carcinomatous substance, but are not on that account less frequent and destructive than those which arise in the proper and collateral circulation in cephaloma. In general the softening is less complete, the hemorrhage not so considerable, and the sloughing more extensive in the former than in the latter.

Softening may take place in any portion of a carcinomatous tumour, although it has been maintained that the central portion is the primary seat of this change. Instead of being softer, the centre of the tumour is often much harder than any other portion of it. In such cases it consists of a nucleus of firm, grey, semitransparent substance and obliterated bloodvessels, forming a central depression, around which the rest of the tumour presents a radiating structure. The depression is not observed unless when the tumour is divided, or is situated on the surface of an organ, as the liver, where tumours of this kind are generally met with. In the former case the depression arises in consequence of the softer substance, after the division of the tumour, raising itself by its elasticity above the unyielding nucleus; in the latter it is produced by the peritoneum adhering to the surface of the tumour when small, and preventing its developement in that direction. If the tumour does not come in contact with the peritoneum until it has acquired a considerable size, it presents no such depression, or only a very small one. Hence the reason why, in carcinoma of the liver, we meet with some tumours having a smooth globular surface, and others with a central depression of greater or less extent.

Nerves have never been detected in any of the varieties of carcinoma as a *new formation.* They are sometimes included within agglomerated tumours, or even in a single tumour that has happened to form in a situation through which they pass. It is on this account that some pathologists have supposed the carcinomatous matter to be supplied with nerves; and M. Maunoir of Geneva* hazarded the opinion that cephaloma, no doubt from its frequently resembling the substance of the brain, is in reality this substance effused by the nerves when under the influence of some peculiar morbid state; an opinion to the accuracy of which the facts related in the preceding pages do not leave even the semblance of probability.

The last circumstance connected with the pathological anatomy of carcinoma to which we shall allude, is the developement of the subcutaneous venous system sometimes so

* Loc. cit.

conspicuous when the disease affects the breast in the form of a tumour, or any other external part where the skin is capable of considerable extension. The dilated and varicose state of these veins is simply the consequence of the mechanical obstacle occasioned by the tumour to the venous circulation in its vicinity, and not the result of any special influence exercised by the disease. It is produced by tumours of every description, similarly situated,—fatty tumours and even cysts, and cannot therefore be considered as furnishing any evidence of the existence of carcinoma in particular.

The great difficulty generally experienced by physicians in distinguishing carcinoma under the various forms which it presents in the different stages of its developement, and in different organs of the body, will, we trust, furnish a sufficient excuse for our having given such a lengthened description of what strictly relates to the anatomy of the disease. If we have not succeeded in conveying a clear impression of this part of our subject, much assistance may be derived by consulting the coloured plates of the second and third fasciculi of the author's work on the Elementary Forms of Disease.

Local and other relations of carcinoma.—There are *no organs*, and *few tissues*, which may not become affected with carcinoma. Among the former, the stomach, liver, uterus, breast, and testes, are *much more frequently* the seat of the disease than any of the other organs of the body. It is also worthy of remark that it is met with more frequently in certain portions of organs and systems than in others. Thus, when it affects the uterus, it is almost always the os tincæ in which it commences; in the stomach it is much more frequently the pyloric than the cardiac orifice; it much more often affects the stomach than the œsophagus or intestines; the large than the small intestines. In the latter it is rarely met with, and perhaps only in the duodenum and commencement of the jejunum; and in the former it is exclusively confined to the rectum, sigmoid flexure of the colon and ileo-cœcal valve, unless when propagated from a neighbouring organ by contiguity of tissue.

If we pass in review the several tissues subject to carcinoma, we find that the cellular is infinitely more so than any of the other tissues in which the disease occurs, although we have proved that it is far from being so frequently the primary seat of the disease as was, and still is, generally believed. The mucous and cutaneous tissues are the next in the order of frequency, and lastly the osseous, venous, and arterial. We have never observed the disease in cartilage, tendon, or ligament; but we have shown, when treating of the mode of its formation in the stomach, that, contrary to the general opinion, the muscular tissue of this organ is frequently the seat of it.

The number of organs that may become affected with carcinoma in the same individual varies considerably. In some cases there may be only one organ or tissue affected with the disease, as the stomach, intestines, œsophagus, liver, lungs, kidney, uterus, testis, breast, brain, eye, tongue, chin, cellular tissue, lymphatic glands, bone, capillaries, and veins. In other cases it may be found in a great many organs and tissues in various stages of its progress. It is seldom that double organs, such as both eyes, the mammæ, testes, or kidneys, are affected at the same time. We have never met with carcinoma of the pancreas, muscular, venous, and arterial tissues, serous, mucous, and fibrous membranes, without the disease being present in a neighbouring organ or tissue, and from which it was communicated to the former.

The greater liability of some organs and tissues than others to become affected with carcinoma is a circumstance of considerable practical importance. So, likewise, is its occurrence as a primary and secondary affection. In this latter respect the disease may be *secondary* only as regards the *order of its appearance*, the same morbid condition of the economy which gave rise to it in one organ giving rise to it in the others, which become successively affected; or it may be secondary in one organ in consequence of the *intimate physiological connexion* existing between it and another previously affected; and, lastly, it may be secondary from *mere contiguity* of tissue.

In the first case the secondary appearance of the disease is recognised partly by the extent which it occupies, and partly by the physical and anatomical characters which it presents in the different organs in which it is present. By the same means, and more especially in consequence of two or more organs being found to be much more frequently than others affected with the disease, we infer that its propagation in the former is influenced by the intimate physiological connexion which is known to exist between them, as is exemplified in carcinoma of the uterus and mammæ, and of the liver and stomach succeeding to each other. The secondary production of carcinoma from contiguity of tissue, whether of a similar or dissimilar kind, is frequently observed; such as the gradual extension of the disease from the walls of the stomach to those of the intestines, and from the latter to the parietes of the abdomen; from the stomach to the liver; from the uterus to the bladder or rectum, and *vice versâ*. But in all these cases the contiguous tissues and organs become united or continuous before the disease passes from the one to the other, which is then propagated by the gradual molecular deposition of the carcinomatous matter, in the same manner as we see it accomplished in the skin during the ulcerative stage of the disease.

An opinion very different from that we have now given respecting the secondary production of carcinoma has long been entertained, chiefly by surgeons. Finding, as they frequently must have done, cancer in an internal organ which had given no signs of its presence until after it had existed for a greater or less length of time in some external part, they considered the production of the disease in the former situation to be subsequent to that in the latter,

and to arise in consequence of the absorption of a specific virus from the supposed primary disease, and its transmission into the system. This opinion was strengthened by the fact that symptoms of cancer of an internal organ frequently make their appearance soon after the breast, testicle, or other external part has been removed by a surgical operation, and was considered as fully confirmed by another fact, viz. that the lymphatic glands situated in the vicinity of a cancerous tumour or ulcer are seen to become affected during the progress of the primary disease. We shall only remark with regard to this view of the secondary production of carcinoma, that the facts adduced are far from justifying the application which has been made of them; for they furnish no proof that the occurrence of the disease internally, at any period subsequent to its existence externally, may not depend on the same morbid condition of the economy producing its effects successively or simultaneously, in a greater or less number of organs, inasmuch as we know that carcinomatous tumours may exist for a considerable period, even in the most important of the internal organs, without giving rise to any appreciable modification of function calculated to lead to their detection. Hence, under whatever circumstances the signs of carcinoma may present themselves for the first time in an internal organ, we cannot determine either the length of time it may have existed, or the relative order of its succession. Besides, the extension, as it is called, of carcinoma from the breast or testis, for example, to the neighbouring lymphatic glands, affords no proof that it takes place through the medium of absorption; for we have found these glands in the axilla, and in the lumbar region, extensively diseased in carcinoma of the breast and testis, without any of the carcinomatous matter of which all these were composed being visible in the lymphatic vessels passing from the one to the other. The more natural explanation of the occurrence of the disease in these glands in such cases is, that, being subjected to the irritation which accompanies the latter stage of the disease, (the period at which the lymphatic glands are generally observed to become affected,) they become the seat of congestion, and, as we have already endeavoured to shew, the material element of carcinoma being contained in the blood, it is separated from this fluid and deposited in their substance.

We are, however, well aware that there are cases in which this matter is absorbed and accumulates in the lymphatic glands; but from the circumstance just stated, and from the fact already noticed that these glands may be the only organs in the body in which, after the most careful examination, the disease is found to exist, we are surely not entitled to say that they are always secondarily affected, whatever signification we may attach to this term. We have seen several instances of cephalomatous tumours formed exclusively in the mesenteric glands and abdominal lymphatic glands; and in one case the latter glands of the principal regions of the body, on both sides of the neck and under the jaws, in the axillæ and groins, in the chest and abdomen, were extensively affected with the disease, and forming tumours varying from the size of a cherry to that of an egg. The spleen was the only other organ which presented any trace of the disease.

Carcinoma is a disease which is far from being equally frequent at the *different periods of life*. It is observed to make its appearance most frequently in the male from between thirty to forty or fifty years of age, and in the female after the cessation of the menstrual discharge, than at any other period of life. It is also on account of the more complicated nature of the organs of reproduction in females that they are more subject to the disease, generally considered, than males; for the uterus and mammæ are the organs which, in the former, are most frequently the seat of the disease. In the latter it rarely makes its appearance in the breast, and not so frequently in the testes as in the uterus. The stomach and liver are, according to our own observations, the most frequent seat of the disease in males, although these organs are, perhaps, equally so in females. The tongue, and especially the lips, are often affected in the former and rarely in the latter. It is also worthy of remark that from childhood up to the age of puberty, and even to twenty or twenty-five years of age, we seldom meet carcinoma unless in particular organs or regions of the body. Thus it is chiefly the lymphatic and mesenteric glands, the great joints, as the elbow and knee joints, the brain, and cellular tissue, where it is considerable in quantity; whereas the stomach, intestines, uterus, and mammæ are almost exempt from the disease till a later period of life. And it is interesting to observe that the exceptions to its non-occurrence in these latter organs within the period alluded to are met with in such of them only the exercise of whose functions are susceptible of being prematurely and preternaturally excited, particularly the testes and ovaries.

These remarks on the relative frequency of carcinoma under the circumstances of age and sex apply to the disease generally, and not to both species and their varieties; for while scirrhoma is rarely met with within the period which we have specified, cephaloma is of frequent occurrence, and seldom proceeds to such an extent or with such rapidity in advanced as in early life; a circumstance which may probably depend on the greater activity of nutrition and the more plastic quality of the blood in the latter than in the former condition of life; and thus also a corresponding character may be given to the morbid products which manifest themselves in each.

The frequency of carcinoma is said to be considerably influenced by *temperament*. Thus out of forty-four cases of the disease in which the original temperament was sufficiently characterised, Breschet and Ferrus found the lymphatic to prevail twenty times, the sanguineous twelve, the bilious eight, and the nervous two; and in almost all the patients submitted to their observations, the lymphatic temperament had

acquired a marked predominance during the progress of the disease.*

The observation of carcinoma in individuals of different *habits* and *modes* of life submitted to the influence of various external agents arising out of locality, profession, or climate; in the married and unmarried; in women who have or who have not had children; in the poor and wealthy; in the temperate and debauched, &c. &c. has not led to very satisfactory results regarding the relative frequency of the disease. It is, however, said that it is as rare in peasants and country-people in general, as it is common among the inhabitants of large cities; and that it is more frequent in the lower and higher than in the middle classes of society.

Causes and nature of carcinoma.—The observations which we have made on the relative frequency of carcinoma as to age, sex, temperament, and condition of life, contain the greatest part of what we have to say on the *predisposing* causes of the disease. Among these have long been enumerated the frequent and direct operation of irritating substances; external injuries, especially blows; the abuse of stimulating potions; immoderate indulgence in venery; the depressing influence of moral afflictions; bad food, conjoined with the debilitating effects of cold and otherwise unhealthy habitations; the injurious influence of one or more of these predisposing causes on particular organs being determined or modified by the individual or accidental circumstances of the case. The frequent occurrence, however, of carcinoma in individuals in whom none of these predisposing causes seem to have co-operated in the production of the disease, as well as its non-occurrence in many who have been subjected to the influence of these causes, has led many pathologists to consider it as having an hereditary origin. They believe that the *germ* of the malady, or *cancerous virus*, is transmitted from the parent to his offspring, and cite, in favour of their opinion, the occurrence of the disease in several members of the same family. This opinion, however, has few advocates, particularly since Alibert,† Biett, and Dupuytren‡ have shown that the carcinomatous matter may be introduced in the form of inoculation into the digestive organs, the serous cavities or veins, without giving rise to the disease; experiments, it may be remarked *en passant*, to which no more importance can be attached than to the fact that the disease may occur in several individuals of the same family. A more generally received opinion, and one much more in accordance with the results of accurate observation, is, that the manifestation of the disease is at all times, and under all circumstances, dependent on the previous existence of a peculiar state of the constitution, either congenital or acquired, termed *diathesis*. The evidence on which this opinion rests we have in great part already exposed when treating of the seat, local origin, and mode of formation of carcinoma. We have shown that the material element of the disease—without which it can have no existence—is contained in the blood, is separated from this fluid after the manner of nutrition or secretion, either in the molecular structure, or on the free surface, of organs; and that, while the formation of the disease is thus going on, there may be no appreciable, physical, or physiological modification of the part in which it is observed. It is thus that we meet with carcinomatous tumours in the brain, which, from their bulk and other characters, must have existed long before the functional disturbance of the organ gave signs of their presence; and we have an equally striking example of the silent developement of these tumours in the eye, until, acting simply as a foreign body, they obstruct the rays of light, and render vision more or less imperfect. In persons, too, apparently in the enjoyment of the most perfect health, we often see the disease making its appearance in the form of a small pimple, proceeding more or less rapidly in its course, extending in breadth and in depth, and terminating ultimately in death, in spite of all the means which art has devised. In others, a similar pimple arises under similar, or even unfavourable, circumstances, proceeds like the former to ulceration; and although it may have been neglected, irritated, and excited from time to time, and maltreated in every possible way, disappears, and leaves the patient in perfect health. There is, indeed, no form of inflammation which may not exist for any definite length of time, and in every organ of the body, without being followed by carcinoma. Of the truth of this position every candid inquirer must be fully aware, although it is still attempted to support the unphilosophical theory which maintains that this disease is always preceded by chronic inflammation. It would, however, be a great practical error were we to overlook the influence of this pathological state on a constitution predisposed to carcinoma; for this disease does make its appearance in organs which we have every reason to believe would not have become affected with it, had they not been previously modified by the former. We must, therefore, conclude that, if carcinoma makes its appearance in individuals however they may have been placed in regard to the operation of what are called predisposing and exciting causes, there must be present in such individuals a peculiar condition or disposition of body, previous to the manifestation of the disease. In what this disposition consists, we are entirely ignorant. Its very existence is made known to us only by means of the peculiar characters of the products to which it gives rise. We have certainly seen that the great function of nutrition is that which is more especially affected, and that, as the material element of carcinoma is contained in the blood, it is highly probable that a modification of this fluid constitutes the primary if not the essential condition of the formation of the disease. But, unacquainted

* Dict. de Méd. t. iv. art. *Cancer.*
† Description des Maladies de la Peau, p. 118.
‡ Dict. des Sciences Médicales, t. iii. p. 677.

as we are with the nature of nutrition as a physiological function, we can offer no explanation of the nature of the change effected in the blood, nor, consequently, of the nature of carcinoma. It is, however, an interesting fact,—the result of our anatomical researches in particular,—that, as carcinomatous formations derive the materials of which they are composed from the blood, instead of their being local *transformations* or *degenerations* of pre-existing tissues, they do not, in this point of view, form an exception to the law, viz. that the natural and healthy solids, as well as the fluids of secretion, derive also their respective materials from the same source; and, therefore, we are led to hope that a more intimate knowledge of the manner in which these two functions are performed will enable us, at some future period, to determine the nature of a disease which hitherto has only been rendered more obscure by the attempts which have been made to explain it.

Symptoms of carcinoma.—Considered in a general point of view, the symptoms of carcinoma refer to changes taking place during the progress of the disease, as they occur in the carcinomatous substance itself, in the organs in which it is contained, and in remote organs or the constitution generally. The symptoms are therefore local or general. The former are referable to changes in the bulk, consistence, form, colour, temperature, sensibility, circulation, nutrition, and special functions of the organ affected; the latter to changes in the functions of circulation, nutrition, and innervation in general. Both series of phenomena are greatly modified by the seat, stage, or period of the disease. They present also marked differences in the two species of carcinoma, those observed in the first species being often absent in the second; or, being present in the former from the commencement, either do not occur in the latter at all, or only towards its termination. We shall pass in review the *local* and *general* phenomena which accompany the presence of carcinoma in those organs the diseases of which belong more especially to the province of medicine.

Local symptoms.—Few of the changes to which we have referred the *local* symptoms of carcinoma are discoverable in internal organs, and all of them may be absent in the early stage of the disease. Changes in the *colour*, *temperature*, *circulation*, and *nutrition* of the affected organ, cannot be detected by direct observation; and those of *bulk*, *consistence*, and *form*, can be determined only in certain organs, and at a more or less advanced period of the disease, such as the stomach and intestines, liver, spleen, kidneys, ovaries and uterus, lungs, and mesenteric glands; in all of which organs these changes may be recognized either by the touch, percussion, or auscultation. But it is more particularly the change of bulk which is detected by these means, and which, as a local symptom of the presence of carcinoma, is that to which the greatest importance is to be attached. The increase of bulk which accompanies the presence of carcinoma is not perceptible till the disease has made some progress. It is most considerable in solid organs, such as the liver, kidney, ovary, &c., and is seldom very marked in hollow organs, such as the stomach or intestines. Considerable increase of bulk may, however, have taken place in the walls of the stomach and intestines, without our being able to detect its presence, which happens when the carcinomatous matter accumulates in the direction of the internal surface of these organs. In such cases an increase of bulk of a different kind is produced, viz. dilatation, in consequence of the obstacle presented by the carcinomatous matter to the passage of the food or fæces. When dilatation of the stomach is thus produced, the obstacle is situated at the pylorus; when of the small intestines, it is, in the great majority of cases, situated at the termination of the duodenum or commencement of the jejunum, and caput cœcum coli; and at the sigmoid flexure of the colon and rectum, when the dilatation occupies the large intestines. The increase of bulk which the stomach and intestines acquire in consequence of an obstacle of this kind is sometimes very great. In some cases of scirrhous pylorus, the stomach has been found to occupy the greater part of the abdominal cavity, stretching down to the symphysis of the pubis, and from one lumbar region to the other; and the large intestines sometimes measure from four to six inches in diameter, when similarly affected. We have seen the small intestines equal in size to the ordinary dimensions of the stomach. It is important to know that the extent of the dilatation is not to be taken as the measure of the extent of the disease. The greater the dilatation the greater we may infer is the obstacle by which it is occasioned; but this obstacle may consist in a slight scirrhous enlargement, which prevents the passage of the food or fæces as effectually as when it is occasioned by one or more tumours of considerable size or great thickening occupying several inches in length of the whole circumference of the walls of the stomach and intestines.

There are two circumstances connected with the dilatation of these organs from carcinoma which merit particular notice. The first is the *disappearance* of the dilatation at a particular period of the disease. This may happen a considerable time after the dilatation was first perceived, and is the consequence of the destruction of the carcinomatous substance from softening, ulceration, or sloughing. The obstacle being thus removed, a free passage is opened to the accumulated contents of the stomach and intestines, and the dilated walls of these organs are allowed to contract, and in some instances regain their natural dimensions. The second circumstance is the *reoccurrence* of the dilatation, which we have observed to take place only in the intestines. It does not occur, unless the mucous and muscular coats have been destroyed by ulceration, after the destruction of the carcinomatous substance, and not until cicatrization has commenced. The cicatrix being formed of

cellulo-fibrous tissue, contracts and produces stricture of the intestine. The passage of the fæces is again obstructed, and the intestine acquires an increase of bulk much greater than before the destruction and removal of the carcinomatous substance. We shall again allude to these changes in bulk when speaking of the modifications of function, and the diagnosis of carcinoma in the digestive organs.

The increase of bulk which accompanies carcinoma of the liver is often very considerable. Cases have been met with in which the left lobe of the liver extended into the left hypochondrium, and the right down to the iliac fossa on the same side. It is always produced in this organ by the accumulation of the carcinomatous matter in the form of tumours, which may often be felt projecting above its surface. It is chiefly from this latter circumstance that we are enabled to detect carcinoma of the liver. It is, however, necessary that the tumours should occupy the convex surface of the liver, and that this organ should project beyond the false ribs.

In one instance only have we found the spleen, when affected with carcinoma, much increased in size; it was nearly six times larger than natural. We have also found the kidney enlarged to the same extent in a young person, but it is seldom more than twice its natural size in this disease. Carcinoma of the uterus is not accompanied by any perceptible increase of bulk, unless examined *per vaginam*, when, in the early stage of the disease, the os uteri is found enlarged and projecting into the vagina. The ovaries acquire the size of the fist or even of the head of a child, but never become so large as when they are the seat of dropsy, or contain fibrous tumours. We have never seen the bulk of the lungs so increased by the presence of the carcinomatous deposit as to give rise to dilatation of the walls of the chest. We have already noticed the great increase of bulk which accompanies carcinoma of the mesenteric and lymphatic glands.

The only modification of the *sensibility* which, as a local symptom, accompanies carcinoma, is that of pain. There is, however, no symptom of carcinoma more deceptive than pain. The importance attached to it, more particularly when it possesses a *lancinating* character, must have originated in the study of the disease in external parts of the body, as the face, breast, or the skin and subjacent tissues in general; for there are several organs in which the pain is either very slight or seldom acquires the lancinating character ascribed to it: such is the case in carcinoma of the liver, spleen, kidneys, ovaries, stomach and intestines, (with the exception of the rectum,) the mesenteric glands, and even the brain. It is also to be remembered that pains, described by patients as lancinating, may occur without any trace of carcinoma being found in the organs to which they are referred.

Of all the varieties of carcinoma, it is that of scirrhus which is most frequently accompanied with pain; and it is also in this variety that the pain is most severe, acute, and lancinating. In medullary sarcoma this symptom is less frequent and severe than in any of the other varieties. But it is not according to the several varieties of carcinoma that we are to form an estimate either of the frequency or severity of the pain. For this symptom may, in both these respects, be said to vary with the degree of induration of the carcinomatous substance; of the distension or compression, and of irritation to which this substance gives rise in the neighbouring tissues. Under the influence of the two former of these conditions, pain would seem to result from compression of the nerves which happen to be included within the dense carcinomatous substance, or that are distributed in its immediate vicinity. Pain from irritation may also be produced under similar circumstances, but it is much more frequently when softening and sloughing of the carcinomatous substance, and ulceration of the neighbouring tissues, have taken place, that pain from this cause makes its appearance, and acquires a degree of severity which gives rise to the most intolerable suffering. It is in this stage of the disease that pain occurs in internal organs, in consequence of the extension of the irritation to the nerves of sensation.

The pain may be intermittent, remittent, and continued, whatever may be the organ affected with carcinoma. The intermittent character is most frequently observed during the early stage of the disease; and the remittent and continued during the progress of softening, sloughing, and ulceration. Numerous circumstances concur to produce these varieties in the duration of the pain in carcinoma; but in the great majority of cases they appear to depend on varying and opposite states of the sensibility and circulation of the affected organs. For we know that the direct application of those means which increase the sensibility and circulation excite, in an organ affected with carcinoma, pain when absent, and increase it when present; whilst those remedies which are known to diminish the sensibility and the action of the vascular system, effect also a diminution or an entire cessation of the pain in this disease.

The symptoms which depend on the *modifications of the functions of organs* affected with carcinoma, are far from being so conspicuous as the fatal character of the disease would lead us to suppose. We allude to the *special* modifications of function observed in carcinoma of internal organs. Before taking a general view of these modifications of function, we may remark that there is not one of them which may not be found to accompany other diseases than carcinoma. They nevertheless require to be studied with great care, because of the effects to which they give rise being sometimes more intolerable than the disease itself, and requiring a separate mode of treatment.

The modifications which are observed to occur in the special functions of organs, present great variety not only in different organs, but also in the same organ, according to the stage, extent, and situation of the disease. Thus the function of digestion is not so frequently

disturbed in the early as in a more advanced stage of the disease, nor is the disturbance so great in the former as in the latter case. This difference in the effects of carcinoma on the function of digestion may be explained on the following principles, viz. that the carcinomatous substance, when first deposited, acts merely mechanically, and therefore does not interfere with the function of digestion, unless it occupies a great extent of the walls of the stomach, or prevents the egress of the digested food; whereas during its subsequent developement, this substance undergoes those changes which we have already described, viz. softening, sloughing, and ulceration. The absence of irritation in the former case, and its presence in the latter, furnishes an obvious reason why digestion is seldom disturbed in the one case, and more frequently and to a greater degree in the other. The influence of carcinoma as to extent and situation, over the function of digestion, is very great. A carcinomatous tumour of from three to four inches in diameter, and projecting from one to two inches above the mucous membrane of the stomach, if situated at the small or large curvature, may be unaccompanied by but a very slight derangement of the function of digestion; whereas a tumour not larger than a filbert situated at the pyloric orifice, may disturb this function to an extreme degree. It is, indeed, very often in consequence of the mechanical operation of carcinoma preventing the egress of the food or chyme, that we are first led to detect disorder of the function of digestion, and to suspect the nature of the disease on which it depends. In such cases more or less of the digested food is retained; the succeeding meal is partially or imperfectly digested; the stomach becomes distended, and being irritated by the continual contact of its contents, rendered more stimulating by decomposition or fermentation, contracts forcibly, and they are rejected by vomiting. Vomiting is an invariable consequence of carcinoma of the pylorus, accompanied with a diminution of bulk of the orifice of this part sufficient to interrupt or impede the exit of the chyme or indigested food. Perhaps the most frequent cause of vomiting is the mechanical obstacle occasioned by the carcinomatous substance in the pyloric portion of the stomach. This modification of the function of the stomach as a mechanical effect, we have never observed in carcinoma of any other portion of this organ. Vomiting, however, frequently occurs, whatever may be the situation of the disease, in consequence of the irritation which accompanies the softening process, and the ulceration by which it is followed. Vomiting from irritation may, in general, be distinguished from that occasioned by a mechanical obstacle situated at the pylorus. The former takes place however small the quantity of fluid taken into the stomach; the latter, only when the quantity is considerable. Vomiting from irritation is sudden, and accompanied by a disagreeable or painful effort; that from a mechanical obstacle gradual, and instead of being accompanied by pain, frequently affords relief from this state or a considerable degree of uneasiness. It is in this case a kind of passive act, the consequence of the great dilatation of the stomach, and sometimes of the inferior portion of the œsophagus also. The presence of dilatation of the stomach, which is easily detected by percussion, will enable us to distinguish vomiting from a mechanical obstacle from that occasioned by irritation.

The periodical character of vomiting is, in the great majority of cases of carcinoma of the stomach, to be attributed to the presence of a mechanical obstacle at the pylorus. The vomiting occurs at certain intervals, which vary with the extent of the obstacle, the quantity and kind of food taken, and other necessary and accidental circumstances, as the susceptibility of the patient and the state of those organs which exercise a sympathetic influence on the function of digestion. In some cases of this kind, the vomiting, after having continued for several weeks or months, disappears for a considerable time before it recommences, and in other cases ceases entirely. We have met with examples of both cases, referable to opposite physical conditions of the pyloric orifice. In both cases the vomiting depended on the pyloric orifice being obstructed by thickening of its walls, or the presence of projecting or pendulous tumours; and the partial or permanent cessation of this symptom, to the patency of this orifice being restored, in consequence of the destruction of the carcinomatous substance. The return of the vomiting in the former case was owing to the return of the disease in such a form as to obstruct anew the exit of the contents of the stomach; and in the latter, the entire cessation of this symptom was to be attributed to the progressive extension of the ulcerative and sloughing processes, and, consequently, the complete removal of the obstructing cause.

The *quantity* and *quality* of the matters vomited are variable. Both will be modified by the quantity and quality of the food and drink; the former by the capacity of the stomach, and the absence or presence of irritation; the latter by the nature of the ingesta, the state of digestion, and the stage and variety of the disease. It is only at the early stage of carcinoma, or at least before softening and ulceration have taken place, that the vomiting consists of a watery or mucous secretion. At a more advanced stage, the rejected food is less altered by the digestive process than before, and is often accompanied by a quantity of gas of a disagreeable odour. In the great majority of cases, and always towards the termination of the disease, the contents of the stomach rejected by vomiting contain a substance resembling the lees of wine, a mixture of chocolate, or soot and water. This substance may appear in the form of little particles, patches, or streaks, among the other matters vomited, or it may be in such quantity as to give to the whole contents of the stomach a deep brown or black colour. Its appearance always indicates the effusion of blood into the cavity of the stomach from hemorrhage, either in consequence of the softening of the carcino-

matous substance, or the sloughing of this substance and of the contiguous parts. It is on this account regarded as a fatal symptom, and as indicating the speedy termination of the disease. (The cause of the black colour of the effused blood we have already explained in the articles MORTIFICATION and PERFORATION. It is also at this period that the odour of the breath and the rejected matter is most offensive; and that the appetite, if not previously much affected, is entirely lost, perverted, or replaced by a morbid craving for peculiar kinds of food. There is only one other circumstance connected with vomiting to which we shall allude, viz. the rejection of the food taken the previous day or even at a later period, whilst the last meal is retained. This kind of choice, as it would seem, of the stomach between fresh and digested food, is not frequently observed. We do not recollect to have observed it except in cases of carcinoma of the pyloric portion of the stomach.

The modifications of the special functions of the intestines produced by carcinoma are in many respects very similar to those which we have described as occurring in the stomach. We have already noticed the mechanical influence of the disease in preventing the passage of the food and faeces, the accumulation of the latter, and the subsequent dilatation of the intestine. In no other respect does carcinoma interfere with the functions of the intestines, except when it gives rise to great irritation or inflammation of the mucous membrane and subjacent tissues, or when it terminates in sloughing and ulceration. Diarrhœa is the consequence of the former, and hemorrhage a frequent attendant on the latter of these morbid conditions. The rejection of faecal matter by vomiting is not often observed in carcinoma of the intestines. The stools sometimes present the same melanotic character as the matters rejected by vomiting in the last stage of carcinoma of the stomach. They also indicate the last stage of the disease in the intestines, coincide with the appearance of the hemorrhage, and depend on the subsequent discolouration of the effused blood.

Carcinoma of the liver may occur without any appreciable derangement of the special function of the organ being observed. We are disposed to believe that a suspension of the secretion of the bile very seldom occurs in the disease. In the great majority of the cases of jaundice which we have seen to accompany carcinoma of the liver, we have found the ductus communis choledochus, the hepatic duct or its principal branches, much compressed or obliterated by the carcinomatous substance in the form of large tumours. The same mechanical operation of these tumours on the trunk of the vena portæ or its larger divisions in the liver, prevents the return of the blood of the chylopoietic viscera to this organ: hence that form of ascites which always accompanies this state of the portal vessels.

There is often no apparent alteration in the quantity or quality of the bile, even in the most extensive forms of carcinoma of the liver. This fact is determined not only by the colour of the faeces during life, but by the examination of the organ after death; the substance of the liver presenting no unusual colour, and the gall-bladder being filled with bile of the natural consistence and colour.

There is no apparent modification of the secretion of the urine in carcinoma of one of the kidneys, although the disease may be so extensive as to leave no trace of the natural structure of the organ. We have never found both kidneys affected. On the contrary, the sound one is generally larger than natural, and appears to supply by its increase of bulk or energy the place of the other, as the quantity of urine voided in a given time is not sensibly diminished.

The much more frequent occurrence of carcinoma after than before the cessation of the menstrual discharge, prevents us from estimating accurately the influence which this disease exercises on the special function of the uterus and ovaries. Impregnation, however, has been known to take place in carcinoma of the os uteri, and of one of the ovaries. For farther information on carcinoma of the female organs of generation, see UTERUS, DISEASES OF.

Only a few remarks are necessary on the modifications of function which accompany carcinoma of the spleen, pancreas, mesenteric and lymphatic glands, epiploon, and serous membranes in general. With regard to the spleen, we have only to remark that its cellular organization may be completely effaced by the presence of the carcinomatous matter, and consequently it is rendered incapable of receiving more blood than is necessary for the nutrition of its solid parts, and the growth of the disease. Carcinoma of the duodenal extremity of the pancreas, in consequence of the compression of the duct which passes in this direction, gives rise to an accumulation of the secretion of this organ, and great dilatation of the duct throughout its whole extent. It is in consequence of the increase of bulk of the pancreas which accompanies such cases, that we are sometimes led to suspect retention of the secretion of this organ. Diminished or suspended absorption are the occasional consequences of carcinoma of the mesenteric and lymphatic glands. Emaciation, when attributable to no other cause, may be regarded as indicating the modifications of function alluded to, of the former glands, and œdema of some external part, of the latter, both of which are rare occurrences, particularly œdema. An accumulation of the secretion of serous membranes, and a greater or less degree of obstruction to the motions of the contained organs, are the functional derangements which accompany carcinoma of these membranes, and of the epiploon. The latter, when affected with carcinoma, is generally drawn up in the form of a thick irregular mass, and fixed to the stomach along its great curvature; or it is sometimes split into several portions attached above to the stomach, and below to the uterus, ovaries, or walls of the abdomen, forming so many thick bridles, which not only interrupt

the motions of the intestines, but sometimes pull the stomach downwards, giving rise to an uneasy dragging sensation in the latter organ, and a sense of tightness or constriction in the former.

The function of respiration may be interrupted to such a degree by the mechanical presence of the carcinomatous substance, as to terminate in fatal asphyxia. We remember one case in particular of this kind. It occurred in a young man about twenty-five years of age, who, six weeks previous to his admission into hospital, performed the active duties of a soldier. He complained only of difficulty of breathing; he had a slight cough, followed occasionally by the expectoration of a small quantity of mucus. The difficulty of the respiration rapidly increased, and terminated in asphyxia, without the occurrence of fever or emaciation. Both lungs were nearly filled with large masses of the medullary sarcoma. The remaining pulmonary tissue was compressed, but not otherwise altered. This case affords a striking example of the mechanical effects of carcinoma, and the rapid and extensive developement of the medullary variety of the disease. Carcinoma of the heart has been seldom met with to any great extent, and so far as we know, no particular modification of function has been observed to accompany its presence. We have already minutely detailed the changes effected by this disease in the capillary and venous circulation.

The functional lesions which accompany carcinoma of the brain, cerebellum, and spinal cord, vary considerably with the seat of the disease relative to these organs individually, as well as to particular portions of them. But in neither of these respects does it give rise to any symptom which can be regarded as pathognomonic of its presence. As a foreign body, it gives rise sometimes to a degree of compression sufficient to produce partial or complete paralysis; loss of memory, or difficulty of speech; and derangement of the intellectual faculties. But these latter changes depend principally on the irritation and softening of the substance of the brain in contact with the carcinomatous mass. Even paralysis is more frequently produced by these subsequent changes than by compression. We have met with two cases of medullary sarcoma of the cerebellum, characterized by a remarkable developement of the function ascribed to this organ by Gall. Both patients, young men, were between 18 and 19 years of age. The left lobe of the cerebellum in one of them contained a carcinomatous tumour, of the variety mentioned above, as large as a hen's egg; in the other the tumour was less, and projected from the centre of the cerebellum into the fourth ventricle. We could not ascertain how long they had practised the act of pollution, but both were emaciated and weak when admitted into hospital. One of these patients was left to himself, and died about two months after his admission, in a state of extreme debility. The other lived nearly three weeks. When warned of the fatal consequences which must soon follow the practice which had already reduced him to a state of great misery, he declared that although he was conscious of the nature of his situation, it was not in his power to resist the influence under which he felt himself compelled to act. His hands were secured, but without the desired effect. As a last resource, the whole of the prepuce was removed, yet in this mutilated state he attempted to gratify the fatal propensity. He died a few days afterward, having had several severe convulsive attacks.

Paralysis of the superior and inferior extremities, of the muscles of respiration, of the bladder and rectum, have been observed in carcinoma of the spinal cord. It is hardly necessary to observe that the seat and extent of the paralysis depends on the portion of the spinal cord occupied by the disease.

General symptoms.—The general symptoms of carcinoma do not make their appearance before the last stage of the disease. Their severity depends much on the nature of the organ and the extent to which it is affected; but it is principally the irritation produced by the presence of the carcinomatous substance during the period of softening, sloughing, and ulceration, that determines the gravity of these symptoms. It is in this, the last stage of the disease, that the circulation and innervation become deranged, and that fever and a diminution of the nutritive function are first observed. It is likewise at this period, but more frequently a few days or weeks before death, that the skin assumes a pale earthy, or dull ochry tint; that debility and emaciation make rapid progress; and all the functions of the economy become implicated in the deteriorating influence of the disease. It is this group of the general symptoms which constitutes what is called the *cancerous cachexia*. The febrile symptoms, as well as the diminution of nutrition, in general are greatest when the seat of carcinoma is the uterus or stomach; and least in those organs, as the brain and lungs, in the former of which softening, and in the latter compression, may terminate in death, before either of these symptoms have become conspicuous. General dropsy does not often occur, and is never great. Ascites frequently accompanies carcinoma of the liver, for the reasons which we have already stated. Dropsy of the inferior extremities occurs more frequently in carcinoma of the ovaries and uterus than of any other organ. It is the consequence of compression of the iliac veins, but it may also be occasioned by the extension of the inflammation which accompanies the ulcerative stage of the disease to these vessels. Compression of the vena cava by tumours in the liver, or by the enlarged mesenteric glands, may also give rise to the same state of the inferior extremities.

Diagnosis.—It is not until carcinoma has made considerable progress, that we are sometimes able to recognise its presence in internal organs by means of a careful consideration of the local and general symptoms which we have enumerated. We have had frequent occasion to remark how little importance is in general to be attached to any one of these symptoms taken individually. But when the local signs, viz.

the changes in the bulk, form, and situation of organs, occasioned by the disease; its relative frequency in different organs and in particular portions of the same organ, are taken in connexion with the special and general modifications of function which may be present in individual cases, the greatest possible assistance is afforded us in establishing the diagnosis. The degree of facility with which this important object may be accomplished will depend on the number of the signs and symptoms present, and the possibility of detecting them by the means of investigation in our possession. Thus it is more easy to detect carcinoma of the stomach than of the lungs, of the latter than of the brain; because of our being able to ascertain the presence of the greater number of the local signs of the disease in the first case, only a few of them in the second, and none at all in the third. And when the sense of sight can be applied with that of touch and hearing, the diagnosis seldom presents much difficulty, as in the case of carcinoma of the os uteri and rectum.

It is necessary to observe that too much reliance is not to be placed on the presence of those general symptoms which constitute the cancerous cachexia; for there are morbid conditions of the stomach and duodenum, associated with derangement of the biliary secretion, which give rise to a state of debility and emaciation, accompanied with discoloration of the skin, which so closely resembles the cancerous cachexia, that the one is not to be distinguished from the other. The difficulty of establishing the diagnosis in such cases is likewise increased by the circumstance that the same chronic character prevails in both. There is, therefore, no possibility of distinguishing between carcinoma of the stomach and such morbid conditions of the same organ, unless the local phenomena of the former be very conspicuous.

It is hardly necessary to remark that the presence of carcinoma in an external part of the body is to be regarded as a diagnostic sign of great importance, in all cases of a doubtful character in which functional derangement of an internal organ has existed for some time. In such a case we should regard the frequent occurrence of vomiting after meals as indicating the existence of carcinoma of the pylorus, even should no tumour be felt in this situation, or dilatation of the stomach. If the presence of a tumour were detected in any part of the abdominal cavity, we should not hesitate to say that it was of the same nature as the external affection; and the occurrence of paralysis, under the same circumstances, would justify us in attributing it to carcinoma of the brain or spinal cord.

We shall not, in this general article, attempt to determine how far it may be possible to distinguish carcinoma from other diseases to which internal organs, considered individually, are subject. Besides, in the description which we have given of the signs and symptoms of carcinoma, we have already endeavoured to point out those which more especially characterize the presence of this disease in individual organs.

Prognosis.—In no disease is a fatal termination so universally admitted as in carcinoma. The possibility of the cure of carcinoma of internal organs has never been supported by substantial evidence; and the examples are few indeed in which we are disposed to believe that the disease has been removed from an external part by surgical or other means, without its recurrence in the same or some other part of the body at some future period.

Treatment.—A host of remedies have been proposed for the cure of carcinoma; the greater number of them have been tried in almost every form of the disease, but they have nearly all failed to justify the high praises formerly bestowed on their curative virtues. Some of them, however, have been found to retard, if not to arrest the progress of the disease; and, what is of great importance, to alleviate the sufferings and prolong the life of the patient. We shall notice those remedies only the successful administration of which has been rendered evident in carcinoma of external organs, as under such circumstances the nature of the disease is less likely to have been mistaken. We shall speak first of those remedies which effect a salutary change in the nutritive function of the affected organ, and thereby retard or arrest the progress of the disease; secondly, of those best calculated to prevent, remove, or mitigate the local and general effects to which it gives rise.

I. The remedies which retard or arrest the progress of carcinoma consist of those which exercise a direct or indirect influence on the nutritive function of the affected organ. Among the former, or those which operate directly, the local abstraction of blood by means of leeches, and compression, hold the first rank. The first of these means should be employed for a considerable length of time, at intervals of one, two, or three days, and the quantity of blood taken should be regulated chiefly by the strength of the patient. The diminution of bulk of the original tumour which follows this mode of treatment, is sometimes very considerable. In the great majority of cases the tumour is not entirely removed. It may be reduced from the size of a hen's egg to that of a nut, and in this state remain stationary for years without giving rise to pain or any inconvenience whatever. The alternate use of local bleeding and compression effect more rapidly the reduction of bulk just noticed than when either is employed separately; but the former should, as a general rule, be always employed so as to produce a certain degree of indolency in the tumour, before the latter is had recourse to.

The beneficial effect of pressure, first employed by Mr. Young,* has been satisfactorily determined by M. Recamier, one of the physicians of the Hôtel Dieu of Paris. The following are the general results obtained by this physician:—

1st. Of one hundred patients treated by M. Recamier for carcinomatous affections, sixteen appeared to be incurable, and underwent

* Cases of Cancer, &c. London, 1816.

only a palliative treatment. Thirty were completely cured by compression alone; and twenty-one, submitted to the same means, derived considerable benefit from it. Fifteen got rid of the affection radically, by means of ablation alone, or chiefly by ablation combined with pressure; and six by means of compression and cauterization. In the twelve remaining patients the disease resisted all the means employed.

2d. Tumours similar, or at least analogous to those which degenerate into incurable cancer, are cured by methodical compression, and some other internal and external remedies.

3d. When a tendency towards resolution of a swelling of the mammary gland, which has not yet degenerated, has been produced for a considerable length of time by means of compression, the resolution of the swelling continues even after the compression is no longer employed; but if the swelling has degenerated, and, after having obtained a great diminution of its bulk, compression be laid aside, the swelling may resume its former bulk, and its degeneration proceed with greater rapidity than before.

4th. Compression may assist in preventing the return of cancer after ablation.

5th. The resolution of chronic inflammation is greatly favoured by compression alone, or combined with local bleeding, &c.

6th. Various tumefactions of the neck of the uterus are resolved by compressing this part by means of a pessary in the form of a hollow cone terminating in an open olive-shaped extremity.

7th. It is reasonable to hope, that if compression were employed at an early period, that is to say, before the degeneration of those tumours susceptible of this mode of treatment, the resolution of a greater number of them would be obtained, and the necessity of the ablation of cancer of the breast, so frequently followed by a return of the disease, when not encysted, be greatly diminished.*

Although compression and local bleeding cannot be employed in the treatment of carcinoma of internal organs, properly so called, we have thought it proper to notice the results which M. Recamier states he has obtained by their external application, as encouraging to the physician, and as affording a strong presumption that the cure of this disease, even in internal organs, is not altogether beyond the resources of his art.

It is also in consequence of a modification of nutrition in general, and consequently of that of the affected organ, that the beneficial effects of some general remedies, in carcinoma of external organs, are chiefly to be attributed. Some of these remedies appear to modify nutrition by effecting some unknown change in the composition of the blood, as aconitum, conium, and arsenic; others, by acting on the capillary circulation and absorption, as mercury in alterative doses, and various preparations of iodine.

* Recherches sur le Traitement de Cancer, par M. Recamier, t. i. p. 474.

The beneficial effects of tonics, as preparations of iron, the fixed and volatile alkalies, mineral waters, such as those of Plombières, Barèges, and Vichy, and all other remedies which increase the vital energies, invigorate digestion, and promote absorption and secretion, may also be referred to a favorable change induced in the nutritive function of the affected organ, by the introduction of these remedies into the circulating system.

The salutary operation of these local and general remedies is much increased by a judicious combination of both, regulated according to the circumstances of individual cases. But while employing any of these remedies, it is of the utmost importance to regulate the diet and regimen of the patient in such a manner that neither of them may interfere with the operation of the remedy employed. M. Recamier, in the work already referred to, has shewn that the curative virtues of conium, for example, depend greatly on the quantity of food consumed by the patient; that is to say, the operation of this remedy was more or less powerful when only a small quantity of food was allowed, and hardly perceptible when the quantity was considerable. While using the conium, he therefore restricts the patient to a severe diet; and in this way he says he has succeeded in curing several cases of carcinoma of the uterus, liver, spleen, mammæ, testes, and of the extremities. The following are the principles of the treatment:—

1st. The patient takes a dose of the extract of conium, evening and morning, two hours before the first and two hours before the last meal. The amount of the first dose is half a grain, which is gradually increased to six grains each time. This dose is continued for a fortnight in order that the organs may become habituated to its operation, and is afterwards increased to twelve grains each time, beyond which it is not necessary to carry the remedy, because of its influence being sufficient. The twelve-grain dose is continued for from two to three or four weeks.

2d. After each dose of the conium, as well as at meals, the patient uses a decoction of sarsaparilla, (composed of two ounces of the root to two pounds of water,) instead of water.

3d. Only the third of the ordinary quantity of food is allowed, which ought to be very simple, and divided into three small meals.

4th. If the conium disagree in one form, it should be given in another, or the aconitum may be used instead, but in lesser quantity than the conium. Towards the end of the treatment the dose of the conium is gradually diminished, and the diet gradually increased.

M. Recamier ascribes the success he has obtained in the use of the conium, not only to the strict observance of these dietetic rules, but also to the method he has employed in the preparation of the extract. The plant is submitted to the action of the vapour of vinegar or alcohol, before the juice is expressed from it; the juice is afterwards exposed to the heat of a sand-bath, and evaporated to the consistence of an extract. The extract thus obtained has not

the nauseous odour of that usually employed, whilst it possesses all the deobstruent virtues, and sits better on the stomach than the latter.

11. The remedies best calculated to prevent, remove, or mitigate the local and general effects of carcinoma of internal organs, vary with the nature of these effects and the seat of the disease. The state of irritation and fever, and pain, at whatever period of the disease they may occur, may be greatly moderated by the use of the conium, aconitum, opium, hyoscyamus, the acetate or muriate of morphia; whilst at the same time the use of all kinds of stimuli is to be avoided, particularly if the digestive organs be the seat of the disease; and the patient himself kept as much as possible in a state of quiet of body and mind. If the os uteri be the seat of the disease, additional benefit may be derived from the use of leeches applied to this part, and also sedative injections. It is only in this latter situation that sloughing and ulceration can be detected, and local remedies applied to remove some of the disagreeable effects of the one, or retard the progress of the other. The chlorurets of lime and soda are, perhaps, the best remedies we can employ in this case, as they not only destroy the disgusting odour which accompanies this stage of the disease, but remove the putrid and irritating fluids which are then discharged. The retention of the contents of hollow organs, from compression or obstruction, is an occurrence which ought to be guarded against by regulating the quantity and quality of the food, for negligence in this respect may be followed by fatal consequences, if the obstacle be situated in the intestines.

It is not in our power to prevent the occurrence of ascites from compression of the vena portæ, nor of œdema of the inferior extremities from compression of the cava in carcinoma of the mesenteric glands, or of the iliac veins when the ovaries or uterus are affected with this disease. But the quantity of the effused fluid may be prevented from becoming so great as to affect the respiration, or give rise to painful distention of the integuments, by the use of those remedies usually employed in dropsy from obstruction to the return of the venous blood. (See Dropsy.)

When carcinoma has arrived at that period when the cancerous cachexia announces the extension and fatal termination of the disease, the efforts of the physician must be directed solely to the mitigation of the sufferings of the patient. It would indeed be a valuable discovery—a remedy capable of removing pain without producing any injurious effects on the economy; for if this symptom were removed, there are many cases in which carcinoma would run a much longer course, and give rise to comparatively little functional derangement.

We have not in the course of this article alluded to the perforation of hollow organs from carcinoma. With regard to this termination of carcinoma, we shall only remark that it most frequently takes place in the uterus and stomach, the rectum and urinary bladder, the transverse arch of the colon and jejunum, and the peritoneum. The perforation of the rectum, bladder, and peritoneum, is the consequence of the extension of the disease from the uterus; that of the transverse arch of the colon, the consequence of its extension from the stomach. (See Perforation, Peritonitis, Stomach and Uterus, diseases of.)

(Robert Carswell.)

SCORBUTUS.—This is the general appellation of nosologists for the disease long known in our own country by the name of *scurvy*. The latter term, however, in professional as well as in popular use, has had an extended and very vague signification, embracing various morbid conditions of the skin which differ often essentially from each other, and are unallied to the subject of the present article. Illustrations of this remark might be adduced from various sources. As an instance, in the English translation of the Pentateuch the word scurvy is twice used synonymously with scabies in the Latin.* This and similar applications of it we think may be traced to its early use in an adjective sense; the substantive scurf having its literal prototype in the Saxon language, and referring, as is well known, to exfoliations of small particles of the cuticle; an occurrence not uncommon in the disease now called scurvy, but which has no title to a characteristic symptom.

The word *scorbutus*, as Good observes, is neither Greek nor Latin, nor belongs to any language whatever, but is an intolerable barbarism, deduced probably from the Sclavonic word 'scorb,' the identical disease of which we have to treat having been frequently endemic in Russia and other northern countries: it has gratuitously received a sort of Latin termination. It has also been referred to 'schorbert' in the Danish language, and 'scorbeck,' *i. e.* sore mouth or 'scheurbuych' in the Dutch. Most authors, says Lind, have traced it to 'schorbock,' a griping or teazing of the belly, by no means a usual symptom, but so stated by a mistake in the etymology of the word. Scorbutus has also been called gingibrachium and gingipedum, from its affecting the gums, arms, and legs. It is probable also that the word 'stomacace,' (from στοματις and κακος, disease of the mouth) and 'sceletyrbe' (from σκελος, the leg, and τυρβη, disorder) have by the ancient writers been employed to designate this affection. It may be well also to mention here that 'scorbutus' has two derivatives, which have had the same extensive and corresponding misapplication as the original, viz. the terms scorbutic and antiscorbutic, the former referring to a peculiar virus supposed to be the common root of a large class of diseases, the latter to the substances employed for their removal, constituting a very formidable and extraordinary catalogue.

To prevent misconception, it seems necessary for us to premise that the following discussion relates to a peculiar disease, distinct, so far as we know, from the papular, pustular,

* Lev. xxi. 20, xxii. 22.

squamous, and other diseases of the skin which have been unfortunately confounded with it; a confusion which has given rise to evils of the greatest magnitude, as exemplified not only in the errors of the careless and illiterate, but in their endless dissemination with all the force of authority from the written doctrines of the respected and erudite. It may not be without its use to mention that from the confusion of terms above adverted to, the best medicine for the prevention and cure of scorbutus was for a very long period overlooked and neglected, to the immense sacrifice of human life; and from the same cause it is stated that on the recommendation of Boerhaave, mercury was employed by the medical officers of the imperial army of Hungary in 1720, in the treatment of four hundred soldiers suffering from real scorbutus; every one of whom having been subjected to a course of this medicine died in consequence.*

Scorbutus, or true scurvy, is a disease which pervades the whole of the human frame, and is characterized by general debility, fœtor of the breath, sponginess and turgidity of the gums, livid subcutaneous spots, particularly at the roots of the hairs, ecchymoses, spontaneous hemorrhages, and frequently contraction of the limbs. Cullen has placed it in the class *Cachexiæ* and order *Impetigines*, and has thus defined it: "In regione frigida post victum putrescentem, salitum, ex animalibus confectum, deficiente simul materia vegetabili; asthenia, stomacace, in cute maculæ diversi coloris, plerumque livescentes, præsertim ad pilorum radices." Mason Good has arranged it in his class *Hæmatica* and order *Dysthetica*, as one of three species under the generic name *Porphyra;* including under it every variety of petechial eruption not depending on fever. The first species, viz. "P. simplex—petechial scurvy," he has defined "spots numerous but small and flea-bite shaped, chiefly in the breast, arms, and legs, paleness of visage." The second "P. hæmorrhagica—land scurvy," in which the spots are circular, of different sizes, often in stripes or patches irregularly scattered over the thighs, arms, and trunk; occasional hemorrhage from the mouth, nostrils, or viscera; great debility and depression of spirits. In the third species, viz.: "P. nautica—sea scurvy," the spots are of different hues intermixed with some which are livid, principally at the roots of the hairs, teeth loose, gums spongy, and bleeding, breath fetid, debility universal and extreme. The first and second species having been particularly discussed in the article Purpura, in conformity with the usage of modern writers, require no further comment in this place than that they have been so distinguished from the circumstance of their having frequently occurred in young persons living in the interior of the country, and previously enjoying good health with all the necessaries and comforts of life, but who, nevertheless, having failed to derive benefit from the diet and regimen usually found adequate to the cure of sea-scurvy, have not unfrequently been recovered by opposite means; circumstances which appear to indicate some essential differences in the pathological conditions under which they occur. This opinion has been further strengthened by the blood drawn from the veins being also dissimilar; under the former circumstances being livid and very loosely coagulable, and under the latter having the usual appearances characteristic of an inflammatory disease. It is to be remarked, however, that the scurvy as it is developed at sea is a form of disease in its characters precisely similar to that which was commonly termed land-scurvy long prior to the distinction of Mason Good above adverted to; the only difference being that of the situation of its occurrence and the class of persons (mariners) who have been most frequently its victims. In our own country, though now happily a rare disease, it was formerly, even in the inland parts, of great frequency; and in other northern states, particularly on the shores of the Baltic, where the products of vegetation, at least in their fresh state, have formed a very insignificant portion in the diet of its inhabitants, it is now even occasionally endemic. Its former frequent occurrence in besieged towns and garrisons, under the combined circumstances of defect in the quantity and quality of food, fatigue, anxiety, disappointment, and exposure to the united influence of a cold and damp atmosphere, further prove that any particular influence from the sea is not essential to its generation. A memorable instance in point presents itself in the account of the siege of Thorn; where we find that between five and six thousand of the garrison, besides a great number of the inhabitants of the town, were cut off by the disease, when the Swedes, who were the besiegers, were altogether exempted from it; and it is further remarkable that no sooner were fresh vegetables admitted to their use than the mortality subsided, and the disease disappeared.*

Considerable discrepancy of opinion has prevailed as to the origin of scorbutus; whether it be of recent date, or referred to in the earliest productions of medical literature. It has been contended, chiefly by the continental writers, though some of high estimation in our own country have coincided in the opinion, that the ancient physicians were acquainted with it, although it has not been accurately described by them. On the other hand, there are authors of great celebrity, amongst whom are to be found Friend, Lind, and Trotter, who have maintained that the Greeks, Romans, and Arabians never could have witnessed it; considering it indigenous to the colder regions of the globe, and chiefly incidental to the privations consequent to long voyages, which, from their ignorance of the compass and the science of navigation generally, they never undertook. Sieges, however, and seasons of dearth have been common to every period and country, the former of much longer duration in ancient than in recent times; and though experience has

* Elements of Medical Logic, by Sir Gilbert Blane, M.D. p. 217.

* Lind on Scurvy, Part III. ch. ii. p. 395.

determined that the climates, or at least the vegetable productions of tropical latitudes, and their consequent use in the diet of the inhabitants, would in general insure its prevention, we have abundant proof that its existence is not incompatible with high temperatures. The ancient physicians, too, it is contended, have left us details more closely corresponding to the symptoms of scorbutus in our present acceptation of the word than any other disease with which we are acquainted. Thus Hippocrates, in his description of disorders of the spleen, has noted the occurrence of the following assemblage of symptoms. "The abdomen is distended, and subsequently the spleen is enlarged, becomes hard, and the seat of acute pain; the complexion is changed and has a dusky (μελας) pallid appearance, like the colour of a pomegranate; a disagreeable odour is exhaled from the ears and gums; the latter recede from the teeth, and ulcers break out on the tibiæ like nocturnal pustules or blotches (οκοια περ επινυκτιδες;) the limbs are attenuated and the bowels costive." Again, in his second book of Prognostics, he observes that in those who have tumid spleens, the gums are diseased and the mouth emits a fetid odour, but those whose spleens are enlarged without any consequent hemorrhages are attacked with ill-conditioned ulcers in the legs and black scars. His description of the convolvulus sanguineus* more nearly represents the scurvy than that of the σπλην μεγας. "A bad odour is emitted from the mouth, the gums recede from the teeth, and blood is effused from the nostrils; but sometimes ulcers break out on the legs, and while some are healing others break out afresh, the skin about them is of a dark colour, thin and tender, and the patient is not disposed to walk or use any exertion." In the original the affirmative is asserted, that the patient is disposed to exertion, a circumstance so inconsistent with ulcerations of the legs, hemorrhages, and other symptoms, that commentators agree that the negative particle (ου) must have been omitted: this derives further confirmation from some additional remarks of the same writer, referring to a former description of another kind of convolvulus for the remaining symptoms, in which it is said that the patient's legs are wearied, and if he walk they tremble, and if he should ascend an acclivity that he breathes with difficulty, the elbows being raised as if they were suspended, &c.; the causes of which, he states, are heating food taken by persons using little or no exercise, and who, thus weakened, were suddenly forced to take long and fatiguing journeys in very cold weather; the ειλεος, it must be remembered, being a term not confined by the ancients to express affections of the smaller intestines, but applied to denote also pains in the other parts of the abdomen.† Celsus has given a similar character of the ulcerations attending scurvy to that of Hippocrates: "Ulcera autem omnino non sanescunt, aut certe cicatricem vix recipiunt;" and in another part seems to have translated the observations of Hippocrates: "At quibus magni lienes sunt, his, gingivæ malæ sunt, et os olet, aut sanguis aliqua parte prorumpit; quorum si nihil evenit, necesse est in cruribus mala ulcera et ex his nigræ cicatrices fiant:"* and in another passage, on tumefactions of the spleen, he has almost confirmed the conjuncture above mentioned, expressly observing, "in intenta ambulatione cursuque dolor et quædam difficultas est;" and he thus proceeds: "hoc vitium quies auget, itaque exertione et labore opus est, habitâ tamen ratione, ne febrem ista, si nimium processerint, excitent."† Aretæus, (lib. i. c. 14,) Paul of Ægina, (lib. iii. c. 49,) and Avicenna, (lib. iii. c. 2,) as well as other Greek and Arabian physicians, have described the same chain of symptoms.

It seems highly probable also that the true scurvy has been referred to both by Strabo and Pliny; by the former of whom we are told that the Roman army, sent into Arabia under Ælius Gallas in the reign of Augustus, underwent great hardships and fatigue from difficult marches, sometimes in a marshy unhealthy country, and at others from long and troublesome navigations, which Syllæus purposely protracted. "Proinde," says he, "ad Album Pagum pervenit, jam exercitu oris et crurum vitiis (qui morbi sunt ei regioni peculiares) tacto stomacacen et sceletyrben dicunt; quorum illa circa os, et circa crura resolutio quædam est ex aquis et herbis proveniens."‡ Pliny has left an observation which seems to bear on the same point. He states that the Roman army, under the command of Cæsar Germanicus, having encamped in Germany beyond the Rhine, near the sea-coast, met with a fountain of sweet water, by the drinking of which in the space of two years the teeth dropt out, and the joints of the knees became paralytic (compages genubus solverentur). The physicians, he adds, called the disease stomacace and sceletyrbe, and discovered a remedy for it, viz. herba Brittanica, "a salutary medicine not only in disorders of the mouth and nerves, but for the quinsey, bite of serpents," &c.§

It has been denied, however, that the sceletyrbe was an indication of scurvy, because Galen has spoken of it as a kind of paralysis,‖ by which the patient is disabled from walking straight; but such an effect does not seem at all inconsistent with the detail of the symptoms. It has been argued, also, that the stomacace may have stood for aphthous and similar disorders of the mouth; and that other concomitant symptoms equally constant and remarkable, particularly the petechiæ and ecchymoses, could not have failed to elicit the notice of the early writers if the disease they described had been

scurvy. On the other hand, from the comparative rarity of the occurrence of scurvy in the southern climates, it is not to be presumed that the attention of the ancient physicians should have been very particularly directed to it. There is, besides, a peculiarity in the combination of the symptoms, a difficulty in referring them to any other known disease, and an apparent identity of circumstances under which they have been induced. It is likewise an established fact that in many instances the presence of scurvy has been acknowledged, and it has been expressly noticed, without the appearances which have been supposed to constitute the deficiency in the description of the ancient writers. Thus Sennertus observes, "In aliquibus nullæ erumpunt maculæ; aliis tota crura violaceo pinguntur ut tibialia ejus coloris superindueta jurares." To cite another authority, Nitzch, who had very extensive experience of the disease as physician in the imperial Russian armies, and published an elaborate account of it in the year 1747, has noticed the occasional appearance of the other symptoms of scorbutus without the petechiæ which usually accompany it.*

From a consideration of all the circumstances of the question at issue, it appears a reasonable conclusion that the conjecture of the antiquity of the disease is well founded, and that the slight diversity of the effects, if any, by which it has been manifested at different periods, is to be accounted for by the infinity of varying circumstances which exert their modifying influences on disease, rather than by any essential differences in the actual morbid condition under which it has been induced. It will be sufficient to mention the diversity of periods, of seasons, of climates, of localities, of occupations, of diet, besides numberless others of a moral nature. It is further corroborative of the antiquity of scorbutus, though we mention it in continuation of its history rather than with the view of dwelling on incidents from which no deductions of practical value are to be drawn, that with the revival of literature after the siege of Constantinople, we find an undoubted record of its occurrence. It is characterized in the most particular manner by the Sieur Joinville, from the appearances it presented in the Christian army under St. Louis IX. in Egypt, about the year 1260. They had only one sort of fish, viz. the bombette, and their religion would not suffer them to eat meat during Lent; circumstances which, together with bad air and great scarcity of water, were supposed to have induced the disease.† In the year 1486, it is stated by Fabricius in his account of the antiquities of his own country, (Misnia,) to have been a new and unheard-of disease, spreading as supposed by contagion, and proving extremely dangerous.‡ In 1497 it was the acknowledged occasion of dreadful havoc in the crew of Vasco de Gama in his passage of discovery by the Cape of Good Hope;* and its destructive ravages have since been awfully pourtrayed in the narratives of the early English navigators, particularly in those of Cartier, Sir Francis Drake, Davis, Cavendish, and Dampier. Sir Richard Hawkins mentions that within his naval experience he had known of 10,000 men having perished by the scurvy;† and from the same cause Commodore Anson, in the course of his voyage round the world, lost more than four-fifths of his men.

Until the year 1796, scorbutus may be said to have been the universal scourge of our maritime connections; and it is supposed to have destroyed more sailors than the various accidents incidental to a sea life, united with the terrific consequences of naval warfare. Happily, however, since the above-mentioned period it has been of very rare occurrence in our ships of war and naval hospitals; so rarely, that on the high authority of Sir Gilbert Blane, the year adverted to may be regarded as the era of its extermination. The accomplishment of this he attributes in an unqualified manner to the curative as well as preventive use of citric acid; no instance of the disease having occurred in his extensive experience which resisted its influence. To such testimony, perhaps it behoves us to yield our implicit assent; but, satisfied as we are with the immense mass of evidence adduced in favour of the wonderful efficacy of the remedy referred to, we cannot but take into the account the co-operative influence of the great improvements in naval economy, successfully commenced with a view to the prevention of scorbutus by the justly esteemed navigator Captain Cook, and brought to comparative perfection under the happy auspices of the enlightened and venerable director of the medical department of the navy, Sir Gilbert Blane himself. The records of medicine abundantly prove the prevalence, and even the great fatality of scorbutus on our own shores at a former period, although its appearance at the present day is most rare, as is well known to every practitioner of medicine. This salutary change is fully accounted for by the drainage of the country; by the introduction of fresh vegetables as a considerable proportion of the habitual diet of the people; and those improvements in our national economy by which the use of fresh meats has been rendered available at all seasons of the year, and substituted for the dried and salted provisions formerly a principal article of subsistence throughout the winter. The want of fresh vegetables at former periods is plainly evinced by the historical fact, that as late as the commencement of the sixteenth century the art of gardening was so little understood in our country, that Katharine of Arragon, queen of Henry VIII., to procure a salad, was obliged to despatch a messenger to the Netherlands for it;

and it was near the close of Henry's reign before the necessary vegetables for the purpose, as well as cabbages, turnips, carrots, and some other edible roots, were produced; the small quantity of this kind of food previously used having been imported from Holland and Flanders.*

But to return to the general history of scorbutus. Krantz, the historian of Saxony, is supposed to be the first writer whose works are extant who calls it scurvy; and the next, Euritius Cordus, in his Botonologicon, published in 1534, wherein the chelidonium minus, called by the Saxons schorbock root, is extolled as a remedy. It is mentioned, also, in the same manner in the Medicina Herbaria of J. Agricola, published in the year 1539. But in an intermediate period, in 1535, we find that the most decisive and deplorable effects of it were evinced in the crew of James Cartier in his second voyage to Newfoundland, when we are informed of the providential discovery of a remedy (in previous use amongst the people of Stadacona,) viz. the decoction of the bark and leaves of the ameda or hameda, afterwards gratefully designated by them "the tree of life."† In 1555, the History of Northern Nations, by Olaus Magnus, contained, amongst the diseases peculiar to them, a long description of scorbutus. Soon afterward we find three cotemporary physicians of eminence treating expressly of it, viz. Rousseus, Wiems, and Ecthius. The works of the two former, in the opinion of the learned Astruc, were not published until the year 1580, and the epitome of Ecthius, which, according to Forrestus, was the transcript of a letter dated 1541, not until 1583. In 1604 appeared a work on the subject by Engelanus, which for many years was regarded as the standard of public opinion. This was succeeded in 1624 by that of Sennertus, and in 1627 by the description of Vander Nege, drawn from personal observation of its extensive prevalence at the siege of Breda. In 1667 Willis published a systematic treatise on the disease, which, like that of Engelanus, continued for some time to be the prevailing authority. In 1708, however, it gave place to the observations of Boerhaave, and to him succeeds a long list of writers; but, as of those who preceded him, we shall mention such only as have been held in estimation, attaching the dates of their several publications.‡ Mead, in 1749; Russell and Huxham, in 1750; Addington, in 1753; Bisset, in 1755; Lind, in 1757; Macbride, in 1767; Hulme, in 1768; Milman, in 1782; Trotter, in 1797; and Blane, first in his work on the Diseases of Seamen, published in 1785, and subsequently in a paper on the health of the navy, inserted in the sixth volume of the Medico-Chirurgical Transactions of London, in 1815, and transcribed in a pamphlet of the same title printed for private circulation in 1830. Besides the above mentioned, there are doubtless others which merit attention; and much valuable information on the subject is to be found in the periodical miscellanies, chiefly of a remote date.

Symptoms.—The symptoms which constitute scorbutus having rarely if ever appeared except when there has been an obvious exposure of the subject of them to the concurring influence of several of those termed its predisposing causes, other indications of the approach of the disease will be confirmed, or the suspicion of it diminished, in proportion as such a connection of circumstances can or cannot be ascertained. Of the predisposing causes the most uniformly present has been the combination of cold with humidity of atmosphere, either general or partial; whilst at the same time the diet has consisted of food defective in its nutritious qualities, and particularly of provisions rendered dry and hard by the process of salting as usually adopted to preserve them for sea use, together with a total privation, or the use of a comparatively insignificant quantity of succulent vegetables in their fresh state. Under this privation, as it has frequently occurred at sea, a craving desire for them, particularly for such as are of an acid taste, and also for pure water when the supply of that article has been scanty, has been so often observed to precede the disease, that practical authorities have considered such desires as premonitory symptoms. Their operation has been feelingly portrayed in the narrative of Lord Anson's voyage, on the occasion of the approach of his ships to the island of Juan Fernandez; the scenery of which having been depicted, the writer observes, "Such a scene, so beautifully diversified, must have been delightful to an indifferent spectator; but in the distressed condition of the Centurion's men, who were in a manner languishing for the land and its vegetable productions, a situation of mind which always attends the scurvy, it is not to be conceived with what transport and eagerness they viewed the shore, and how impatiently they longed for the greens, the fresh water, and the other refreshments then in sight." And it is further observed, "that those only who have endured a long series of thirst, and can readily recal the desire and agitation which the ideas alone of springs and brooks have at that time raised in them, can judge of the emotion with which they eyed a large cascade of the most transparent water, which poured itself from a rock near one hundred feet high into the sea at a small distance from the ship." "Those who had been long confined to their hammocks now exerted all the strength they had left in crawling up to the deck to feast their eyes with the reviving prospect. Thus they coasted along the shore, contemplating the enchanting landscape, which improved as they advanced; but the night closed upon them before they had discovered a proper bay. At four the next morning the third lieutenant was despatched with the cutter

* Hume's History of England, ch. xxxiii.

† "I am inclined to believe, from the description given by Cartier of the ameda tree, that it was the large swampy American spruce. Some have supposed it to be the sassafras, others the white-thorn; but in his third voyage he mentions the white-thorn, and makes the ameda to be three feet in circumference."—Lind on Scurvy, p. 178.

‡ Lind's Treatise on Scurvy. Lond. 1757.

to discover the bay they sought for, and at noon he returned with the boat laden with seals and grass; for the boat's crew did not stay to search for better vegetables, as they well knew that even *grass* would prove a dainty, and indeed it was soon eagerly devoured."*

Another indication of the scorbutic diathesis, unnoticed by preceding writers, says Sir Gilbert Blane, is a soft indolent tumour, which arises under the skin on a part which has received a slight blow or contusion, so slight as not to break the skin. It most commonly appears about the elbow or forearm, and generally disappears without inconvenience, its contents being absorbed.† Scratches and wounds which under other circumstances would scarcely elicit attention, are apt to proceed to troublesome ulcerations, and betray their real character with the further developement of the disease.

Amongst the more obvious symptoms, the earliest is usually a change of colour in the face, which, as well as the rest of the skin, becomes pale, and has a bloated appearance. When narrowly examined, it is seen that the lips and caruncles of the eye, where the bloodvessels lie most exposed, are of a greenish hue. The countenance denotes the state of the mind, which is depressed. The patient complains of lassitude, and is averse to all kinds of bodily exercise; the inability to use it is soon manifested by stiffness and feebleness of the knees, and excessive fatigue and breathlessness or panting are the consequences. The gums soon become itchy, swelled, and are apt to bleed upon the gentlest friction. On inspection they present a livid red appearance, are soft and spongy, and become extremely putrid and fungous. The odour of the breath is, as may be supposed, excessively offensive, and hemorrhages are apt to occur from the gums, as also from other parts of the body.

The skin at this time feels dry, and continues so through the whole course of the disease. If the patient be feverish, it is extremely rough, sometimes resembling that which is vulgarly called goose-skin. But most frequently it is smooth and shining, with suffusions of reddish, bluish, or rather black and livid spots. These are of different sizes, occupying spaces from the smallest possible to that of a handbreadth or more, increasing generally with the progress of the disease. They are to be seen chiefly on the legs and thighs, often on the arms and trunk, but more rarely on the head and face. The legs are apt to be œdematous, the swelling at first being confined to the ankles, and conspicuous only in the evening, but gradually extending to the whole limb, and becoming less and less transient.

Such are the most constant and essential symptoms of the disease in its first stage; but a diversity is sometimes observed in the order of their appearance. Thus, when there has been great debility from previous illness, the gums for the most part are first affected; whereas, when the individual has been deprived of exercise in consequence of a fractured bone or other injury, the parts so affected become first scorbutic. As for example, if a patient is suffering from a strain of the ankle, the first indication of scorbutus will be pain, swelling, and œdema of the leg, with the purple subcutaneous spots and ecchymoses which more especially characterize the disease. It is remarkable, also, that if there have been previous disease, particularly rheumatism, chronic pains from bruises, and other effects of local injuries, these are apt to be renewed, and the disease on which scorbutus may have supervened to appear in a more aggravated form.* A striking instance in confirmation of the preceding remark is mentioned in the account of Lord Anson's voyage. The individual spoken of had been wounded, about fifty years before, at the battle of the Boyne, but had speedily recovered, and had continued well for a great number of years preceding an accession of scorbutus; but upon this, and during its progress, the same wounds broke out afresh, and appeared as if they never had been healed; nay, what is still more astonishing, the callus of a broken bone, which had been completely formed for a long time, was found to be destroyed, and the fractured part as if no consolidation had ever taken place.

The subjects of scorbutus frequently suffer from shifting pains: some complain of them, according to a common expression, throughout their bones, being particularly severe in their limbs and lumbar region, and in the joints and legs when they are swelled. But the most frequent seat of pain is the thorax; a sense of constriction in it with stitches on coughing being usual symptoms. "I believe indeed," says Lind, "it will universally be affected unless the bowels are very open. The pain shifts from one part of it to another, often to opposite sides, and is at first perceived upon coughing only; but in a more advanced stage it commonly fixes in a particular part—most frequently in the side, where it becomes extremely severe and pungent, so as to affect the breathing—a dangerous symptom." As scorbutic pains often change their position, so they are always exasperated by motion of the body, especially the pain of the back, which on such occasions proves very troublesome.

The next thing observable is, that if any epidemic should prevail at the same time with scorbutus, the subjects of the latter are in consequence predisposed to be attacked by it, even if there should appear to be no correspondence between the two diseases. Such a concurrence, however, Lind considers much more fortunate than when the new disease may be, as he terms it, of a putrid nature, as small-pox, measles, dysenteric fever, &c; "it is then," he adds, "that co-operating with the scorbutic acrimony, they produce most fatal and malignant symptoms." The head is seldom or never affected with pain, unless when fever is present, which may be considered altogether an adventitious circumstance. When

* Anson's Voyage round the World, 1740-4, ch. iii.
† Observations on Dis. of Seamen, 1785, p. 465.

* See Lind on Scurvy, chap. ii.

fevers supervene on scorbutus, they usually prove fatal; but that species which at a former period was most destructive, more so even than the plague, was the petechial or goal fever, of which we read in works of the last century, contracted in large, crowded, and sickly ships or prisons. According to the habit and constitution of the patient there will be some diversity in the performance of the alvine function. In some patients it is natural, in others there is extreme constipation; but generally the bowels are in a relaxed state, and the dejections are extremely fetid. The appearance of the urine is very variable at different times, even in the same patient, except that it is generally high-coloured, and soon becomes rank and fetid. It is said, also, to turn blue vegetable infusions to a green colour. The pulse varies according to the habit of the patient and stage of the disease, being in general slower and more feeble than in health. After a time the patient is commonly deprived of the use of his inferior extremities, the flexor tendons of the ham being contracted and the joints swelled; livid spots and ecchymoses are to observed, particularly on the legs, and frequently hard and very painful swellings in different parts. "In some," says Lind, "I have seen, without any swelling, the calf of the leg quite indurated." There is great proneness to syncope upon exertion, and not unfrequently upon occasions of this kind, or any sudden exposure to a fresh atmosphere, scorbutic patients have instantly died. The tendency to profuse hemorrhages increases with the progress of the disease, and these are apt to take place from the nose, gums, lungs, intestines, &c., as well as from any ulcers which may be present.

Besides the morbid appearances of the gums already mentioned, they are liable to be affected with deep ulcerations, the teeth most commonly are loosened and often fall out; but caries of the jaw rarely ensues, nor is this affection of any of the bones a usual consequence, but has probably been considered so from the occasional complication of scorbutus with syphilis; as ptyalism has also from its synchronous occurrence when mercury has been exhibited for the cure of the latter disease.

When scorbutus approaches its fatal termination, the painful and livid swellings above referred to often break, and assume the fungous appearance characteristic of scorbutic ulcers. The hemorrhages become more profuse and general; the increasing dyspnœa is accompanied in some cases with pain under the sternum, but most frequently in one of the sides. In others, however, without any complaint of pain, the respiration becomes suddenly quick and laborious, and death unexpectedly puts a period to the disease. The mind throughout is depressed and anxious, but at last there is generally a total indifference and apparent torpor of every faculty. The appetite for food is rarely impaired, and death has even seized the sufferer in the act of eating. Nyctalopia is an occasional occurrence in the progress of scorbutus, though rarely noticed in the descriptions of it. Dr. Hulme recorded its appearance in his inaugural dissertation printed in 1765; and Sir Gilbert Blane states that it had been reported to him by Mr. Telford. It was also a common occurrence amongst the scorbutic patients in the garrison of Gibraltar, during the siege of that place. (See NYCTALOPIA.)

To the complications of scorbutus with other diseases is to be attributed the Protean character which has frequently been ascribed to it, and which, from a comparison of descriptions, it would seem to have manifested. The conjoined diseases have been most frequently such as are incidental to the same predisposing causes, namely, fevers, continued, intermittent, and remittent; rheumatism, diarrhœa, and dysentery. It has often also been complicated with syphilis, and occasionally with catarrh and ophthalmia. Besides these, numerous other diseases are mentioned by writers as having preceded its occurrence; but scorbutus always exerts the predominating influence, and sometimes even has simulated the worst form of idiopathic disease, as phthisis pulmonalis,* the symptoms of which have subsided on the treatment appropriate to the removal of the former.

Scorbutic ulcers are to be recognized by the following characteristics: instead of pus they excrete a thin, fetid, sanious fluid, mixed with blood; their edges generally are of a livid colour, and as it were puffed up; a coagulum is soon formed on their surface, which can with great difficulty be wiped away or separated from its subjacent parts. These are soft, spongy, and putrid. When, however, the removal of this coagulum has been effected, the same appearance presents itself again after the lapse only of a few hours, and soon constitutes a soft bloody fungus of considerable size, formerly familiar to sailors, and commonly called by them *bullock's liver*, which in its boiled state the former resembles both in colour and consistence. "It often rises," says Lind, "in a night's time to a monstrous size, and although destroyed by cauteries actual or potential, or cut smooth with a bistory, in which case a plentiful hemorrhage generally ensues, at the next dressing it is as large as ever."

Pathological anatomy.—Although scorbutus, as we have already stated, was until the latter end of the last century a very fatal disease, and has been the subject of numerous dissertations, few accounts have recorded the *post-mortem* examinations of individuals who have died of it. On this part of the subject the essay of M. Poupart, from observations made at the hospital of St. Louis in Paris,† is the most minute and explicit we possess. Added to the external appearances of the body as described in the living subject of the disease, extravasations

* Medico-Chir. Review, for June, 1824. On scurvy in his Majesty's ship Leander, on a voyage from Trincomalee to the Cape of Good Hope.

† Mémoires de l'Academie des Sciences, 1699, p. 237.—Also Lind on Scurvy, p. 255.

of dark-coloured blood have been found very generally under the integuments, in the muscles so as to render them hard and rigid, and in some of the glandular parts of the body, particularly the spleen. The brain was always in its natural state. Serous fluid was frequently found in the thorax, stated to have been of various colours, and so corrosive as to excoriate the hands which had been wetted with it. In some who had suffered from dyspnœa, and had died suddenly, the cavity of the chest and also the lungs were void of *serum;* but there were adhesions of the pericardium to the latter, and of the lungs to the pleura costalis and diaphragm. In some who died suddenly without any obvious cause, the auricles of the heart, it is stated, were as large as a man's fist, and full of coagulated blood. The glands of the mesentery were generally obstructed and swelled. Some of these were found partly corrupted and imposthumated. In the liver of some few, the extravasations were hardened. The spleen was three times bigger than natural, and fell to pieces as if composed of coagulated blood. Sometimes the kidneys and lungs were studded with imposthumes. The ligaments of the joints were corroded and loose, and instead of the synovial fluid there was only a greenish liquor, to the causticity of which the corrosion of the ligaments was attributed. The epiphyses were found entirely separated from the shafts of the bones, the cause in the living subject of a crepitating noise on motion, which was sometimes distinctly audible. In some, the cartilaginous portions of the ribs were separated from the bone, and the bony part, at the point of separation from the cartilage, was carious to the breadth of four fingers. In some subjects, on squeezing the sternal extremities of the ribs the spongy portion was separated in a corrupted state, leaving only the external and internal bony plates. In some were found abscesses of the glands of the groin and axilla. Dr. Mead tells us, that upon opening the abdomen of a scorbutic patient he was struck with amazement at the monstrous size of the spleen, which weighed five pounds and a quarter, whereas the liver weighed but four pounds and a quarter; but its bulk seemed to be its only defect; for it retained its natural shape and colour, and had not the least scirrhosity or other hardness. Its interior parts were as usual of a dark livid hue, with lax fibres and deep-coloured blood.*

In the beginning of the disease, according to the observations made by the surgeons of Lord Anson's expedition, (Mr. Ettrick and Mr. Allen,) the blood as it flowed out of the orifice of the wound might be seen to run in different shades of light and dark streaks. As the disease advanced, it ran thin and seemingly very black, and after standing some time turned thick and of a dark muddy colour; the surface in many places of a greenish hue, without any regular separation of its parts. In the third degree of the disease it came out as black as ink, and though kept stirring in the vessel many hours, its fibrous parts had only the appearance of a quantity of wool or hair floating in a muddy substance; and when it issued from the body, as in hemorrhages, the appearances of this fluid were the same as to colour and consistence, whether it was discharged from the mouth, nose, stomach, intestines, or any other part. In dissected bodies, the blood in the veins was so entirely broken that by cutting any considerable branch, the part to which it belonged could be emptied of its black and yellow liquor. The extravasated blood was also precisely of the same kind.

Diagnosis.—The symptoms already detailed as characteristic of scorbutus, considered in connection with the circumstances under which they are stated to occur, or in other words its immediate causes, are sufficient data to render it distinguishable from every other disease; but in the present state of our knowledge a consideration of the latter is necessary to prevent it from being confounded with certain forms of purpura, viz. purpura simplex and purpura hemorrhagica; both of which until a recent period were regarded as manifestations of the disease under discussion. Good, as already stated, has classed the three together as species of the same genus, under the name Porphyra, Scurvy,—an arrangement which was sanctioned by the opinion of Willan, who viewed them as allied. A comparison of the symptoms alone would seem to warrant the conclusion that they are constituted by diversities of degree only of the same morbid condition. But that this uniformity does not exist, particularly as regards purpura hemorrhagica and scorbutus, has been inferred from the successful issue of the treatment of the former by the pursuance of the antiphlogistic system, especially by the exhibition of purgatives, and in some instances even by bloodletting, when the occasional causes of the latter have not been found to exist, and the remedial measures appropriate to its removal had been resorted to in vain. In many instances a plethoric state of the system and a febrile disposition have pointed out the divergence from the line of symptoms which characterize scorbutus, and the peculiarity has been further marked by the nature of the diet and the previous condition of the patient. But it must be acknowledged that it is often impossible to recognize the distinction between purpura and scorbutus, or appreciate any difference in their occasional causes, except that amongst those of the latter the influence of a cold and humid atmosphere appears almost, if not always, essential to its production. When the state of the pulse and the condition of the patient has suggested the advantage of bloodletting in purpura hemorrhagica, the appearance of that fluid on being allowed to stand has been that of blood drawn in inflammatory diseases, presenting on its surface a thick and tenacious coat of coagulated lymph. The cruor has also been firm and cohesive, and difficult of diffusion when shaken in the serum, and altogether different, (as will be seen

* Medical Works of Richard Mead, M.D. Dublin, 1767, p. 421.

by comparison with the description already given,) from blood drawn in scorbutus.

Prognosis.—Although scorbutus has "slain its tens of thousands" on land as well as at sea, and from its former fatality was not inaptly classed amongst pestilential diseases, the means of treating it have been so well ascertained and established, that for the most part, having citric acid at command, and still more certainly an abundant supply of fresh and succulent vegetables, with the power of protecting the patient from a continuance of the operation of its occasional causes, its cure may be much more certainly anticipated than that of any other disease in which the visible effects are as general and as threatening to the extinction of life. When deprived of the means above specified, as formerly often happened at sea, and as is even now frequently the case as regards fresh vegetables, citric acid may in general be depended on as a very efficient antidote; but without it the probabilities of arresting the progress of the disease will be infinitely diminished, and the recovery of severe cases rendered hopeless.

The first favourable symptom in the advanced stages of the disease, when fresh fruits and vegetables have been obtained, is a change from a constipated to a lax state of the bowels; the skin becomes moist and soft; some increase of bodily power follows; a tranquil pulse together with an improvement in the appearance of any ulcers which may be present; and a change in the aspect of the petechiæ and ecchymoses, their livid colour gradually assuming a yellow hue from the centre to the circumference, the skin at the same time resuming its natural colour, is then observed.

The most unfavourable symptoms are dyspnœa, stitches in the side, frequent faintings, a weak and quick pulse, involuntary evacuations, and excessive hemorrhages. An unexpected and fatal termination of scorbutus has occasionally, we have said, taken place upon any unusual exertion, or on sudden exposure to a fresh atmosphere. When complicated with other diseases, as dysentery or diarrhœa, the unfavourable aspect of scorbutus is rendered still more so, in proportion to their severity and the difficulties there may be to encounter in checking their progress. Diseases, also, of an incurable nature, the tendencies to which have been previously established, may be developed by the presence of scorbutus, such as phthisis, and other organic lesions productive of hydrothorax, ascites, &c. But at the same time, in forming a prognosis, it must be borne in mind that phthisis itself and other organic lesions have been simulated by this disease, and that their symptoms have subsided when the peculiar affection which constitutes scorbutus has been subjected to its appropriate treatment; and that the most unfavourable sequelæ will sometimes disappear when solely consequent upon the disease under discussion.

Causes.—The predisposing causes, or those which induce an aptitude in the body to be attacked by scorbutus when exposed to its usual excitants, are numerous, and vary in their nature, but concur to occasion debility whatever they may have been. Thus we find that preceding diseases, whether acute or chronic, have been very common precursors, and that persons recovering from fevers, or who have been previously weakened by frequent relapses, have been often subjects of it. Indolence and inactivity appear also to have contributed to produce the susceptibility. The persons in a ship's crew termed *skulkers* or sluggards have been usually the first attacked; and it has been observed that those whose condition on board-ship exempts them from much exercise, have also been early amongst the number affected. We are told that in one of Lord Anson's ships, the Centurion, out of fifty cases of scorbutus four only survived, and of the whole number of marines attached to the squadron (seventy), all but eleven died of it. It has been observed also in the Dutch service, that if there were seven on board that had the scurvy, four of these were marines, though the number of the latter was, of course, proportionately much less than that of the sailors. Corpulent persons have appeared to be peculiarly prone to it, and on shore it has been observed to affect individuals of sedentary occupations more frequently than those engaged in the active duties of life; and where it has been endemic, very frequently to attack the sedentary mechanics whilst the rural population have entirely escaped. On the other hand, however, excessive fatigue, overexertion, and want of necessary rest, induce the same predisposing condition. Thus, it has not unfrequently occurred after long and harassing marches, and at sea succeeded occasions of much laborious duty; numerous instances of which might be adduced if space were allowed us for the detail.

But of all the predisposing causes, none has been observed to have more frequently, if not invariably, exerted its influence than cold combined with moisture, either from the atmosphere generally, or from the equivalent influence of a humid apartment or damp clothes. When scorbutus made such havoc in Lord Anson's squadron on doubling Cape Horn, the weather had been very tempestuous, the wind cold and cutting, accompanied with snow and sleet. At the siege of Azof, when the Russian army suffered from it severely, the same circumstances existed. In the account of his voyage round the world, La Perouse states that he was very fortunate in preserving his crew from scorbutus, an effect which he attributed entirely to maintaining a dry state of the atmosphere between the decks. Captain Cook's success in this respect seems to have depended considerably on similar precautions. In Captain Parry's first voyage for the discovery of a North-West passage, the influence of humidity in this particular was very conspicuous. "Mr. Scallon," he states, "had been complaining for some days of pains in his legs,—first considered by the surgeon as rheumatic, but which he was soon convinced by the appearance of the gums depended on scorbutus. This occurrence, so uncommon

amongst the officers of a ship, led to a particular enquiry as to its cause, and it was discovered that Mr. Scallon's bedding was in so damp a state in consequence of the deposit of moisture in his bed-place, as to render it no longer questionable." In Captain King's expedition in 1826, the crews of the two ships which he commanded, viz. the Adventure and the Beagle, continued healthy until May 1828, when scorbutus began to shew itself whilst in the straits of Magellanes, notwithstanding they were plentifully supplied with lemon-juice, sugar, preserved meats, pickles, cranberries, fish, wild fowl and wild celery. There was, however, excessive moisture of the atmosphere, and great mental depression prevailed in the crews from want of occupation, which in this instance would seem to have been excitants of the disease.

Mental depression, indeed, appears on most occasions to have had a powerful influence in predisposing persons to scorbutus. During its endemic prevalence, the timid, the discontented, and the inactive, have been frequently the first attacked. From this cause probably it is that newly impressed seamen have been particularly liable to it, and that it has often shewn itself among the inhabitants of besieged towns. Hypochondriacs and persons of a melancholic temperament have been so commonly its subjects, that the hypochondriacal disorder, the atrabilious habit, and scorbutus, have by many of the old writers been considered as different degrees of the same disease.* Amongst a variety of other debilitating circumstances conducive to scorbutus, exposure to the impure air of crowded apartments and the free use of ardent spirits have been so commonly its precursors, that they require to be especially particularized. It has also been observed that individuals of uncleanly habits, both with regard to their persons and clothing, have been more liable than others to the disease.

Various opinions have been entertained as to the immediate or exciting causes of scorbutus, and, as frequently has occurred in reference to epidemic or endemic diseases, its propagation has been attributed to contagion. Sennertus, Boerhaave, and Hoffmann, are of the number of those who have advocated this opinion; and in Sir Gilbert Blane's work, published in 1785, we find that it was not discountenanced by him. It has been so completely subverted, however, by subsequent experience that it would be needless to discuss the question. Its hereditary transmission has also been asserted, but of this there is no satisfactory proof or even plausible argument.

At all times it has been an accredited opinion that its origin has been referable, with the concurrence of the predisposing circumstances already mentioned, to an insufficiency of nutriment, or to some noxious qualities of the ingesta, and these for the most part included in the following particulars—in certain impurities in the water or other liquids used for drink; in a preponderating proportion of farinaceous substances ill-fermented, or which have not undergone that process, or otherwise in a faulty state; in the use of animal food in a state of putrefaction, decomposition, or hardened and changed in its nature by the process of salting, as for sea use; simultaneously with privation or an insufficient supply of fresh vegetables, or a scanty allowance of such dietetic drinks as contain their elementary principles.

The connection of scorbutus with the use of such diet has to a certain degree been rendered obvious by the successful issue of changes in the dietary of our own navy, determined on in consequence of the numerous facts corroborative of the supposed influence of the former system on the generation of this particular disease. The necessary concurrence of so many circumstances apparently essential to its production renders it impossible to estimate their individual operation, and this knowledge can be obtained only (if the opportunity should ever occur) by a more full and exact inquiry into the co-existent condition of the blood and other fluids of the body than has ever yet been made. From its former prevalence principally amongst seafaring people, an idea has been entertained that the large quantity of salt used in their food was exclusively an excitant of scorbutus; but Dr. Lind has shewn that the daily use of considerable quantities of sea-water has in no degree aggravated it, and that an entire abstinence from salt or salted meat has had no mitigating effect on its symptoms.* It is certain also that scorbutus has prevailed where the operation of this article could not even have been suspected; as, for instance, on the occasion of Lord Anson's ships leaving the coast of Mexico, when they were plentifully supplied with fresh meat. The soldiers in the Russian armies, who suffered from scorbutus at the siege of Azof, had no salt provisions. During a scarcity of corn it raged amongst the poor inhabitants of the colder districts of Italy near the Alps, who subsisted chiefly on the decoction of roots, and often passed whole days without any food at all. In the Transactions of the College of Physicians, Dr. Milman has related two cases of the disease appearing in a very severe form in individuals who had lived for three months on tea, without milk or sugar, or any other article of diet except bread.† From its occurrence also in prisons, and so lately as the year 1819 in the Milbank Penitentiary, under a dietary of fresh animal and vegetable food combined, it may be inferred that the prejudicial effect of salted meat depends either on its being deprived of its nutritious qualities, or upon its being otherwise rendered indigestible. It is also somewhat corroborative of this view, that the

* Enquiry into the source of Scurvy, by Francis Milman, M. D. 1782.

* Page 52.

† Milman on Scurvy, ch. ii.

direct effect of the addition of salt to blood out of the body is a change of its colour from black to red, the reverse of which is the consequence of scorbutus in the blood of the living body. With regard to diet, however, the most constant peculiarity which has apparently caused the occurrence of scorbutus, has been a deficiency in the proportion or an entire privation of *fresh* vegetables, or rather, it should be said, of those which are of a succulent nature,—as an instance in point, may be mentioned the occurrence of scorbutus in Porchester Castle and at Norman Cross, about the beginning of the late revolutionary war, before those arrangements were put into practice which afterwards so effectually secured the health of the prisoners. Under similar circumstances it appeared in a prison-ship near Porchester Castle.* In these situations, however, it is to be remembered that there was a cooperation of several circumstances conducive to the disease, viz. deteriorated air, a dull uniformity of life, depression of spirits, want of exercise, &c. &c. It is scarcely necessary to observe that the saline effluvia in sea-air has been alledged as the cause of scorbutus. It is obvious that a circumstance so constantly prevailing at sea and on its shores could never have had so partial a consequence, and that the disease has almost entirely disappeared, though the cause alleged remains the same. It has been moreover remarked that there are few artificers so healthy as those who prepare salt from sea-water, and are thus continually exposed to the impregnated vapour which rises in the processes of drying and purifying this article.†

The hypotheses which have been promulgated in explanation of the physical condition on which scorbutus, or, in technical language, its proximate cause, depends, have accorded with the revolving doctrines of general pathology, but have been chiefly founded on those principles which refer disease to morbid changes in the fluids, or else to a corresponding condition of the properties of the living solids. For the most part, and up to the present day, scorbutus has been attributed to the former, even by those who have ably advocated the opposite opinions with regard to disease in general. Much further investigation, however, into the elementary components both of the solids and fluids of the body in their healthy and morbid state, and into the influences of external agents upon them, than has hitherto been made, is requisite to clear up the difficulties of this intricate question. The peculiar opinions on the subject which from time to time have elicited attention require to be noticed in this place, but it must be premised that the principles of treating the disease founded upon them have been very inadequate to the end in view, which has been achieved most completely by observation alone, or, in other words, by that enlightened empiricism which suggests the right application of established facts in the art of therapeutics, although much knowledge may be wanting to elucidate the nature of the changes produced in the body by which the object is effected.

The early writers on scorbutus have applied the general doctrines of the humoral pathology to the explanation of its various phenomena; more especially ascribing them to a putrid state of the blood, occasioned, as it was supposed, by defect in the function of the spleen, this organ at the period having been considered essential to the process of sanguification. Willis,* consistently with his pathological speculations in general, referred scorbutus to a state of *dyscrasy* of the blood, which he fancifully described as of two kinds, under the terms of the sulphureo-saline and the salino-sulphureous; the former to represent a supposed superabundance of sulphur, for the correction of which he taught that the depleting system was requisite, and above all things the avoidance of the hot and acrid antiscorbutics; whilst, on the contrary, in the *salino-sulphureous*, when the salts of the blood were supposed to predominate, he considered the warmer medicines were proper, and such as contained a volatile salt, together with preparations of steel and other tonics. The dyscrasy of the blood, he further presumed, was the occasion of a corresponding state of the nerves, or, according to his system, of the *liquor nervosus;* which thus secondarily, he imagined, conduced to the manifestation of some of the symptoms. The opinions of Boerhaave† on this subject appear to have been equally hypothetical: he contended that scorbutus was occasioned by that part of the blood which constitutes the crassamentum being inordinately thick and viscid, and the serous portion too thin, salt, and acrid. The acrimony of this fluid he imagined was either acid or alkaline, according to the nature of the food by the use of which the disease appeared to be induced: if, as at sea, it had consisted of salted meats, or of such as yielded little nutriment, as a consequence that there would be an acid, or, to use his own phrase, a muriatic acrimony; but if the food had been in a putrid state, that the acrimonious principle would be alkaline.

Although Hoffmann exposed the fallacy of the humoral pathology in general, his views of the nature of scorbutus coincided for the most part with those of Boerhaave; and Cullen, who first and most successfully controverted the same system of pathology, admitted its influence in giving rise to this disease. Presuming from the appearance of the blood, from that of the secretions and excretions, and from the fetor of the breath, that a morbid condition of the blood does give rise to it, he contends that a putrefaction or a nearer

* See a paper on the health of the Navy, by Sir Gilbert Blane, in the London Med.-Chir. Trans. vol. vi. p. 502. 1815.

† Opera, cap. De Scorbuto.

approach to it than is consistent with health, is a necessary consequence of living entirely upon animal food, without a frequent supply of vegetable aliment, and thereby of producing and evolving a larger proportion of saline matter. In confirmation of this, he observes that every interruption of perspiration, that is, the retention of the saline matter, contributes to the production of scurvy, whether produced by the direct application of cold, or by any other circumstance which might weaken the force of the circulation, such as the neglect or want of exercise, fatigue, and despondency of mind. It will be sufficiently obvious, he adds, that if the preternaturally saline state of the blood in scorbutus be admitted, the throwing into the body along with the aliment an unusual quantity of salt may have a great share in producing the disease. Even (he proceeds) supposing such salt to suffer no change in the animal body, the effect of it may be considerable; and this will be rendered still more probable, if it may be presumed that all neutral salts consisting of a fixed alkali are changed in the animal body into an ammoniacal salt, which he apprehends to be that especially prevailing in scurvy.* Sir John Pringle supported a similar doctrine, that scurvy was the result of "a gradually accumulating putrefaction" in the blood, from the putrescency of salted food, which he deemed the chief cause of the disease.†

The theory of fixed air, which was considered the principle of cement or bond of union on which the firmness, soundness, and cohesion of bodies depends, was advanced by Macbride in support of the opinions which referred scorbutus to a putrescent tendency in the blood; the loss of that principle appearing to him to account for the altered state of this fluid, and the method of cure depending on its restoration, which he proposed to effect by conveying it to the body by the free use of the infusion of malt and essence of wort. Dr. Trotter differed from his predecessors in his application of the pneumatic doctrines of pathology to this disease, the remote causes of which, in his view, tended to deprive the blood of oxygen; and to the restoration of this principle through the medium of the acid fruits he attributed their antiscorbutic efficacy. "We are of opinion," he remarks, "that the citric acid is decomposed by the organs of digestion and assimilation, after which the oxygenous principle is blended with the circulating mass." This supposition Dr. Trotter considers as further confirmed by the blackness of the blood discharged, and by the speedy change to a florid hue which the fungous ulcerations assume within a few hours after the acids have been administered.‡ Dr. Beddoes adopted the same hypothesis, but extended it to the abstraction of oxygen from the whole system, in explanation of the phenomena of the disease.

* First Lines of the Practice of Physic, by William Cullen, M. D.

† Obs. on Diseases of the Army. Appendix, p. xci.

‡ On Scurvy, p. 141.

Lind disputed the idea of putridity of the blood in scorbutus, and referred the primary changes to a relaxation of the tone of the animal fibres, a weakening of the powers of digestion, together with a stoppage of perspiration, the tendency of which, he admits, was to produce *spontaneous putrefaction*, the process of nutrition being suspended.* This view of the subject was followed up and most ably advocated by Dr. Milman, in an essay remarkable also for the elegance of its composition, published in 1782. "Whether," says he, "I consider the nature of the causes producing scorbutus, or the actual state of the blood in the disease, or the secretions which occur in its progress, they all concur to make me believe that it does not consist in a putridity of the blood. Nor does there appear to be any quality which can be discerned or defined in the blood of scorbutic persons by which the nature of their disease can be characterised." The theory which Dr. Milman has substituted it would exceed our limits to enter into in detail, but it consists of the following propositions:—that scorbutus is not a disease of the fluids, but of the solids; that its seat is in the muscular fibre; that its proximate cause consists of a gradual diminution of the vital power; and that the subsequent diminished cohesion between the particles of the muscular fibres, and the tendency of these to putrefaction, are links of the chain. In reference to the action of salt provisions, he considers, with Lind, that they tend to excite scorbutus not by their saline, but by their indigestible nature, and through defect of nutriment occasion an enfeebling of the vital principle productive of languor in all the functions of the body, and ulteriorly of a general disposition to putridity.† This view of the proximate cause of scorbutus is supported by the argument that all its predisposing causes are of a debilitating nature, and by the extraordinary influence of mental impressions in favouring its occurrence as well as its prevention and cure, such impressions being considered inadequate to the occasion of a sudden change in the chemical condition of the fluids. The agency of such impressions, however, through the medium of the nervous system, is supported by numerous illustrations in the phenomena of health and disease. On the other hand, it must be acknowledged that those means which appear to contribute in general to the strength and activity of the solids, such as fresh animal food, soups, wine, bark, and a variety of other tonics and stimulants, have been found to exert very inferior powers over the disease in comparison with the vegetable acids; which, nevertheless, are well known to produce an attenuating effect on the body, and this not unfrequently whilst they are accomplishing its cure.

Broussais contends that in scorbutus, whatever may be its cause, there is first an irritation of the internal membrane of the digestive canal; 2dly, an imperfect assimilation of the elements, especially of fibrin and gelatin, either in the

* Lind on Scurvy, p. 234.

† Milman on Scurvy, chap. vi.

tissues formed out of them, or in the blood which directs them to different parts of the body; 3dly, that in consequence of defect of nutrition a diminished cohesion of fibre ensues, which accounts, in his view, for the imperfect contractility and fragility of the muscular fibre, for the rupture of vessels and the escape of their fluids, and, finally, for the easy disorganization of the tissues on the occurrence of scorbutus.*

We shall conclude this part of the subject by noticing some observations of Andral, which appear to us to be most consistent with all the facts on which an opinion of the nature of scorbutus can be established. In the threefold respect of the vital phenomena, intimate structure, and chemical composition, no line of demarcation can be drawn with strictness and precision between the blood and the solids. Physiologically speaking, it is impossible to conceive that one of these two parts of the same whole could be modified without the other being so likewise. On the one hand, inasmuch as the blood nourishes the solids, and as without its presence they cannot support life, the state of the solids cannot but be influenced by the state of the blood. The chemist might as well say that the nature of a body does not depend on the nature of the elements that compose it. On the other hand, the solids, considered with respect to their relations to the blood, form but two classes, the one contributing *to make* the blood, such as those concerned in the processes of absorption, digestion, arterial circulation, and respiration; the other contributing to *unmake* it, those, namely, concerned in the processes of venous circulation, secretion, and nutrition. No one solid, therefore, can undergo the slightest modification without producing some derangement in the nature or quantity of the materials destined to form the blood or to be separated from it. Physiology, then, leads us to the conclusion that every alteration of the blood must be succeeded by a modification of the solids. Viewed in this light, there is no longer any meaning in the disputes between the solidists and the humorists; and the system appears to constitute but one great whole, indivisible in the state of health as well as in that of disease. With regard to scorbutus in particular, he observes that the causes under which it is developed epidemically, the symptoms that characterize it, the remarkable state of the blood itself, and the nature of the lesions discovered on examining the bodies, all combine to prove that this disease depends on a primary alteration of the blood.†

Prevention of scorbutus.—The prevention of scorbutus in this and in some other countries in which it formerly prevailed having been completely effected, or rather the disease having disappeared in consequence of the dietetic consumption by all classes of persons of fresh vegetable food at every season of the year, of drinks which contain their elementary principles, of water in a pure state, of milk, of fresh animal food, and the disuse, as an article of daily subsistence, of dried and salted meats, together with the general drainage of the country, the greater security, dryness, and warmth in the dwellings, the improvements in clothing, and greater attention to cleanliness, it would be superfluous to enter into a formal detail of measures for its prevention on land; more especially as the process of civilization advances us so much the farther from the sources of this and other epidemic diseases. But, although improvements comparatively as great have been effected in our naval economy, and have been sufficient to lead to the general extermination of scorbutus, yet under particular circumstances the greatest vigilance has been frustrated by the superior power of its occasional causes, and their unceasing operation at sea renders unremitting attention to certain prophylactic measures necessary to ensure security against its occurrence. These consist of the removal, if possible, or, at least, of the counteraction of the predisposing and occasional causes of the disease; and in the daily use of a certain quantity of lemon-juice, the preventive efficacy of which is well established although its operation has not been satisfactorily explained. The application of such preventive measures has for the most part been happily illustrated in the narrative of the memorable voyage of Captain Cook. To his sagacity we are indebted for the first impulse to those regulations by which scorbutus is so successfully prevented in our navy. It will be remembered that the crew of his predecessor Lord Anson, in a similar voyage of discovery, had experienced the most dreadful havoc from this disease, and the prevention of it seemed to present as great difficulty to himself as any circumstance of his projected voyage. The maintenance of the general health of his men he discerned was the main point of security, and to command this he was especially careful that they should not be subjected to excessive or unnecessary fatigue, and as much as possible that they should be protected from the noxious influence of a cold and damp atmosphere. In the first place he instituted three instead of two watches,* by which eight hours of uninterrupted rest were allowed to his men for four of duty; their strength was consequently more recruited, and they were also less exposed to the weather than if they had been at watch and watch, and if necessary they had dry clothes to change. The hammocks and bedding every fine and dry day were not only ordered upon deck, but each bundle was unlashed and so spread out that every part was exposed to the air. Besides

* Treatise on Physiology applied to Pathology, Transl. Philadelphia, 1832.

† Andral's Pathol. Anat. translated by Townsend and West, vol. i. p. 641 and 678.

* Dr. Trotter disputes the advantage of this arrangement. "We," he observes, "who see things on the spot, and daily accustomed to reason on the discipline of ships, are clearly decided in favour of two watches; our most accomplished and intelligent officers have also from experience put it beyond dispute."—Medical and Chemical Essays, By Thomas Trotter, M.D. p. 25. We believe, however, that *three watches* are now the more general custom in our navy, at least in large ships.

the ordinary methods of whitewashing and scraping the decks, stoves were kindled and carried successively through them, which not only served to dry the ship, but, by heating the impure air below and rendering it specifically lighter than the common air, to make it rise and pass through the hatchways. In the torrid zone he shaded his people from the scorching sun by an awning over the deck, whilst in his course within the Antaretic circle they were provided with coats of woollen stuff, furnished with hoods to cover their heads. He attended also particularly to their diet, taking care that there should be always a plentiful supply of water both for this purpose and for the promotion of cleanliness. He prohibited the custom of using the fat which was boiled out of the salted meats in lieu of other food; having observed that symptoms of indigestion were the common consequence, and the latter not unfrequently a preliminary of scorbutus.* Captain Cook begins his list of preservative stores with malt. "Of this," he says, "was made sweet wort,† and given not only to those men who had manifest symptoms of the scurvy, but to such also as were considered most liable to it." This article, although he did not consider it adequate to the cure of scurvy, he praised as one of the best anti-scorbutic medicines known in his day. Sooins or sowens,‡ an article of diet well known in Scotland, was also considered by him of great anti-scorbutic efficacy, and was dealt out to his men in messes sweetened with sugar and flavoured with some French prize wine, which, though sour, was thought to improve the flavour. Captain Cook was provided with lemon-juice prepared for sea use, but the necessary quantity not being understood, it was neglected and erroneously underrated. But the article of most extensive use for the same purpose was sour kroute (sour cabbage), well known in German diet. Sour kroute or croute (*Saures Kraut*, German; literally sour herb or pickled cabbage,) is prepared by slicing the soundest and most solid cabbages in the way cucumbers are used in this country. In this state they are put into a barrel in layers, hand high, and over each is strewed a handful of salt and carraway seeds; in this manner it is rammed down, stratum super stratum, till the barrel is full, when a cover is put over it, and it is pressed down with a heavy weight. After standing for some time in this state, it begins to ferment, and it is not till the fermentation has entirely subsided that the head is fitted to it, and the barrel is finally shut up and prepared for use. Vinegar, as some have supposed, is not employed in its preparation. It was recommended to the use of the British navy by Dr. Lind, the great freedom of the Dutch from scorbutus having been attributed to the free use of it. The quantity allowed was two pounds weight to each man per week, besides a pound and a half to two pounds with every gallon of pease, for making soup. He was supplied also with portable soups, which, as far as possible, he made the vehicle of vegetable aliment; and by such means, and by diminishing the quantity of salted provision, to his honour be it said, he preserved his crew from scorbutus, although the period of his voyage had extended to three years and eighteen days, passed in all latitudes from 52° N. to 71° S. It is still more remarkable that of a company of 118 men he lost but one, who there is reason to suppose was labouring under phthisis previous to his departure from England.

The comparative exemption of our own navy from scorbutus during the last thirty-five years, is, we conceive, to be attributed in no small degree to the regulations enforced for the maintenance of the general health of the sailors, together with the improvements by which this object has been advanced. A frequent inspection of the men's clothing is made, to ascertain whether there is a sufficiency for the purposes of personal cleanliness and of protection from the effects of the weather, both as regards their bedding and wearing apparel. The strictest attention is given to the ventilation, cleanliness, and dryness of ships. For what are called windsails (which were found to be imperfect and inconvenient ventilators, from their use being inadmissible with hatches closed in bad weather when they are most wanted, and when the men were asleep, on account of the large volumes of cold air which they admitted) has been substituted a contrivance free from those objections, borrowed from a French frigate: this consists of square wooden trunks (for which brass tubes have since been used) running from the hold or lower deck and terminating in the open air. A contrivance which has still more recently been preferred, is a funnel placed vertically near the middle line of the ship, before the foremast, leading through the forecastle-deck where there is neither hatchway nor ladder, and under which are the sleeping-places. The removal of all offensive substances by sweeping and scraping has been much more particularly attended to than formerly; but instead of washing the decks, particularly in cold or damp weather, the preservation of dryness, so essential to comfort and health, as well as to the prevention of scorbutus, has been carefully studied, and rubbing

* *Milman*, p. 33.

† Infusion of malt, proposed as a preventive as well as a remedy for scorbutus, was recommended by Dr. Macbride on the supposition that it would ferment after being taken into the stomach, and give out carbonic acid gas—its alleged remedial principle. Laying aside all regard to the theory on which it was suggested, experience seems to have determined that it is a nutritious beverage, and that it has been productive of considerable advantage in the objects for which it was proposed. It has been used rather as an article of diet than medicine, and has been generally directed in the quantity of from one to four pints daily.

‡ This food is prepared by putting some oatmeal into a wooden vessel, pouring hot water upon it, and continuing the infusion till the liquor begins to taste sourish, i.e. till a fermentation comes on, which, in a place moderately warm, may be in the space of two days. The water is then poured off from the grounds, and boiled down to the consistence of a jelly.

with hot sand, scraping, and portable fires, have been generally substituted. By these precautions, also, the deteriorated agency of moisture on the ship's provisions, as well as on other articles in common use, has been prevented, and thereby a source cut off, which otherwise might have been largely conducive to the generation of this disease. This important point has been further promoted by having portable fires in iron stoves carried all over the ship. Formerly a prolific source of foul air and bad smells in ships were the putrescent matters absorbed and retained by gravel, sand, and other earthy substances used for ballast, for which are now substituted small masses or pigs of iron; and iron tanks, instead of the lower tier of water-casks, are placed over the iron ballast. The tanks adverted to are cubes of four feet in dimensions, each capable of containing about two tons of water: as they are not corruptible, like wood, they impart no bad quality to it, and by their durability insure an ample supply; whereas the decay of casks in long voyages and in remote parts of the world where they cannot be replaced, has occasioned the utmost distress.

The improvement suggested by Sir Robert Seppings, Surveyor of the Navy, and explained by him in the "Philosophical Transactions" for 1814, the object of which was to add to the strength, solidity, and durability of ships, has been highly conducive to the purity of the air in them; first, by the obliteration of those cavities under the floor of the hold which used to be the receptacle of filth and vermin, and the perpetual sources of offensive and noxious exhalations; secondly, from commanding at all times the most perfect ventilation, the timbers of the frame which run up the side of the ship maintaining a constant communication with the open air, with the hold and spaces between the decks; thirdly, by virtue of this new construction, a ship being less liable to leakage, together with the new method of ballasting, all the unwholesomeness and offensiveness belonging to bilge-water is done away.

The promotion of the general health of seamen, and consequently the prevention of scorbutus, is further effected by the superior quality of all the articles of victualling; by the plentiful supply, when in port or within reach of it, of fresh meat, succulent vegetables and fruits; and when at sea, by the daily use of cocoa for breakfast, or of tea, coffee, sugar, &c. and a less proportion of ardent spirits. To these are to be added the more liberal allowance as to quantity of the diet at sea; and, under circumstances particularly conducive to the generation of the disease, an increased allowance of farinaceous articles in lieu of the necessary diminution in the rations of salted meats. The former consist for the most part of biscuit, wheat-flour, oatmeal, peas, and pearl barley, and, as substitutes for fresh vegetables, though of infinitely inferior anti-scorbutic efficacy, dried raisins, currants, prunes, preserved fruits, spices, pickles of various kinds, vinegar, molasses, and as much wine for each man as is equivalent to one-half of the allowance of spirits, the latter being suspended.*

But to the general supply of lemon-juice, judiciously dispensed to ships of war since the year 1795, Sir Gilbert Blane ascribes the complete eradication or rather the prevention of scorbutus. Usually, after ships have been a fortnight at sea, to every individual in them a fluid ounce of lemon-juice mixed with an ounce and a half of sugar is served out daily, which, with the addition of water and of wine or spirits, affords a grateful beverage, the use of which is enforced when the neglect of it is suspected, or under particular apprehension of the invasion of the disease. It is in consequence of this prophylactic, Sir Gilbert Blane infers, that there are now many surgeons in the navy of long standing who have never seen a case of the disease; and, as appears from the inspection of a great number of journals, that it has either not appeared at all, or else in so slight a degree that it was speedily checked by an increase of the quantity of the antidote. No other remedy yet known can ward off, he observes, this dreadful scourge of mariners under the use of salt provisions for an indefinite length of time; nor does it produce, he adds, any bad effects on the constitution like some specifics in other diseases. The decisive superiority of lemon-juice has led to the disuse of a variety of articles formerly in repute for the prevention of scorbutus, such as sour kroute, infusion of malt, essence of spruce, elixir of vitriol, &c. Of the sour kroute we have already spoken; and we have alluded to the use of the infusion of malt. "Although," says Dr. Trotter, "I have no idea of impeaching the veracity of those who established the credit of the malt preparation, yet I must beg leave to observe that in my own practice I have not seen it attended with any good effects. Lind speaks of it only as a very nourishing liquor, well adapted for scorbutic patients." The essence of spruce,† or rather spruce-beer, the form in which it has been commonly used, seems to possess, says Sir Gilbert Blane, similar and equal anti-scorbutic virtues with fermented malt liquor, as beer or porter; and it has this advantage, that the materials for preparing it can be readily carried about and used as occasion may demand.‡ The use of elixir of vitriol in the cure of scorbutus was of very early date, and, on the principle that what will cure will prevent, it was recommended to the use of the navy by Dr. Huxham, who states that it had been found "greatly serviceable." The assertion, however, is not corroborated by general experience, and the converse of the proposition seems more applicable to the circumstance in

* See Paper by Sir Gilbert Blane on the Health of the Navy.—Med.-Chir. Tr. vol. vi.

† Captain Ball states that the essence of spruce a little diluted did wonders at St. Domingo, both in prevention and cure. It acted as a purgative, and was therefore carefully administered; it sat on the stomach when every thing else was rejected.—Med. Naut. by T. Trotter, vol. i. p. 349.

‡ Observations on Diseases of Seamen, p. 302.

question; at most, probably, it has been useful in correcting the unwholesome qualities of impure water, for which purpose it has been occasionally added to it in very minute proportion.

We have yet to mention the necessity, in a prophylactic point of view, of regular exercise. Although often called upon for extraordinary exertion, it occasionally happens with seamen that there are long intervals in which systematic attention to this branch of hygiene is especially requisite. Independently of its direct influence on the maintenance of the general health, it may be made subservient to an equally important object in the prevention of scorbutus, viz. to occupation of mind, and in sailors, its diversion from those gloomy views to which, under suspension of duties, they are peculiarly prone; a fact which, however astounding it may at first appear, reflection will assent to be consistent with his condition. To separate, as his duties require him, under perilous circumstances from those to whom he is linked by the bonds of affection; to be peculiarly subjected to disappointment, and to unexpected delay in schemes to which the brightest hopes are attached; to have been taught by reason and experience that the perils which he has no fear to encounter are frequent and more than ordinarily liable to frustrate them; and in many instances the necessary system of moral discipline being wholly inconsistent with the physical condition, are circumstances sufficient to account for the state of mind above mentioned. The despotic system, formerly in force, of impressing seamen, doubtless had a powerful influence in predisposing them to disease. Their country, says Dr. Trotter, has taken advantage of their situation, and their service is indispensable to the safety of its commerce and territory. It is only therefore mild treatment that can reconcile an impressed sailor to his fate, and if he be so unfortunate as not to overcome it, some fatal disease, as scurvy, will be the consequence: among people of this description it first makes its appearance. An officer, therefore, cannot too minutely study the genius and the temper of those he is to command; but the good effects of it and the satisfaction he will experience, will more than repay his assiduity.

In the narrative of Captain Parry's voyage already referred to, it appears that that able officer was fully impressed with the expediency of amusement as well as of exercise for the preservation of the health of his men, and was particularly aware of the anti-scorbutic efficacy of occupations being afforded to them. The mode of their pursuance must depend on the circumstances which are present, and much of the advantage must arise from the ingenuity and address with which the means are devised. The narrative of Captain Parry's expedition to the Polar seas affords a happy illustration in point, many circumstances of it having been congenial to the production of scorbutus, but which, nevertheless, by salutary precautions was most successfully opposed. Although some of these have been already discussed, their practical application with that of others is so advantageously set forth in the following passage, that no apology, we conceive, is necessary for transcribing it. "The commander finding himself shut in for a long and dreary winter, devoted his attention, with judicious activity and a mixture of firmness and kindness, to mitigate those evils which even in lower latitudes had often rendered an arctic winter so fatal. His provisions being very ample, he allowed the sailors weekly a pound of Donkin's preserved meat and a pint of concentrated soup, instead of a pound of salt beef; beer and wine were served instead of spirits; and a certain allowance was made of sour krout, pickles, and vinegar. The sailors were also called together daily and made to swallow a quantity of lime-juice and sugar in presence of the officers; their improvidence being such as to afford otherwise no hope of their spontaneously imbibing this salutary draught. Their gums and skins were also regularly examined, in order to detect scurvy in its earliest symptoms. It was necessary to be very economical of fuel, the small quantity of moss and turf which could be collected being too wet to be of any use. By placing the apparatus for baking in a central position, and by several other arrangements, the cabin was maintained in a very comfortable temperature; but still, around its extremities and in the bed-places, steam, vapour, and even the breath settled, first as moisture and then as ice; to dry and remove these annoyances became therefore a part of their daily employment."

Exercise, it is stated, was enforced on the men when they were prevented from leaving the vessel, by obliging them to run round the deck to the tune of an organ; this they did not at first entirely relish, but no plea against it being admitted, they converted it at last into matter of frolic.

To keep their minds agreeably occupied, schools, masquerades, and plays, were adopted; in reference to the latter it is observed that the very expectation thus raised among the seamen, and the bustle of preparing a room, were extremely salutary, and when the *North Georgian Theatre* opened, with "Miss in her Teens," these hardy tars were convulsed with laughter, not a little excited perhaps by viewing their officers in the singular and novel position of stage performers. At all events the Arctic management was extremely popular. As the small stock of plays contained in one or two chance volumes was soon exhausted, original compositions were produced and afterwards formed into a collection. The officers had another source of amusement in the *North Georgian Gazette*, of which Captain Sabine became editor, and all were invited to contribute to this chronicle of the frozen regions. Even those who hesitated to appear as writers enlivened the circle by severe and good-humoured criticisms.

Treatment.—Recovery from scorbutus, to use an expression of Lind's, presents a re-

markable instance of the quick diminution of the effect from the cessation of the cause; an observation which has been so amply confirmed by experience that it may be regarded as a most important axiom in the therapeutic consideration of the disease. There are remedies, nevertheless, which expedite and even effect its removal under disadvantageous circumstances, and this with a degree of rapidity which, considering its apparent ravages, seems most extraordinary and peculiar to itself, the more so from our knowledge of its nature being very imperfect, and the salutary operation of such remedies by no means obvious. We reject theory, therefore, from our consideration of this part of the subject, in the spirit of the following remark of one who has well appreciated its importance in practical medicine: "Cujus autem rei non est *certa notitia*, ejus opinio certum reperire remedium non potest. Verumque est, ad ipsam curandi rationem nihil plus conferre quam experientiam."*

It has been found an essential step to the relief of a person suffering from scorbutus that he should have the advantage of a dry atmosphere, both as regards the apartment which he inhabits, and the various articles of his bedding and wearing apparel. Next to this, to gratify the cravings of his appetite, an instinctive index, apparently, to the chief corrective of his disease, by a satisfying supply of esculent fruits and fresh vegetables: "be they of any sort," says Lind, and all experience has verified the remark, "they will for the most part prove effectual." At different periods, however, a specific virtue in the cure of scorbutus has been attached to particular articles of the vegetable kingdom, and those which are succulent and possessed of an aromatic quality, especially the alkalescent plants of the class tetradynamia, have been regarded as powerfully anti-scorbutic;† but that their power in this respect does not depend on their alkalescent property is proved by the fact that the vegetables and fruits in which the acid principle abounds have been alike efficacious, and even in a still higher degree. Of the latter, those of the genus Citrus, and of the natural order Hesperidæ, viz. the Citrus medica, lemons—C. aurantium, oranges—C. acida, limes—C. decumana, shaddocks—particularly the three first, have obtained pre-eminent repute, even to the extent of being considered specifics—a denomination to which they appear to be as much entitled as medicines adapted to the cure of any disease. Their efficacy, however, having been gainsayed by a physician whose writings have attracted considerable notice,* and their claim to therapeutic estimation resting entirely on experience of their effects and deference to

* *Celsus*, lib. i.

† Formulæ for the preparation of medicines for the cure of scurvy were formerly inserted in the Pharmacopœias of London, Edinburgh, and Dublin, under the titles of Succi Scorbutici and Succi ad Scorbuticos; these were compounded of the juices of garden scurvy grass (cochlearia officinalis); brookline (veronica beccabunga); water-cresses (nasturtium officinale); and Seville oranges. Besides these, of the infinite number of anti-scorbutics which have been in great popular estimation, and commonly recommended by medical writers until within the last half century, the chief are the horse-radish (cochlearia armoracia); garden purslane (portulaca oleracea); black and white mustard (sinapis alba et nigra); the biting stone crop (sedum acre); celandine (chelidonium minus); marsh trefoil (trifolium palustre); common and Roman wormwood (absinthium latifolium et tenuifolium); fumitory (fumaria purpurea); hemp agrimony (eupatorium cannabinum); the garden radish (raphanus sativus); the garden lettuce (lactuca sativa); the garden endive (cichonium endivia); common juniper (juniperus communis); dandelion (leontodon taraxacum); the common onion (allium cepa); garlick (allium sativum); the leek (allium porrum); squill (scilla maritima); the potato, sliced and raw in vinegar (solanum tuberosum); the fir (pinus abies); sorrel (rumex acetosa); &c. Bishop Berkeley wrote a treatise, in 1744, to insist on the curative efficacy of tar-water in scorbutus; and Alston, (1750,) another on the superiority of lime-water for the same purpose.

* Dr. Stevens: see his Observations on the Healthy and Diseased Properties of the Blood, 8vo. London, 1832. Dr. Stevens's denunciation of the treatment of scorbutus by the administration of vegetable acids, seems to rest on the general effect observed of their admixture with the blood out of the body—viz. that of changing its colour from red to black, and by consequence, on the supposition that in this as well as in some other diseases in which the latter quality has particularly characterized the appearance of that fluid, such means would be found not only to keep up but to aggravate the disease. This morbid appearance Dr. Stevens attributes to its privation of its saline constituents, and hence in scurvy, and in other diseases in which it is in a black and vitiated condition, he asserts that "the natural saline waters, or the active non-purgative alkaline salts, act like a charm," (p. 309)—it being the property of these substances (contrary to that of the vegetable acids) on their addition to black blood out of the body to change its hue to red. On this principle Dr. Stevens explains the good effect attributed to the nitrate of potash in the treatment of scorbutus, and on the same ground would administer the muriate of soda, to the excessive use of which its production (as observed in the text) has been commonly attributed. Dr. Stevens, however, in another place (p. 451), has stated that during a residence of twenty years in the West Indies *only one case of scurvy* had come under his notice, and that case, he asserts, was decidedly brought on by the excessive use of citric acid, which an American gentleman had been recommended to use as a preventive against yellow fever; consistently with his theory too, that on its being laid aside and the carbonate of soda substituted, the patient was completely cured in three weeks. "To those," he observes, "who are disposed to see the contrast betwixt the effects of the neutral salts and the citric acid in the treatment of scurvy, I would recommend the perusal of Mr. Cameron's paper on this disease, which they will find in the Medico-Chirurgical Review, for 1829"—more conveniently, perhaps, for that purpose inserted in our text, and which, if considered with that degree of candour which the cause of therapeutic science demands, would only serve to prove what little credit is due to the following remark of his own, (p. 264.) "With respect to scurvy it would not be difficult to prove, from the writings of Trotter and others, that this disease, which at one period was so distressing in the British navy, was frequent and fatal almost exactly in proportion to the quantity of citric acid which was used as a preservative, and unfortunately also as a *cure* for the disease."

authority confirmatory of it, we conceive it necessary to enter into detail of evidence in support of the treatment of the disease by the remedial agents the efficacy of which has been denied.

The earliest notice we can find in reference to this point is in the third epistle of Rousseus, dated 1564, wherein it appears that some Dutch sailors who were suffering from scurvy, and the cargo of whose ship on their return from Spain consisted of lemons and oranges, accidentally discovered that their use was the means by which they recovered their health. "And if people," observes Lind, (p. 160,) "had been less assiduous in finding out new remedies, and trusted more to the efficacy of these fruits for preventing this fatal pestilence to seamen, the lives of many thousand sailors, and others, especially during the last war, might in all probability have been preserved. But some have been misled to recommend many other things, as of equal, if not superior, anti-scorbutic qualities to these; and have reduced them to a level with other acids, and many falsely supposed anti-scorbutic medicines; from whence the many unhappy disappointments hitherto met with in preventing this disease at sea seem to have arisen."

In 1593, Sir Richard Hawkins experienced the anti-scorbutic efficacy of lemon-juice in his crew, who were attacked by it in its virulent form within three or four degrees of the equinoctial line. In a work of considerable merit, entitled the Surgeon's Mate, or Military and Domestic Medicine, by John Woodall, master in surgery, dated London, 1636, we find an excellent disquisition on scurvy, and the following apposite remarks: "further experience teacheth, which I have oft found true, that where a disease most raigneth, even there God hath appointed the best remedies for the same grief, if it be his will they should be discovered and used; and note, for substance, the lemmons, limes, tamarinds, oranges, and other choice of good helps in the Indies, which you shall find there, do farre exceed any that can be carried thither from England, and yet there is a good quantitie of juice of lemmons sent in each ship out of England by the great care of the merchants, and intended only for the reliefe of every poore man in his neede, which is an admirable comfort to poore men in that disease. Also I finde we have many good things that heale the scurvy well at land, but the sea chirurgeon shall do little good at sea with them, neither will they indure. The use of the juyce of lemmons is a precious medicine, and well tried; being sound and good let it have the chiefe place for it will deserve it, the use whereof is: It is to be taken each morning, two or three spoonfuls, and fast after it two houres, and if you add one spoonful of *aqua vitæ* thereto a cold stomack it is the better. Also if you take a little thereof at night it is good to mixe therewith some sugar, or to take of the syrup thereof is not amisse. Further note, it is good to be put into each purge you give in that disease. Some chirurgeons also give of this juice daily to the men in health as a preservative, which course is good if they have store, otherwise it were best to keep it for need." In want of these he adds, "use the juice of limes, oranges, citrons, or the pulp of tamarinds, and in want of all these use oyle of vitrioll, as many drops, as may make a cup of beere, water, or rather wine if it may be had, onely a very little as it were sower." In another place he writes, "And generally note that bitter and sower medicines prevail most to the cure of this griefe, amongst which you have that are approved goode thereto, those that follow as chiefe, juyce of lemmons, of limes, of citrons, and oranges." In the account of his voyage to the East Indies, published in 1683, Dellou, a French physician, recommends for the prevention of scurvy, that each person on board should provide himself with the juice of citrons, lemons, and dried fruits, especially prunes. The same remedies we find recommended in the treatise of Martin Lister, published in 1694.

It is remarkable, however, that epidemic scurvies were allowed to rage in various parts of the world, and in none more than in the British navy, for more than a century and a half after Woodall had pointed out the usefulness of lemon juice, without its being generally employed. So complete was this neglect, that in 1740, when Lord Anson proceeded on his circumnavigation, no provision of any kind appears to have been made against the disease, and we find Mr. Walter, the chaplain of the expedition, and discriminating historian of it, declaring that "in some instances the prevention and cure of the malady could not be effected by any management or remedies which could be made use of at sea:" (p. 113.) But it is mentioned that on *nearing* the island of Tinian, lat. 15°. 8′. north, and in 114°. 50′. west longitude from Acapulco, it was part of a very grateful account of it they obtained from a Spanish prisoner, that it afforded plenty of lemons, limes, sweet and sour oranges, cocoanuts, and bread-fruit. We are informed also that on making shore their sick amounted to 128, and notwithstanding the extreme debility of the greatest part, twenty-one of them dying on the day of their arrival and the following day, yet during the whole two months in which they staid there, they did not lose above ten more, and that the remainder reaped such benefit from the fruits of the island, and "*in particular those of the acid kind*, that within a week most of them were so recovered as to be able to move about without assistance."

The calamities of this unfortunate expedition, and the sufferings they underwent, created a general interest, not only with medical men, but with the public at large, on the cause and nature of the disease, and the most likely means of controlling its ravages.

The stamp of correct observation founded on most extensive experience, which Dr. Lind's treatise on the subject, published in 1753, has been always acknowledged to bear, renders his testimony of the highest worth. "The result of all my experiments was," says he, "that oranges and lemons were the most effectual

remedies for this distemper at sea. I am apt to think oranges preferable to lemons, though, perhaps, both given together will be found most serviceable." In another case, "I cannot omit upon this occasion observing what caution is at all times necessary in our reasoning on the effects of medicine, even in the way of analogy, which would seem the least liable to error. For some might naturally conclude that these fruits are but so many acids, for which tamarinds, vinegar, *sp. salis. elixir. vitriol.* and others of the same tribe, would prove excellent succedaneums. But upon bringing this to the test of experience we find the contrary. Few ships have ever been in want of vinegar, and for many years before the end of the late war all were supplied sufficiently with el. vitriol. Notwithstanding which the Channel fleet often put on shore a thousand men miserably overrun with this disease, and many hundreds besides died in their cruises. Upon those occasions tar-water, salt-water, vinegar, and el. vitriol. especially, with many other things, have been abundantly tried to no purpose; whereas there is not an instance of a ship's crew being ever afflicted with this disease where the beforementioned fruits were properly, duly, and in sufficient quantity, administered."

Again, says this observer, "in seemingly desperate cases the most quick and sensible relief was obtained from lemon-juice, by which I have relieved many hundred patients labouring under almost intolerable pain and affliction from this disease, when no other remedy seemed to avail." Finding the acid to operate violently upon the stomach and bowels of those who were much weakened, he recommended the addition of wine and sugar, as constituting the best anti-scorbutic, and was in the practice of ordering about four ounces and a half of lemon or lime-juice, and two ounces of sugar, to be put into a pint of Malaga wine, which he thought sufficient for any weak patient to take in twenty-four hours. Dr. Trotter, however, states as the result of his experience that any such preparation was unnecessary, and that the happiest effects were produced by allowing the patients to suck the juices immediately from the fruits themselves.

In another place Dr. Lind says, "summer fruits of all sorts are here in a manner specific, viz., oranges, lemons, citrons, apples, &c.;" he moreover devised a method of preserving the juice of the two first-mentioned, so as to render them available at all times and in all climates, whether in the midst of the ocean or under the artic circle.

The testimonies of Sir Gilbert Blane and Dr. Trotter in favour of the anti-scorbutic efficacy of these fruits are equally strong, and when we consider the extensive opportunities of observing this disease which fell to the lot of these three eminent physicians, their qualifications for forming correct opinions, and the immense mass of evidence adduced by them in support of the remedies in question, the conclusion is irresistible that their adaptation to the removal of this disease is established on as firm a basis as that of any article of the materia medica to any disease whatever. The late venerable and talented director of the medical department of the navy, has in the year 1830 confirmed the opinion he gave to the world of these remedies in 1785, by the triumphant fact that the scurvy has been prevented, subdued, and totally rooted out of the navy by the general use of lemon-juice, supplied for the first time at the public expense in the year 1795, and which operated so speedily that in less than two years afterwards it became extinct and has remained so.* Of all the articles either of medicine or diet he had observed for the cure of scurvy, lemons and oranges are of much the greatest efficacy. They are real specifics, if any thing deserves that name; but upon what principle their superior efficacy depends, and in what manner they produce their effect, he acknowledges that he was wholly at a loss to determine, the only sensible effect being a small increase of some of the secretions. In another place he says that he has never seen the scurvy resist the juice of these fruits, and in the perusal of several hundreds of surgeons' journals that he had met with only two cases which seemed to resist it. "It is sui generis—nil simile nec secundum." "It may be affirmed with truth that it performs not only what no other remedy will perform in this disease, but what no known remedy will effect in any known disease whatever."†

Dr. Trotter, in his account of the health of the fleet in 1795, remarks, "from the middle of March to the 12th of June, upon comparing notes from the reports of surgeons, it appeared that not less than three thousand cases of scorbutus (the subjects of which were unfit for duty) had been cured on board ship by the fruit or preserved juice, and that twice that number with slighter symptoms were relieved by the fruit, the juice, and salads."‡ Mr. Moffat, surgeon to H.M.S. Triumph, 1796, in which scurvy had prevailed to a considerable extent, reported to Dr. Trotter, "that the scorbutic cases as usual yielded to the lemon-juice in every instance. So general," he adds, "was the tendency to it, that almost every case of contusion or ulceration was attacked with the disease, nor could their cure be accomplished without a few doses of the acid."§ In p. 151, vol. i. of the Medicina Nautica we find the following entry:—"Jan. 2, 1796. This day the squadron under Rear-admiral Harvey arrived at Spithead, after an absence of eighteen weeks from England, bringing three thousand soldiers from Isle Dieu. This squadron had been repeatedly supplied with refreshments from Plymouth and Cork. The scurvy appeared nevertheless *in all the ships*, but was quickly cured by lemon-juice." In the report of Mr. Ken-

§ Ibid. p. 157.

ning, surgeon of the Invincible, dated June 8, 1795,* in which ship there had been in all one hundred and sixteen cases of scorbutus, it is stated that of twenty-eight attacked in the month of April, the worst were supplied with three lemons and one orange daily, the others with two lemons, and that *in every instance* after the third day, and sometimes sooner, they began to recover, and were shortly well. In May fifty-six fresh cases were treated with the same remedies with equal success. In the latter end of the month the fruit was all expended, but there still remained a few gallons of lemon-juice, which lasted until the 2d of June. Patients continued to apply, and two of those that had been recovering before the lemons were expended, got worse in the short interval from the 2d to the 5th day, the day on which a fresh supply of lemons was received. Their complaints were soon checked by the *fresh fruit*, but not so fast by the juice, though it was given in some cases to a pint per day." In Lord Bridport's squadron, which (in 1795) had suffered severely from scorbutus, there was not a case in which lemon-juice was given where it did not produce a cure in the space of a few days.†

Dr. Baird, surgeon of the Hector, a ship in which scorbutus prevailed to a considerable extent, gives the following account: "I began with giving the lemon-juice in the quantity of an ounce and a half daily, and encouraged by the material change I perceived in about four days, I increased it to three or four ounces per day, always taking care to join a sufficient quantity of sugar to prevent it from irritating the bowels; in twelve or fourteen days the worst of them were able to return to duty, every symptom being then removed, except some slight degree of stiffness in the hams, which gradually wore off." "When I consider," he adds, "the alarming progress which the scurvy was making among the Hector's ship's company previous to the administration of lemon-juice as a preventive, the sudden check given to it afterwards and its powerful effect in very bad cases, I think I shall not be accused of presumption when I pronounce it, if properly administered, a most *infallible remedy*, both in the cure and prevention of the disease."‡

Mr. Walker, surgeon of the Hannibal in 1795, writes, "during our late cruize numbers were afflicted with that disease (scurvy); the citric acid to the quantity of three ounces per day cured many, and always stopped its progress. It was given with wine in the following manner:

℞ Vin. rub. ℥ii.
Succi lim. ℥i.
Sacchari, ʒii. *m.* fiat haustus ter die sumendus."§

Dr. Trotter himself remarks that the superior efficacy of the acid fruits in the cure of scurvy is so well ascertained, that it might seem superfluous to add any fresh remark to what is so fully admitted. These articles are certainly more beneficial as they approach to the nature of the citric acid, which is that abounding in the lime, lemon, &c. Our summer fruit in this country, such as the apple and gooseberry, lose their acidity as they come to maturity, so that in their immature state they contain most of that principle valued in the cure of scurvy. "In all cases of scurvy," he adds, "which I have attended, I have remarked the longings and desires of the patient for acids, which also have been mentioned by some of the earliest writers on the disease, and more or less by others since that time. It is one of the strongest instincts in nature we are acquainted with. Having repeatedly observed the scorbutic slaves throw away the ripe guavas, while they devoured the green ones with much earnestness, I resolved to try if there were any difference to be remarked in their effects. For this purpose I selected nine blacks, affected in nearly a similar degree with scurvy. To three of these I gave limes, to three green guavas, and to three ripe guavas. They were kept under the half-deck, and served by myself twice or thrice a day. They lived in this manner for a week, which was about the time we left the coast of Africa, and it is to be remarked that the three negroes restricted to the ripe guavas continued in much the same situation, while the others were almost well."

Whenever the fresh fruit, i.e. oranges and lemons, can be procured, they should be preferred to their juice prepared by evaporation for sea use according to the methods devised by Dr. Lind, and to the crystallized citric acid obtained according to Scheele's formula by combining the fresh vegetable acid with lime, and then precipitating by means of sulphuric acid.* The former by keeping is somewhat liable to spoil, though, as stated by Mr. Moffat, a naval surgeon of experience, he found it fully adequate to the purpose of the fresh juices at the end of fifteen months. The crystallized acid, reduced to the strength of lemon-juice by solution in from sixteen to eighteen parts of water, is, however, an excellent substitute for the fresh juice. This solution should not be prepared long before it is required for use, being apt to undergo decomposition, but in its recent state it has proved equally efficacious, according to the testimony of Dr. Trotter and others, with the fruits themselves.† Although all the esculent fruits and fresh vegetables have been found effective in the cure of scorbutus, and particularly, as we observed before, those in which an acid principle prevails, it seems impossible to estimate their relative powers in this respect. The vegetable acids which have had trial, viz. the acetic and tartaric, appear to have exerted little if any power over the disease, nor

have we any proof that the sulphuric, the nitric, and the muriatic acid, though frequently tried, have been at all beneficial.

Mr. Patterson, a surgeon in the navy, published a treatise in 1794, in which he infers that a solution of nitrate of potassa in vinegar is preferable to lemon or lime-juice as an antidote to scorbutus; its good effects he ascribes entirely to the oxygen contained in the former. At first he used a solution of two ounces of nitre in one quart of the ship's vinegar, and gave half an ounce of the solution, to some twice, to others thrice in the day, and as frequently bathed the local affections with it. From the good effect it produced, which was unattended either by nausea, colic, or diarrhœa, he was induced to increase the dose of the above-mentioned solution to an ounce, and to repeat it as before. At length, instead of two, he dissolved four ounces of nitre in a quart of vinegar, and used it in the same quantities and manner as before. He adds, "some patients cannot bear the solution without the addition of water, whilst others without the least inconvenience bear it undiluted. The discharge by stool, or the presence of gripes and nausea, guide me with respect to increasing or diminishing the dose; but, at the same time, it is not a slight degree of nausea, colic, or diarrhœa that renders an alteration in the quantity of the medicine necessary. To a great number of scorbutic patients eight ounces of this strong solution, containing one ounce of nitre, have, in the course of the day, as long as such a quantity was necessary, been administered to each with the greatest success. Also, a circumstance no less curious than pleasing, large and frequently repeated doses of this medicine have been given in cases of scorbutic dysentery, and instead of increasing I have always found it remove the disease. Sometimes, notwithstanding the free use of the nitric vinegar, I have known constipation take place to a considerable degree, in which case I have found intermediate doses of the potassæ supertartras necessary and highly advantageous. This very constipated state generally occurred where the disease was far advanced; but in a few particular cases in delicate habits, and where the disease was not far advanced, I perceived even small doses of the nitric vinegar ruffle the stomach and intestines; to prevent or remove which I have found two, three, or four grains of camphor with each dose of the medicine very effectual."

The beneficial effect of the nitrate of potash in scorbutus has been more recently testified by Mr. Charles Cameron, surgeon in the Royal Navy, in a letter, dated December 10, 1829, to the Commissioners for Victualling. The Fergusson, he states, sailed from Ireland on the 16th of December the preceding year, with two hundred and sixteen male prisoners, amongst whom scorbutus, in several instances combined with dysentery, prevailed to a considerable extent. Before reaching Rio Janeiro their state was such that he had reason to fear he should lose several, and others were fast approaching the same lamentable condition. Having on several occasions experienced the excellent effects of a "solution of nitre," as recommended by Patterson, he was induced to employ it. "From the moment I commenced the use of it," he observes, "many, although almost hopeless cases, began to improve rapidly, and before we accomplished one-third of our voyage, I found the health of the sick improve so fast under the new treatment, that I did not think it necessary to go into any port, and on our arrival at Sydney the general health of the prisoners was much better than when they embarked in Ireland. I am willing," he adds, "to ascribe much of this favourable change to the effect of climate, but I feel assured that a solution of nitre in vinegar or lemon-juice is the best remedy ever proposed in the treatment of scurvy."

Two of the patients who recovered exhibited symptoms of the last stages of phthisis, and expectorated large quantities of purulent matter. With regard to the patients in general, he says, the most distressing symptoms which they complained of in the early stages of the disease were, a sense of oppression and sinking at the pit of the stomach, which a few doses of medicine invariably relieved or totally removed. Mr. Cameron's preparation consisted of eight ounces of nitre dissolved in so much vinegar as made the solution amount to sixty-four ounces. Sometimes equal parts of vinegar and lime-juice were used, a little sugar was generally added to render it more palatable, and about four drops of ol. menth. piperitæ, diffused in a small portion of alcohol, was added to the whole, which rendered it more grateful to the stomach. An ounce of this solution was a dose, and from three to eight doses, according to the stage of the disease and the severity of the symptoms, were given at equal intervals during the day, from six o'clock in the morning till eight at night. Mr. Cameron, at the conclusion of his letter, observes that he had previously tried nitre in several bad cases of scurvy, where neither vinegar nor lemon-juice could be obtained, and, except that sometimes it did not appear to sit so easy on the stomach, with the same beneficial effects.

With the view of restoring the supposed deficiency of oxygen to the scorbutic system, it has been proposed to impart it to the body through the medium of the lungs; but the attempt which was made in cases of the disease as it appeared in the voyage of La Perouse round the world, was wholly unsuccessful.

From the salutary effect in cases of scorbutus produced by vegetable matter in general, peculiar efficacy has been ascribed to particular articles, the use of which accident or analogy from time to time has suggested; it may be that future discoveries will determine their relative title to the estimation in which they may have been held, and the precise principle on which it depends, but the superiority of lemon-juice as an expeditious and certain remedy being well established, other articles of the vegetable kingdom, and the drinks prepared from them, are to be regarded rather as useful auxiliaries, and may be selected from

those in popular repute as the inclination or particular habit of the patient may dictate. It will be no inconsiderable advantage also to introduce them to use according to the dietetic form most grateful to the taste, instead of prescribing the nauseating compounds which until the last half century were supposed to possess especial virtues conducive to the removal of this disease.*

Beer, porter, simple infusion of malt, cyder, perry, spruce beer, various wines made from the subacid fruits, and even pure water, will present useful and agreeable beverages to scorbutic patients. The Lisbon diet drink (decoctum sarsæ compositum) and the compound decoction of guaiacum have also been found serviceable for the recovery of patients from this disease. Of the dietetic vegetable substances, those which have been commonly preferred and considered to be most especially adapted to the removal of scorbutus, have been the various subacid fruits, and the several herbs used in salads, a form in which with their usual additions, vinegar and mustard, they have been considered especially efficacious. Dr. Trotter, in his Medicina Nautica, has adduced numerous instances of their efficacy, and the popular favour they elicited serves to corroborate the opinion entertained of them by professional writers for this particular purpose.

Another agreeable method of supplying the system with vegetable aliment, and which has been advantageously adopted in scorbutus, has been the combination of it with fresh animal matter through the medium of broths and soups, as well as in the ordinary forms in which they are commonly prepared for dinner use. Lind states that milk is useful to scorbutic patients, with whom it generally agrees, but that whey, "by reason of its more diuretic and cleansing quality, is preferable."

"Thus," says the last mentioned writer, "we have numberless instances of people after long voyages, miraculously, as it were, recovered from deplorable scurvies without the assistance of many medicines, for which, indeed, there is no great occasion, provided the green herbage and fresh broths keep the belly lax, and pass freely by urine, sweat, or perspiration."

Since scorbutus has become a very rare disease, the materia medica has been enriched by the addition of some valuable articles the general properties of which suggest their adaptation to the purposes of its treatment; these are the chlorides of lime and soda, and the sulphate of quinine. At sea, the chloride of lime will doubtless be advantageously applied to the preservation of water and to the correction of such as may be putrescent, to the prevention of unwholesome exhalations, and to the general purification of the air. Solutions of it as gargarisms and lotions for ulcers give promise of considerable advantage, and from the little experience already had of its internal use, encouragement is given to its further trial. Dr. Robertson informs us that he has used the chloride of soda in one instance—with the benefit he anticipated.* With some other remarks with which he has been so kind as to favour us on this disease, he observes, "I had occasion, in the year 1831, to see a case resembling scurvy in all its phenomena, (indeed, had it occurred in a seafaring person instead of a person living in a midland county, I should have pronounced it a well-marked case of that complaint,) where the liquor chloridis sodæ, given in doses of half a drachm in conjunction with the decoctum lichenis Islandici, had a strikingly beneficial effect. The patient was speedily brought by it from a state of cachexia threatening death to a very tolerable degree of health and enjoyment. Were it ever my fortune to treat scurvy extensively again," he adds, "I should trust chiefly to quinine or the chloride of soda internally, and to the chloride of lime properly diluted as a topical application; with, of course, a liberal supply of vegetable matter where it could be obtained."

The costive state of the bowels which occasionally prevails to an extreme degree must be counteracted by aperient medicines, or, if need be, by the stronger purgatives. In many instances the advantage derived from the operation on the alvine canal of a single dose has led to their frequent repetition, and the most beneficial results have ensued. Lind was favourable to the combination of medicines of this class with diuretics, or to the use of such as embraced the twofold property. Selections have accordingly been made from the supertartrate, acetate, and sulphate of potash, the tartrate and sulphate of soda, and the sulphate of magnesia, dissolved in the infusion of senna, of tamarinds, or of prunes, with the addition of some aromatic tincture, and further combined if requisite with jalap, rhubarb, aloes, scammony, colocynth, or some of their preparations.

The complication of inflammatory disease with scorbutus in constitutions naturally robust and not much debilitated, will sometimes require venesection and the general adoption of the antiphlogistic treatment, according to the nature and degree of the supervening disease; but diarrhœa, dysentery, pneumonia, and other morbid conditions which have been co-existent with it, have not unfrequently resisted modes of treatment peculiar to them, and have disappeared together with scorbutus when the remedies appropriate to the latter disease have been had recourse to.

In reference to the concurrence of scorbutus and dysentery, Dr. Trotter observed that they frequently disappeared together, and readily yielded to a diet of fresh meat, citric acid, and

* "A vegetable substance called *nopal*, the stalk of the cactus opuntia, which keeps well at sea, has been lately discovered in India to be an extremely salutary article of diet, and to resist scurvy; but the author read in the surgeon's journal of one of the East India Company's ships, that in spite of the use of this and of spruce beer at the same time, sixteen cases of scurvy arose, in one of which it was so severe as to prove fatal."—Paper by Sir Gilbert Blane, on the Health of the Navy; Medico-Chir. Tr. vol. vi. p. 501.

* See Dublin Hospital Reports, vol. v. 1830.

esculent vegetables, without requiring any of those remedies more particularly adapted to the last mentioned disease, as it occurred under other circumstances.* The same remark has been illustrated by Sir James M'Gregor, in his reference to a case of severe ophthalmia, which appeared conjointly with slight symptoms of scorbutus where the latter disease was endemic. It resisted a variety of applications, both external and internal, for five months, when the acid of limes was thought of, which in twelve days effected a cure.†

In some cases of apparent phthisis accompanying scorbutus, we find in the observations of Mr. Cameron already cited, that the disappearance of both forms of disease was evidently effected by the remedies appropriated to the removal of scorbutus alone.

It has been commonly observed, that however promising and speedy recovery from scorbutus may be, to prevent its recurrence it is necessary for a considerable time to persevere in the counteracting regimen, and to avoid as much as possible the predisposing and occasional causes of the disease. When fresh vegetables can be procured, and the object is not to cure, but to guard against a relapse, the use of acids will be advantageously suspended. Practical authorities have expressed opposite opinions as to the general effect on the constitution of their continued use, but on the whole there is good reason to believe that, when long continued, they have produced injurious effects on the digestive organs.

Great care should be taken that scorbutic patients be not too suddenly exposed to an atmosphere differing in its temperature or other qualities (except in point of dryness) from that which they have breathed for some time previously. Any sudden exertion should also be avoided, for numerous instances might be adduced in which inattention to these particulars has been immediately followed by death, in cases in which it was not in the least to be expected. We read in the narrative of Lord Anson's voyage, that in the removal of his crew from the Centurion to the island of Juan Fernandez, twelve of them died on being exposed to the fresh air; and on the first breaking out of the disease many of the people, though confined to their hammocks, were cheerful, talked in a loud strong tone of voice, and eat and drank heartily, but on being only moved in their hammocks from one part of the ship to another immediately expired. Others, trusting to their seeming strength, resolved to get out of their hammocks, but died before they could reach the deck, and it was common to see the men drop down dead upon a violent effort of duty.

The local affections which are manifested in scorbutus are often extremely distressing, but, it must be remembered, are always secondary to the constitutional disorder, increasing in malignancy with its progress, and manifesting a contrary disposition whenever a salutary change has been effected in it: this correspondence, too, takes place with an almost incredible degree of rapidity, and such as is rarely, if ever, exemplified under any other circumstances of disease. The constitutional disorder, therefore, should be the first object of regard in the cure of every local lesion which depends on scorbutus; a contrary procedure only can account for the numerous and complicated formulæ which are to be found in the early treatises upon it, all of which, it may be inferred from accumulated experience, will be nugatory whilst their immediate cause is allowed to continue uncorrected. Local applications, however, with the cotemporaneous use of constitutional remedies, are not unproductive of advantage. To relieve the spongy and rotten state of the gums and of the mucous parietes of the mouth and pharynx, astringent gargles, particularly those containing sulphate of alum, have been found very serviceable. Two drachms of this substance, or more, may be dissolved in half a pint of water or of a decoction of cinchona for the purpose. Lind recommends also the tincture of cinchona, which may be used alone, or mixed with port-wine or camphor mixture. The tinctures and other preparations of myrrh, of kino, of catechu, may likewise be selected from the class of astringents for the same purpose, and will be advantageously diluted with water or with camphor mixture, to be sweetened and inspissated with honey. In the advanced stages, the mineral acids have been found more efficacious; water, barley-water, the infusion of roses or other vegetable substances acidulated with the sulphuric or muriatic acids, and made agreeable with the addition of honey or simple syrup, will form convenient gargles. "The quantity of the acid," says Lind, "must be proportioned to the greater or less degree of putrefaction. The fungus must be often removed, or if needful be cut away; and by frequent gargarizing the mouth kept as clean as possible. Where the ulcers appear deep and spreading, they are to be checked with a touch of *vitriol.* or *sp. salis*, either by itself, or diluted according as the patient bears it." Analogical reasoning leads us to infer that a solution of chloride of lime is peculiarly adapted to the purposes of this disease, whether in the form of gargle for the mouth, or as an immediate application to ulcers in other parts. To the latter the astringent applications already mentioned as useful in the corresponding condition of the mouth and gums have been advantageously employed. "Sulphate of alum, in the proportion of two drachms to a quart of water," says the experienced and talented writer of the Medical Topography of New Orleans,* (Edin. Med. and Surg. Journal, vol. xii. p. 146) in his observations on 'the Sloughing Scorbutic Ulcer' as it appeared extensively in that place, "was upon the whole an admirable local remedy, and seemed to possess wonderful powers in stopping the ravages of sphacelus, and giving a healing tendency to spreading ulcers. In the same cases equal parts of basilicon and oil of turpentine

* Med. Nautica, vol. i. p. 377.

† Edin. Med. and Surg. Journ. vol. i. p. 283. 1805.

* Dr. Robertson, of Northampton.

(melted and applied warm to the ulcer), mixtures of lime juice, or rum and water, charcoal cataplasms, common poultices, bark decoctions, and bark in powder, were employed; but though they kept the sores cleaner, they were often of no avail to arrest the sloughing process." Several of the early writers, and Lind amongst the number, particularize the unguentum *Ægyptiacum** as adapted to the ulcerations of this disease. Mr. Murray, a naval surgeon, in a communication to Dr. Lind, observes, "I have applied a strong tincture of bark lately to scorbutic ulcers, and have found it highly beneficial. The powder of the hydrargyri nitrico-oxydi sprinkled on the fungoid ulcerations, and the ointment of this substance, after the sloughs have been removed and the ulcers cleansed by carrot and other detergent poultices, have also been of some use; but no permanent benefit is to be anticipated from any other treatment than a diet of nutritious food of which fresh vegetables constitute a considerable proportion, the efficacy of which will be materially augmented by including amongst them the acid fruits or their juices, such as lemons, limes, shaddocks, apples, pears, gooseberries, &c. whilst at the same time the patient is secured from the influence of the predisposing and occasional causes of the disease." The latter remarks apply also to the œdematous swellings of the legs and the rigidity of the hamstrings, for which local relief also is often demanded. Frictions with warm flannels, (which for this purpose were formerly medicated with the fumes of benzoin, amber, and warm aromatic gums,) have answered this end, and have been advantageously followed up by gentle compression with bandages. But in extreme cases, warm fomentations, local steam-baths, or, as Lind has recommended, sweating the limb "by burning of spirits," (the local vapour-bath of the present day,) with some of the various other contrivances in common use for the promotion of heat locally, are better calculated to afford relief.

An important part of our duty would be unperformed were we to limit ourselves to the detail of those means by which scorbutus has been successfully treated, for we know not what additional light may be reflected on the obscure parts of this subject by a knowledge of such as have been found unsuccessful. The cost of the experience, too, by which it has been gained forbids its waste, and in practical medicine it must be acknowledged that a beacon is often of not less use than a guide. In the first place, "it is to be observed," says Lind,† "that this disease, especially when advanced, by no means bears bleeding, even although the most acute pains upon the membranes, a high degree of fever, and dangerous hemorrhages would seem to indicate it. The patient generally dies soon after the operation. Nor does it bear strong cathartics, which are often injudiciously administered in its commencement. From blisters there is danger of a gangrene. As to vomits, though I have never had any great experience of their effects, yet by the observation of others squill vomits have been found serviceable. 2dly. Persons in the advanced stages of this disease are not, without great caution and prudence, to be exposed to a sudden change of air. On such an occasion they are to be given a glass of generous wine well acidulated with lemon or orange-juice, which is likewise the best cordial in their fainting fits. The sloth and inactivity belonging to the disease are not to be mistaken for wilful idleness. This," continues Lind, "has proved fatal to many, some of whom, when obliged by their officers to climb up the shrouds, have been seen to expire and fall from the top of the mast. 3dly. After a long abstinence from green vegetables and fruits, scorbutic persons should be treated like those nearly starved to death; that is, not permitted for a few days to eat voraciously, or surfeit themselves; otherwise they are apt to fall into a dysentery, which often proves fatal.

"Lastly, medicines of the fossil or mineral kind, such as steel, antimony, and especially mercury,* do manifest harm. Opiates occasion an unaccountable depression of spirits, with a sense of oppression on the chest, and when absolutely necessary, as in fluxes, should be of the warmest kind," (i. e. we presume combined with aromatics and cordials.)

(W. Kerr.)

SCROFULA.—The term scrofula is derived from the Latin *scrofa*, a hog; and χοιρας, the corresponding word in Greek, plainly acknowledges a similar origin, (χοιρος, a pig:) but whether this etymology has arisen from the filthy condition in which scrofulous children are often found, or from the hog being subject to a similar disease, or from the appearance presented by scrofulous glands lying in clusters under the skin, or from the tumid throat and neck of such subjects, is not so easy to determine, and seems of small importance to inquire. It is sufficiently evident, however, that a strong association existed in the minds of the Greeks and Romans between scrofula and the animal in question. Another term by which this malady has been designated is struma. Celsus very distinctly describes the disease as it affects the absorbent glands, under this name; and adds that it occurs also in the female breast. Among modern nations the French have named the disease *les ecrouelles*,† probably a corruption of *scrophules;* the Germans *der kropf*, from the swelling under the

* Gray, in his Supplement to the Pharmacopœias, gives the following as the formula for this ointment:—Rough verdigrise ppd. ʒv. honey ʒxiv. vinegar ʒvii.; boil to a proper consistence.

† Page 216.

* Sir Gilbert Blane stated to the select committee of the House of Commons appointed to inquire into the state of the Penitentiary at Milbank in 1823, that if he had found, when he was in office as commissioner, a navy surgeon who by his journal had administered a particle of this medicine in the treatment of sea scurvy, he should have felt it his duty to move that such surgeon be struck off the list.—Edin. Med. and Surg. Journ. vol. xxii. p. 142.

† In some parts of Scotland the disease is called by the common people "*the cruels;*" an evident corruption of the French word.

chin; and the English the king's evil. This last term commemorates the imaginary virtues of the royal touch, to which, from the time of Edward the Confessor till the reign of Queen Anne, multitudes of cases of scrofula were submitted, and very many of them were supposed to have been cured. A similar practice existed in France, with equal belief in its success; and miraculous powers for the cure of scrofula were likewise claimed for different Romish saints, for the heads of certain noble families, for the seventh son, and for many consecrated springs in different parts of Christendom.

It may be truly asserted that no original temperament, complexion, or frame of body, confers complete immunity from scrofula; yet a little observation will convince us that individuals possessing certain characteristics are more frequently the subjects of this malady than others. The scrofulous constitution is often indicated by a fair complexion, light silky hair, long shining eye-lashes, large, watery, and often blue eyes, with dilated pupils, and a red patch on either cheek, contrasted with a dazzling whiteness of the skin, which is itself usually thin, smooth, and readily irritated by slight causes. Thus scrofulous individuals are more liable to chilblains, which appear often on their hands; and in such persons the application of a blister is generally followed by an eruption of pustules on the skin around, and the formation of successive crusts. The insertion of a seton, the wounds of leeches, and even simple venesection sometimes produce the same effect: so great, indeed, have we known the irritability of the skin in scrofulous children, that washing with scented soap has caused the immediate appearance of a papular eruption. Scrofulous persons often present the look of florid health and a full habit; but the soft parts are flabby, and easily shrink away under fatigue, privation, or disease; and when the operation of these causes is completely at an end, such individuals are restored with the same rapidity to their former plethoric condition. The scrofulous habit is, in short, characterized by a deficiency of what has been termed *stamina*, and enduring tone. Children who possess this constitution are familiarly known as feverish children; a very slight irregularity of diet or exposure to cold or moisture throwing them immediately into a state of febrile excitement. Their frames possess an undue proportion of irritability, and they are peculiarly prone to attacks of inflammation. The mucous membranes of the scrofulous, like the external integument, are also delicate, and their vessels readily give way and pour out blood: thus bleeding from the nose is a common occurrence in persons of this constitution; and in them hemorrhage is more frequent from the urinary passages and ramifications of the windpipe. The conjunctiva in scrofulous individuals is very liable to inflammation, and the mucous membrane of the intestines is readily irritated and diarrhœa induced. In such subjects the mucous secretions are very abundant and often acrid, and the membranes themselves frequently become thickened: hence arise excoriations of the nostrils and of the upper lip, which becomes in consequence chapped and swollen; and the half open mouth is a common characteristic of scrofulous persons, owing to the partially obstructed state of the nasal passages. Most scrofulous persons are of small stature, and have slender limbs; nor is it very uncommon in such individuals to find some member or organ imperfectly developed, defective in its power, or curtailed of its proportion: yet multitudes of scrofulous persons are met with of a very different description—individuals remarkable, some for their lofty stature and apparent strength, and others for the surpassing symmetry and beauty of their persons.

The moral and intellectual qualities of the above, which is the largest class of scrofulous subjects, correspond with, and in all probability are derived from those of their bodies: the temper is quick and irritable; the desires and passions are ardent; the perception is keen, the imagination is predominant over the judgment; and the mind is characterized by a want of firmness and solidity, and an inability to persevere steadily in the pursuit of any one object. To this observation, however, there are many brilliant exceptions, where the strumous constitution is seen combined with mental qualities of the highest order.

In a second class of persons who are disposed to scrofulous disease, the complexion is dark, the skin harsh, and the habit indolent; the countenance is swollen and pasty, and all the functions of the body are sluggish and imperfect: the nervous energy is feeble, the feelings are obtuse, and the moral and intellectual powers occupy a very low rank. Scrofulous cases of this character are not by any means uncommon in Britain, although far more rare than those first described; but extreme instances are frequent in some districts of Switzerland and France; and in these human nature appears reduced almost to the level of the brute creation, assuming forms which awaken feelings of humiliation and disgust. Scrofula, which is always tedious and difficult of cure, becomes still more obstinate and unmanageable when it makes its appearance in those of a dark complexion and sluggish temperament.

This disease exhibits itself under a great variety of symptoms, according to the part of the body which it happens to affect: hence the difficulty of framing any definition of it which is at once accurate and comprehensive.

The most certain evidence of the existence of scrofulous disorder is afforded by the production of a soft, brittle, unorganized matter resembling curd or new cheese, which is found mixed with the purulent contents of scrofulous abscesses, or deposited in rounded masses of different degrees of firmness, and varying in bulk from the size of a millet-seed to that of a hen's egg: sometimes it is contained within the natural cavities and canals of the body, sometimes it is enclosed in cysts, and occasionally it is diffused, as if by infiltration, through the natural texture of a part. To the

rounded masses of this substance, which, as they enlarge, often acquire the irregular form of a tuberous root, the name of *tubercle* has been assigned, and the substance itself has been named *tuberculous matter*. We venture to assert that the presence of tuberculous matter is a satisfactory proof of the existence of scrofula; but we do not by any means maintain that scrofula cannot exist without the deposition of this substance. The researches of pathological anatomy have satisfactorily shewn that scarcely any living texture of the human body is altogether exempted from tuberculous deposits. This morbid production has been observed on the free unbroken surfaces of mucous membranes, within mucous follicles, and forming the contents of lymphatic vessels the tunics of which were themselves sound :* granules of tuberculous matter, sometimes insulated, sometimes clustered together, have also been detected within the clots of blood contained in the cells of the spleen.† The history of tubercle certainly entitles us to consider it as a morbid secretion; but when it is thus found lying free within a healthy lymphatic vessel, or enveloped in the coagula of the splenic cells, we are led to suspect that in such cases it has probably been formed by some change in the constitution of the lymph or blood, from an alteration in the proportions of their ingredients, or the addition of some coagulative substance, or the withdrawal of something which these fluids usually contain. The cellular tissue has been hitherto considered as of all others the most common seat of tubercle; but Dr. Carswell has stated that it is far more frequently met with in contact with mucous surfaces; and he has certainly adduced very strong arguments in support of this opinion, which he has also illustrated by most beautiful engravings.‡

For a particular history of this substance in its etiological, pathological, and chemical relations, we must refer the reader to the articles Tubercle and Tubercular Phthisis, and content ourselves, in this place, with noticing such circumstances as have more especial reference to the subject of the present article.

According to Dupuy,§ all the domestic animals of France, not excepting the dog, as well as those imported from warmer countries, are subject to tuberculous deposits: his researches further shew that this disease in the inferior animals is much more frequently combined with the presence of vesicular worms than it is in man. He has traced the conversion of the cysts containing these animals into collections of tuberculous matter, and has thus given a degree of support to the opinions of Dr. Baron, who maintains that all tuberculous disease originates from vesicular worms or minute serous cysts. But although we admit that such adventitious cavities often become, at least in the inferior animals, the nests in which the matter of tubercle is deposited, the assertion that all tubercles arise in this manner may well be disputed when we find that such cysts or vesicular worms, or traces of them, are by no means always coexistent with tuberculous disease, and that they often attain a very great magnitude without exhibiting any symptoms even of incipient transformation.

Opinions directly opposed to each other have been held by writers of great eminence as to the immediate cause of tubercles; one party ascribing their origin in every case to inflammation;* another as exclusively asserting that they are in no instance dependent on inflammatory action, and that when inflammation co-exists, it does so as the consequence, and not the cause, of tubercles.† After carefully reviewing the discussions on this question, we have come to the conclusion, that on some occasions tubercles have been found where no symptom of previous inflammation could be recollected, nor any trace of it discovered on inspection after death;‡ while in other instances the deposition of tuberculous substance seems to have been distinctly connected with the developement of inflammatory action. But as inflammation often occurs without the formation of tubercles, it is obvious that this alone is not sufficient for their production, and that the addition of something else is required to that end. Inflammation, therefore, may be viewed as an occasional cause of tubercles, producing this effect only in frames of a scrofulous disposition.

Some organs are more liable to tuberculous deposits than others, and the liability differs at different periods of life: the organs which are most frequently affected with tubercles in children are not those in which they are oftenest met with in adults. In children the disease tends more to implicate several organs at once; and in them it is more common to find the lungs unaffected, although tubercles be discovered in other parts of the body.§ The existence of tubercles in the fœtus is certainly rare, but it has been proved beyond question

† *G. L. Bayle*, Recherches sur la Phthisie.—*Laennec*, Auscult. Médiate.—*Gendrin*, Hist. Anatom. des Inflammat.—*Lobstein*, Anat. Patholog. tom. i. This able advocate of these opinions admits the production of what he terms miliary granulations on the surfaces of inflamed serous and mucous membranes, but denies their identity with tubercles. In this manner he endeavours to set aside the arguments drawn from such cases as those of Dr. Alison, and also the results of the experiments of Cruveilhier and others, who produced the appearance of myriads of small tubercles by injecting mercury into the bloodvessels and lungs of animals; each minute globule being found enclosed within an effusion of tuberculous-like matter. These experiments we have always considered as any thing but conclusive: for where is the evidence that the effused matter is truly tuberculous?

§ *Lombard*, op. cit.

by the dissections of Langstaffe,* Lombard, West, Orfila,† and Chaussier:‡ they continue infrequent from birth till two years, after which they are often met with; and during the fifth year their occurrence appears to be much more common than at any period before puberty. From eighteen till forty tubercles very frequently occur; affecting, however, chiefly the lungs, intestines, and some parts of the lymphatic system.

These results are drawn from the researches of pathological anatomy; but to speak merely from symptoms, independent of the verifications of dissection, scrofula has been observed by us in the form of enlarged axillary glands within the first fortnight after birth: it is not usual, however, for the absorbent glands to be affected till the period of the first dentition; the occurrence is still more frequent during the second. At puberty the disease often disappears spontaneously, and after this age external scrofula is very rarely observed to originate; but instances are not wanting in which persons well advanced in life have been attacked for the first time by scrofula, more especially among those who have been long confined in prisons or workhouses. To shew the various ages at which the disease may develope itself, Lalouette§ states that in a scrofulous family one daughter was affected at fourteen, another at sixteen, a third at twenty-six, and the father at sixty-six. Cases have occurred to the writer where scrofula has appeared in youth, undergone an apparent cure, and again manifested itself in advanced life, when it proved fatal.

In former times it was believed that scrofula was communicable from one individual to another; and the occurrence of the disease in many members of the same family, and its diffusion among the inhabitants of particular districts, seemed, through a loose mode of reasoning, to afford ground for this opinion. Positive experiments have been made by Kortum,‖ Goodlad,¶ Hebreard,** Le Pelletier,†† and others, to propagate the disease by rubbing in scrofulous matter, and by inserting it under the skin of animals, and even of the human subject; while Pinel, Alibert, and Richerand,‡‡ have carefully watched the effects of allowing scrofulous and healthy children to associate together without restraint; but in no instance was there the least reason for believing the malady to be communicable by any of these modes of infection. The observation of British practitioners fully corroborates the opinion of the non-contagious nature of scrofula, although the writers of this country have not directed so much attention to the subject; because a belief in the contagion of scrofula was abandoned by our physicians long before it ceased to be current among those of the continent.

In this respect scrofula differs remarkably from that form of tuberculous disease in animals which has been named glanders; for this last is not only communicable from one animal to another, but also to man.* It would be curious to enquire whether glanders in man is itself communicable to other human beings: that it is so is by no means improbable, for it has been proved by experiment to be capable of being communicated from man to the inferior animals.† It is proper here to state that M. Dupuy has expressed strong doubts of the contagious nature of glanders, and has asserted that he knows of no well-conducted experiment in favour of this doctrine, but some against it. He is disposed, on the contrary, to refer glanders to hereditary transmission, and to various unfavourable circumstances in the rearing of horses, similar or analogous to those which are admitted as predisposing to scrofula, such as cold, damp, and shady pastures, insufficient nourishment, and the debilitating effects of castration.‡

Daily observation must convince us that a scrofulous constitution is often transmitted from parent to child; therefore the disposition to the disease may be truly said to be hereditary; nay, the dissections already referred to prove the actual development of scrofula even before birth, in the progeny of a strumous mother. Like other hereditary gifts, it may miss one generation and reappear in the succeeding; just as some individuals are observed to resemble in external appearance their grandfathers more than their fathers.

A striking example of the hereditary nature of scrofula was lately presented to the writer by a family respecting whom he was consulted. The father was a tall, thin, and sickly man, who suffered much every year from winter cough; the mother a person of full relaxed habit, with a look of florid health, and in fact not often affected with illness. Of nine children to whom she had given birth, two females and six males had died with phthisical or mesenteric symptoms, between the ages of three and fifteen months; the survivor was a boy nearly twelve years old, who enjoyed moderately good health. The last of these little victims of transmitted disease died just as he had completed his third month, after having suffered under symptoms of phthisis. On inspecting the body, the lungs were seen mottled with many yellow spots, and when cut into they exhibited myriads of tubercles, varying from the size of a small mustard-seed to that of a pea: all of them were opaque, and many converted into pus. The glands at the root of the lungs were

enlarged, indurated, and some of them converted into abscesses, the walls of which were lined with firmly adherent fibrine, and their contents were a thick purulent fluid. The mesenteric glands were enlarged, hardened, and many of them contained softened tuberculous matter. The spleen contained some small granules of a white colour and cheesy consistence. There was a good deal of subcutaneous fat, but none in the omentum. A very few weeks after the death of this child, the father, who had been eager to learn whether his offspring drew their fatal disease from himself or from their mother, declined rapidly in strength, and fell a victim to phthisis.

Scrofula is supposed by most writers to be of more frequent occurrence among females than males; and Le Pelletier* has stated, as the result of a comparison of the cases in the Parisian hospitals, that the proportion of strumous females to males is as five to three. In all enquiries into the relative prevalence of disease in the two sexes, it must be recolleeted that the female population, especially of large towns, considerably exceeds the male; and hence it is to be expected that a greater number of scrofulous females will apply for medical relief. But on reviewing the matter carefully, and referring to an examination of hospital patients made for another purpose, we are convinced that the disease is really more frequent in the female sex. Dr. Cullen was of opinion that scrofula was oftener transmitted from the father than the mother, which he conjectured might arise from the circumstance that more scrofulous men than women enter the married state; but he has nowhere explicitly asserted that males are more liable to the disease than females.†

We proceed now to pass briefly in review the various parts and organs of the human body in which scrofula most commonly appears, and to point out the modifications of this disease induced by the different properties and textures of the parts affected.

The first which presents itself is the common integument; and here several forms of cutaneous disease are distinctly referable to the class of scrofulous affections. The three species of porrigo named favosa, larvalis, and furfurans, together with eczema impetiginodes and rûbrum in their chronic forms, may be fairly enumerated among strumous diseases; at least if we are entitled to draw any inference from the facts that these eruptions are found in combination with the generally admitted symptoms of scrofula, and are as often benefited by anti-strumous remedies as the symptoms just mentioned are usually observed to be. Eruptions of this description, when they affect the scalp, ears, and face, are very apt to occasion swelling of the glands at the back part of the head, on the sides of the neck, and under the jaw; at first from simple irritation, or perhaps the absorption of morbid fluids; afterwards, the swelling becomes permanent, from the deposition of tuberculous matter. Other causes of an irritating or inflammatory kind, as dentition and exposure to cold, are known to produce such glandular tumours, terminating like the others, where the habit is strumous, in the deposition of the same curdy substance. Thus we have a second order of parts more deeply seated than the skin, affected with scrofula, often from the causes stated above, and sometimes, it would seem, spontaneously. The absorbent glands, indeed, are the parts of the body which have long been regarded as the peculiar seats of scrofula, and their enlargement and induration are still considered as affording more unequivocal evidence in the living body of the presence of that disease than any other circumstance except the discharge of tuberculous matter. A lymphatic gland, when first affected with scrofula, is soft and fleshy, and its size is increased; the texture, as proved by inspection, then becomes firmer, and the colour paler than in health: as the disease proceeds, portions of the gland are observed to have altogether lost their flesh-colour, and acquired a degree of semitransparency, and a texture approaching to that of cartilage; at length a deposition of soft white or yellowish curd-like substance is found to have taken place, and the true scrofulous tubercle is now manifest.*

The size to which strumous glandular tumours attain is in some instances enormous. The lower jaw and upper part of the neck are occasionally seen hung round with such voluminous swellings as completely to deform the countenance; and we have seen, in the case of a strumous middle-aged male, both groins occupied by vast glandular tumours, the larger of which equalled in size the half of a child's head at birth. These inguinal swellings were firm, nodulated, and without pain; they had commenced only six months before as clusters of hard kernels, which by degrees enlarged and coalesced into the enormous morbid masses now described. It has been stated by a very able and accurate observer that scrofulous glands always possess a higher temperature than the healthy parts in the vicinity; but the trials which we have made, and they were often repeated, did not detect any greater heat in such swellings, unless when they were actually inflamed.

Scrofulous glands are commonly supposed to be obstructed and impervious to the fluids which are naturally transmitted through them, but it is certain that they are in many instances capable of being injected with mercury from the intrant lymphatic;† and hence we may infer that, though partially changed, some portion of them may still give passage to their proper fluids.

Scrofulous tumours do not uniformly originate from the degeneration of lymphatic glands, but arise in many cases from the deposition of

* Sur la Maladie Scrofuleuse.

† First Lines. *Scrofula.*

† *Soëmmering*, De Vasis Absorbentibus, sect. 37, p. 90.

tuberculous substance in the subcutaneous cellular tissue, in different parts of the body, quite independent of any absorbent gland: their resemblance, however, to glandular swellings is such as to deceive the inexperienced; nay, they were named even by Wiseman, the first surgeon of his day, *adventitious glands*. When these scrofulous tumours are cut into, they are found to be composed of cysts varying in size and density, usually lined with a fibrinous exudation, and filled with tuberculous substance, sometimes crude, at others softened, or converted into curdy pus.

Absorbent glands affected with scrofula, and cysts of tuberculous matter in the cellular tissue, may remain for a long time without exciting any irritation; but their tendency is to become soft by the secretion of purulent fluid from the internal surface of the cavity, which is soon followed by inflammation of the integuments. Ulceration succeeds, and the morbid contents are discharged from the body, sometimes by one, at others by many small apertures: but a cure does not follow; either fistulous openings remain, discharging a thin glutinous fluid mixed from time to time with curdy particles, or an indolent ulcer succeeds, or both may result from the expulsion of tuberculous matter. The contents of scrofulous glands and tumours on the surface of the body occasionally undergo the cretaceous transformation: after remaining long indolent, suppuration at last takes place, and masses of earthy substance, sometimes of considerable bulk, are extracted from their cavities. On macerating these calculous concretions in water, we have found them to separate readily into a multitude of gritty particles like dried mortar. In some instances, strumous glands are converted into prominent spongy tumours of a red colour, and covered by a silky cuticle, which frequently breaks, and gives issue to small superficial collections of purulent matter.

Scrofulous ulcers are characterised by their flabby and often pale granulations, and the thin unhealthy integument which usually overlaps their margins. This undermined skin is of a purplish or livid hue; shewing the languor of its capillary circulation, and its proneness to be destroyed by gangrenous erosion. Such ulcers, though usually productive of little uneasiness, sometimes become exceedingly irritable and painful, requiring the employment of powerful narcotics to give relief to the patient. The thin discharge which scrofulous sores yield often concretes upon their edges into straw-coloured crusts, under which the ulcer, if small, sometimes heals. Scrofulous cicatrices possess a peculiar wrinkled and puckered appearance, with small portions of projecting skin, and even complete bridges admitting a probe to pass beneath them; features by which their real origin, long after a cure, may be readily discovered. These appearances of scrofulous scars seem to be produced by the great attenuation and irregular destruction of the integument, and the slow and interrupted mode in which such ulcers heal; and they may always be in a great measure prevented by careful and judicious surgical treatment. When scrofulous cicatrices are cut into and examined after death, the affected glands are found wasted away, no vestige of them being left excepting a few bands of condensed cellular tissue attached to the cicatrised integument. The healing of a scrofulous ulcer is often followed by the advance of other tumours to suppuration, or perhaps the formation of new ones in some adjoining or distant part of the body. Thus one train of evils succeeds another, till the constitution of the patient begins to yield to the debilitating effects of the irritation and discharge, or the disease fastens on some organ of greater importance in the economy, and life is at length destroyed by hectic fever, colliquative perspirations, and diarrhœa.

Another form in which scrofula sometimes attacks the integument is that of lupus, the usual seats of which are the lips and nose; but we have also seen it affecting the genitals. Scrofulous lupus commences by the appearance of small red button-like prominences, which usually remain indolent for some time, then become excoriated and form eroding ulcers, with pale shining spongy granulations and encrusted margins; or, perhaps, the work of destruction goes on under a thick incrustation, which drops off from time to time, to shew the ravages which have been committed. The progress of the disease is sometimes hastened by the formation of sloughs, especially when the parts are cartilaginous; and in this way perforations are made into the nostrils, and sinuses scooped out within the thickness of the lips. In lupus of a well-marked scrofulous character the face usually becomes swollen and raised into pallid flabby prominences, which deform the countenance, and give to it a very sickly and disgusting aspect. See the article Noli me tangere.

Scrofulous individuals are subject to the formation of large chronic abscesses, which sometimes arise with great rapidity, as if from a sudden deposition of fluid rather than as the consequence of regular suppuration. The usual seat of such abscesses is in the cellular tissue connecting the large muscles, or within their sheaths, and under fasciæ; and their contents are at first a serous effusion, afterwards sero-purulent fluid, with curdy flakes; and more rarely a thin pus. In such cases sloughing of the cellular tissue is not uncommon; spongy masses of it, like wet tow, coming away along with the discharge, or plugging up the lancet puncture. These abscesses are named by French writers *abcès froids* and *abcès par congestion*; and their origin is usually the irritation of some diseased joint or bone in their immediate vicinity. It does not appear that abscesses of this description result from the softening of tuberculous matter previously deposited, but that the curdy flakes are thrown out from the internal surface of the abscess during the formation of its more fluid contents.

The lymphatic system has been generally considered as the primary, and by some the only seat of scrofula; and in all treatises on

the diseases of the absorbent vessels this malady occupies a prominent station. In almost every case of advanced scrofulous disease of the mesenteric glands, the lacteals connected with them will be found affected, and more or less filled with tuberculous matter; but the absorbents in other situations have not been very often observed to be the seats of strumous disease. Several well-authenticated cases, however, are recorded, in which tuberculous matter was found deposited within these vessels, and that in such quantity as completely to obstruct them.*

The following instance of scrofulous affection of the lymphatic vessels occurred to the writer. A gentleman, after applying an astringent lotion to a simple excoriation of the cervix glandis, was affected with indurated swelling of the prepuce, and the appearance of hard tortuous cords within the integuments of the penis, which after a few days could be traced all the way to the pubes. A glandular swelling took place in one groin, which after a considerable interval suppurated, burst spontaneously, and at length healed. No perceptible benefit accrued from a slight mercurial and purgative plan of treatment; but amendment commenced under the use of sarsaparilla and iodine, and the disease wholly disappeared after a tour of several weeks' duration, since which the individual has continued to enjoy good health.

The inflammation of the superficial lymphatics in the horse is believed by the best writers on veterinary medicine to constitute the disease named *farcy*;† and M. Dupuy‡ regards the small tumours termed *farcy buds* as tuberculous deposits.

The sublingual and submaxillary glands are often the seat of scrofula; the parotid more rarely, but a chronic swelling of that organ is occasionally seen in scrofulous subjects of a dark complexion. Tumefaction of the tonsils is seldom absent, when the strumous constitution is strongly marked: this exists from an early period of life, and is perhaps in some instances congenital. The tonsils so affected jut out in rounded tumours from between the arches of the fauces; they are peculiarly prone to inflammation, and when it occurs, the swelling is often such as to threaten suffocation, especially when stimulant astringent gargles have been incautiously employed. The inflamed tonsils become speedily spotted with aphthous crusts, which are succeeded by superficial ulcerations, always indolent, and sometimes ending in brown excavated ulcers, which we have known to exist for weeks without any remedy being used, and then to yield rapidly to cinchona.

Scrofula occasionally attacks the tongue,* the disease alternating with strumous eruptions, especially in the face: it sometimes assumes the form of aphthous ulcerations and fissures of the margin; but its most characteristic features are small knots or nodules superficially imbedded in the substance of the organ, varying in size from a grain of small shot to that of a horse-bean. They cause no uneasiness unless when firmly pressed, and then the pain is slight and pricking. The mucous membrane covering them is red and prominent, and soon breaks in the centre, giving rise to an ulcer, which spreads and destroys by sloughy erosion, with much pain, profuse salivation, furred tongue, and fetid breath. The ulcers under proper treatment become clean, contract, and heal; but the hardness remains, fresh nodules form in other parts of the organ, and the same train of suffering is gone through after a longer or shorter interval, according to the state of the patient's health and the regularity of his mode of life, until a decided improvement be produced on the constitution by time, change of climate, or the employment of remedies.

The mucous membranes are frequently affected with scrofulous disease: allusion has just been made to the aphthous exudations and superficial sores which appear on the tongue and tonsils of strumous individuals: in other instances there are small blisters and excoriations on the inside of the lips and cheeks, and on the fauces, and that wholly independent of any syphilitic disease, or the previous exhibition of mercury. The pituitary membrane in scrofulous subjects is easily irritated, and the secretion of mucus is usually copious and often acrid: nay, in some instances the morbid condition of the part proceeds so far as to induce small ulcerations, constituting one form of ozœna. If the progress of this affection be not arrested, the fine long laminæ within the nostrils become in part denuded, and at length necrosed; and it is from the decomposition of dead osseous substance that the horribly offensive odour is produced which renders this malady so peculiarly disgusting. To those around the patient it is always so; but he himself is sometimes unconscious of the odour, in consequence of the diseased condition of the pituitary membrane, and the loss of smell resulting from it. The most frequent cause of ozœna is, without doubt, syphilis; but it occurs chiefly in those syphilitic cases where the habit is strumous, and it is met with also as the effect of scrofula alone. It has not been ascertained whether ozœna ever originates from the deposition of minute tubercles on the pituitary membrane; but that this sometimes occurs is far from improbable. In the glanders of horses, which is an analogous affection, the existence of tubercles in the lining membrane of the nostrils has been satisfactorily shewn by Dupuy to form a leading feature.†

‡ De la Maladie Tuberculeuse.

* Mr. Russel has alluded to this affection, but without describing it. See Russel on Scrofula.

† De l'Affection Tuberculeuse, pp. 30 & seq.

Scrofulous children are more liable than others to inflammatory affections of the windpipe, and to that fibrinous exudation on its mucous surface which occurs in croup; yet this cannot properly be classed among strumous diseases.

But the ultimate terminations of the respiratory mucous membrane are frequently the seat of scrofula: some eminent pathologists, indeed, are of opinion that the air-vesicles of the lungs are the usual situations in which tuberculous matter is originally deposited in cases of scrofulous phthisis. Dr. Alison informs us that he has repeatedly found tuberculous matter in the air-vesicles, these minute cavities being partly filled with air and partly with this substance;* and the dissections of Dr. Carswell,† which he has so happily perpetuated by his drawings, appear to us to have set this point completely at rest. M. Gendrin, however, asserts that the substance effused into the air-vesicles is nothing more than the product of common inflammation, and not at all tuberculous; but he candidly admits that Laennec expressed a contrary opinion while the subject was before them, and he is ready to acknowledge that inflammation is a powerful occasional cause of the production of tubercle.‡

The digestive mucous membrane is subject through its whole extent to scrofulous disorder of function, and in its intestinal portion at least to extensive scrofulous transformations. A feeble action of the stomach is an almost uniform accompaniment of well-marked strumous disease; and the mucous lining of the alimentary canal is in such cases either torpid or unduly irritable, the food remaining lodged as a source of oppression and disturbance, or being hurried rapidly forward, and expelled before it has had time to afford adequate nourishment to the system. Tubercles are met with in the walls of the intestinal tube in children, and still more frequently in adults: Louis states that in his examination of more than 350 phthisical subjects above the age of fifteen, he found tubercles in the small intestines of one-third, and in the large intestines of one-ninth of the whole.§

The subsidiary organs of digestion and assimilation suffer also from scrofula; but the spleen and the pancreas are more frequently the seats of tubercles than the liver; yet the last of these organs is more or less functionally deranged in almost all strumous cases, which the chalky and various-coloured motions of such patients sufficiently demonstrate. The great irritability of the mucous tunic of the intestines in many scrofulous cases, and the tubercles which so often form within the mucous follicles and walls of the tube, naturally lead to ulceration, and hence arise many cases of disease of the mesenteric glands. At first they become merely swelled, but ultimately tuberculous deposits take place within their substance, constituting what has been named mesenteric consumption, or tabes mesenterica. For a full account of this affection we refer the reader to the article TABES MESENTERICA.

Scrofulous disease of the mucous membrane of the female genital organs is of frequent occurrence, and forms the most obstinate description of leucorrhœa, producing languor and debility, disordering and sometimes putting a total stop to menstruation, and in very many cases preventing conception. The morbid discharge in this disease is interrupted on the appearance of menstruation, and is increased in quantity before and after that occurrence. It varies in character from an opaque white mucus to a greenish yellow or blood-streaked purulence; and the surface which furnishes it is not limited to the vagina, but apparently extends throughout the whole internal lining of the uterus. It does not appear that tubercles have been detected in the vagina, but scrofulous ulcers have been seen there, probably arising from the destruction of tubercles, while the cavity of the uterus itself and the Fallopian tubes were found filled with tuberculous matter.* Tubercles have also been found imbedded in the walls of the uterus, and still more frequently in the ovaria.†

In men, scrofulous disease of the mucous membrane of the urinary channels and cavities is not unfrequent; and it is an affection particularly obstinate and unmanageable. The writer has known it to continue in the urethra for five years, at the end of which time it came under his care. The urethral membrane was then so soft and spongy that the most cautious attempt to introduce an instrument occasioned a profuse hemorrhage: after a lengthened treatment, the discharge at last yielded to tonics, the cold plunge-bath, and astringent injections. Chronic, or mucous cystitis, is often of a scrofulous character, (see CYSTITIS;) and there is ground for believing that the same affection passes up along the ureters, and even extends itself within the chambers of the kidney. Tuberculous deposits have been found within the coats of the bladder,‡ and lining the interior of the ureters;§ very frequently also in the cavities and substance of the kidneys, and sometimes in the renal capsules.‖ The glands of Cowper, the prostate, vesiculæ seminales, and testicles, have all been found the seats of tuberculous deposits. They occur most frequently in the prostate gland and testicles, particularly in the latter; and the symptoms to which they give rise render them objects of considerable importance to the

practical physician as well as to the surgeon. See PROSTATE GLAND, DISEASES OF.

The changes produced in the testicle by scrofula vary considerably, according to the degree of attending inflammation, and the rapidity with which the disease has formed. We have, most commonly, a hard solid enlargement of the organ, usually affecting first the large head of the epididymis, slow in its growth, and obstinate in resisting the operation of remedies. It may remain indolent for some time, but at length abscess forms, the serotum inflames, adheres, and gives way, discharging a curdy substance mixed with pus. The disease now extends to other parts of the epididymis and to the body of the testicle; sinuses form under different parts of the inflamed integument; and fistulous openings take place, which give issue to a thin ill-conditioned fluid, mixed with curdy particles. At other times a more rapid inflammation occurs, and an abscess forms, which on bursting discharges scrofulous pus; a fistulous opening succeeds, the gland wastes away, and at length nothing remains but a small, shrunk, and hardened mass. On dissecting a strumous testicle, the natural fabric of the organ is found more or less indurated by the deposition of dense organized substance; tuberculous matter is discovered in different spots, in the tubuli seminiferi epididymis, and sometimes even in the vas deferens. Small scrofulous abscesses are also occasionally found disseminated through the substance of the gland.* This disease is much more common after puberty, when the actions of the testicle are awakened, and it has become exposed to numerous causes of irritation and injury; but we have known it occur at a very early age, in the case of a child which exhibited other strong marks of the strumous constitution. In almost every instance only one testicle is attacked at first, but after a time the other is usually affected; and it is not uncommon for both to continue suffering from the disease at the same time. Andral has well remarked the frequency of scrofulous affection of the testicle, and has pointed out the palpable omission of Louis, who has assigned no place either to the testicle or the bones in his enumeration of parts in which scrofulous deposits have been found.

Another organ which is subject to scrofula is the mamma; scrofulous disease of which occurs both before and after puberty, but much more frequently after that period, and often during the excitement of the first lactation. Scrofula of the mamma appears under different shapes, and in its earlier stages is not always easily distinguished from disease of a more formidable character. Sometimes a hard lump forms in the breast, and remains nearly quiescent for several years; at others the whole gland is affected with scrofulous enlargement; but in every case of the disease its tendency is to suppuration, and the purulent matter discharged is more or less mingled with curdy flakes: instances likewise occur in which large masses of tubercular substance come away.* In the progress of such cases the integuments become inflamed, assume a livid colour, and are extensively detached from the parts beneath; new abscesses and apertures form, and the adipose and glandular tissues are traversed by many fistulous passages, while the contiguous parts are condensed and hardened. In strumous disease of the breast, there is always an enlargement of the gland instead of that contraction which occurs in one form of carcinoma: the tumour is tender when squeezed, never possesses the stony hardness which exists in the disease just named, and there is never, we believe, retraction of the nipple.

The mucous membranes of the eye and lachrymal passages are peculiarly liable to scrofulous disease; its influence on the latter is indicated by the long-continued discharge of puriform mucus, varying in its colour and consistence; while strumous inflammation of the conjunctiva constitutes a very large proportion of all the inflammatory affections to which this organ is subject. Beer asserts that in Vienna nine-tenths of all the cases of ophthalmia in children are of a scrofulous character;† and Benedict of Breslau estimates the proportion in that city as high as ninety-five in the hundred.‡ The eruption of the minute vesicles, (phlyctenulæ) or pustules, which occurs in scrofulous inflammation of the conjunctiva, seems to approximate it to other diseases of the same class, when numerous crops of very small tubercles are seen on the investing membranes of various organs; but it does not appear that true tuberculous matter has ever been detected in any part of the eye.§ Scrofula likewise attacks the margins of the palpebræ and Meibomian follicles, causing the appearance of vesicles and ulcerations named ophthalmia tarsi; and it is believed by Mr. Todd to occasion chronic enlargement of the lachrymal gland.‖

The organ of hearing, like that of sight, is the frequent subject of scrofula, which in many instances is productive of early deafness, and, there is reason to believe, is the cause of that imperfection of hearing which is sometimes seen to pervade several members of the same family. The lining membrane of the external auditory passage is in most instances the seat of this disease, which is usually marked by profuse watery, then mucous, and at length purulent discharges, forming what may be named strumous otorrhœa. It is in general unattended with danger, but it rarely exists without producing a greater or less imperfection of hearing. In some instances, however, the disease spreads more deeply; the

§ Strumous disease of that organ seems to exist also among animals. M. Dupuy considers the specific ophthalmia of horses as one of the consequences of the tuberculous affection.

‖ Dublin Hospital Reports, vol. iii.

membrane of the tympanum becomes inflamed and is perforated, the small bones of the ear are discharged, and irremediable deafness ensues; or perhaps caries of the petrous portion of the temporal bone takes place, and the result is fatal. (See Otalgia and Otitis.) Strumous otorrhœa has been known to alternate with other mucous discharges, such as leucorrhœa and chronic cystitis;* and its disappearance has been followed by enlargement of the cervical glands, swelling of the testicle, and various diseases of the eyes and skin.† Like other scrofulous affections it sometimes resists all remedies, and at length disappears at puberty.

The synovial membranes of joints are undoubtedly much more liable to disease, in scrofulous subjects, than others; inflammation is more readily excited, and effusion of fluid into their cavities is more easily induced. In such persons we frequently observe several joints affected at the same time. In a case of six years' duration, lately placed under the writer's care, the left hip-joint, the right knee, and the joints of the right great toe were all suffering under disease, with displacement of the head of the femur and shaft of the tibia; there were, besides, many ulcers and sinuses around the joints, and indurated cervical glands: this patient had a strongly marked strumous countenance. The secretion of scrofulous pus into synovial cavities is not uncommon, but the existence of tubercle within the substance of the membrane itself appears to be of rare occurrence. Dr. Craigie states his belief that tubercle has been found in the synovial membrane of the hip-joint.‡ There is indeed a remarkable change of structure, which takes place slowly in the synovial membranes, particularly that of the knee-joint, and which, as it occurs most frequently in the scrofulous, some may be inclined to regard as of scrofulous origin. This morbid alteration of texture, which was first accurately described and illustrated by Mr. Brodie,§ consists of the conversion of the synovial membrane, and afterwards of the adjacent soft parts, into a pulpy substance of a light brown colour, intersected by white membranous threads, and traversed by minute red vessels. But there is another affection of the joints, in which the characters of scrofula are unequivocally exhibited; in this the disease originates in the cancellous structure of the bones, which is found to contain deposits of tuberculous matter; and the cartilages and synovial membranes are affected secondarily by the spreading of the inflammation.

In scrofulous persons the bones are more slender throughout; their cortex or outer wall is much thinner, and their interior more soft and vascular than the bones of persons of sound and vigorous constitution: in the inferior animals affected with tuberculous disease, according to Dupuy,* this peculiarity is still more strongly exhibited. Scrofulous children sometimes fracture the thigh or leg merely by falling on the carpet; and in other instances the bone does not snap across, but bends like a piece of tin; and the injury may be remedied by straightening it as we do a rod of that metal. The effects of scrofula on the bones are considerably different, according to the comparative density of their texture; but in all instances the process of disorganization appears to commence by an increase of their vascularity, or a greater or less degree of inflammation. In the dense fabric of the bones of the skull and the shafts of the long bones, scrofula is a frequent cause of necrosis; while in the spongy heads of bones, the small bones of the hand and foot, and the bodies of the vertebræ, this disease manifests itself, first by increased vascularity and softening of the cancellated structure, while the firm exterior remains entire and unchanged; then a deposit takes place of a clear yellow fluid, which is succeeded by or probably converted into a soft cheesy substance or true tubercular matter.† This alteration in the texture of the bones is slow in its progress, and its existence is not indicated by any decided symptoms until it is considerably advanced. A dull and deep-seated pain gives the first warning of the disease, the soft parts then become swelled, the motions of the neighbouring joint are restrained and painful, and abscesses now form around it, containing a scrofulous pus; the investing cartilages and synovial membrane next suffer, effusion takes place into the articular capsule, and perhaps a high degree of inflammation is induced by the escape of tuberculous matter or a portion of necrosed bone into the cavity of the joint. In the progress of the disease the destruction of the head of the bone or edge of the socket, and of the ligaments which preserve the bones in their places, enables the more powerful muscles to draw the lower one from its situation, and produce what is named secondary luxation. The writer has repeatedly observed dislocation of the tibia produced by the separation of the epiphysis from the shaft of the bone; the leg being in this manner completely displaced, although the articular surfaces of the knee-joint were in proper apposition.

Not only the bones but also their investing membrane or periostemn is subject to tubercular deposits,‡ giving rise to swelling, inflammation, suppuration, detachment of the periostenm from the bone, and ultimately to necrosis, or absorption of the osseous tissue, which is replaced by dry tuberculous substance without softening of the bone. To this form of tuberculous disease we would refer some of those cases which have been named osteo-steatoma. This morbid deposition, which we have seen lying in contact with the bone in large

angular masses, bears a striking resemblance to suet or adipocire, but its nature is truly that of coagulated albumen, for it emits, under a strong heat, the odour of burnt cheese or horn, and produces no greasy stain when rubbed on paper.

Scrofula manifests itself by unequivocal proofs both in the bodies of the vertebræ and the fibro-cartilaginous substance which is interposed between them. The former become more vascular, are softened by the partial absorption of their earthy and saline constituents, and afterwards receive a deposit of yellow, cheesy, or true tuberculous matter. These changes naturally lead to caries and destruction of the bone, which yields to the superincumbent weight; and the spine bends at an angle more or less acute according to the number of vertebræ which are diseased. The bend is in general directly forward; but when the sides of the vertebræ have suffered most, the curve is of course lateral.* In the progress of this disease the soft parts around become affected, and collections of purulent matter form, which, passing down in front of the spine and along the course of the psoæ muscles, ultimately make their appearance under Poupart's ligament at the upper part of the thigh, and sometimes on both sides, nearly at the same time. On other occasions the matter points in the loins, or near the anus; and in some rare instances it has burst into the spinal canal, with an immediately fatal result.

When chronic disease has thus been producing such extensive disorganization in the osseous substance of the spinal column and in the soft parts around, it is not to be expected that the membranes of the spinal cord, the medullary substance itself, and the nerves which branch from it, should escape injury; accordingly we find that the first symptoms of caries of the spine are, a feeling of weight and aching in the part, itching and numbness, pains shooting round to the front of the trunk; and, when the disease is farther advanced, pains and twitching of the limbs, succeeded by palsy of all the parts below the affected vertebræ, and of the sphincters of the bladder and rectum. The nervous symptoms are not always limited to the parts below the seat of the disease; in some cases we have pains of the arms, although the disease be situated in the middle dorsal vertebræ.† On inspecting the contents of the spinal canal, where death has occurred during the existence of caries of the bones, effusions of serum or plastic lymph are found between the osseous surface and the dura mater, and sometimes they are found firmly adherent; plastic lymph and pus are also discovered within the arachnoid, or the membranes are found glued together. Tuberculous deposits have been observed within the substance of the spinal dura mater, and between that membrane and the arachnoid; most commonly connected with scrofulous disease of the bones, but sometimes wholly independent of it.* The medullary substance itself has in such cases been found softened or attenuated; sometimes entirely destroyed for a short space, and the vacuity filled up with a sanious pus.

When scrofulous disorganization of the bones has been effectually checked, it is astonishing to mark the effects made by nature to repair the loss and support the fabric by new osseous growths: we have even occasionally seen them formed in the vicinity of the disease, even although its activity was still unabated.

Scrofulous affections of the spine often commence in the intervertebral substance, which becomes soft in the centre, and is then destroyed by ulceration and absorption; the disease afterwards extending to the bodies of the vertebræ. There is no reason to doubt that ulceration of the intervertebral substance is in most cases of a scrofulous nature; yet it must be admitted that tuberculous matter has very rarely been observed in this texture; partly, perhaps, because it has not often been carefully sought for. Andral states that he once met with a mass of tubercles within the substance of the intervertebral cartilages.†

Lateral curvature of the spine has been supposed by some writers to be in almost all cases produced by strumous disease of the bodies of the vertebræ. Certain it is that scrofulous individuals are most liable to lateral curvature of the spine; but this may with more propriety be ascribed to a general debility and relaxation of the frame, and of the muscular and ligamentous systems in particular, than to any positive softening of the osseous texture. Were the bones softened from scrofula in every case of lateral curvature, how is it possible that so many cures should be effected, or that such multitudes of females should be met with in comparatively good health, yet having permanent lateral flexure of the spine? Scrofulous disease of bones in other cases requires powerful counter-irritation to check its progress; but in this form of spinal disease, rest in the horizontal posture, friction, a regulated exercise of the muscles, and attention to the general health, are sufficient, in a great majority of instances, to accomplish a cure. Lateral curvature of the spine not unfrequently precedes angular projection from caries: hence it has been inferred that the latter is but the second stage of the former disease: of this, however, there is no proof; nor is it at all unnatural that a feeble individual, whose spine sinks readily into a serpentine bend, should afterwards become the subject of a more formidable disease, affecting the bones themselves. The vertebræ after death, in cases of serpentine curvature, are most commonly found free from disease,‡ which would seem to shew that scrofulous softening of the bones is rarely the cause of this deformity; for it is highly im-

‡ *Shaw*, Diseases of the Spine. We have lately examined a number of preparations with a view to this point, and the result fully corroborates the assertion of Mr. Shaw.

probable that so great a change in the texture and form of the vertebræ should be repaired without leaving behind it some traces of its previous existence.

The serous membranes in different parts of the body often exhibit decided marks of scrofulous disease, myriads of minute tubercles or tuberculous granulations being found adhering to their surfaces or imbedded in their tissue; and sometimes enveloped in the false membranes connecting them, which have formed during inflammation. Thus the pleura, the arachnoid, the pia mater, the peritoneum, are frequently found affected with scrofula; and a few instances are recorded where tubercles have been observed in the pericardium.* When this disease attacks the membranes of the brain, its symptoms are usually the same as those of acute hydrocephalus; and its termination takes place by effusion within the skull or spinal canal, to which sometimes is superadded softening of the medullary substance. The children of scrofulous parents are well known to be more prone than others to cephalic disease; and in this manner the whole offspring of such individuals are sometimes cut off in succession during infancy. When tuberculous disease affects the peritoneum, it seems, whether originally induced by inflammation or not, to produce, after a time, that state: dropsical effusion then follows. As the disease proceeds, the fluid is absorbed, and the opposite surfaces, loaded with tuberculous matter, become glued together, obliterating the cavity of the peritoneum, and fixing the floating viscera in their places. We have seen this disease in a boy of twelve years pervading the whole trunk, gluing the contiguous viscera to each other, to the parietes of the chest and abdomen, and to the diaphragm, filling up the anterior mediastinum, and presenting numerous white cheesy tumours within the substance of the viscera themselves. The heart alone was free from disease. A separation of the lowest part of the sternum, which was much softened, had taken place, and the point of the ensiform cartilage was directed forwards and upwards; a consequence, apparently, of the swelling of the abdomen, and the restraint imposed by the strong adhesions on the motions of the chest in respiration. Such cases are always complicated with scrofulous disease of the mesenteric glands, and usually with ulceration of the coats of the intestines, which have thus been perforated, allowing a free communication through the adherent sides of the contiguous tubes. In some cases it has appeared that the ulceration had commenced in the peritoneal surface;† while in others the mucous lining of the bowel seems to have been the first eroded.‡ The same result will follow from both processes; but certainly the ulceration from within outwards is what we consider most likely to happen, from the greater proneness of mucous membranes to that state.

The frequent occurrence of scrofula within the central organs of the nervous system has been satisfactorily ascertained. Wiseman, whose knowledge on this subject greatly surpassed that of most of his contemporaries, appears to have suspected the fact; but it was reserved for modern pathologists* to shew how frequently tubercles are formed within the encephalon and spinal cord. Before the age of two years they are not common; but from this period onwards till puberty they are of frequent occurrence. Their most usual seat in the brain is the upper part of the hemispheres; and in the spinal cord they occur much oftener in the cervical than in the dorsal or lumbar portions: according to the most accurate observers, they are very often enclosed in cysts.† It is singularly deserving of notice that tubercles have been repeatedly found in the nervous centres where no symptom during life had induced any suspicion of their existence; and the scalpel has as frequently been unable to disclose any deviation from healthy texture in the substance immediately surrounding them.

The thyroid gland was long believed to be peculiarly subject to scrofula; and the chronic enlargement of that organ, named bronchocele, was at one period regarded by the best writers of their day as a distinctly scrofulous disease:‡ nay, it is remarkable that even in recent times the introduction of iodine as a general antistrumous remedy originated in the supposed connexion of bronchocele with scrofula. But on reviewing the history of the two diseases, we shall find so many points of difference as to convince us that they are altogether distinct and independent. (See article Bronchocele.) In support of this opinion it may be sufficient here to state that bronchocele is of rare occurrence in the large manufacturing towns of Britain; while scrofula prevails throughout their population, cutting off thousands in infancy, and scattering among the survivors the germs of debility and protracted disease. The thyroid body, though rarely the seat of true scrofula, is not wholly exempt from it, more than one instance of its occurrence having come under our observation. The disease commences with a moderate degree of swelling, which is followed by the formation of a small indolent abscess: this after a time bursts spontaneously, discharging a thin pus mixed with curdy flakes; the apertures remain fistulous for a considerable time, while the tumefaction of the gland subsides.

The lungs have long been known to be particularly liable to scrofulous deposits; and so rare is it to find tubercle in any other situation without also finding it in the lungs, that Louis states he never met with an instance in all

his numerous dissections excepting once, in the case of a man who had died of fever.* Scrofulous disease of the lungs constitutes what has been named tubercular phthisis; to the article on which the reader is referred.

The heart has been found affected with scrofula but rarely: Dr. Otto† of Breslau, a very learned and able pathologist, never once met with a case of this sort; yet several cases of its occurrence are on record from Fabricius Hildanus‡ and Needham§ down to Andral,‖ Lobstein,¶ and Macmichael.** Tubercle of the heart never occurs except when the system is strongly imbued with strumous disease; and its existence in this situation does not appear to have been indicated by any peculiar diagnostic symptom.

The occurrence of scrofulous disease in the voluntary muscles appears to be not less uncommon than in the heart: instances, however, have been met with of tuberculous deposits in these organs, both in the human subject and the monkey.††

The effect of scrofula in modifying the symptoms of a large proportion of the diseases to which the human frame is subject has been long known to medical observers, and meets us daily in the course of our practice. Inflammatory affections, in a particular manner, exhibit the effects of this influence; losing the acuteness of their character, and becoming tardy and indolent, difficult of cure, and requiring for its accomplishment the use of stimulants and tonics. Frequent and striking examples of these facts are presented to us by many of the early consequences of syphilitic infection, and by the extensive tribe of ophthalmic diseases. Injuries of the soft parts, particularly where there has been much loss of blood, also often afford unequivocal evidence of the presence of a strumous habit: hence it is common for persons who are jealous of the imputation of scrofula to declare that their wounds are always readily healed. So strong sometimes is the modifying power of scrofula, that the writer has known the stump of a strumous girl's arm, which was removed on account of an extensive laceration, to discharge distinct curdy matter at the second dressing.

Scrofula appears to possess a certain degree of connexion with several other diseases. Some congenital affections, such as hare-lip, spina bifida, and external hydrocephalus, are more frequently met with among scrofulous children than others; and it is worthy of remark that in many cases of congenital peculiarity or defect, the same have been observed in ancestors, or near collateral relatives of the patients.

Of all the diseases allied to scrofula, perhaps the most closely connected is rickets, (see art. Rickets;) yet the distinction between the anatomical characters of the two diseases is sufficiently well marked. In rickets the whole texture of the bone is softened, though not exactly in the same manner in both species of that disease; but in scrofula, tuberculous matter is deposited in the cancellous structure, the outer wall remaining entire, or becoming necrosed; or tubercle invades the bone from the periosteal surface, the osseous substance being removed by absorption. Encephaloid or medullary tumours may also be enumerated among the affections connected with scrofula; they occur chiefly in individuals of a strumous habit, and the materials of which they are composed bear in their last stage of softening a considerable similitude to those of tubercle.* There is a fungous tumour, occurring in the lips and cheeks of young scrofulous subjects, which we have repeatedly met with: in its external characters it bears a very close resemblance to encephaloid; but it is formed with much greater rapidity, and admits of cure by a well-directed alterative and purgative treatment, and the application of leeches, astringents, and escharotics. It is the opinion of some experienced practitioners, that carcinoma occurs more frequently in persons of a strumous constitution than others; and our own observation inclines us to entertain a similar belief. The concurrence of scrofula with urinary calculus has led to the supposition that the two diseases are intimately connected; but it does not appear that they are in any way dependent on each other: the same causes, however, are likely to induce both. (See art. Calculous Diseases.)

The greater sensitiveness of most scrofulous individuals renders them more prone to diseases of the nervous class: hence an aggravated form of hysteria is more frequent in such persons; and we think, with Dr. Cheyne, that epilepsy affects strumous subjects oftener than others. (See Epilepsy.) The diseases of the mind claim an alliance with scrofula, which has not attracted the attention of writers on this subject so much as it seems to merit. An eminent physician of great knowledge and experience in the treatment of insanity has stated

This writer has given a very interesting account of the tuberculous affections, particularly phthisis, occurring in monkeys at the Jardin des Plantes.

* The earliest distinct account of encephaloid as it affects the extremities, is to be found in Ruysch Observat. Anatomico-Chirurgic. No. 81, where he describes it under the title of the spongy or ossivorous tumour, and states that it was known to the Germans under the name of *schwamm*, and to the Dutch under that of *been eter*.

to us his belief that more than one-half of those who are subject to mental derangement are of a scrofulous constitution, having some manifest indication of its existence in their persons. With the view of elucidating this subject, we examined all the paupers of a lunatic establishment. Of forty-four females, exactly one-half presented indurated or enlarged glands of the neck or throat, and several had extensive scrofulous cicatrices. Of forty-six males, twenty-eight had no decided symptoms of scrofula, though several of these had the strumous aspect; sixteen presented the marks already mentioned in reference to the females; and two belonged to families known to be afflicted with scrofula in an aggravated form. All of these ninety lunatics were adults, and not one of them exhibited any active symptoms of scrofulous disease. It has been remarked to the writer by the physician already referred to, that he has often observed active scrofulous symptoms to alternate with attacks of mania. In several cases he has known the purulent expectoration of phthisis to cease during the urgent symptoms of insanity; and on the other hand, reason has been seen to return before the pulmonary disease proved fatal—soothing the feelings of affectionate relatives, and shedding a calm over the last days of the consumptive lunatic. In accordance with what has just been stated, the severity of the symptoms of scrofula does not appear to promote the developement of mental disease, but rather to impede it; for in families eminently scrofulous, we have sometimes observed the individual least afflicted with that malady to be the victim of insanity; while those who suffered most from scrofula possessed sound minds; as if the local irritation, or the drain from the body, afforded some protection against mental derangement. It has often been remarked by medical writers, and the observation of every physician must confirm the accuracy of the statement, that precocity of mental developement, and superior genius, are in a great majority of instances the accompaniment of the scrofulous constitution.

Causes.—In considering the causes of a disease so deeply rooted in the constitution as scrofula is universally acknowledged to be, it is necessary to direct our attention to circumstances very remote in the history of those who are its subjects. The foundation of a scrofulous habit is frequently laid during the fœtal state, by the transmission of that peculiar organization of the frame from parents who themselves possess it. Nothing, indeed, can be better established as the result of general observation than the hereditary nature of scrofula. This peculiarity of constitution may also be communicated to the fœtus by some defect of energy in one or both of the parents, arising from extreme youth, or very advanced years, or great disparity of age, or that premature decay which is induced by a life of dissipation, or the debilitated states resulting from protracted illness; or, on the part of the mother, repeated miscarriages, and by defective nourishment and other similar causes. Various occurrences, likewise, may take place during gestation—such as accidents, frights, prolonged disease, mental distress,—which interfere with the proper developement and growth of the embryo, and entail upon the child that feebleness of constitution which, if not identical with scrofula, leads to its appearance on the application of causes not adequate under other circumstances to produce that disease. The writer was recently called upon to examine a boy of six years, labouring under a complication of scrofulous ailments; the history of whose case may serve to illustrate the influence of injuries received by the mother during gestation. In this instance the mother was a tall and rather slender woman, apparently enjoying good health: the boy was puny for his age, his movements were quick and restless, his articulation very imperfect, and his mind in a state approaching to idiocy: the lips were seamed with the scars of former ulcers, the conjunctivæ relaxed and injected, the tarsi inflamed, ulcerated, and almost without cilia; the countenance pale and bloated; the skin dry and scaly; many of his teeth were gone, and most of those which remained were in a state of decay; the cervical glands were indurated, but not much enlarged. The last phalanx of one thumb was double, and each extremity of the fork had a perfect nail. He had always been a very sickly child, had had repeated suppurations in the groins, and was then labouring under chronic diarrhœa, part of his food passing undigested. During the time that his mother was pregnant with him she had suffered many severe falls, the first towards the end of the third month.

Scrofula is also observed to originate in the healthy offspring of healthy parents under certain circumstances, the principal of which are habitual exposure to cold and damp, privation of free air and light, and want of healthful exercise. Instances are recorded where persons previously in good health have been affected with scrofula after being confined in the dungeons of a prison, and there scantily fed.* The influence of such causes in producing tuberculous disease in the inferior animals has been made the subject of experiment by Dr. Jenner,† Dr. Baron,‡ and others; and the results have satisfactorily shewn both the great extent of that influence, and the power which we possess of removing the factitious disease by replacing the animals in healthy situations, and supplying them abundantly with wholesome food. The operation of cold and damp, as causes of scrofula, is greatly augmented even by a slight local injury.

A moist, cold, and variable climate, like those of Great Britain and Holland, is particularly favourable to the developement of scrofula; in proof of which it is sufficient to adduce the great prevalence of the malady in both of those countries. A very cold or a hot climate, on the other hand, serves rather to protect us

* *Pinel*, Nosog. Philos. t. iii. pp. 380, 385.

† *Jenner*, in Beddoes on the Med. Use of factit. Airs.

‡ Delineations, &c. pp. 25 et seq.

against scrofula; the former, dry and bracing, invites to exercise, and promotes digestion, and thus strengthens the system; while the latter favours the excretions, particularly that of the skin, and preserves the body from those sudden changes of temperature which in our island so often lay the foundations of scrofulous affections. But when an individual whose constitution has been formed in a warm climate is removed to a cold and variable one, the occurrence of scrofula is exceedingly frequent; convincing proofs of which are every day afforded by those natives of warm climates who reside in our island, as well as by the diseases of birds, monkeys, and other animals which have been brought to us from warmer latitudes.* Indeed it is not necessary for the inhabitants of warm climates to leave their native countries to experience the effects of a cold and variable atmosphere in the production of scrofulous disease; it is sufficient for them to ascend their own mountains, when they will be exposed to the same influences, and suffer the same evil consequences as if they had removed to a more northern climate.† The information communicated by Dr. Ferguson regarding the diseases of the black troops in different situations in the West Indian islands, illustrates this point in a very interesting and satisfactory manner.‡

Among the causes which appear to give rise to scrofula in children, are the practices of rearing them by the hand and suckling them too long—two extremes, both of which often lead to the same result, the imperfect nourishment of the child. The former of these is a fruitful source of scrofula in England, the latter in Scotland, where it is usual among the labouring classes for children of sixteen and eighteen months to be still at the breast: in some instances we have known them suckled for upwards of two years. A similar injurious effect will be produced by allowing the same wet-nurse to suckle several children in succession, which we have known to be pursued as far as three, when debility and symptomatic amaurosis forced the woman to resign her charge. Imperfect nourishment of the child, and consequent tendency to scrofula, is also likely to be induced in those cases where the wet-nurse menstruates regularly during lactation. It is an opinion professed by Wiseman and other writers of great ability and experience, that a scrofulous wet-nurse may occasion the disease to appear in the child to whom she gives the breast; and the idea appears consistent with reason, not on account of the existence of any scrofulous poison, capable of being imbibed by the infant, but because it is natural to suppose that the milk of a scrofulous female will not afford the same substantial nourishment as that of a woman in sound and vigorous health.

Another cause of this disease is confinement in ill-ventilated apartments; for the deficiency of pure atmospheric air cannot be long endured, especially during youth, without the most injurious consequences. While the frame is building up and the constitution acquiring that character which is to distinguish it through life, all the processes of the economy are peculiarly active, and any defect of what is to perfect the animal fluids and give energy to the nervous power, is felt with greater force, and is productive of much more injury than at an after period. Ill-aired apartments are in general imperfectly lighted, and the want of this vivifying influence of light favours the formation and developement of scrofula; for the human body requires a certain exposure to light for the proper performance of its functions, little less perhaps than plants, although in them the loss of colour renders the effects of seclusion more strikingly manifest. The experiments of Edwards on the spawn of frogs and on tadpoles clearly demonstrate the agency of light on the formative processes of living organization. He found when the light was excluded that the eggs were never fully hatched, and that tadpoles did not undergo their transformation at all, or did so after a considerable delay; but their size increased, although they were kept in darkness.* In accordance with the results of these experiments, it has been observed that monstrous births are exceedingly frequent among the miserable occupants of the dungeons under the fortifications of Lille.† We may in part ascribe to the deficiency of light the prevalence of scrofula among the inhabitants of cellars and of narrow alleys, where the beams of the sun never gain admittance. We are even inclined to think that the custom now so general among the wealthier classes in this country of sitting in darkened rooms during the day is far from being conducive to vigorous health; and where the young are concerned, we do not hesitate to say that it must be injurious. It is a custom borrowed from the luxury and effeminacy of warmer latitudes, and one which is calculated to enervate the body and induce a tendency to strumous disease.

In a great metropolis like London, where the moving crowds of human beings and the number of carriages are such that children cannot be allowed to go abroad in the streets, they grow up feeble and often scrofulous; while in villages and even in some populous towns, where they are almost constantly at play in the open air, they prove healthy and vigorous. The mischievous effects of the want of air, and sun-light, and healthful exercise, may be seen among the rich as well as the poor, though not to the same extent. The confinement, mental fatigue, and anxiety to which

† London Medical Gazette, Sept. 29, 1832.

female children in particular are so unremittingly subjected during their education, prove fertile sources of scrofula in boarding-schools, and even in the families of the higher classes: bodily health is too often sacrificed to the idol of accomplishment, and the intellectual powers, perhaps originally of excellent quality, are forced into a state of extreme culture and morbid precocity, destructive of all genuine soundness and vigour.

Acute diseases, especially those accompanied with cutaneous eruptions, as small-pox, measles, and scarlet-fever, are often observed to have the effect of producing the developement of scrofula; and the more tedious the convalescence, the more frequently do symptoms of this disease ensue. Various other causes of debility prove the means of developing scrofula —as long watching, protracted anxiety of mind, severe study, especially in the young, habits of dissipation, excess in sexual indulgences, solitary vice, profuse discharges of all kinds, repeated syphilitic disease; the abuse of mercury, of narcotics, of warm bathing, and of powerful evacuants. Different local irritations have the effect of causing the neighbouring lymphatic glands to swell, and where a strumous tendency exists, to become the seats of tuberculous deposits, as we see exemplified in the consequences of difficult dentition, and of the inflammatory affections of the mucous membranes of the respiratory and alimentary canals. Too great indulgence in sleep has been enumerated among the causes of scrofula, and excess in this particular will certainly debilitate, and thus dispose to the disease; but we are inclined to believe that the indulgence in sleep which appears to induce scrofula is, in fact, usually occasioned by that feeling of weakness and exhaustion which is among the earliest symptoms of the approaching developement of the disease.

Treatment. — The treatment of scrofula naturally divides itself into the preventive and curative, the former of which is the more generally successful, and obviously the more important. All children are liable to become scrofulous, and those more especially whose parents or near relatives are the subjects of this disease. Hence particular attention is required to prevent the formation of the strumous constitution in children, and the developement of the disease in those who may from birth be marked by this peculiarity of organization. Indeed, it will not be undeserving of our care to influence as far as we can the sound and perfect formation of the embryo, by more than ordinary attention to the health of the mother during her pregnancy, wherever there is reason to apprehend the existence of a scrofulous disposition.

When the child of a scrofulous father is born, the infant, unless the mother is free from all traces of the disease, ought to be consigned to a wet-nurse of sound and robust constitution, having an abundant supply of milk. This alone ought, for some months, to be sufficient for the nourishment of the child; but after a time, should it appear delicate, a little isinglass jelly may be allowed in addition, or liquid yolk of egg, or beef-tea, together with some preparation of wheaten meal or flour, or pure starch. Daily immersion in cold water, and gentle friction of whole body, will be found of great utility. The child ought to be warmly clothed, to be carried about in the open air as much as possible, and the apartment in which it sleeps ought to be kept at a steady moderate temperature, and perfectly well ventilated. All rooms occupied as nurseries for children ought to be spacious and lofty, never situated in a sunk floor nor in an attic, and, if possible, considerably above the level of the ground— directions which will be readily understood, when it is recollected that low rooms are ill ventilated and often damp, while those in the attic story are particularly liable to variations of temperature.

As the child grows up, a similar plan of management will be found to avert, as far as it can be accomplished, the formation of a scrofulous habit, and the developement of the disease in those who exhibit that tendency. A plain and nutritious diet, containing a larger than usual proportion of animal food, warm clothing, daily exercise in the open air, the cold plunge-bath, cool and well-ventilated rooms, moderation in the pursuits of pleasure, of study, and of business; strict temperance and virtuous habits; may be said to comprise all that is most likely in our mode of living to give protection throughout life against the occurrence of scrofulous disease. To those in affluent circumstances who can be removed to a climate more genial than that of Britain, such a change, if judiciously made in early life, will confer a still greater security from scrofula.*

When a well-marked strumous tendency exists, the management of the mind urgently demands our attention; and attempts ought to be made at a very early age to correct whatever is deficient or excessive in its operations. Children who are of a dull and apathetic character ought to be roused by presenting to them objects which are likely to interest and enliven, while the ardour of others in the pursuit of knowledge should be cautiously repressed; and when the genius gives promise of unnatural precocity, means should be used to retard the unfolding of the mind, and allow the faculties to mature themselves by slow degrees. The moral feelings, in an especial manner, require a strict control for the purpose of giving them a just direction, and preserving individuals of a sensitive character from indulging in those extravagant manifestations of sensibility which, if permitted, are apt to endanger the soundness of the mind.

Before proceeding to consider the cure of scrofula, it will be necessary to direct our attention to the different conditions of those who are afflicted with this disease. It is frequently engrafted on a feeble and attenuated frame; but it exists also in combination with

* *Dr. James Clark*, On the Influence of Climate. See also art. CLIMATE, in this work.

a plethoric habit, perhaps deceiving with a false shew of strength; the first of these forms being often exemplified among the poor, the second among the rich, although not by any means uniformly so. Hence a broad line of distinction arises between the methods of treatment adapted to such different types of the disease. In the former a generous diet and stimulating remedies are required; in the latter spare living, moderate evacuants, and local depletion are necessary: both, however, demand the employment of those tonic means which tend to communicate vigour to the constitution, and which increase that power of resisting the occasional causes of disease and repairing the injuries of the frame; a power which it is the remarkable characteristic of the scrofulous constitution to be devoid of, or to possess in a very imperfect degree.

To consider, in detail, the method of treating each of the extensive class of strumous affections would involve us in the repetition of what will be found under various specific heads of disease, and swell the present article far beyond its due limits. It will be sufficient, after premising a few general remarks, to pass in review the chief of the numerous remedies which have been held in estimation for the cure of scrofula; pointing out, as we proceed, the particular circumstances under which they have appeared to produce most benefit.

The management of scrofulous patients, in respect of air, exercise, clothing, and diet, must be conducted upon the principles already laid down, but varied according to the exigencies of each individual case, still keeping steadily in view the improvement of the constitution.

On the subject of diet, it is deserving of notice that, besides those varieties before alluded to, a very nourishing food may be prepared by boiling a small bag filled with suet in cow's milk. We have made trial of it on the recommendation of Dr. Paris,* and found it to answer remarkably well in cases of scrofulous marasmus when almost every other article of diet caused irritation of the bowels, and passed through undigested. It bears a near resemblance to goats' milk, but has the advantage of being more astringent.

Some eminent writers have not hesitated to state their belief that air, exercise, and proper clothing and diet, comprise the best and only method of controlling and removing scrofula. To such an opinion we cannot subscribe, although we fully acknowledge the vast importance of attending to these particulars, and the natural progress of cases of external scrofula towards a cure, after the age of puberty. An amusing instance of the effect of air and exercise alone in the cure of a scrofulous sore in the leg is afforded by the case of a young nobleman, who, after suffering under a variety of regular treatment, had a hole cut in his stocking, and was sent to range the fields, when a crust soon formed, and the ulcer healed. It is worthy of remark that this individual became afterwards insane.

1. *Evacuants.*—Although it be true, in a general sense, that scrofula is a disease of debility rather than of strength, and that profuse discharges, whether natural or artificial, prove among the most powerful of its exciting causes; yet in the early stage of many scrofulous diseases, and sometimes during their progress, a cautious employment of evacuants is found to be productive of the best effects; but it is only by a careful study of the existing symptoms of inflammation in each individual case that we are enabled to make use of depletory means with confidence and success. In strumous persons the occurrence of inflammatory symptoms is to be watched with unceasing care, and above all those of the respiratory mucous membrane, as well as of the serous membranes of the head and abdomen: a well-timed venesection in such cases may be the means of cutting short symptoms which would speedily induce the eruption of a crop of tubercles; on the fatal consequences of which, whether slow or rapid in their progress, it is unnecessary to enlarge. Leeches are often preferred from the timidity of patients and their friends, and sometimes perhaps from the indolence of medical attendants; but their effects are frequently irritating and exhausting, and, even in children, far inferior to those of the lancet. Cupping is also preferable to leeching, the ease and rapidity with which blood can be taken by this method placing it nearly on a level with venesection. The detraction of blood from the vicinity of parts suffering from scrofula, or in danger of becoming the seats of scrofulous affections, is in very many cases necessary; and in these both leeches and cupping may be employed, but under the guidance of a wise discretion, for which no general rules can be given. To promote the efficacy of sanguineous depletion, and supply its place when circumstances render it unsuitable, the tartrate of antimony may be exhibited in small doses, as a nauseant and diaphoretic; and it will sometimes be necessary to have recourse to this remedy during the progress of the tonic plan of treatment when it appears, as often happens, to be producing too much excitement. The tartrate of antimony or ipecacuan is also used, with excellent effects, in emetic doses, for the purpose of preparing the stomach for the reception of tonic medicines in many scrofulous cases.

Long-continued nausea, whether produced by sea-sickness or by the persevering use of tartar emetic, has a powerful effect in dispersing indolent tumours, and has been successfully employed for that purpose. Two cases of this nature, and one of presumed tuberculous phthisis, cured by the use of nauseants, have been communicated by Dr. Jenner; and he has expressed a hope that by such remedies we shall be enabled to effect the absorption of tubercles.* All that we know of the action

* On Diet, 2d edit.

* Baron's Inquiry, pp. 158, et seq.

of the absorbents leads us to believe that they are capable of removing tubercle; and that such an operation, to a certain extent, does really take place, is proved by the changes which that substance undergoes in its progress to the cretaceous transformation. If tuberculous masses of long standing are thus changed, what reason have we to doubt that the soft curdy matter of which they are at first composed is often absorbed and carried back into the circulation, to be converted into some less noxious constituent, or altogether expelled from the system?

The action of strong purgatives is sometimes, though rarely, required in scrofulous diseases; but the neutral salts combined with the administration of mercurials are very useful, as we shall presently point out. Moderate aperients, and those which tend at the same time to improve the powers of digestion, are required in the treatment of almost all scrofulous cases. Rhubarb and soda, and rhubarb and magnesia are well adapted to such cases; and as a mild evacuant, when the bowels are loaded, castor-oil is very serviceable.

2. *Mercurials.*—Of all the remedies employed in the treatment of scrofula, perhaps none have enjoyed a greater reputation than mercurials; but it is only from their purgative and alterative effects that they prove beneficial, and not when they produce that powerful influence on the frame which so rarely fails to ensue from their free exhibition. In the forms of calomel and blue-pill, mercury enables us to relieve the bowels from those morbid accumulations which are so apt to collect in strumous cases, and to restore to the liver its healthy action, which is rarely preserved, at least for any length of time, during the existence of scrofula. The success of a mild alterative plan of treatment, aided by the use of saline purgatives with senna, has been admirably illustrated by Mr. Abernethy;* and more exclusively in reference to the disease now before us by Mr. Lloyd.† Other mercurial preparations are also employed with benefit in different forms of scrofula: thus the hydrargyrum cum creta will be found very serviceable when the secretion of bile is faulty or deficient, whether combined with a torpid or relaxed state of the bowels, as in the early stages of mesenteric disease. The internal use of corrosive sublimate is also valuable, particularly in scrofulous ulcerations and leucorrhœal discharge; provided it be administered cautiously and in minute doses, such as the eighth of a grain three times daily. It seems to act rather by stimulating the mucous membrane of the alimentary passages, and promoting perspiration, than by any influence it exerts over the secretion of the liver. Mercury has likewise been employed in the form of ointment, rubbed on the skin, for the relief of scrofula, and, according to the report of Mr. Brandish,‡ with the most beneficial effects. It was his practice to use it in small quantities, continued nightly for months, but never during the cold season: it is proper to add that he avoided the full operation of the mineral, and combined its employment with the internal exhibition of liquor potassæ, with a generous diet, and the occasional use of vegetable tonics. Of this practice, in cautious and experienced hands, we are inclined to think favourably, although it must be admitted that medical opinion in the present day is adverse to the employment of mercurial frictions in scrofulous cases generally. But the local application of camphorated mercurial ointment to diseased joints and indurated testicles is now acknowledged to be in very many instances highly efficacious.*

As a sequel to the subject of mercurials, it will not be out of place to mention another remedy, less hazardous in its operation, but not of less approved efficacy in scrofula,—namely, *sarsaparilla*. We find it recommended by Wiseman,† and after a period of neglect it has been again restored to merited favour. It is a mild tonic, and well adapted to those cases where the skin is in a harsh and unkindly state: it proves a restorative to the stomach, and is found very useful in the chronic diarrhœa of strumous children. The decoction is the usual form in which this drug is exhibited, but the bulk of this preparation often renders it objectionable, particularly for children; and in most cases, both of children and adults, a much more concentrated preparation, such as the solid or fluid extract, will be found to possess many advantages. Powdered sarsaparilla, conjoined with soda, is an excellent form, though much less palatable than the extracts: it has been given with marked benefit in scrofulous disease of the tongue.

A feeble digestion, and prevailing acid condition of the stomach and alimentary tube, are the frequent concomitants of scrofulous disease; hence the employment of the *alkalies* and alkaline earths, but particularly the former, has been attended with very beneficial effects in its treatment. All the alkalies have been used with advantage in scrofula; but the liquor potassæ is that which in our hands has proved the most decidedly useful. The dose must be large, as Mr. Brandish has shewn—from half a drachm to a drachm and a half three times daily, for an adult; given in malt tea, mild ale, or infusion of hops.‡ Carbonate of soda is generally more agreeable to patients, and may be given freely with good effect, especially when combined with sarsaparilla, cinchona, or bitters. The volatile alkali (carbonate of ammonia) has also been administered in scrofulous cases,§ and with excellent results. But its stimulant and diaphoretic properties render it suitable only for cases in which there exist

torpor, languid circulation, impaired appetite, and a dry husky state of the skin, such as we often meet with among the poor, and in that form of the disease so well characterised by Alibert,* under the designation of *scrofule momie*.

A considerable number of the remedies which have enjoyed reputation in the treatment of scrofula, have belonged to that class which increase the secretion of urine. The alkalies which we have just considered are of this description; and besides these we may enumerate the muriate of lime, the muriate of barytes, and nearly all the mineral waters to which scrofulous patients are in the habit of resorting. These saline remedies not only promote the secretion of urine, but act gently on the bowels, and thus, especially when conjoined with the exercise and free air enjoyed at a watering-place, increase in a remarkable degree the powers of digestion, and so prove beneficial to the scrofulous invalid. In their specific effects we have no confidence. Muriate of barytes is now very rarely prescribed; and muriate of lime almost as seldom, excepting in the combined form in which it is furnished by nature at various mineral springs.

The opinions which we have already expressed regarding the nature of scrofula may have prepared our readers to look for the most valuable remedies in this disease under the head of *tonics*. Even inflammation, which in most cases requires depletory measures, is, when combined with scrofula, and thus rendered indolent in character, often successfully treated by tonic remedies: this is especially true of those inflammatory affections which are attended with little or no constitutional disturbance, as in strumous inflammation of the conjunctiva, where the efficacy of cinchona has so long been acknowledged. This admirable drug is, without doubt, the most efficacious of all the tonics used in scrofula, and, from the concentrated form in which it can now be exhibited, the most generally available. The virtues of cinchona in strumous diseases were first brought into notice by Dr. Fordyce,† and from that time until now it has enjoyed more or less favour. Sulphate of quinia has now very generally superseded it, having become a remedy of every day prescription. It is one, however, which requires to be carefully watched, and immediately intermitted when it produces, as it often does, a degree of feverishness. Other vegetable tonics and bitters have been administered with advantage in scrofula, such as calumba, gentian, and hop; and in Germany coffee made from roasted acorns has found many advocates, although, as Benedict‡ informs us, it often proves constipating and induces a feverish state.

Of the metallic tonics used in scrofula, iron is that which has been found the most beneficial. The best forms of exhibiting it are the vinum ferri, the muriated tincture, and the subcarbonate in powder: the chalybeate mineral waters also have often proved eminently serviceable in this disease.

Arsenic is a metal of much more questionable efficacy; but we have known it productive of great benefit in allaying the pain attending strumous affections of the bones and periosteum. Gold was given by Lalouette in scrofula, and its use has lately been revived by Chrestien as a remedy for syphilis.

In the advanced stages of scrofulous affections, one of the most permanent and exhausting symptoms is profuse perspiration; for the purpose of checking which the mineral acids, particularly the sulphuric and nitric, have been given with great benefit: their use, however, is apt to cause irritation of the bowels, and thus we are forced to alternate them with opium, or altogether to abandon their employment. The root of the tormentil has been recommended as a substitute, but it seems to possess very feeble powers of repressing either perspiration or diarrhœa. The mineral acids are also useful in restoring the tone of the stomach, and thus they frequently prove of great service in the treatment of scrofula.

Scrofula, as a chronic disease, often accompanied with feeble action of the stomach, and indeed of all the assimilative organs of the system, seems naturally to require the exhibition of stimulating remedies. In regard to dietetic stimulants, animal food, as we have already stated, is proper in a large proportion of strumous cases, and in some ale and wine may be given with great advantage. Of these, ale is the more nutritious and less heating, and when sound and well seasoned with hops, it proves in many cases a valuable auxiliary to the medicinal treatment of scrofula,—an opinion which is not given on theoretical grounds or the mere authority of others, but from what we have had frequent occasion to observe. Bitter tinctures have been prescribed in this disease, and that of Peyrhile, which contains also a proportion of alkali, was long a favourite among the French. Its effects, however, are known to have been often injurious, because too stimulating; and in the present day it is seldom or never employed.

Iodine, a powerful stimulant of the alimentary mucous membrane, and of the whole absorbent system, has lately been added to the catalogue of anti-strumous remedies; and as yet it can scarcely be said that a just estimate has been formed of its real virtues. The evidence contained in the writings of numerous authors, and the results of our own experience, prove satisfactorily that iodine possesses very considerable efficacy in removing scrofulous swellings of the lymphatic glands; and there is some reason even to believe that it is capable also of inducing the absorption of tuberculous deposits.* This remedy is successfully employed both internally and locally, in each of which modes it increases the action of the ab-

* *Gairdner*, On Iodine, pp. 52 & seq.; also, Baron's Inquiry.

sorbents; and in the latter it likewise often induces suppuration of strumous tumours, and thus hastens their removal. After attracting for a time the attention of the medical profession, iodine was beginning to experience a degree of neglect, when the appearance of M. Lugol's Memoirs restored its reputation.* His extensive series of experiments in the employment of this substance have placed in a very clear and convincing light the powers which it possesses of controuling and even curing scrofula. The trials which we have made of it serve to confirm the representations of M. Lugol; but we are ready to admit that his strong partiality in its favour may in some instances, perhaps, have led him a little beyond the limits of legitimate induction. For farther information regarding the employment of iodine in scrofula, we beg to refer to M. Lugol's last memoir, where a full account will be found of his most improved method of administering this powerful drug. Iodine, like arsenic and some of the mercurial preparations, is apt to cause pain of stomach, and in some instances headach; and when taken in excess, to produce an inflammatory condition of the alimentary mucous membrane, diarrhœa, and even bloody motions. The first of these symptoms is relieved by wine of cinchona, but the others require that the remedy be discontinued; and when resumed, that the dose be reduced. In cases where iodine has produced debility and loss of appetite, while manifestly reducing the scrofulous swellings, we have obtained a return of health and continued diminution of the tumours, by administering in its place sulphate of quinia with extract of sarsaparilla and aromatic sulphuric acid. The evidence of many practitioners, whose veracity and correctness of observation are above suspicion, proves that iodine, when long continued in full doses, frequently produces great weakness and emaciation; but M. Lugol is disposed to throw doubt on this opinion, and he even asserts that, in his experience, thin females have not become emaciated, nor corpulent ones lost flesh. It ought to be remarked in explanation of this discrepancy, that the doses which he prescribes are usually small, always moderate, and much diluted; and that he endeavours to accomplish by long perseverance what others have attempted by rapidly pushing the remedy to its utmost limit. In these particulars, we conceive, consists the superiority of M. Lugol's mode of treatment. It is proper to state here, that he also avails himself, in the treatment of scrofula, of the auxiliary means of air, exercise, warm clothing, and good diet; and employs, besides, baths of watery vapour, of iodine, and of sulphureous water.

The use of *baths* in the treatment of strumous affections is of great value, the kind of bath made choice of being determined by the existing state of the patient. Sudden immersion in cold water, and especially sea-water, has long been an approved remedy in scrofula; but when the strength of the patient is so reduced that no kindly glow follows, and when there is decided feverishness, the cold plunge-bath is not admissible. In such cases the warm-water bath, and still more that of vapour, will be found highly soothing and restorative. To weak scrofulous invalids, the well-managed application of steam has very often proved signally beneficial. A greater degree of excitement may be communicated to the cutaneous surface, when the general torpor of the system or the indolence of the diseased parts demands it, by the employment of warm saline water, or impregnating the water or steam with irritating gases, such as sulphurated hydrogen, carbonic acid,* chlorine, or iodine. The use of baths of every kind ought always to be followed by friction; and this alone is a valuable mean of restoring the healthy actions of the skin, and furnishing a substitute for that bodily exercise which the condition of the scrofulous patient often disables him from using. In cases of abdominal obstruction and affections of the spine and joints of the extremities, the great benefit derived from friction is attested by all who have seen it carefully practised.

Other modes of stimulating the scrofulous patient are afforded by electricity and galvanism: hitherto these have been employed principally as local remedies for the dispersion of strumous swellings, and with excellent effects;† but they will be found equally, if not more beneficial, as general means of exalting the nervous energy, and improving the tone of the whole frame.

Like all diseases occasionally attended with pain, scrofula requires at such times the use of narcotics, and, among these, opium under various forms of preparation certainly holds the first place. Hyoscyamus, belladonna, and conium are also used with advantage; and the last obtained at one period, through the writings of Dr. Stoerck, a particular celebrity for its anti-strumous virtues. It has, both as an internal and external remedy, a considerable power of relieving pain; but none which we have observed of a truly discutient nature.

Topical treatment.—Of the local treatment of scrofula, it may be supposed that the physician ought not to speak; but, although this branch of the subject falls immediately within the province of surgery, we may yet be permitted to state generally our views regarding this matter. Long observation of scrofulous diseases has convinced us that much active surgical interference is usually injurious, and that mild and soothing modes of treatment are, on the whole, more generally successful. Thus the laying open of sinuses, the cutting away of undermined integument, and the application of strong escharotic ointments, often exasperate instead of improving the case; while small counter-openings, moderate pressure, brushing the integuments around ulcers and

† *Underwood*, Surgical Tracts.—*Birch*, on the Medical Application of Electricity.

fistulous openings lightly with nitrate of silver; and the application to strumous sores of bread-and-water poultices, astringent washes, lime-water, and the black mercurial lotion, proves very serviceable. When a scrofulous ulcer is highly irritable and painful, the bruised fresh leaves of the hemlock applied as a poultice seldom fail to give relief. In ulcers of the tongue, carrot pulp and Peruvian balsam are the best applications.

Indolent scrofulous tumours, when the health is little reduced, may be dispersed or made to suppurate by continued pressure or by blistering, which can be employed when the situation of the swelling will not admit of pressure. As soon as suppuration has taken place, and the matter approaches the surface, it ought to be evacuated by a small puncture, which will hasten the cure and diminish the chance of an unseemly scar. When the parts continue inflamed and hardened, poultices of bread and water, or rags dipped in cooling lotions, are the best applications; but when the discharge is considerable, finely carded cotton with gentle pressure checks the profuse secretion, and gives comfort to the patient. In those sudden depositions of fluid which sometimes occur in strumous cases, it is not always prudent to make an opening as soon as fluctuation can be detected; for by a little delay and soothing means we have not unfrequently known the fluid to be wholly absorbed.

The eczematous and impetiginous eruptions which occur in scrofulous individuals are greatly benefited by astringent applications, such as the liquor subacetatis plumbi and liquor aluminis compositus; and when these diseases have proved obstinate, the unguentum picis will often completely remove them This last application we have found particularly efficacious in those crops of psydracious pustules and extensive exfoliations of the cuticle which are so frequently seen on the fingers of scrofulous females and delicate children.

The tumid upper lip, so distinctive of scrofula, and often amounting to a deformity, may be greatly reduced or altogether removed by the repeated application of nitrate of silver. When the ulcerated fissures of the lip are very painful, relief will be obtained from the hemlock poultice, and nitrate of silver can be afterwards had recourse to.

Strumous enlargements of the tonsils were formerly treated by excision, and cases requiring this procedure do sometimes occur: the practice is as old as Celsus, and is still a favourite with the Baron Dupuytren; Dr. Hosack of New York has also lately borne testimony to the safety and advantage of this operation. When it is not absolutely demanded, the employment of iodine, leeches to the throat, the light application of nitrate of silver to the tumours, and a gargle of oak-bark, will generally prove sufficient, if not for a complete cure, at least to keep the swellings within moderate bounds.

Scrofulous diseases of the bones and joints require, in their first stage, local depletion, and at a more advanced period counter-irritation by croton oil, blisters, tartar emetic ointment, caustic issues, or moxa. The warm-water douche and careful friction are also eminently useful in indolent cases. A very successful plan of managing diseased joints has of late been made public by Mr. Scott,*—consisting of the application of camphorated mercurial ointment, pressure, and complete rest of the affected articulation without confinement of the patient.

When all hope of recovering a diseased portion of the body is at an end, the question immediately presents itself whether such part ought not to be removed by an operation, and the patient thus freed from what is in itself useless, perhaps burdensome, the cause of constant irritation, and in many cases of exhausting discharge. Scrofulous bones and joints are peculiarly of this description, and the question of their amputation is seldom determined without the concurrence of the physician. It has been asserted that amputation in such cases merely puts off the evil day, and that the patient, at no distant period, is destroyed by scrofulous disease of some other and more important organ; but the futility of this opinion is daily attested by the numerous living instances, not only of those who have suffered amputation for scrofulous affections in early life, but of multitudes of others who have survived with contracted and distorted limbs from the ravages of the disease. In considering the propriety of amputation, it is necessary to determine how far the continuance of the affection brings the patient's life into hazard, and whether he has still sufficient strength left to undergo the operation. It is truly surprising to observe how small a degree of vital force is adequate to carry a patient safely through an operation under such circumstances; but it must be remembered that amputation, severe as it certainly is, removes the very sources of irritation and exhaustion which are rapidly undermining life. This operation is nugatory when another important joint, or a vital organ, as the lungs or bowels, is already the seat of incurable disease; and in such cases unquestionably it should not be performed. Great caution, however, is required in making our final decision; for every practitioner of experience has seen instances where the symptoms of visceral disease appeared almost to preclude hope, and yet have yielded on the removal of the local irritation, and a cure has been the happy result.

(W. Cumin.)

SEDATIVES, from *sedare*, to calm. These are medicines which directly depress the energy of the nervous system, and diminish preternaturally increased action. They exert an immediate influence over the nervous system, by which its energy is either greatly weakened or wholly destroyed. They thus have a two-fold action, first, upon the nervous system, and, secondly, through it upon the

* Observations on the Treatment of Chronic Inflammation, &c.

muscular: if the dose be large, the individual quickly loses his volition and becomes vertiginous; the nerves of sensation cease to respond to ordinary impressions; consciousness fails; syncope supervenes, and in a few seconds life is extinct.

With the exception of Dr. Young* and Dr. Billing,† medical authors in general have confounded sedatives with narcotics. There is no doubt, however, that the distinctive characteristics of both classes are well marked, and that the boundaries of each may be readily traced. The only circumstance, indeed, which has prevented the distinction from being at all times perceived, is the transitory nature of the excitement which follows a large dose of a narcotic, and the rapidity with which the symptoms of diminished sensibility and mobility supervene, as if they were induced without any previous increased action. In the operation of every narcotic the depressing effect, therefore, is preceded by increased action; and both the degree of the collapse and the rapidity of its appearance depend on the extent of the previous excitement. In small or moderate doses, narcotics augment the force and increase the frequency of the pulse, promote the secretions, and elevate the powers both of the body and the mind, and if these doses be repeated at proper intervals, this excitant effect is maintained; but, if the dose be not repeated, the transitory nature of this excitement becomes conspicuous, and a state of depression or collapse follows, in which languor, dulness of sensation, and sleep ensue.

Such are the effects of a narcotic. The administration of a sedative, on the contrary, whatever be the dose, is not followed by any perceptible quickening or augmentation of the pulse, but by an immediate diminution both of its force and frequency, and by a general feeling of depression, too decided to be overlooked. It is, indeed, evident that this effect is exactly the opposite of that of an excitant; and if the dose be large, not only is the sensibility diminished, but the whole power of the sensorium is at once completely paralyzed. We are perfectly aware that Majendie and others regard the sedative influence of one of the most efficient of this class of medicines, the hydrocyanic acid, as that of transient excitement, followed by an immediate state of collapse; but the result of our own experiments on living animals is adverse to this supposition: the instantaneous diminution of the general powers of the system, the prostration of strength, the stupor, numbness, sleepiness, vertigo, and depression of the animal spirits, all indicate an immediate influence on the nervous energy. With these observations in view, and with the experiments of Mr. Brodie on some poisonous substances before us, we may venture to assert that it is upon the nerves of sensation chiefly that *direct* sedatives operate.

When sedatives are taken into the stomach, if they do not destroy life, their influence is much weakened after a certain time has elapsed, and soon afterwards it altogether ceases. It may, however, be maintained in the same manner as that of narcotics, by the repetition of the dose at moderate intervals; but the impression becomes weaker after each renewal of it, until it is almost lost, unless the dose be greatly augmented. If these statements be correct, it is evident that sedatives operate directly on the nerves of sensation, and that this effect is not the result of a stimulus rapidly exhausting the excitability of the nerves, but of a direct impression of a peculiar kind on the nervous system, which instantaneously destroys the susceptibility of the nerves for receiving impressions from external stimulants.

Owing to the ideas which we acquire in early life, the effects of excitants are connected with mechanical impressions, and, therefore, the mind has less difficulty in admitting the hypothesis that every instance of collapse must be preceded by a previous state of excitement, than that something is either abstracted from the nerves, or that some alteration takes place in these organs, which diminishes their faculty of receiving impressions. It is true that no organic change can be detected in the nerves of animals killed by sedative poisons, and we are equally unable to affirm from inspection that any thing has been abstracted from them, yet that some change has occurred is undoubted, as they are no longer susceptible of being excited.

Whether we can assume that the sedative effect is immediate, not secondary, is questionable; but we imply its direct character from the local effect of powerful sedatives where they are applied in small quantity to a limited portion of the surface of the body; as, for example, if the finger be held over the mouth of a bottle of hydrocyanic acid, it is numbed, and it continues so for a considerable time without any extension of this effect to the rest of the body. When the quantity is larger, their influence ceases to be partial, and is extended over the system; and when it is very large, the same rapid destruction of life follows as when the sedative is taken into the stomach. Sedatives consequently differ from many of the other classes of medicines, in their effects being more regulated by the extent of the dose than by the state of the body. Upon the whole we conceive that there are sufficient reasons for separating sedatives from narcotics, and allotting to each a distinct place in the arrangement of the materia medica.

Let us examine their influence, as physiological agents, on the different organs of the living system.

1. *On the digestive organs.*—No sensation in the stomach is experienced when a sedative is taken into it, except occasionally that of nausea: the influence of the sedative is rendered obvious rather by the change which follows in the state of the digestive function than by any thing which can be referred to the condition of the organ itself. If the viscus be morbidly irritable, the influence of the sedative is acknowledged by the diminished suscepti-

* Introduction to Medical Literature.
† First Principles of Medicine, p. 44.

bility of the gastric nerves, by the improvement of digestion from the lessened irritability favouring the formation of a more healthy, because more slowly secreted, gastric juice.

In this respect, when the dose is moderate, the direct influence of the sedative is local and confined to a certain set of nerves, although the general system ultimately benefits by the change thus effected,—a fact daily illustrated in the administration of hydrocyanic acid in dyspepsia; whereas the influence of narcotics is invariably propagated over the system, even when they are administered in small doses.

If the dose of the sedative, however, be increased, the impression then extends to the brain, and is manifested by slight vertigo, transient insensibility, sinking of the pulse, failure of the muscular energy, particularly in the thighs, general lassitude, and mental depression. If the dose be larger, but within the limit of a poison, it must be admitted that sensations, for example weight and an obtuse pain in the forehead, are superadded, which seem to indicate previous excitement; but that this has not existed is highly probable, since we know that coma may proceed from inanition as well as from increased action in the brain, and that stimulants are frequently requisite to relieve symptoms closely resembling those requiring venesection and depleting remedies. Taken into the stomach, therefore, sedatives operate directly upon the nerves of that organ, and, within a certain limit with respect to dose, the effect which follows is strictly local.

2. *On the circulating and respiratory organs.*—When the influence of a sedative extends to the general system, the action of the heart and arteries is diminished, but not in the ratio of the impression on the nervous system. Schubarth asserts that the heart loses its contractility, but the experiments of Coullen,* with which those of the author accord, lead to an opposite opinion. In poisoning by hydrocyanic acid, the heart continues to pulsate, and the intestines continue to display their peristaltic and vermicular movements after the death of the animal, and they do not lose their contractility for some time; at least such is the case when hydrocyanic acid is taken, and it is probable that the same occurs when other sedatives are employed. As far as relates to the lungs, if sedatives be applied directly to them either in the form of gas or of vapour, the effect is both more rapid and more decisive than when they are swallowed; the respiratory function is almost instantaneously suspended; no change takes place in the blood, which retains its venous character, and, on examining the organs, nothing is perceived which can authorize the idea of excitement having existed: death, in fact, is the result of the complete destruction of muscular irritability. When taken into the stomach, the action of sedatives on the lungs is greatly modified; the blood, however, remains dark-coloured and retains its fluidity.

* Researches, &c. p. 146.

3. *On the nervous system.*—It is unnecessary to repeat that the nerves are the organs on which the influence of sedatives is chiefly and directly exerted; but little is known with regard to the nature of the impression, except that it is different from that of any exciting agent; and after the most minute inspections of the brain, the spinal cord, and the nerves, in cases of death from poisoning by sedatives, no other conclusion has been arrived at. Whatever may be the impression, it is assuredly not that which is followed by excitement.

4. *On the secerning system.*—Sedatives produce effects which, to an ordinary observer, might seem almost at variance with the foregoing opinions: thus, salivation has occasionally followed the employment of hydrocyanic acid;* and the secretion of urine is not unfrequently greatly augmented by whatever produces a sedative effect on the system. But such results do not necessarily imply previous increased vascular action in the salivary glands and the kidneys: thus we know that in the lowest condition of the nervous excitability in fatuity, salivation is one of the most ordinary attendants, and under the influence of fear and other depressing passions, nothing is more common than a sudden and copious secretion of urine. Upon the whole, we have sufficient reason for concluding that there are powers which can destroy excitability and life without causing previous excitement, or, at least, without any signs of its being discoverable. This is not the result of the administration of narcotics, and therefore we feel authorized in forming a distinct class of sedatives.

In treating of sedatives employed as therapeutical agents, we may arrange them under two heads; 1. *direct*, or those which operate by their immediate influence on the nervous system; and, 2. *indirect*, those which operate through the medium of the vascular system.

1. The first and most powerful of the direct sedatives is *hydrocyanic acid*.† This acid, as prepared for medicinal use, is one-sixth only of the strength of the concentrated acid, but it differs from it in no other particular. It is colourless, limpid, and has a penetrating odour, which causes headach, nausea, and fainting, when inhaled in considerable quantity by the nostrils. This odour has been erroneously compared to that of the peach blossom,—an error originating from the odour of the volatile oil, which is, in some instances, as in the peach kernels, blossom, and leaves, and in the bitter almond, mingled with this acid. The odour of the free acid, when well examined, cannot be confounded with that of the peach blossom.‡

* Lond. Med. Journ. Feb. 1823, p. 128.

† This name is a compound of *ὑδῶρ*, water, and *cyanogen*, (a compound substance, named from *κύανος*, *blue*, and *γίνναω*, *to produce*,) signifying a producer of blue, as it gives the blue colour to the ferrocyanate of peroxide of iron, or Prussian blue.

‡ The plan of this work forbids any detailed account of the various methods proposed by Vauquelin, Gay Lussac, Robiquet, Pessinau, Frantwain, and others, for preparing the medicinal hydrocyanic acid; but it may be useful to describe the following

The pure acid is extremely volatile, and even the diluted or medicinal acid is so much so as to be greatly weakened when not carefully preserved. It is also spontaneously decomposed when it is not kept in a cool place: the best method of preventing this decomposition is to place the bottles containing it in water, or in porous jars saturated with moisture. In prescribing hydrocyanic acid, it is essential to know that it is decomposed by the aqueous solutions of chlorine and the oxides of antimony, and is precipitated by nitrate of silver and sulphate of copper. These substances are, therefore, incompatible in prescriptions with hydrocyanic acid, but it may be combined with the salts of iron if no alkali be present. This acid is the active principle of laurel water, the distilled water of the leaves of the prunus *lauro-cerasus*; cherry water, distilled from the bark of the cluster cherry, prunus *padus*; the kirch-wasser of the Germans, which is a spirit distilled from the fruit of the same species of prunus; and the oil of bitter almonds, now occasionally employed as a medicine, and very generally in confectionary.* But along with the acid in these and similar preparations, there is a volatile oil, the odour of which, as we have already stated, is very distinct from that of the hydrocyanic acid, is stimulant, and possesses poisonous properties nearly equal to those of the acid.† It is, however, not a direct sedative, but resembles a narcotic in its operation: thence the effects of the oil of bitter almonds and laurel-water differ considerably from those of free hydrocyanic acid.

Concentrated hydrocyanic acid cannot be employed as a medicine.* The same circumstance, the powerful influence of this acid on the nerves of sensation, which renders it so awfully formidable when it is taken in doses sufficient to produce its poisonous effects, renders it in the hands of the prudent and well-informed practitioner, when its dose is judiciously regulated, its administration properly timed, and its effects are carefully watched, a remedy possessed of powers which cannot be obtained from any other substance, and it is, therefore, extensively employed.

The use of hydrocyanic acid is indicated in diseases connected with a state of excessive or morbid sensibility, and those depending on a highly irritable state of the nervous system. This general statement is not solely influenced by the opinion which we maintain of its direct sedative power, and were the assertion that it produces at first a transient excitement capable of demonstration, it would not affect in any degree the administration of the acid; for as this excitement is said to be of a very transitory nature, it need not be taken into account in estimating the sedative powers of the remedy. In idiopathic fever hydrocyanic acid has been rarely if ever employed; it has, however, been supposed to act beneficially in hectic, moderating the force of the circulation and suspending the night-sweats which always accompany this symptomatic fever;† but, in reference to phthisis, the eulogy bestowed by some practitioners on this acid has not been merited. Neither, with the exception, perhaps, of phrenitis, is it calculated for the relief of the diseases classed by nosologists under the title Phlegmasiæ: even in phrenitis we have had no experience of its utility, but knowing that the inflammation of the membranes of the brain morbidly augments the general sensibility, as illustrated by the impatience of light and of sound, we are disposed to recommend its employment as an adjuvant to other remedies in this state of the brain. In pleurisy it has

processes, by which any practitioner can readily prepare it for himself.

1. Put into a wide-mouthed phial a solution of one part of bicyanide of mercury, dissolved in eight parts of distilled water, and pass through it a stream of sulphuretted hydrogen gas, extricated in another phial from a mixture of equal weights of sulphuret of iron and strong sulphuric acid, diluted with two parts of water. The gas must be passed as long as any sulphuret of mercury in the form of black powder is formed; the fluids then filtered, and any excess of sulphuretted hydrogen removed by agitating the solution with a little carbonate of lead, and filtering a second time.

2. Put into a phial twenty-two grains of cyanuret of potassium, and pour over it a solution of fifty grains of pure tartaric acid in six fluid drachms of distilled water, and eight of rectified spirit. After agitating the phial occasionally, secure the stopper, and set it aside until the precipitate falls to the bottom: then decant the clear acid. The acid thus formed should contain one grain of hydrocyanic acid in every fluid drachm, which is easily ascertained by adding in small quantities to a given portion of it peroxide of mercury finely levigated, as long as agitation enables the acid to take it up. By dividing the weight of the peroxide dissolved by four, the quotient expresses the quantity of real acid contained in the diluted acid. No heat should be employed.

* Hydrocyanic acid is found in the leaves and kernels of almost all the plants of the natural order Amygdaleæ, and in the pips of some of the Pomaceæ and Aurantiaceæ; it is formed when copaiba is distilled with diluted nitric acid.

† When the volatile oil of bitter almonds is redistilled, the first portion which comes over smells strongly of hydrocyanic acid, and affords indications of its presence when tested; but it smells very faintly of the peach-blossom: the second portion exhales a more powerful odour of the peach-blossom than the first, but less of that of the hydrocyanic acid. The first portion operates as a powerful direct sedative in the same manner as free hydrocyanic acid; the second, besides operating primarily as an excitant, produces violent convulsions when it poisons. What remains in the retort, if the distillation have been carried far enough, crystallizes on exposure to the air, and absorbing oxygen, acquires all the properties of an acid; this is completely inert on the living system. Vogel has suggested that these changes depend on the process, and he supports his opinion by the fact that a quantity of bitter almonds, which, if made into an emulsion, may be swallowed with impunity, when distilled would yield a product more than sufficient to destroy the life of one individual.

* For an account of its poisonous influence on the animal system, as well as that of the diluted acid, the oil of bitter almonds, and laurel-water, with the modes of detecting these poisons and of counteracting their effects, we must refer our readers to the article TOXICOLOGY.

† Historical and Practical Treatise on the Internal Use of the Hydrocyanic Acid, &c. By A. B. Granville, M.D. &c. p. 59. 1820.

been found beneficial in moderating the cough, one source of exasperation of the inflammation of the serous membrane; but beyond this it has no pretensions to be regarded as a remedy in this disease.

In the exanthemata, except as an external application, hydrocyanic acid holds forth no prospect of benefit. In the state in which it is found in the bitter almond, it was employed as an external sedative so early as the time of Celsus in several external diseases; his formula in a painful pustular disease, which he describes as peculiar to infants, is the following: "lapidis, quem pyriten vocant, partes octo, cum quinquaginta amaris nucibus miscetur, adjiciunturque olei cyathi tres."* But even as an external application, the volatile oil of bitter almonds requires to be used with much caution, and Coullen has recorded the case of a child killed by the leaves of the prunus *lauro-cerasus*, applied to a sore on the neck.† The free acid has been recommended by the author of this article in the proportion of ℥iii to ℥vi of bitter almond emulsion, as a lotion in impetigo or running tetter. In such cases also, when the irritability is very considerable, it may be combined with the acetate of lead according to the following formula:

R. Acid. hydrocyan. ℥iv.
Acet. plumbi, *gr.* xvi.
Alcoholis, ℥i.
Aquæ distillatæ, ℥viiiss. M.

This lotion not only soothes the irritability of the diseased surface, but also disposes the skin to renew its healthy action, and is productive of the greatest comfort to the patient: it has been found very useful in prurigo *inveterata*, in the various forms of psoriasis, and several other skin diseases attended with itching and tingling.

In passive hemorrhages no advantage can be expected from hydrocyanic acid; but in active forms of the disorder, much confidence may be placed on the internal use of it. In hemoptysis, by rapidly augmenting the dose from three minims (the medium dose) to twelve minims, or until the pulse begin to afford indications of the deleterious influence of the medicine, we have seen the most happy results in the absence of any organic affection. In phthisis, as we have said, the powers of hydrocyanic acid have been much overrated; nevertheless as a palliative it is not without its value. In small doses frequently repeated, it diminishes the hardness and frequency of the cough, and lessens the general hectic tendency; but more is not to be expected from it in this respect than from some of the narcotics. It has, however, one advantage over narcotics, namely, that, besides moderating the cough, it frequently favours sleep without exciting those sweats which are too often augmented when opium is employed. At the same time, as its tendency is to lower the powers of the system, it is in the early stages only of this disease that it can be regarded as likely to prove beneficial even as a palliative. Its employment in phthisis, in the combined state in which it is found in laurel-water, is, indeed, of no recent date, most of the old works on consumption enumerating laurel-water amongst the means to be employed for soothing the cough. From some experiments made by M. Jorg, at Leipsig, we might infer that it would prove injurious in the early stage of the disease, as well as in every inflammatory affection. This physician exhibited the cherry laurel-water in doses progressively increased from five to twenty-five, and finally to one hundred and twelve minims. He states that the symptoms were those of concentrated action of the brain, a sensation of weight in the head, drowsiness and torpor of the intellectual functions, lassitude, retardation of the pulse, and headach, preceded by a dull pungent pain of the head, chiefly in the region of the optic nerve. It also was attended with symptoms not unlike those of bronchitis. M. Jorg refers these symptoms to plethora of the cerebral vessels, but they may depend on paralysis of the brain itself. These observations are at variance with our own experience. We have found the laurel-water and also free hydrocyanic acid almost specific in that affection of the trachea which has been termed phthisis trachealis, and which is often as fatal as tubercular phthisis. The natural combination of hydrocyanic acid in the bitter almond emulsion is also an excellent vehicle for the administration of the compound powder of ipecacuanha in the above-mentioned diseases.

In affections of the mucous membrane, hydrocyanic acid is a much less equivocal remedy than in the diseases already mentioned. In chronic catarrh, and under certain circumstances in dysentery, sufficient proofs of its efficacy have been recorded. In the latter disease, when given at the same time with full doses of calomel, to the extent of four or five minims for a dose, in the bitter almond emulsion, and repeated at short intervals, it allays irritation and improves the secretions and excretions of the intestinal canal. On the same principle its power of allaying irritability, and thereby favouring a slower and consequently more healthy secretion of the gastric juice, the author of this article was induced to recommend its employment as a sedative in dyspepsia.* Dr. Elliotson prosecuted this suggestion, and laid the results of a very extended trial of its powers in St. Thomas's Hospital before the profession.† In dyspeptic affections it may be combined with the decoction of Iceland liverwort, infusion of calumba, or the extract of sarsaparilla; or it may be administered in water, from three to five minims for a dose, with the addition of ℥i. of tincture of calumba or of any simple bitter. In pyrosis it affords relief on the same principle, by allaying the morbid irritability of the stomach.

It is in spasmodic affections, however, as

* See Granville's Historical and Practical Treatise on the Internal Use of the Hydrocyanic Acid. First Edition, 1819.

† Numerous Cases illustrative of the Efficacy of Hydrocyanic or Prussic Acid in Affections of the Stomach, &c. 8vo. 1820.

may be readily conceived, that the sedative powers of the hydrocyanic acid are most conspicuous. In spasmodic asthma, even when the pulse is small, irregular, and often not easily distinguished, we have seen it act almost instantaneously, relieving the oppressed state of the pulmonary circulation, and restoring the free action of the respiratory organ. In hooping-cough, also, this acid displays the most striking influence when early resorted to and judiciously administered. After emptying the stomach with an emetic, and purging briskly, it may be immediately administered three or four times a day, in doses of one or two minims, according to the age of the patient, in ℥iß of the bitter almond emulsion, sweetened with a few drops of syrup of tolu. It is seldom necessary to change the prescription, except to increase the dose of the acid, until the cough ceases, which generally occurs in less than a month or six weeks after commencing the use of the remedy. It is requisite to confine the patients to a graduated temperature, and to restrict them to a milk and vegetable diet. In epilepsy, chorea, hysteria, and tetanus, the results of the trials of hydrocyanic acid have been of a description which do not admit of any decisive opinion of its value in these diseases. In hydrophobia it has been tried both in this country and on the continent; in a few instances it appeared to allay the violence of the paroxysms;* but, as may be supposed, the effect was transitory, and in no instance has it warded off the fatal termination of the attack.

The essential oil of bitter almonds has been proposed as a substitute for hydrocyanic acid, on the plea that the strength of the medicine can be more certainly determined, and that it is less likely to suffer decomposition than the free acid from the influence of air, light, and variations of temperature. Twelve minims of the volatile oil of bitter almonds, dissolved in a fluid drachm of olive oil, and formed into an emulsion with mucilage, are regarded as equivalent to four minims of the ordinary medicinal hydrocyanic acid. An objection, however, to the use of this oil is the excitant property of the volatile oil with which the hydrocyanic acid that it contains, is mixed; it also produces an uncomfortable effect on individuals of a peculiar idiosyncrasy. Some people cannot eat even a single bitter almond without suffering severely from nettle rash, attended with vomiting and vertigo; a circumstance, as we have already stated, depending on something in the kernels independent of the hydrocyanic acid, which is further demonstrated by the fact that the sweet almond sometimes causes the same inconvenience, although no hydrocyanic acid has been detected in it.

A more useful substitute for the hydrocyanic acid than the volatile oil of the bitter almond, is the *cyanide of potassium*, which, although it does not hold a place in any of the British pharmacopœias, yet possesses sedative properties equal to those of the free hydrocyanic acid. In solution it is a hydrocyanate; but in this change it loses none of its sedative properties. One part of the cyanide and eight parts of water form a solution which may be administered in the same doses as the hydrocyanic acid; and in this state it has been successfully employed in neuralgic affections by Dr. Buttigny and Dr. Lombard of Geneva. They have also used in the same disease an ointment compounded of five grains of the cyanide and one ounce of lard. The cyanide has also proved useful in rheumatism.*

In closing our account of this powerful sedative, candour obliges us to notice some experiments and facts which have been published on the opposite side of the question, with regard to the mode in which its influence on the nervous system is effected. The author of this article supports the opinion that it operates directly on the nervous system, whilst Majendie, Orfila, and others contend that it is previously absorbed. The only experiments we shall notice are those of Dr. Krimer of Aix-la-Chapelle, who found that when it is applied directly to the neurilema of the nerves, or to the surface of the brain and spinal cord, it displays no activity. He also supposes that he has ascertained that it does not kill, even when applied to the tongue, until it is evaporated by the heat of the mouth, and is absorbed into the pulmonary circulation; destroying life first by diminishing the action of the heart and arteries, and then by extinguishing the energy of the spinal cord. Dr. Krimer found that when the arteries and veins of a part are tied and the nerves left free, if the acid be applied to a wound it produces no effect; but the instant the ligatures are removed, it displays its power: on the other hand, also, death occurs when the nerves are divided if it be introduced into the vessels. When all the vessels of the stomach, says Dr. Krimer, are tied, although the nerves remain entire, hydrocyanic acid when introduced into the stomach does not produce its usual effect; but it operates immediately when placed on the tongue, and in thirty-six minutes it can be detected in the blood by reagents: such is the case, also, when it is inhaled, without the vapour coming in contact with the nerves of the tongue.

Notwithstanding the apparent conclusiveness of these experiments, we cannot accord with the inferences deduced from them. For instance, we cannot conceive how the acid can be taken into the pulmonary circulation, and yet not act on the nerves in its vicinity; and an assumption is made respecting pulmonary absorption, which requires to be proved. On these accounts, and from having witnessed the instantaneous effects of this acid when taken in large doses, we see no reasons sufficient to alter our formerly expressed opinion regarding its mode of action.

* See Transactions of the Medico-Chirurgical Society of London, vol. xiii. p. 298.

* A method of obtaining this cyanide in a state of great purity has been lately discovered by Mr. R. Lamins.

Tobacco is another sedative of great power. The experiments of Mr. Brodie have rendered it probable that there are two efficient principles in tobacco; one, an *empyreumatic volatile oil*, which operates directly on the brain and the nerves of sensation, or on the sensibility of the system; the other a saline substance, *(nicotina,)* which appears to influence chiefly the motor nerves, confining its sphere of action particularly to the heart, which it renders insensible to its natural stimulus, the blood, and thereby causing death. In whatever manner this volatile oil is procured, its effects are so powerful on the animal economy, that, when it is applied to an abraded surface, or introduced into the rectum, it causes almost instant death.* When tobacco is infused in boiling water, this volatile oil is partially taken up by the liquid, and produces the sedative effects which always more or less result from the exhibition of tobacco enemata; but the greater part of the influence of the tobacco clyster is due to the nicotina, which, in the tobacco, is probably combined with some acid that increases its solubility. The sedative influence of nicotina is such that the action of the heart ceases even before that of the diaphragm,—an effect directly the opposite of that which occurs from the administration of hydrocyanic acid. The influence of both the components of tobacco is evidently directly sedative, without even the most transient stimulant effect, whether the infusion be introduced into the stomach or into the rectum.

It is remarkable, with the knowledge which the profession possess of the sedative influence of the tobacco clyster, that it should ever have been employed in cases of suspended animation: it is indicated and has been successfully used in cases of incarcerated hernia. If one drachm of the dried plant infused in a pint of of boiling water and strained, be thrown into the rectum, great muscular debility, partial insensibility, and sometimes cold clammy sweats almost immediately supervene; relaxation of the spasm follows, during which the gut is replaced. But occasionally the aid thus afforded to the taxis is not unattended with hazard; and in certain states of the system of some individuals which are not obvious, but greatly influence the action of the remedy, it is evident that it must not be inconsiderately resorted to, nor indeed at all whilst the least chance of any other means proving useful remains.† When it does not succeed, and the operation must be performed, the patients do not recover so well as those who have not been subjected to its use. The sedative influence of tobacco has also been taken advantage of, in smoking the plant for the relief of spasmodic asthma, violent tooth-ach, and some painful affections of the face.

The *hydrosulphuret of ammonia*, although less frequently employed than either hydrocyanic acid or tobacco, is a most powerful sedative, depressing the action of the heart and arteries by operating directly on the nervous system. In very moderate doses, namely five minims in a tumbler of water, it causes nausea and vomiting; and, when the dose is increased, drowsiness and vertigo supervene. It was employed and strongly recommended by Mr. Cruickshanks in diabetes mellitus, for destroying the ravenous appetite and morbid action of the digestive organs which always accompany that disease; but it has been very little used.

Two gaseous compounds of hydrogen, *sulphuretted hydrogen* and *carburetted hydrogen gas*, exert a powerful sedative influence on the animal economy, which proves rapidly fatal to animal life, if breathed, even when largely diluted with air. The former is noticed here rather with the view of alluding to the share which it has in causing the depression that always occurs in those febrile affections in which it is extricated largely in the intestinal canal, than to refer to its therapeutical properties, although its employment in phthisis has been suggested. There is undoubtedly a copious evolution of it in all low fevers, and its direct sedative influence on the intestinal nerves is the chief cause of the collapse which attends these diseases; to obviate this is, therefore, of much consequence, and the influence of chlorine in decomposing this gas by forming muriatic acid in combining with the hydrogen whilst the sulphur is deposited, points out an easy and effectual method of doing so. Either the aqueous solution of chlorine, or of the chloride of soda, should be administered in these cases. The presence of the gas is detected by the extremely offensive odour of the faeces; and still more decidedly by holding slips of paper covered with carbonate of lead over the vessels containing them. If sulphuretted hydrogen be exhaled, the carbonate will be immediately blackened.

The second of the above-mentioned gases, *carburetted hydrogen*, has been employed for medicinal purposes, as a sedative, in phthisis; but its use requires much caution, as, even when diluted with twenty or thirty times its bulk of common air, it cannot be respired for more than a minute or two without causing nausea, dizziness, and other symptoms of dangerous nervous depression. Although so destructive to animal life that it cannot be taken into the lungs undiluted without producing instantaneous death, yet to no gas does the system become so soon habituated; consequently the degree of dilution which is at first requisite, may be gradually reduced with impunity. The trials, however, which have been made of it as a remedy in phthisis are as yet

* This oil is gradually deposited in the wooden stems of the pipes of the Hottentots, who employ it for destroying serpents. Mr. Barrow mentions having witnessed its effects when applied to the tongue of a poisonous snake; the reptile stretched itself out, became stiff, and died in an instant.

† When the tobacco clyster produces deleterious effects, they should be immediately obviated by throwing into the rectum a strong infusion of nut-galls, or any other substance containing a large proportion of tannin and gallic acid, so as to combine with the nicotina, and by destroying its solubility, to render it inert. Brandy, ammonia, and other stimulants, should also be administered by the mouth, and artificial respiration maintained for some time, or until the sedative influence of the medicine begins to disappear.

far from sufficient to determine accurately its influence in that disease.

2. The *indirect* sedatives operate on the nervous system through the medium of the blood, either by altering the properties of that fluid so as to unfit it for affording the requisite stimulus to the brain and nervous centre, or by abstracting it in quantity sufficient to bring the brain into a similar state from defect of stimulus, or, as it were, from inanition.

The first of the sedative agents belonging to this division of the class which requires to be noticed, is *carbonic acid gas*. The influence of this gas in causing suffocation when it is attempted to be breathed undiluted, as it never enters the lungs, but causes a constriction of the muscles of the glottis, so that no air can enter the lungs, and no change take place in the blood passing through them, is supposed to be negative; thence the question, whether this gas is positively or negatively sedative? But although this gas is never admitted into the lungs in attempts to respire it, and therefore may be regarded as negatively sedative, yet there are facts which demonstrate its positive sedative properties. Thus, if the body of an animal be immersed in an atmosphere of carbonic acid gas, whilst atmospherical air is freely admitted to the lungs, sedative symptoms occur, such as weight in the head, dimness of sight, singing in the ears, vertigo, &c.; and that it even exerts a local influence on the nerves was demonstrated by an experiment of Dr. Priestley, who, having excited pain in a blistered hand by immersing it in oxygen, relieved the pain instantly by plunging the hand into a jar of carbonic acid gas. It is also a well known fact that the pain of a cancerous ulcer is allayed by directing upon it a stream of carbonic acid gas which has passed through water; and it is to the presence of this gas in the carrot and other fermenting poultices, that they are indebted for their sedative properties. On these accounts, although we have arranged carbonic acid gas among the *indirect* sedatives, yet it in some measure belongs also to the former division of *direct* sedatives.

Carbonic acid gas was at one time much employed as a sedative in phthisis: Dr. Percival introduced it as an antiseptic, and from the result of thirty cases concluded that it abates the hectic and improves the expectoration;* and Dr. Withering, who also looked upon it merely as an antiseptic, found that similar effects resulted from its administration. Favourable opinions of it were given by Dr. Dobson,† Dr. Hulme, Dr. Beddoes, and Dr. Fenwick of Durham: on the contrary, the experiments of Dr. Mnehry,‡ who gave it a fair trial in five cases without material benefit, and our own experience, have led us to place little confidence in it, even as a sedative. When it is employed, it should be largely diluted with common air; the best proportions are four parts of the air to one part of the gas.

The only other indirect sedative which requires to be noticed is *bloodletting*. It is scarcely necessary to remark that a certain quantity of the circulating fluid is required to be present in the bloodvessels, in order to support the energy of the brain and nervous centres; and, therefore, that when this proportion is diminished, the result is a sedative effect on the system. In man the average quantity of blood in proportion to the weight of the body, in a healthy adult subject, is as *one* to *five*; when a greater relative proportion exists, a diseased state of the body, plethora, takes place; when a smaller, the body becomes emaciated. If blood be suddenly abstracted from the vessels, a series of phenomena occur which demonstrate a diminished state of vitality; and if the quantity taken away be greater than a certain proportion of the whole, then death almost immediately ensues. But these effects do not depend altogether upon the quantity of blood contained in the vessels or abstracted from them, but partly upon other circumstances, which ought always to be kept in view when bloodletting is intended to operate as a sedative.

If these phenomena depend on the state of the vascular system in health, it is evident that a powerful effect must result, in disease, from the abstraction of blood, whether this be effected by opening a vein, by cupping, or by leeches. The immediate depression of the vital powers which follows this abstraction must have been early rendered obvious, from the effects of hemorrhages arising from the accidental rupture of vessels; and thence artificial means were adopted to diminish excitement by opening a vein. The syncope which succeeds is much regulated by the habit of the patient, the nature of the disease, and the manner in which the blood is abstracted; but as a particular inquiry into the morbid effects of bloodletting and the methods of obviating these are given in detail in other parts of this work, we think it unnecessary to enter into minute details, referring the reader to the articles BLOODLETTING, FEVER, INFLAMMATION, and PLETHORA.

(A. T. Thomson.)

SEX, DOUBTFUL.—Among the freaks of nature, there is none which has given rise to more erroneous ideas or more barbarous practices than those varieties in the formation of the organs of generation, which have given origin to the term *hermaphrodite*. This word, derived from Ερμης, Mercury, and Αφροδιτη, Venus, conveys the notion of an individual partaking of both sexes, and capable of both begetting and conceiving. The ancients believed in the possibility of such a combination in the human body; and enactments existed, both in Greece and Rome, ordering the destruction of infants born with confusion of the sexual organs. At Athens all the unfortunate beings considered to be hermaphrodites were thrown into the sea, and at Rome into the Tiber. In modern times it is admitted that

* Percival's Essays, vol. ii. p. 308.

† Medical Commentary on fixed Air. London, 1779.

‡ Inaugural Dissert. Gott. 1797.

no such phenomenon ever existed in the human species as a perfect hermaphrodite; although there are numerous instances of preternatural structure which gives the appearance of a double sex. In the lower orders of organized bodies hermaphrodism is common; thus in vegetables it is so prevalent as to have led some to suppose it to be an attribute of the order; and the more nearly the other classes of beings approach the vegetable, the more common is this combination of sex among them. Of this zoophytes, mollusca, acephali, and gasteropodes are examples. In these animals two kinds of hermophradism exist: in some it is absolute, that is, the animal is capable of impregnating itself, as in some of the bivalves, as oysters and muscles; but in others, as the univalves, this power is not possessed, but a union of two individuals is necessary, both, however, becoming impregnated at the same time.

We look in vain for any such admixture in the higher orders of animals, though some extraordinary approaches towards it are recorded. According to Sir E. Home* and J. Hunter † such combination is most frequently met with in neat cattle, the individuals so circumstanced being known by the name of free martins. In these, however, the testes and ovaria are always too imperfect to perform their functions. Instances are not wanting in the human species, in which, either from malformation of the genital organs in one or other of the sexes, or from a real attempt at mixture of the two in the same individual, considerable difficulty arises in deciding on the proper sex. This is the point to which the present article is more particularly directed, and it should be recollected that it is one of material importance; for upon the opinion pronounced by medical examiners may depend the employment in life of an individual, the right of inheritance to property, and the judicial decisions concerning impotence and sterility.

Sir E. Home‡ considers that all the monstrous productions hitherto noticed and described as hermaphrodites may be reduced to one of the four following classes:—1. malformations of the male; 2. malformations of the female; 3. males with such a deficiency in their organs that they have not the character and general properties of the male, and may be called neuters; 4. where there exists a real mixture of the organs of both sexes, although not sufficiently complete to constitute the double organ.

1. *Malformation of the urinary and generative organs of the male.*—Cases of this class usually depend upon imperfection of the scrotum and urethra; there is no deficiency of the natural parts, nor addition of foreign parts, but the confusion of sex arises from the scrotum being split along the middle line, each half containing a testicle, and resembling one of the labia majora of the female. The deep slit between these parallel folds of skin very much resembles the vulva, and the similarity is heightened by the circumstance of the urethra being usually split likewise in these cases, and opening in the perineum, which, having a red and tender appearance, is easily mistaken for the vagina. In consequence of the urethra terminating at the perineum, the penis is imperforate; and thus, if it be of small size, it may be supposed to be the clitoris. It is this malformation of the male organs which more than any other has given origin to mistakes respecting the mixture of the sexes. The case of the negro described by Cheselden* was of this kind. In him the scrotum was divided into two separate bags, with a deep slit between them, representing the labia majora and commencement of the vagina. Over these hung down the penis; the imperfection of the scrotum extended to the canal of the urethra,—a circumstance appropriately compared to the fissure of the hare-lip being continued through the bony palate. The penis was united by its under surface, through its whole length, to the folds of skin containing the testicles, resembling an enlarged clitoris, to which resemblance the absence of the urethra contributed. The urethra opened with a large aperture in the perineum, between the divisions of the scrotum, and from its size was mistaken for a vagina. Cheselden describes another case similar to the preceding, which he met with in the person of an European.

Persons afflicted with such malformation as we have described have not only been taken for females, but have been married as such. Adélaide Preville was married, and lived the last ten years of her life in Paris, and died in the Hôtel Dieu of that city. Giraud discovered by examination of the body after death that it was of the masculine sex, and except a false vagina, which consisted in a cul-de-sac placed between the rectum and bladder, this individual presented no resemblance to a female.† There is a very remarkable case related by Marc,‡ in which an individual, after having passed for a female for many years, was at length discovered to belong to the male sex, and was restored by public ordinance to his proper station. On the 19th of January, 1792, the curé of the parish of Ber certified the birth of a girl, and gave her the name of Marie Marguerite. This child arrived at the age of 14 without having particularly attracted the attention of the parents. It shared the bed of a younger sister, and grew up among other young persons with whom it was associated by education, exercise, and childish amusements. At this time Marie complained of pain in the right groin, where a tumour soon manifested itself. The village surgeon took it for a hernia, and applied a truss. This instrument gave too much pain to be borne, and was soon laid aside. The tumour descended, and the pains ceased. Some months afterwards the left groin was affected in a similar manner, and on the

* Phil. Trans. 1799.

† Recueil périod. de la Soc. de Méd. Paris.
‡ Dict. des Sciences Méd. t. xxi. p. 91 et Jour. de Méd. Chirurg. et Pharm. Paris, Feb. 1806.

supposition of the tumour in it being also a hernia, a double truss was put on, which was as speedily thrown off as the former. At 16 years of age an offer of marriage was made, but refused by the parents as an unsuitable match for their daughter. Three years afterwards another proposal was made and broken off, after having been accepted of. Nevertheless, as Marie advanced in age, the graces of her person began to disappear; her clothes did not fit as well as before; her air and carriage had something extraordinary; from day to day her tastes changed, and became more masculine; indoor occupations seemed to interest her less, and she preferred field-work to her former duties. These masculine dispositions, and the report of the surgeon that Marie had been hurt in such a manner as to prevent her ever marrying, did not prevent a third lover from aspiring to her hand. This match was much desired by the friends on both sides, but the parents of Marie, knowing that she was not formed as other women, and recollecting that she had never menstruated, did not wish to deceive the son of an old friend, and determined on having a medical examination of their daughter. Worbe was requested to perform this office. The surprise of all was great indeed when he declared Marie to be a man. She (or he) shed tears at the announcement, and was for some months before she could be reconciled to the idea of not being a woman. At last he took the resolution of petitioning the authorities to alter the registry, and declare him of the male sex. A commission was accordingly appointed, consisting of three medical men, to inquire into the circumstances of the case, who reported that on examination they found the scrotum divided through its whole extent, each division containing a rounded body, which they recognized as true testicles. Between these parts a fleshy prolongation was observed, having a cleft at its extremity, but imperforate, covered by a process of skin, which was in reality the prepuce. The penis was but little developed; and beneath it, at about an inch and a half from the margin of the anus, an opening was discovered, caused by the abrupt termination of the urethra in the perineum. As to the rest of the body they found nothing remarkable, except a considerable developement of the breasts, resulting, as they imagined, from the form of clothing usually worn. They therefore gave it as their opinion that Marie belonged to the male sex; and the authorities declared it to be so, and ordered that the registry of birth and baptism should be altered. Dr. Worbe states that in 1816 this individual was 23 years of age, hair and eyebrows auburn, a light beard appearing on the upper lip and chin, the sound of the voice masculine, height four feet eleven inches French measure, skin very white, constitution robust, and the limbs round but muscular. The form of the pelvis did not differ from that of a male, the knees were not inclined inwards, and the hands and feet were large and strong. A year had not elapsed from the time of his metamorphosis when he was considered as one of the best farmers in the canton. On being questioned with respect to what he felt when sleeping with females, whether he had not desires different from those of others, and if curiosity had not prompted him to discover what opportunity permitted him so easily to observe, he answered, blushing, "quelquefois, mais je n'osais pas."

Dr. Schweikard* has published the history of an individual who up to the age of manhood was esteemed to belong to the female sex. He had been baptized as a girl, and regarded as such, until to the astonishment of all he demanded permission to marry a girl then pregnant by him. He submitted to an examination, when it was found that the penis was situated lower than ordinary, not quite two inches long, and a little less bulky than usual. The imperforate glans offered a slight curve towards the lower part; the inferior surface of the corpora cavernosa was deprived of urethra, but presented a channel or groove along its middle line. Behind and under the corpora cavernosa, between their root and the anterior superior part of the scrotum, a prominent oval opening was remarked; this was the orifice of the urethra, through which the urine flowed, and in consequence of its vicinity to the penis, the stream was conducted along the under surface of that organ so as to appear to issue from its orifice. The scrotum, situated below this opening, contained the right testicle only, that of the left being probably retained in the abdomen. In all other respects the physical constitution of this individual was perfectly masculine. According to his account, the desire for women and the secretion of semen were observed at puberty. He had frequently performed coition, and had, besides a child born before marriage, two other children well formed, born in wedlock. This case was evidently only an instance of hypospadias, of which malformation we have already spoken in the article IMPOTENCE; and it is a further confirmation of the opinion there advanced, that persons labouring under it are not to be considered as incompetent to procreation. It is most probable that the semen during the act of coition was conducted along the penis, as the urine is stated to have been, at least so far as to enter the vagina. A case very similar to that just mentioned is detailed by Dr. Wageler.†

The malformation of which we have now spoken is that which most frequently causes mistakes in the male, but by a careful examination of the individual the obscurity must be easily removed. There are other degrees of imperfection which are sometimes observed, but can never lead to much confusion. One of these consists in a close application of the penis to the anterior surface of the scrotum, by a continuation of the skin of the latter over the former. In such a case the penis is bound down in its unnatural situation, and the urine passes downwards; the erection of the organ cannot take place; it may become turgid,

* Hufeland's Journal, t. xvii. No. 18.

† Annales de Méd. Politique de Kopp. v. 129.

but never erect, and intromission is of course impossible. A case of this description occurred to Mr. Brand,* in the person of a child seven years of age, who had been baptized and brought up as a girl; he found a malformation of the male sexual organs consisting of the presence of such an unnatural integument. By a slight incision he liberated the restricted part, and proved to the parents that they had mistaken a boy for a girl.

Another form of lusus which has given rise to mistake of sex, is that in which the urinary bladder, or rather the rudiment of it, opens directly above the pubis, through a deficiency of the abdominal muscles and integuments at that part. In these cases the bladder can scarcely be said to exist; all that appears of it is a red fungous mass protruding through the integuments, consisting of the mucous lining of the viscus, with the ureters opening on it together with the vesiculæ seminales and vasa deferentia. The penis is always very short, scarcely exceeding two inches, and, from deficiency of the urethra, imperforate. The testicles are generally well formed, but are sometimes retained in the abdomen. Persons with this malformation are observed to vary in their sexual appetites; some being totally deficient in sexual desire, others exhibiting it in a trifling degree, while others have it strong. It may readily be supposed that persons constructed in this manner are impotent; but it sometimes happens that the vasa deferentia open in a small tubercle at the root of the penis, in which case it is possible that impregnation may be effected by the individual. It is only by such a disposition of parts we can explain the pregnancy of a young girl in Linlithgow in Scotland, stated to have resulted from her sleeping with a young person, who from a malformation, such as we have described, was supposed to be a female.† It is plain that if the seminal ducts opened externally above the pubis, such an event could not have taken place.

2. *Malformations of the female generative organs.*—There are two sorts of malformation in women which may lead to error in judging of the sex. The first consists in excessive dimensions of the clitoris. Although hypertrophy of this organ occurs most frequently in warm countries, it has also been observed in cold. Sir E. Home doubts that it ever takes place in these latitudes, and also is of opinion that even in those situations where it is most frequently observed, the enlargement never proceeds to such a length as to lead to any serious doubt. There are, however, some instances on record in which the increase in size was such as to cause the clitoris to resemble and be mistaken for the male organ. Columbus notices an instance in which it was the size of a finger. Haller observed one case in which he states that it was seven inches in length; and it has been said to reach the extent of twelve inches.* However, notwithstanding any excessive dimensions of the clitoris, an attentive observer will readily discover the difference between the genital organs of a female with such a developement, and those of a male. Thus, for instance, in a celebrated hermaphrodite exhibited in Paris and London in 1777, named Marie Auge, the clitoris was found to resemble perfectly the male organ, but it was unprovided with a urethra, and imperforate; it was situated above the other parts of generation, which presented no peculiarity, except an unusual contraction of the vagina. Schneider met with an instance in a child of two years old still more likely to mislead; he examined it after death, and found neither labia majora nor minora, nor the usual cleft between them; the clitoris was an inch and a half long, resembling a penis, with a well formed glans and prepuce, but it was imperforate, a small spot occupying the situation at which the male urethra terminates. Some lines below this organ there was an opening, by which the urine was transmitted; but this passage seemed also destined to perform the functions of a vagina, for it led directly to the uterus, and was of a length proportionate to the age of the subject; the vaginal rugæ were distinct, and at the upper part of the orifice a small opening was observed which led to the bladder, and was in fact the orifice of the true urethra. In Sir E. Home's† paper on hermaphrodites he gives an account of a Mandingo negress whose clitoris was two inches long, and of the thickness of an ordinary thumb: at first view the extremity seemed formed like a glans, but on more minute examination it was found imperforate, and not so round as a true glans, but more pointed; the clitoris was capable of erection, during which state its size increased to three inches. The other parts of generation were well formed, the urethra was situated just beneath the clitoris, which obstructed the flow of urine so much as to compel her to raise it when about to evacuate the bladder. Her person was very masculine, the mammæ were little developed, the voice was rough, and the countenance resembled that of a man. Beclard‡ has given a very detailed account of a female who was exhibited in Paris, in 1814, as an hermaphrodite, from which we extract the following. Marie Madeline Lefort was the name of the individual; she was then sixteen years of age, and in the general form of her body resembled a male; the voice was masculine, a beard appeared on the upper lip and chin, the breasts were developed, and the limbs were slightly hairy. The external genitals presented a rounded mons veneris, covered with hair, but the symphisis pubis was elongated as in the male; beneath it protruded a conoid-shaped body, twenty-seven centimetres in length, when

† Loc. cit.

‡ Jour. de Med. Chir. et Phar. Mars, 1815.

flaccid, but more when erect; this was surmounted by an imperforate glans, covered for three-fourths of its extent by a prepuce. Inferiorily this enlarged clitoris was furnished with a canal, which, however, did not run the whole length, but was pierced in the middle line with five small holes, capable of admitting a small probe. Beneath and behind the clitoris, there was a sulcus, bordered on each side by a narrow and short labium, which on being handled gave no sensation of containing any body like a testicle. This sulcus or fissure was very superficial, being blocked up by a dense membrane, but which gave, when pressed by the finger near the anus, the idea that it was spread over a cavity. At the anterior superior part, near the clitoris, this membrane was pierced by a round opening, which readily admitted a moderate-sized catheter. The external abdominal rings were very small, and gave no indication of containing testicles. The urine was passed partly through the opening in the membrane described, and partly through the small cribriform openings in the canal extending along the under surface of the clitoris. This was taken from her own account, as she found it impossible to void urine in the presence of the examiners. The bladder could not be reached by a catheter introduced through the large opening, but the instrument could be easily passed upwards and backwards, and in this manner it glided along the posterior surface of the membrane closing the vagina, which, being felt between the point of the instrument and the finger, seemed about twice as thick as the skin. She had menstruated regularly from the age of eight years, and on one occasion when Beclard examined her during menstruation, he observed the fluid to pass through the opening already described, and the catheter then introduced was withdrawn full of menstrual blood. She considered herself a woman, and preferred the society of men, and was persuaded that a trifling operation would render her fit for matrimony. This individual belonged decidedly to the female sex; she had many and the most essential of the female organs of generation, the vagina and uterus, the latter organ moreover performing its natural function with regularity; and those characters of the male which she exhibited were only of a secondary class, such as the proportions of the limbs and body, shoulders, and pelvis, the size of the larynx, tone of voice, developement of hair, and the prolongation of the urethra beyond the symphisis pubis: this, however, was not complete, for the canal did not extend to the extremity of the mimic penis.

The second kind of malformation of the female generative organs likely to mislead as to the sex of the individual, is a protrusion of the internal parts. The uterus when prolapsed has at times assumed so close a resemblance to the penis that it has actually been mistaken for it by medical men of the highest character. The following case came under the observation of Sir E. Home, who has given the particulars in his paper on hermaphrodites. "A French woman had a prolapsus uteri at an early age, which encreased as she grew up. The cervix uteri was uncommonly narrow, and at the time I saw her (when she was about twenty-five years old) projected several inches beyond the external opening of the vagina: the surface of the internal parts, from constant exposure, had lost its natural appearance, and resembled the external skin of the penis; the orifice of the os tincæ was mistaken for the orifice of the urethra. This woman was shewn as a curiosity in London, and in the course of a few weeks made four hundred pounds. I was induced by curiosity to visit her, and on the first inspection discovered the deception, which, although very complete to a common observer, must have been readily detected by any person intimately acquainted with anatomy. To render herself still more an object of curiosity, she pretended to have the powers of a male: as soon as the deception was found out, she was obliged to go away." There is in the Philosophical Transactions the history of an hermaphrodite which seems to be exactly similar to this, as is fully proved by the menses flowing regularly through the orifice of the supposed penis. The French physicians were, however, so perfectly convinced of her manhood, that they made her change her dress and learn a trade. To this she readily submitted, and the account says she could perform very well the functions of a man, but not those of the other sex.

3. *Males with such a deficiency in their organs that they have not the character and general properties of the male, and may be called neuters.*

This form of hermaphrodism usually takes place in individuals originally intended for the male sex, and is nothing more than the effect produced by atrophy, or absence of the testicles,—a circumstance to which is frequently joined a defective developement of the penis. The genital organs do not appear to grow with the rest of the body, but continue in the same state as at birth. In many the characters of both sexes seem mixed; in others there is a slight predominance of one or the other, discoverable chiefly by moral circumstances, such as the kind of life, habits and pursuits of the individual. An instance of this kind of deformity occurred to Hufeland at Koningsberg. An individual named Marie Dorothée Duriée, aged twenty-three years, was examined by him and Mursinna, who both declared the sex to be female, while Stark and Martens were of opinion that the same person belonged to the male sex.

A marine soldier, aged twenty-three years, in the year 1779 was admitted a patient into the Royal Naval Hospital at Plymouth, under the care of Sir E. Home. He had been there only a few days when a suspicion arose of his being a woman, which induced Sir E. Home to examine into the circumstances. He proved to have no beard, his breasts were fully as large as those of a woman at that age; he was inclined to be corpulent; his skin uncommonly soft for a man; his hands fat and short; his

thighs and legs very much like those of a woman; the quantity of fat upon the os pubis resembled the mons veneris; the penis was unusually small as well as short, and not liable to erections; the testicles were not larger in size than we commonly find them in the fœtal state; and he had never felt any passion for women. In this case the testicles had been imperfectly formed, and the constitution was deprived of the influence which it naturally receives from them. The two following cases shew a still greater degree of imperfection in the male organs: they are mentioned by Sir E. Home.

A woman near Modbury in Devonshire, the wife of a day-labourer, had three children: the first was considered to be an hermaphrodite; the second was a perfectly formed girl; and the third an hermaphrodite similar to the first. In the year 1779 the eldest was thirteen years of age, and of a most uncommon bulk, which seemed to be almost wholly composed of fat; he was four feet high; his breasts as large as those of a fat woman; mons veneris loaded with fat; no penis; a prepuce one-sixth of an inch long, and under it the meatus urinarius, but no vagina. There was an imperfect scrotum with a smooth surface, without a rapha in the middle, but in its place an indented line; it contained two testicles of the size they are met with in the fœtus. The younger one was six years old, uncommonly fat and large for his age; the external parts of generation differed in nothing from those just described except in the prepuce being an inch long. Both were nearly idiots. The immense accumulation of fat, and the uncommon size of these children, accords with the disposition to become fat so commonly met with in the free martin.

4. *Where there exists a real mixture of the organs of both sexes, although not sufficiently complete to constitute the double organ.*—Cases of this description which most nearly approach the absolute hermaphrodite are less common than those we have mentioned. A remarkable instance is mentioned in Dr. Baillie's Morbid Anatomy.* The person was twenty-four years of age, and bore the name and dress of a woman, had the breasts of a female, and no beard, and yet had a very masculine appearance. The clitoris and meatus urinarius had the natural appearance, but there were no nymphæ, and the labia pudendi were unusually pendulous, resembling a split scrotum, and contained a testicle each. The vagina was found to terminate in a cul-de-sac, two inches from the external surface of the labia. She had no partiality for either sex, and had never menstruated.

The Memoirs of the Academy of Dijon contain the following case, communicated by M. Maret.† Hubert J. Pierre died at the hospital in October 1767, aged 17 years. Particular circumstances had led to a suspicion of his sex, and these induced an examination after death. His general appearance was more delicate than that of the male, and there was no down on his chin or upper lip. The breasts were of the middle size, and had each a large areola. The bust resembled a female, but the lower part of the body had not that enlargement about the hips which is usually observed at his age. On examining the sexual organs, a body four inches in length and of proportionate thickness, resembling the penis, was found at the symphisis pubis. It was furnished with a prepuce to cover the glans, and at its extremity, where the urethra usually opens, was an indentation. On raising this penis, it was observed to cover a large fissure, the sides of which resembled the labia of a female. At the left side of this opening there was a small round body like a testicle, but none on the right. However, if the abdomen was pressed, a similar body descended through the ring. When the labia were pushed aside, spongy bodies resembling the nymphæ were seen, and between these and at their upper part the urethra opened as in a female, while below these was a very narrow aperture covered with a semilunar membrane. A small excrescence, placed laterally, and having the appearance of a caruncula myrtiformis, completed the similarity of this fissure to the orifice of the vagina. On further examination the penis was found to be imperforate; the testicle of the left side had its spermatic vessels and vas deferens which led to the vesiculæ seminales. By making an incision into the semilunar membrane, a canal one inch in length and half an inch in diameter was seen, situated between the rectum and bladder. Its identity with a vagina was, however, destroyed by finding at its lower part the verumontanum and the seminal orifices, from which by pressure a fluid, resembling semen in all its properties, flowed. The most remarkable discovery was, however, yet to be made. The supposed vagina, together with the bladder and testicles, was removed. An incision was made down to the body noticed on the right side. It was contained in a sac, filled with a limpid and red-coloured liquor. From its upper part on the right side, a Fallopian tube passed off, which was prepared to embrace an ovarium placed near it. It seemed thus proved that the body in question was a uterus, though a very small and imperfect one, and on blowing into it, air passed through the tube.

In April 1807 an individual was exhibited at Lisbon, uniting the organs of both sexes in the highest degree of perfection that has probably been ever seen. This person was twenty-eight years of age, and possessed of the male organs, a penis, or what represented one, capable of erection, covered by a prepuce, and pierced for a third of its length by a canal, and testicles. The air and appearance were masculine, the colour dark, and a light beard covered the chin. The female organs were labia, vulva, and vagina, well formed, but very small; the larynx and voice were feminine, and so were all the dispositions; she menstruated regularly, and was twice pregnant, but was prematurely delivered each time, once

* 3d edit. p. 410.

† *Mahon*, t. i. p. 100, and Beck by Darwall, p. 143.

at three, the other at five months.* This, if the account respecting the testicles be correct, is the nearest approach to a true hermaphrodite with which we are acquainted in the human subject.

In the Memoirs of the Royal Academy of Sciences of Paris† there is a very accurate description by M. Petit, of a similar mixture of organs. The person had wholly the character of a man, but was of a delicate constitution; he was a soldier, and died of his wounds. The appearance of the penis is passed over; but the scrotum not containing testicles drew M. Petit's attention, and in the dissection he found testicles in the situation of the ovaria, attached to two processes, continued from an imperfect vagina, but having vasa deferentia, which passed in the usual manner to the vesiculæ seminales; the vagina communicated with the urethra between the neck of the bladder and the prostate gland.

With respect to the formation of such monsters as we have spoken of, Sir E. Home was of opinion that the only mode in which it can be explained is by supposing the ovum, previous to impregnation, to have no distinction of sex, but to be so formed as to be equally fitted to become a male or a female fœtus; and that it is the process of impregnation which marks the distinction, and conduces to produce either testicles or ovaria out of the same materials. The following circumstances are in favour of this opinion. The testicles and ovaria are formed originally in the same situation, although the testicles, even before the fœtus has advanced to the eighth month, are to change their situation to a part at a considerable distance. The clitoris in fœtuses under four months is so large as to be often mistaken for a penis, and serves to explain an erroneous opinion at one time maintained in France, that the greater number of miscarriages between three and four months have been remarked to be males; which mistake arose from the above circumstance. The clitoris originally appears, therefore, equally fitted to be a clitoris or a penis, as it may be influenced by the ovarium or testicle. In considering this subject, it is curious to observe the number of secondary parts, which appear so contrived that they may be equally adapted to the organs of the male or female. In those quadrupeds whose females have mammæ inguinales, the males have also teats in the same situation; so that the same bag which contains the testicles of the male is adapted to the mammæ of the female. In the human species, which has the mammæ pectorales, the scrotum of the male serves the purpose of forming the labia pudendi of the female, and the prepuce makes the nymphæ. The male has pectoral nipples as well as the female; and in many infants milk, or a fluid analogous to it, is secreted, which proves the existence of a glandular structure under the nipple. This view of the subject throws some light on those cases where the testicles are substituted for the ovaria; since, whenever the impregnation fails in stamping the ovum with a perfect impression of either sex, the part formed will neither be an ovarium nor a testicle, sometimes bearing a greater resemblance to one, sometimes to the other; and may, according to circumstances, either remain in the natural situation of the ovaria, or pass into the situation proper to the testicle, whether it is the scrotum of the male or the labia pudendi of the female.

Means of ascertaining the true sex of a supposed hermaphrodite.—We say supposed, because, as has been already stated, we do not acknowledge the existence of a true hermaphrodite in the human species. Some cases no doubt have occurred in which it was very difficult to assign the proper sex; but even the most perfect of these complications of the genital organs did not give the individual in whom they existed the power of double copulation. Thus in the case of Hubert Pierre it is not easy to decide to which sex he really belonged: again, we must admit that great difficulty existed in coming to a conclusion when we find such men as Hufeland, Mursinna, Stack, Martens, and Metyger disagreeing. From these and other cases that might be quoted, we must agree that cases do occur in which the greatest difficulty must be felt, and the greatest caution should be used in forming an opinion. These cases of great difficulty all belong to the last class of malformations: in the other classes the solution is not so difficult. In proceeding to make an examination for the purpose of ascertaining the sex of an individual, the greatest care should be taken not to mistake appearances, and these should be all accurately noted down. The different openings that present themselves should be all explored with appropriate instruments, (taking care not to inflict any wound or cause pain,) in order that their direction may be ascertained. An accurate inspection of the whole body should be made, to elicit any predominance of the constitutional characters of either sex that may exist. These examinations should not be made hurriedly, but should continue for a length of time, and be frequently repeated, before a positive opinion is given; for the tastes, habits, and propensities of the individual must be taken into account, as well as the physical conformation in doubtful cases. It is of importance to be informed whether a discharge of blood has ever escaped from any of the openings, and if repeated, whether it has been periodical; as that circumstance alone will be sufficient to decide us in coming to a conclusion. In the case of young children, it is best to wait until the parts become more fully developed, as it has happened that instances of confusion of sex when young have at the age of puberty taken a decided leaning to one or the other sex. Above all, it is necessary to be most cautious in believing all that is stated by the individual or the friends, as, from interested motives, they may misrepresent facts in such a way as to lead us into error.

(T. E. Beatty.)

SMALL-POX.—The most approved authors concur in the belief that the disease known to us by the name of *small-pox* or *variola*, was not described by any of the writers of antiquity. From their silence, therefore, respecting a disorder so fatal, and possessing such very peculiar characters, we may reasonably presume that its origin was subsequent to their times, and that the world had existed some thousand years before it was visited with this dreadful pestilence. Etymology comes here in aid of history. The first authentic passage in which the words *variola* and *pocca* occur is to be found in the Bertinian Chronicle of the date 961.* There being no term for the disease in the Greek or Roman authors, variola was coined in the middle ages from the Latin *varus*, a pimple, or *varius*, spotted, and for several succeeding centuries was applied to designate measles as well as small-pox. From variola are derived the Italian vaiuolo, and the French vérole. The term *poc* is of Saxon origin, and signifies a bag or pouch. The Anglo-Saxons early adopted this word, which was variously spelt, and became pock, pocks, and pox. The epithet *small* in England, and *petite* in France, were added in the fifteenth century.

From very early times attempts have been made to prove the antiquity of small-pox, and even in our days this doctrine has found supporters. Dr. Baron, of Gloucester, the latest writer on the subject, entertains the opinion that small-pox is to be traced in the earliest writings of the Hebrews and Greeks; that it was seen by Hippocrates, and commented upon by Galen. According to this author, the account of the plague of Athens, as given by Thucydides, "presents as accurate an account of the leading symptoms of variola as could possibly be expected from any historian not medical."† In this opinion Dr. Baron is countenanced by Salmasius, Hahn, and more recently by Dr. Willan, in a posthumous dissertation "On the Antiquity of Small-pox." Rhazes, an Arabian physician, and the first acknowledged writer on this disease, laboured to prove that Galen had seen it, but with all his enthusiasm for his master, he acknowledged and was surprised at the unwonted brevity and inaccuracy of his description. This alone may be considered as decisive of the question; but we may further state that Friend and Mead, authors of the highest repute, after devoting great attention to the subject, agreed that there was no foundation for such a notion. We shall be fully justified, therefore, in adhering to the generally received opinion that small-pox is a disease of modern origin.

The first notices of a disorder which exhibits the well-marked features of small-pox, are to be found in the historical writings of Procopius,‡ who flourished during the reign of Justinian the First. The obscurity of its origin, the difficulty of its cure, the universality of its devastations, and above all, the complete immunity from second attacks which are mentioned as characteristic of this epidemic, bespeak it to have been truly small-pox. It began A.D. 544, at Pelusium in Egypt, from whence it spread to Constantinople. This corresponds closely with the era commonly assigned in medical books to the first appearance of small-pox, viz. A.D. 569, the year of the birth of Mahomet. In that year an Abyssinian army, under Abrahah the viceroy, appeared before Mecca, and was unexpectedly compelled to raise the siege. Several circumstances concur to render it probable that the sudden retreat of the army was owing to the breaking out of small-pox, and the dreadful mortality which it occasioned. Bruce, in his travels,* met with a manuscript account of this war, which confirms this story, and strengthens the opinion that small-pox, first appeared in Egypt and Arabia about the middle of the sixth century.

A further question has been raised and keenly agitated, whether the small-pox really began in Egypt, or was conveyed to the shores of the Red Sea from India. Attempts have been made to establish the existence of this disease in China and Hindostan at very remote periods. Mr. Moore, in his history of small-pox, advocates this opinion. He finds in the mythology, the religious institutions, the sacred and historical records, the medical works, and uniform tradition of those countries, abundant proofs that small-pox existed there at a period anteceedent even to Hippocrates.† He then enters into an investigation of the circumstances which may have prevented the spread of the infection from Asia to Europe and Africa. It must be acknowledged, however, that the facts on which Mr. Moore relies in support of this opinion rest on very questionable authority; and as the opinion itself has not met with many supporters, it is not necessary in a practical work like the present to bestow on it more particular examination.

The small-pox, and with it the measles, certainly burst forth in Arabia under circumstances most fatally favourable to their dissemination. It was in the year 622, when Mahomet began to collect the wandering tribes of Arabs whom he led forth, inflamed with religious zeal, against the neighbouring nations. To the devastations of war were now added the ravages of a new and most intractable disorder. But if we owe the introduction of small-pox to the Arabian armies, it is to the physicians of the same nation that we are indebted for the earliest accounts of it. Rhazes, an Arabian physician, who practised at Bagdad about the beginning of the tenth century, is the first author who treats expressly of small-pox. He quotes, however, several of his predecessors, of whom the most ancient is Ahron, a physician of Alexandria, who is supposed to have flourished about the year 622, the era of the Hegira, when Mahomet first went forth as a conqueror and a prophet.

‡ De Bello Gothico, lib. ii.

* Travels to discover the Source of the Nile, vol. i. p. 514.
† Moore's History of Small-pox, p. 35.

The treatise of Rhazes "De Variolis et Morbillis" deserves especial mention for the accurate description which is given of the several kinds of small-pox. His theory of the disease, however, is childish and scarcely intelligible, and his treatment lamentably deficient. He abounds, indeed, with directions for the management of every symptom, and more especially for that of the pustules in their several stages, which is very complicated, consisting of fomentations, fumigations, dry powders, ointments, and other applications chiefly intended to prevent pitting. In most of those instances his prescriptions are harmless, but this merit does not belong to his recommendation of free bloodletting and of the most powerful narcotics in all stages, and even in the confluent forms of the disease. Avicenna, another Arabian physician, gives also a very full and excellent account of the symptoms of small-pox, and he improves upon the treatment suggested by Rhazes, by restricting bleeding to plethoric habits, and to the three first days of the disease. Both Rhazes and Avicenna concur in the opinion that measles and small-pox are only modifications of the same disorder. Avicenna considered measles as a sort of bilious small-pox.

Hali Abbas, a third Arabian author on small-pox, deserves to be mentioned as having made an approach to the doctrine of contagious origin. The theory of small-pox adopted by him, as by all the Arabian physicians, was founded on the commotion and putrefaction of the humours of the body; but Hali observed that one of the accidental causes which excited the movement of the distempered humours to the skin was being in the same place with persons affected with the small-pox, or breathing air contaminated with the pestilential vapour of small-pox pustules. All the Arabian authors believed in the occasional occurrence of small-pox twice in the same person.

The successes of the Saracen arms in Spain and Sicily, during the eighth century, contributed doubtless to the gradual extension of small-pox through the different countries of Europe, but on this subject very little is known. We read that on several occasions a pestilence of fire raged, the body dissolving away as if burnt, with an intolerable fœtor of the putrid flesh. It is reasonable to suppose that some at least of these epidemics were the small-pox: others may have been the true Egyptian plague with buboes.

The researches of antiquarians lead to the belief that small-pox reached England early in the tenth century (907.) There is preserved in the British Museum a curious Anglo-Saxon manuscript, supposed to have been written in that century, containing an exorcism or supplication against the small-pox.* Nicasius was the saint especially addressed on these occasions. All that we read serves to shew how great were the terrors inspired by the small-pox in every period of its career.

The discovery of America by Columbus, which so wonderfully extended the boundaries of human knowledge, was the occasion also of scenes of desolation at which the heart sickens. Among all the calamities incident to that event none can surpass the introduction of small-pox into that continent, which took place in 1517, twenty-five years after its discovery. It is stated, on the authority of the Spanish historians, that in a very short time after the infection reached Mexico, three millions and a half of people were destroyed by it in that kingdom alone. Among the victims was the emperor, the brother and successor of the brave but unfortunate Montezuma.*

From the revival of learning to the present period, no subject has attracted the attention of physicians, both speculative and practical, more than small-pox. Every medical writer has treated of it, and some have devoted themselves exclusively to its study. It would be vain, therefore, to attempt more than a brief allusion to those who have distinguished themselves in this department of medical inquiry.

The humoral doctrines which prevailed in the schools during the sixteenth century led to the universal adoption of the hot or alexipharmic mode of treating pestilential and malignant diseases, including small-pox. Sennertus gives the following account of the practice pursued in his time (1628). The great object was to expel the noxious humour by perspiration, to accomplish which various decoctions of warm seeds are directed, containing mithridate, bezoar, and other drugs, denominated alexipharmic and sudorific. "While using these, every attention is to be paid, especially in winter, to prevent the admission of cold air. The patient is therefore to be tended in a warm chamber, and carefully covered up, lest by closing the pores of the skin the efforts of nature should be impeded, the humours driven upon internal organs, and matters which ought to be expelled retained within the body, to the imminent danger of the patient, and the certainty of increasing restlessness, fever, and other symptoms."†

Such had long been, and such was the state in which Sydenham in 1667 found, the theory and practice of small-pox. Bad as that practice was, it yet had the support of all the learning and all the prejudices of the age. It required, therefore, talent and boldness successfully to oppose it. Sydenham began by separating for ever small-pox from measles, with which, from the days of Rhazes, it had been so strangely yet so obstinately associated. He divided small-pox into two kinds, the distinct and confluent, traced with the greatest accuracy the usual course of both, and added many important remarks to the detail of symptoms given by others, particularly with reference to prognosis. Of the intimate nature or essence of small-pox he professed his ignorance in common with the rest of mankind, but adds immediately afterwards his suspicion that it consists of a specific inflammation of the blood and other humours, and that the inflamed particles, when duly digested and concocted, are

* Moore's History of Small-pox, p. 94.

* Robertson's History of America, vol. iv. b. viii.

† De Variolis et Morbillis, t. vi.

expelled from the body in the form of little abscesses. The chief merit of Sydenham consists in his criticisms on the prevailing treatment of small-pox. These, though worded with the most scrupulous care, and an anxious wish to avoid hurting the feelings of his professional brethren, yet exposed him to much obloquy, and he was calumniated as an innovator and a homicide. He introduced what is now called the cooling regimen, including fresh air, light bed-coverings, and abstinence from wine and all cordial and sweating medicines. The remedies on which he chiefly relied were moderate bleedings, acidulated drinks, and opiates. His principal faults consisted in the timid employment of purgatives, and his fondness for blisters.

Boerhaave, who was born when Sydenham was at the height of his fame (1668), entertained the highest admiration of him, and was contented to adopt almost without alteration the description and treatment of small-pox given in his works. But Boerhaave has the great merit of first putting prominently forward *contagion* as its direct exciting cause. He acknowledges "that as the first man who suffered from small-pox must necessarily have received it without contagion, so may it still be occasionally engendered by causes of which we are ignorant. Nevertheless, as a general law it may be stated that the contagion once generated multiplies itself without any assignable limit, as the smallest spark may spread the widest conflagration."*

The theory and treatment of natural small-pox, placed thus, by the combined labours of Sydenham and Boerhaave, upon their proper footing, underwent no important changes during the last century; the attention of authors was then directed almost exclusively to the new discovery of inoculation, of which we shall treat more fully in a subsequent page.

We now proceed to give a description of small-pox, and have to remark, in the first place, how singularly diversified are the appearances which it presents. A variety of causes contribute to this, but none more remarkably than the previous habit or condition of the body with reference to the contagion of small-pox. It will be useful, therefore, to begin by considering the disease under three different aspects:—

First, as it occurs, casually and for the first time, to those who have undergone no preparatory process. This is called the casual or *natural* small-pox.

Secondly, as it occurs to those who in early life have undergone the process of vaccination. This is called the mitigated or *modified* small-pox.

Thirdly, as it occurs to those who have been inoculated with the variolous virus: the *inoculated* small-pox.

Natural Small-Pox.

This disease is characterized by a long train of phenomena, some of which are peculiar to it, while others are common to it with other acute disorders. From very early times it was observed that these admit of a division into three *stages*. Such an arrangement is strictly natural, and admits of no improvement. These are, the stages of incubation, maturation, and decline; and they will require separate investigation.

1. *Stage of incubation.* Under this head is included the whole period that elapses from the reception of the variolous germ, or virus, into the human body, until the appearance of eruption. Rayer* subdivides it into the two stages of incubation and invasion, the former comprising the interval between the reception of the germ and the *sickening;* the latter extending from the sickening to the appearance of eruption. In very many cases, however, this distinction cannot be made, the two periods running into each other by insensible degrees.

The reception of the variolous poison into the human body casually by the mode of *infection*, (that is, through the medium of the respiration,) takes place in most instances imperceptibly and without symptoms. Occasionally, however, the patient experiences at the moment of imbibing the germ of disease some unpleasant sensation, such as a disagreeable odour, or a feeling of giddiness, or sickness at stomach, or, what is perhaps more common still, an inward sense of alarm or fright. The duration of this stage is subject to some variety. Fourteen days may be stated as the average period that elapses from exposure to contagion to the appearance of eruption. The extremes may be set down as one week and three weeks. This interval is passed differently in different cases. Sometimes the patient, during the whole or greater part of this period, has been weak, languid, low-spirited, and inactive, with impaired digestion and unquiet nights. He has felt poorly, without any assignable cause. In the greater number of instances, however, no uneasiness whatever is experienced until the eleventh or twelfth day after exposure to contagion, when an unexpected and perhaps severe rigor announces the commencement of the initiatory or, as it is sometimes called, the *eruptive* fever. This is accompanied in some cases with severe pain or weakness of the back, so that the patient has dropped down; in other cases with acute pain of the epigastrium, aggravated on pressure, and hence sometimes mistaken for gastritis; with nausea, vomiting, giddiness, or headach. Children are often very drowsy at this period. The nervous system sometimes participates in a more marked manner. There is extreme prostration of strength. The patient staggers in his walk, and the expression of countenance is anxious and haggard: children have an epileptic fit; adults become delirious. These more urgent symptoms generally indicate the approach of a severe form of the disease. Of this there can be no doubt, when, in addition to the symptoms already enumerated, we observe such as denote that the fluids of the body are implicated in the mischief which is going on—that is to say,

* Van Swieten's Commentaries, vol. v. p. 18.

* Treatise on Diseases of the Skin, translated by W. B. Dickinson, p. 108. London, 1833.

when petechiæ appear in different parts, or large patches of subcutaneous ecchymosis, with hemorrhage from the nose, mouth, stomach, bowels, or uterus. Under these circumstances death has been known to take place prior to any unequivocal appearances on the skin. Here the real nature of the disease must always remain in some degree doubtful, but it can often be inferred by tracing carefully the history of the case. It will be found to have succeeded exposure to small-pox contagion within the reasonable limit of time, or it may in its turn have communicated contagion to others. Several well-marked instances have occurred, rendering it almost certain that contagious emanations are thrown off from the lungs and skin even at this early period of the disease.

The duration of the initiatory or eruptive fever of small-pox has been a fruitful source of discussion among authors. Prior to the time of Sydenham the object of physicians was to shorten the period as much as possible, and to promote an early eruption, which they attempted to effect by powerful diaphoretics. Sydenham, on the other hand, maintained that the more tardy the eruption the lighter was the subsequent disease. This observation is not borne out by the results of our own experience; and it is not improbable that Sydenham's judgment might have been in some degree warped by his anxiety to dissuade from that heating regimen of whose injurious effects he was so well convinced. The fact appears to be that the period of the initiatory fever is most remarkably uniform. The eruption in a vast majority of cases shews itself at the end of forty-eight hours from the occurrence of rigor or headach, whether the subsequent disease be mild or malignant, confluent or distinct: in other words, one complete day intervenes. Sometimes, from accidental circumstances, (such as great weakness of constitution,) this period is protracted to seventy-two hours, but never, so far as we have observed, is it shortened. This may be looked upon as a remarkable law of the variolous disease, and a most important means of distinguishing small-pox from other exanthemata, particularly scarlatina, lichen, and measles. In the two former disorders, the duration of the premonitory symptoms is less than in small-pox; in measles it is greater.

II. *Stage of maturation.*—The eruption of small-pox shews itself in the first instance in almost all cases on the face and wrists, and thence gradually extends over the rest of the body. In a very few cases only has it been first observed on the inferior extremities. It consists of minute papulæ sensibly elevated above the general surface of the skin. In some instances the eruption is fully developed over the whole body in the course of twenty-four hours. In other cases, two and even three days elapse before the process is completed on the legs and feet. When the papulæ are few in number, and separate from each other, the disease is called *distinct*; when the eruption is close set and profuse, *confluent*. To the intermediate varieties the old authors gave the name of *contiguous* or *coherent*, but the term *semiconfluent* is preferable. We apply it to designate those cases where the eruption is confluent in one part and distinct in another, as well as those where the papulæ are numerous without actually running into each other.

Arrangement and structure of the pock.—This branch of the subject has excited much attention at various times, and in particular was investigated diligently by Cotugno, (better known under his Latin name of Cotunnius,) an Italian physician, in the year 1771.* When the papulæ are few in number, they will not be found indiscriminately diffused over the body, but arranged in groups of three or five, and assuming a crescentic or semicircular form. When two groups coalesce, a complete circle of papulæ may sometimes be observed. The papulæ have their seat in the true skin; and upon the third or fourth day from their first appearance are converted into vesicles, containing a thin transparent lymph. These vesicles are very curiously organized, being divided into six or eight cells tied together in the centre, which for several days is depressed. This central depression, or *umbilicated* form of vesicle (as it is sometimes called), is very characteristic of small-pox. It is exhibited only in one other disease—cow-pox. The specific matter or poison of small-pox is secreted by the parietes of the minute cells, and the progress of inflammation in the papula is denoted by the inflammatory circle (called areola) which about the fourth day begins to surround it. As the colour of this areola changes to a bright crimson, the lymph in the vesicle is converted into a thick opaque matter, of a white or straw colour. This distends the cells, and gradually increasing in quantity, breaks down the central band, in consequence of which the pustule *acuminates*. In favourable cases this process is usually completed in seven, or at furthest in eight days: occasionally it occupies only five or six days.

During the maturation of the pustules there is always some degree of fever present, varying of course, in violence, with the quantity of eruption, the habit of the patient, and the circumstances in which he may happen to be placed. If the habit of body be good, the season mild, the apartment cool, the diet duly restricted, and the mind free from anxiety, there will be very little fever, even though several hundred pustules are in the process of maturation. There is generally more or less tenderness of the skin present. Occasionally this tenderness is excessive, and productive of the greatest distress.

Confluent form of small-pox.—When the eruption is very copious over the whole or greater part of the body, this, its regular or normal progress, undergoes several important modifications, which are next to be described. In some cases, indeed, the confluent small-pox runs the same course as the mildest forms of the distinct disease. The vesicles are small, and

* De Sedibus Variolarum. Vienna, 1771.

each is surrounded by a minute areola, while the constitutional excitement is moderate. Such a form of small-pox may be characterized as the *confluent superficial*. The most familiar instances of it are presented when the disease is taken after vaccination, but it is sometimes witnessed among persons wholly unprotected.

Analysis of the symptoms of confluent small-pox.—1. The first peculiarity of confluent small-pox, as generally met with, is, that from a very early period it involves not only the cutis vera, but the subjacent cellular membrane in extensive and often violent inflammation. The eyelids are swollen, and by the fifth day the patient is unable to see. The scalp is tense and tender. The parotid glands participate in the increased action of the surrounding cellular membrane, and salivation takes place, with great turgescence of the cheeks. The limbs are tumid, and an erythematous redness often occupies such parts as are free from variolous papulæ. In the most aggravated cases, buboes form in the groin, often with intense pain. The skin being almost wholly occupied with vesicles, there is no areola. The pustules do not acuminate, but appear flat and doughy, and upon the face especially they coalesce into one large sore, which discharges a copious thin ichor. The constitutional symptoms accompanying this kind of small-pox are very severe. The pulse is rapid, with extreme debility, restlessness, and total want of sleep.

2. The second peculiarity of the confluent small-pox is, that the eruption occupies not only the skin but the mucous expansions of the mouth, nose, pharynx, larynx, and trachea to below its bifurcation. The tongue is also occupied with vesicles. The precise structure of the mucous vesicle has not been determined with the same accuracy as that of the cutaneous vesicle; but it runs a course in all respects similar. This complication of mucous inflammation adds immeasurably to the danger of the disease, besides that it modifies some of the other symptoms. Heat of the mouth, pain of the throat, difficulty of swallowing, hoarseness, dyspnœa, and more or less mucous expectoration, are the first symptoms that it occasions. These increase in severity until the eighth day, from which time a copious secretion takes place from all the structures so affected. In a large proportion of cases the swelling occasioned by the inflammation so narrows the opening of the larynx, and the effused matter so blocks up the air-passages, that suffocation is produced. Before this takes place, however, the respiration has been impeded to such a degree as materially to interfere with the due oxygenation of the blood. Hence arises a long and frightful train of symptoms, among which we may particularly enumerate gradually increasing dyspnœa, coldness and paleness of the extremities, lividity of the areola, especially in parts distant from the centre of circulation, a swelled and purple tongue, great restlessness, and a low muttering delirium.

Cases of the confluent form of small-pox are sometimes met with, which are altogether devoid of mucous complication, but they are very rare. The extent of mucous and of cutaneous inflammation, however, are not always and necessarily proportioned to each other. A case may be very confluent on the surface, with but few vesicles in the throat.

3. A third circumstance influencing materially the character of the symptoms in the confluent variety of small-pox, is the early and deep implication of the brain and nervous system. This fortunately is but a rare occurrence The chief symptom by which it is characterised is early and violent delirium, (the delirium *ferox* of old authors,) attended in many cases with such a strong disposition to self-destruction that the utmost care should always be taken to guard against the possibility of accident. Variolous delirium is accompanied with redness of the conjunctiva, contraction of the pupil, and a wild expression of countenance. It generally shews itself at the very commencement of the initiatory fever, but is sometimes delayed until the second or third day from the appearance of the eruption. Excessive restlessness, anxiety, and despondency may be viewed as lighter evidences of the same specific affection of the brain. Nothing indicates its absence so certainly as a calm and collected manner, with a succession of quiet nights, and a confident hope of recovery. Variolous delirium is always most violent in the early periods of the disorder. When the areola begins to form, still more when external inflammation is fully developed, delirium for the most part ceases. Cases of confluent small-pox complicated with delirium are extremely dangerous. A large proportion of them terminate unfavourably, sometimes by affection of the head, (coma,) sometimes by acute inflammation of some other internal part, especially the pleura, brought on or determined by the general derangement of the nervous system. We have stated, as a general rule, that the peculiar affection of the brain and nervous system now adverted to, is associated with a full confluent form of eruption, but occasionally it is found to accompany, and of course very materially to aggravate, the danger of distinct and semi-confluent cases.

4. The fourth circumstance which characterises and modifies the phenomena of the confluent forms of small-pox, is the implication of the *fluids* of the body,—in other words, the concurrence of that state of the blood called by the old writers *dissolved* or putrescent. To these, the most aggravated of all cases, the terms *malignant* or petechial small-pox are generally applied. They are thus distinguished. From the earliest period of the disease, petechiæ are observed in different parts of the skin. Sometimes the extent of subcutaneous ecchymosis is immense. As the vesicles advance to maturation, they fill, not with pus, but with a thin ichor tinged with blood. Hemorrhages break forth from all the mucous structures of the body. The gums bleed often very profusely. There is epistaxis, spitting of blood, vomiting of blood, and the passage of blood by stool. Females suffer from violent menorrhagia,

and abortion never fails to occur to such as are pregnant. There is bloody urine in some cases. All this occasionally happens without delirium, or any other well-marked evidence of cerebral affection. More commonly, however, these conditions, viz. disturbed brain and dissolved fluids, are found associated together. From this appalling variety of small-pox, recovery is scarcely ever met with. Death usually takes place between the fifth and seventh days of the eruption.

Complications. Such are the ordinary phenomena of the natural small-pox in its distinct and confluent forms, when it occurs to persons previously in good health and of sound constitution. But it must be remembered that this disorder may attack those who may be labouring, at the time of seizure, under some other disease, such as pneumonia, hooping-cough, hepatitis, or consumption; and further, that these and other disorders may come on, unexpectedly, at any period, early or late, during the progress of small-pox. An infinite variety of *accidental* symptoms may thus be superadded to those regular symptoms now enumerated. Besides which, small-pox may occur to persons of a weak habit, or in constitutions exceedingly exhausted, and unable to cope with a disease of such severity. It may occur, for instance, to those who have but recently recovered from a severe typhous or scarlet fever. Under these circumstances, we observe a very tardy eruption; collapse without advance of eruption; or in cases somewhat more favourable, an abundant formation of large blebs, containing a thin ichor, with a very tedious and hazardous period of convalescence. To this latter form of the disease the old writers gave the name of the watery or bladder pock.

III. *Stage of decline.* If the maturating stage of small-pox exhibits great diversity of symptoms, so also, even in a more eminent degree, does the stage of decline. The mildness and rapid progress to recovery which some cases present, contrast strongly with the severity, obduracy, and varied dangers of others.

In the distinct and mild form of small-pox the pustules burst and discharge their contents on the sixth, seventh, or eighth day. A scab succeeds, cicatrization commences, and in vigorous constitutions is completed in about eight or ten days. In the very mildest cases of all, which approach to the character of chicken-pox, there is very little discharge of matter, but the pustules harden, and the small portion of pus which they do contain is apparently absorbed. This variety of the disease has been called the dry or horny pock, and it is the most common form in which small-pox shews itself after previous vaccination.

In cases of greater severity, as well in the truly confluent as in those which we have distinguished as the semi-confluent variety, where the eruption is copious, but where the vesicles do not actually coalesce except in a few places, the decline of the disorder is attended with some remarkable phenomena, of which the most important are pitting and secondary fever. Cicatrization is tedious and ultimately effected with such a loss of substance in the true skin as occasions pits and scars, which continue during the remainder of life. From the great vascularity of the face, there is always greater confluence and a higher degree of inflammation there than in other parts. Hence, pitting is chiefly met with in the face, disfiguring and often completely altering the countenance of the sufferer.

Secondary fever.—The febrile symptoms subside entirely in all cases where the pustules have maturated kindly over the whole body; but in all severe cases, that is to say, where the cellular membrane and glands which it envelopes have become involved with the skin in inflammation, the fever, so far from subsiding on the ninth or tenth day, when the maturative stage has closed, is aggravated. The surface of the skin at this time becomes hot and dry, the tongue white, the pustules hard and scaly, the pulse increases in frequency, the patient is tormented with a great, sometimes inextinguishable thirst. Secondary fever is now said to have set in, and the variety of symptoms observed during its progress almost baffles description. The following attempt to enumerate some of the leading phenomena of secondary fever will serve at least to point out the character of this very singular condition

1. In a large proportion of cases, secondary fever is accompanied with some form of inflammatory action on the surface. An efflorescence identical with that of scarlatina occupies the trunk and extremities. Trails of erythematous redness appear in several parts, or a genuine erysipelas attacks the head, trunk, or limbs. In other cases the cutaneous and cellular inflammation is more circumscribed, leading to the formation of abscesses, often of great extent, of boils and carbuncles, and ulceration of those parts which are especially liable to pressure, such as the elbows, hips, and sacrum. In those situations sloughing sores are often met with, which from their extent and depth bring life into danger. In some cases the scalp is the part which receives the violence of the fever. Abscesses form there, or a diffuse cellular inflammation takes place, which is followed by purulent infiltration. Lastly, in a few instances the whole surface is occupied with pustules of *ecthyma cachecticum*, accompanied with fever of the hectic kind, which is with great difficulty subdued.

2. Secondary fever is accompanied, in a certain proportion of cases, with ophthalmia. The subject of variolous ophthalmia is one of great extent and importance. In the early periods of the disease it is not uncommon to observe a considerable degree of conjunctival inflammation, and sometimes a pustule forms at the edge of the cornea; but it is reserved for the decline of the disease to exhibit the aggravated form of this affection. In some desperate cases an intense form of ophthalmia sets in about the tenth day, which rapidly involves all the structures of the eye, and in the course of a few days destroys its entire organization. In other cases the sloughing is confined to a portion of the cornea, and this is followed by

a staphylomatous protrusion of the iris. It is rare to observe more than one eye involved in this very destructive form of inflammation, but still in all countries, and from the earliest periods at which we read of this disease, a large proportion of the blind have been found to owe their misfortune to the secondary fever of small-pox.

3. Another frequent occurrence in the progress of secondary fever is gangrenous inflammation of the genitals. This shows itself in the first instance on the scrotum or prepuce, runs on rapidly to mortification, and in almost all instances ends in the loss of life.

4. The destructive effects of secondary fever, however, are by no means confined to the surface of the body. It frequently happens that without any obvious cause some internal organ receives the violence of the febrile shock. Acute inflammation is set up, and the result is in almost all cases suppuration. The *pleura* is the part peculiarly disposed to suffer under these circumstances. Variolous pleurisy comes on about the eleventh or twelfth day of eruption, for the most part very suddenly, and proceeds rapidly to empyema. We have seen it prove fatal in thirty-six hours. In general, the pleuritic symptoms are violent and well marked. The pain of side is excruciating, and the shortness of breath equally unequivocal; but sometimes there is a latent form of pleurisy. The patient dies without making any complaint of the side, and on dissection one of the cavities of the thorax is found gorged with a sero-purulent fluid. In all cases of secondary fever, a strict attention to the respiratory organs, with such aid as the stethoscope can afford, should never be omitted. In a few cases the substance of the lungs is the seat of an intense form of inflammation, tending to abscess. Children are sometimes attacked with symptoms indicating laryngitis or croup.

5. Affections of the abdominal viscera are very uncommon. Inflammation of the liver and of the mucous membrane of the bowels have been noticed, but they are among the rarest forms of internal disease observable in the progress of small-pox.

6. The brain sometimes suffers during the presence of secondary fever. Phrenitis with delirium occurs in children; and in adults of plethoric habit a state of coma or lethargy is not unusual. But what is most worthy of attention in this respect, is that singular state of the nervous system which accompanies the destruction of large portions of skin, and which is so well known to surgeons as a consequence of extensive burns and scalds. It is characterised by severe and repeated rigors, succeeded by general tremors, low delirium, a weak and rapid pulse, a dry brown tongue, and collapse of the features, terminating in death.

7. The evils attending secondary fever are aggravated by the concurrence of the strumous habit. Nothing developes it more certainly than protracted small-pox. Accordingly, in scrofulous constitutions we see secondary fever complicated with strumous ophthalmia, characterised as well by its complete intolerance of light and abundant secretion of tears as by its obstinate resistance to every kind of remedial treatment. Irritable ulcers form under the lower eyelid, and around the knee, ankle, and elbow joints, and are found very difficult to heal. Glandular enlargements of the neck take place, which sometimes suppurate, but oftener continue indolent and of stony hardness. Children frequently suffer from otitis.

8. To all this must be added the danger of contracting, during the stage of decline, common fever of the typhoid or erysipelatous kind. At the Small-pox Hospital, it is not uncommon to find even the milder cases attacked, during apparent convalescence, with fever, irritable stomach, sore throat, and erysipelas of the face or extremities. This *superadded* disease has in many instances brought life into hazard, and in some has proved fatal. The great peculiarity of it is the concurrence of severe inflammation of the tonsils and subjacent cellular membrane with erysipelas of the head, neck, or back. It appears to have its origin in that vitiation of the air which is almost inseparable from the very nature of an hospital, and which any accumulation of malignant cases, more especially in a disease like small-pox, must necessarily tend to augment. This form of disease might be appropriately designated *hospital fever*. When it has once shewn itself, there is abundant reason for believing that such a fever, whether exhibiting anginose or erysipelatous symptoms, or their combination, is truly contagious.

Prognosis.—The following are the chief grounds on which the prognosis in small-pox should rest.

1. Confluence is always unfavourable, because it necessarily occasions a large drain upon the system; but if the pustules acuminate well, and the areola on the extremities be of a good, that is, crimson, colour, a reasonable ground of hope exists. Confluence on the face is more to be dreaded than in any other part. When the vesicles on the trunk of the body are flat, when the eruption on the face is white and pasty, when the extremities appear of a clarety or livid colour, little or no hope of recovery can be entertained.

2. With reference to prognosis, great attention is due to the state of the larynx. Hoarseness, with copious spitting, occurring at an early period is very unfavourable, as indicating the extent of mischief in that important organ. On the other hand, a natural tone of the voice is a favourable sign, and with a good constitution gives a fair ground of hope, even though the eruption be full and confluent.

3. Quiet nights, composure of mind, a collected manner, and confident hope of recovery are good omens, because they indicate the comparative freedom of the brain and nervous system from all serious complication. Patients who from an early period of the disease are restless, delirious, moaning, and desponding, rarely recover. There is not a worse symptom in children than grinding of the teeth: very few recover in whom it is observed.

4. In estimating the danger of confluent and

semi-confluent cases, the age of the patient merits particular attention. Persons above forty years of age seldom recover from any of the severer forms of small-pox. Infants also are in danger even from a moderate quantity of eruption. In both cases the reparative process is attended with great exhaustion of nervous power, the result of which is that the brain, larynx, or some other important organ loses its tone, takes on acute inflammation, and by its disorganization life is destroyed. The most favourable age for taking small-pox is from the seventh to the fifteenth year, when the powers of life are in the greatest vigour, with the least chance of plethora.

5. The habit of body is likewise to be taken into account. In the middle periods of life the danger of small-pox is much increased by its concurrence with a *plethoric* habit. Great weakness of constitution is equally a source of danger. Of the additional risk which a strumous habit entails we have already had occasion to treat.

6. Everything indicating a dissolved or putrescent state of the fluids is of course most unfavourable, such as petechiæ, menorrhagia, and epistaxis. Recovery from the petechial or malignant form of small-pox, indeed, is so rare as scarcely to enter into calculation.

Mortality of small-pox.—It is commonly stated that one-fourth of those who are attacked by small-pox in the natural way perish. The records of the Small-pox Hospital indicate a somewhat higher proportion. The deaths during the last fifty years at that institution have averaged thirty per cent., the extremes being eighteen and forty-one per cent. The days of greatest mortality, or critical days, as they are called by the old authors, have been much commented upon, and in all ages it has been observed that the eighth (counting from the date of eruption) is the day of greatest danger. The following table, extracted from the register of the Small-pox Hospital for the years 1828 and 1829, illustrates this fact, while it shews at the same time that small-pox proves fatal at various periods, from the third to the thirty-eighth days of eruption. From this table it also appears that nearly two-thirds of the total number of deaths take place during the second week of eruption.

Causes of death in small-pox.—It may not be irrelevant to recapitulate the several causes of death in small-pox. 1. Prior to the maturation of the pustules, that is, between the second and seventh days of eruption, patients die of malignant fever; of that peculiar condition of the fluids and nervous system to which the name of *acute malignancy* may properly be given. 2. Between the eighth and thirteenth days of eruption, the chief cause of death is to be found in affection of the throat, and consequent *suffocation*. 3. In the state of secondary fever, that is, between the fourteenth and twenty-first days of the eruption, death may take place in three ways—either by violent febrile excitement with effusion on the brain; or by sloughing, gangrene, and destruction of large portions of the surface; or lastly, by supervening pleurisy, peripneumony, or laryngitis. 4. At a still later period, that is, after the third week from the appearance of eruption, death may take place from mere exhaustion, or from erysipelas and superadded fever.

Morbid appearances.—It has been remarked from the earliest periods that the internal organs do not suffer in small-pox so extensively or so frequently as might be expected. In a large proportion of cases, the condition of the surface is the sole cause of death. In the throat, however, some very characteristic appearances present themselves, provided death has taken place between the seventh and twelfth days of the eruption. The pharynx, larynx, and trachea are then found covered with a copious, viscid, puriform, or purulent secretion of a grey or brownish colour, thrown out by the numerous vesicles which had formed upon the mucous membrane of those organs. The mucous membrane itself appears thickened, pulpy, and in the worst cases black and sloughy.

There is no point wherein pathologists have more widely differed than in this, whether the specific inflammation of small-pox invades the internal parts! The phenomenon has been asserted as a matter of fact by some, while others have, with equal confidence, denied it. Columnius* made a vast number of dissections with a special view to ascertain whether

* De Sedibus Variolarum, passim.

any of the viscera were the seat of variolous pustules. His conclusion is, that they are exclusively confined to the skin, and those mucous membranes which are in direct contact with the external air. There can be no doubt that this opinion of Cotunnius is strictly correct. Inflammation may originate from accidental causes in any internal organ during the progress of small-pox, and its effects will be seen after death; but these are not to be confounded with, or mistaken for, the specific effects of small-pox on the skin and mucous expansion of the throat and chest.

When death has taken place in the third week from the appearance of eruption, the pleura will sometimes be found inflamed, and coated with layers of coagulable lymph, while in the corresponding cavity of the thorax, purulent matter or a sero-purulent fluid will be collected, often in enormous quantity, compressing by its bulk the lung of that side into a small space. Occasionally a portion of the lung itself is found infiltrated with pus.

In some cases, where great determination of blood to the head has been indicated during life by swelling of the head and face, delirium, headach, and high fever, the bloodvessels of the brain and its meninges are found turgid, with more or less of effusion into the ventricles.

Nothing is more worthy of notice than the freedom of the abdominal viscera from all traces of disease in those who die of small-pox. Among the numerous dissections made at the Small-pox Hospital, we have never been able to detect variolous pustules on the mucous membrane of the intestinal canal. Ulceration of the bowels indeed sometimes takes place in children during the violence of the secondary fever, but differing in no respect from that which occurs in other and more familiar forms of hectic fever.

Pathology.—For more than a thousand years after the first appearance of small-pox, this disease was considered by physicians to have its origin, like other fevers, either first, in some state of the atmosphere, or secondly, in some vitiated condition of the humours of the body. A large portion of the community at the present day are of the same opinion, and confidently believe that the small-pox is, to use their own expression, bred in the blood. The pathologists of the last century, however, from the time of Boerhaave, reasoning from the very peculiar train of symptoms observed in small-pox, and from the comparatively recent date at which it became known, adopted the notion that this disease is in all cases the product of a specific poison or contagion, received into the blood from without. Such is still the general opinion of the best informed physicians. It cannot indeed be denied that great difficulties are experienced in tracing the source of contagion in numberless cases, and that the doctrine of *spontaneous* origin admits of being supported by some ingenious and plausible arguments; but the weight of evidence is decidedly in favour of the invariable origin of small-pox by *contagion*. How the variolous poison was first generated is wholly unknown. A tradition has been handed down by the Arabian physicians* that it was originally derived from the camel, but no substantial reasons for such an opinion have ever been advanced.

The peculiar miasm or morbid matter of small-pox is receivable into the human body in three modes: first, by the lungs through the medium of the respiration: this is called the mode of *infection*. Secondly, by application of the matter to the unbroken surface of the skin or mucous membrane of the nose. This is properly denominated *contagion*, although the terms infection and contagion are generally made synonymous. Thirdly, by application of matter to the wounded surface, which is the mode of *inoculation*.

The diffusion of small-pox by the air in the mode of infection, as thus defined, presents many interesting peculiarities. It takes place much more energetically in certain states of the air than in others. Occasionally the atmosphere appears to be altogether incapable of disseminating the poison. That peculiar, or, as it is sometimes called, *epidemic*, constitution of the air which is so favourable to the propagation of small-pox, is not at all understood. It is neither appreciable by the thermometer, the hygrometer, nor the barometer. Small-pox spreads sometimes in a dry and warm, sometimes in a cold and moist state of atmosphere. The phenomenon may possibly depend upon some electrical state of the air, which has hitherto eluded the researches of philosophers, but which time and closer observation may perhaps eventually succeed in discovering. It has been supposed that the peculiar condition of the atmosphere predisposing to the dissemination of the variolous germ recurs every five or seven years, but no adequate grounds for this opinion appear to exist. Dr. Haygarth† has taken great pains to ascertain the sphere of contagious influence in the case of small-pox—in other words, the distance to which the contagion extends beyond the person of the individual affected. He inclined to the opinion that it was very limited, not exceeding a few feet. There is reason to believe, however, that some fallacy exists in the experiments made to determine this point, and that the distance at which the poison ceases to be energetic is much greater, varying, however, according to the condition of the atmosphere.

Effluvia capable of communicating small-pox are generally considered to be given off by the lungs as well as by the skin, and at every period of the disease from the earliest to the latest. Drs. Haygarth and Heberden maintained‡ that prior to the appearance of eruption, and even for the first two or three days after, a patient is seldom if ever found to communicate infection. We have already, however, expressed our belief, founded on facts within our own knowledge, that even

* See Baron's Life of Jenner, p. 522.

† Inquiry how to prevent the Small-pox, p. 78. 1801.

‡ Ibid. p. 47 and 216.

prior to the occurrence of eruption, while the body is labouring under the premonitory fever, the secretions are infectious. It is admitted by all that the contagious property hangs about the body as long as any scabs remain, which may be said to contain the poison in a concentrated form. Again, it has been well ascertained* that for some considerable period after death the matter of the pustules continues energetic, and that a confluent case will so taint the air as to spread the disease, by infection, for at least ten or twelve days after death.

All mankind, with few exceptions, are susceptible of the variolous poison at some period of their lives. It has been received by the fœtus in utero, by the infant immediately after birth, and by the adult, up to the most advanced period of human life. As a general law, it may be stated that the susceptibility of small-pox is equally great at all ages, but it often happens that a particular individual shall resist infection at one period of his life and receive it at another. Some constitutions imbibe this morbid germ mildly, others with great alarm. In such cases the nervous system may truly be said to be *poisoned* by it. A full and plethoric habit predisposes to a confluent and malignant form of the disease. Huxham has well remarked that the ebullition of the fluids consequent on the circulation of the poison in such persons is, *cæteris paribus*, most severe and dangerous.† Hence the great mortality of the disease in that class of adults who indulge in full living, with a large allowance of ale and porter. At the same time, it must be remembered that the opposite state of body, extreme weakness, is equally unfavourable for the quiet reception and safe elimination of the variolous poison.

The *quantity* of eruption is sensibly influenced by the state of the surface at the period of its developement. Great heat of the apartment, the warm-bath, the use of strong diaphoretics, abundance of bed-clothes, and the local irritation of blisters, all favour confluence. It might be expected that cold would possess some power in diminishing the number of papulæ. It must be confessed, however, that though by injudicious measures we may often aggravate the quantity of eruption, we possess few or no means of lessening it. The character of the disease is not with any certainty influenced by the source whence the infection was derived. The mildest form of what is called varioloid eruption will communicate to another the most confluent and malignant disorder.

Variolous effluvia are very volatile. A free ventilation, therefore, is the most effectual means which we possess of diminishing the danger of contagion. The clothes and bedding of a small-pox patient, if closely wrapped up, will retain and give out the disease to others at great distances of time; while medical men who visit small-pox patients and subsequently go into the open air, seldom if ever communicate the disorder. Dr. Haygarth is of opinion that they never do. Be this as it may, variolous effluvia are rendered comparatively innocuous by dilution.

A few persons pass through a long life apparently insensible to, or unsusceptible of, the small-pox virus. It is a curious and important circumstance that, so far as is yet known, such constitutions exhibit a like inaptitude to receive and nourish the vaccine disease.*

Recurrent small-pox.—Few facts in medicine are better ascertained than that once undergoing small-pox gives to the individual through life complete immunity from future attacks. Exceptions to this law, however, have undoubtedly occurred. They have been noticed in all ages, and stand recorded in the writings of almost all authors who have treated of small-pox.† They are, nevertheless, comparatively rare occurrences, and many persons, practising extensively, have never seen even a single case of the kind. There is no instance recorded of a patient being received twice into the Small-pox Hospital. Second attacks of small-pox, when they do occur, are generally, so far as our own experience extends, different in their character from the first: when the first attack, that is to say, has been severe and unequivocal, the second has been light and trivial, and *vice versâ*. Sir Gilbert Blane remarks‡ that "almost all the well-authenticated cases of second small-pox have been of those persons who in the first instance had undergone it in its most severe and dangerous form." This would seem to connect the recurrence of small-pox with a peculiar proneness in such a constitution to suffer under the variolous germ. Others, again, have attempted to explain this phenomenon on the supposition that the first attack did not perfectly saturate the system. Instances of death from recurrent small-pox are not common, but they are to be found recorded in authors of undoubted veracity. It has been alleged that second attacks of small-pox are more frequent after the inoculated than after the casual disease, but Baron Dimsdale, a high authority on such matters, denies this. A predisposition to receive small-pox more than once has been stated to exist in certain families.

Concurrence of small-pox with other exanthemata.—Among the peculiarities of the contagion of small-pox, the possibility of its simultaneous occurrence with other exanthematous diseases deserves mention. Several cases have been recorded wherein measles and small-pox have appeared together,§ and both diseases have run their regular course uninfluencing each other. Such cases, however, are very rare. It has occurred to us to see at the Small-

pox Hospital several unequivocal cases of the simultaneous existence of small-pox and scarlatina anginosa. Small-pox and cow-pox may sometimes be seen together, each running its natural course, but in general, under such circumstances, one or other disease is modified. This subject will be more fully discussed when treating of vaccination.

Communication of small-pox to the fœtus in utero.—A number of facts illustrating this very curious subject have been collected together by Dr. George Pearson.* From them it appears that the small-pox does not often extend from the mother to the fœtus; that whenever it is so taken, it is fatal in almost all cases to the fœtus; that inoculating a pregnant woman generally destroys the life of the fœtus, and, lastly, that the disease in the fœtus and mother is scarcely ever in the same degree of intensity. Dr. Jenner has published two cases† in which the fœtus in utero took the disease from the mother, without the mother being herself affected, though exposed, of course, to the contagion. Mead entertained the fanciful notion, that if a pregnant woman underwent small-pox without aborting, the child would remain through life unsusceptible of small-pox.

Treatment.—1. It is seldom that opportunities offer of treating this disease in its initiatory stage, for its existence is generally unsuspected until the eruption manifests itself. The eruptive fever of small-pox, therefore, supposing its nature unknown, would be managed like other forms of inflammatory fever. Blood would be taken from the arm, when the pain of the epigastrium or of the head were urgent. Saline medicines in a state of effervescence would be given to lessen the feverish excitement and to allay the irritable state of the stomach. Coldness of the extremities would be met by hot bottles to the feet, sinapisms, and the pediluvium. When from concurrent circumstances, especially a known exposure to contagion, the real nature of the disease should be ascertained or very strongly suspected, the plan of treatment would not be materially different from this. Bloodletting would not then be repeated under a confident expectation that the appearance of eruption would speedily relieve the symptoms. Leeches to the temples would be advisable, provided the headach continued urgent. The bowels should be relieved by injections and the milder kinds of aperients. All drastic purgatives should be then avoided. The saline diaphoretics might be advantageously directed, with the addition of an opiate at night, in cases accompanied by much delirium. Bleeding from the arm is not found to afford relief to that specific affection of the brain and nervous system which ushers in a certain proportion of the severe cases, and accompanies their maturative stage for the first three or four days. Leeches, cold lotions to the head, aperients, and an anodyne at night, offer a better prospect of relief. The antiphlogistic regimen is to be pursued in all its details.

2. During the period of maturation the following plan of treatment is to be recommended. When the stomach remains irritable, with a tardiness of eruption on the extremities, a blister may be applied to the epigastrium, and frequent pediluvia administered, made more stimulating by the addition of mustard-powder. Pain of the fauces with difficulty of swallowing is benefited by the application of leeches to the throat, followed by fomentations made of camomile-flowers or poppy-heads. The bowels are to be duly regulated by aperient draughts, consisting of senna and salts, castor-oil, or jalap with cream of tartar, in sufficient doses to insure one motion daily, or two motions, if the degree of fever requires it. The action of the kidneys in like manner is to be encouraged by frequent doses of the citrate of potash, the liquor ammoniæ acetatis, or any similar mild diuretic. An opiate consisting either of laudanum, of the liquor opii sedativus, or of Dover's powder, may be given at bed-time, if there be any considerable degree of restlessness or of irritation of the skin.

When the surface is tender and painful to the touch, with much heat, cooling lotions may be applied with considerable advantage. Under all circumstances the diet is to be regulated as in other cases of inflammatory fever. Lemonade may be given for common drink, and Sydenham's strong recommendation of small-beer may be unhesitatingly adopted.

Symptoms indicating local inflammation must be met by appropriate means. When cough and copious expectoration of a puriform mucus occur, and give evidence that inflammatory action has spread to the smaller branches of the bronchi, blood should be taken from the arm to the extent of twelve ounces, and repeated according to the exigences of the case, bearing always in mind the drain upon the system which an extensive pustulation will ultimately occasion. When headach, a flushed face, redness of the eye, and activity of the carotid and temporal arteries denote the presence or probable approach of phrenitic inflammation, particularly in persons of plethoric habit, blood must be taken from the arm freely. In the same habit of body it is sometimes advisable to take blood from the arm to moderate the violence of inflammatory action upon the surface, and to lessen the danger during the state of secondary fever. In all these cases the blood will be found buffy, and generally in a high degree. Ophthalmia occurring during the maturative stage is generally relieved by leeches to the temples, a strong purgative of calomel and rhubarb, and lotions containing Goulard and the extract of poppies. In all cases of small-pox it is desirable to keep the chamber darkened to guard as far as possible against this occurrence, and for the same purpose, as well as for the general comfort of the patient, the hair should be taken off at an early period of the disease.

* Duncan's Medical Commentaries, vol. xix. p. 213.

† Medico-Chirurgical Transactions, vol. i. p. 269.

3. The treatment of small-pox during the stage of decline and secondary fever is to be regulated on the following principles. When the disease is mild, a few doses of purgative medicine are useful, to keep down feverish excitement, and to carry off foul secretions, or, in the language of the vulgar, to get rid of the dregs of the disorder. Where the disease has been more severe and secondary fever has set in, the excitement is to be allayed by occasional doses of antimonial powder with calomel, followed by an active aperient. The propriety of purging during the secondary fever of small-pox was for a long period the subject of keen controversy, but the question was satisfactorily settled in its favour. Calomel and rhubarb, senna and salts, and castor-oil are the forms of purgative which will generally be found to answer best.

Bleeding from the arm is seldom advisable in the course of secondary fever, unless accidental and superadded symptoms, such as pleurisy or coma, occur to render it necessary. When the face continues swollen, with tendency to delirium and a very dry skin, leeches should be applied to the temples. In those aggravated cases accompanied with the destructive form of ophthalmia already described, little can be done for the assistance of the patient. The loss of blood which the intensity of the symptoms indicates would be followed by great and rapid exhaustion. To save the patient's life, therefore, the eye must sometimes be sacrificed.

The period of secondary fever is frequently accompanied with symptoms of debility, which call for the employment of tonic and cordial remedies. If there be a cold surface, a trembling hand, and dry tongue, wine should be administered, together with cordial draughts, consisting of camphor julep, ether, and the subcarbonate of ammonia. When the pustulation is profuse over the whole body, and the consequent drain upon the system great, beef-tea should be given freely, with a liberal allowance of porter, wine, or brandy. In this condition of the surface it is extremely useful to absorb the matter by frequently and largely sprinkling the body with some simple dry powder, such as hair-powder, dried flour, the powder of starch, or of calamine. Starch-powder is the best. When sloughy and gangrenous sores have taken place upon the hips or extremities, reliance must chiefly be placed on the administration of wine and brandy, assisted by cordial draughts containing quinine, camphor, the aromatic confection, and laudanum.

Particular symptoms must be met, as they arise, by appropriate remedies. Pains of the legs are best relieved by warm fomentations made of the decoction of poppy-heads. Extreme debility and nightsweats call for the administration of bark and acid. An ecthymatous state of the surface, with languor and loss of appetite, will sometimes yield, and cicatrization advance, under the use of sarsaparilla and small doses of the pilula hydrargyri. In many cases, however, this troublesome sequela of the disease will not give way except to change of air, the beneficial influence of which is very manifest in the convalescence from all the severer forms of small pox. Erysipelas is to be treated by purgatives of calomel and rhubarb, followed by castor-oil; by lotions to the surface, applied either warm or cold according to the feelings of the patient, and the internal administration of saline diuretics, aided towards the decline of the complaint by the decoction of bark.

When small-pox has called into activity the dormant seeds of scrofula, the tonic and alterative treatment usually pursued in the management of that disorder is demanded, although the most scientific efforts of the physician will then too frequently be baffled. The abscesses and ulcers, as well indolent as irritable, which are so often left by small-pox, are to be treated according to the ordinary rules of surgery. There is no peculiar method which can be devised for the prevention of pits and scars. The masks and ointments formerly in use for that purpose, and so highly vaunted, are in reality more hurtful than beneficial. The application of a little cold cream to the hardened scabs is all that can be recommended.

The greatest attention should be paid during the latter stages of confluent small-pox to the state of the scalp. The matting together of the pustules is apt in this situation to occasion extensive abscesses, which are very troublesome and difficult to heal. To obviate these evils, the hair should be kept close cut, the scalp, when hot, should be covered with cold lotions, and purgative medicines administered, to relieve that determination of blood to the head on which the occurrence mainly depends.

Modified Small-Pox.

Small-pox taken casually by those who have undergone no preparatory process of any kind, is sometimes of an exceedingly mild character. The pustules, though perhaps very numerous and close set, do not run into each other, but maturate separately, and *turn*, as it is called, on the fifth day. The eruption feels hard to the touch, and is of the kind commonly denominated seedy or horny. In the works of the oldest authors on small-pox a description of the variety called *horn-pock* or stone-pock may be found.* It is a fair presumption that such natural mildness of disorder is attributable to some fortunate peculiarity in the constitution of the patient.

When small-pox occurs a second time, whether after inoculation, or after the disease casually taken, the second attack is very often of a spurious or anomalous kind. The papulæ are prematurely surrounded with an imperfectly formed areola; some are developed and pustulate; others harden and die away. The eruption is limited to the face, or, at furthest, extends only to the face and trunk. Such instances of a spurious or modified small-pox are recorded in all the old writers, and do not appear to have been of unfrequent occurrence. Their close resemblance to cases of common chicken-pox gave occasion to much ambiguity,

* Van Swieten's Commentaries, vol. v. p. 10.

and even dispute concerning the identity and relations of these diseases.

Since the discovery of vaccination, the milder varieties of small-pox have greatly increased in frequency, so as at the present time to be familiar to every one engaged in practice. Vaccination may be said to have multiplied prodigiously the number of constitutions that imbibe the small-pox mildly. It has generated a sort of artificial habit favourable to the peaceful reception of the variolous virus. It becomes now, therefore, an object of considerable importance to investigate carefully the phenomena of the mitigated or modified small-pox. It is reserved for a future opportunity (see VACCINATION,) to explain the circumstances under which small-pox occurs after cow-pox, and the presumed causes of such an occurrence. All that we now propose is to state the appearances which small-pox presents at some considerable interval of time after vaccination, as, for instance, ten or twenty years.

In a certain limited number of such cases, even when the proofs of correct vaccination have been most undeniable, the small-pox has been found to run its regular course unaltered in its symptoms, and unmodified in any of its features. We cannot, therefore, be surprised if it has sometimes, when so occurring, proved fatal. In an infinitely larger proportion of cases, however, the small-pox, when it attacks an individual who in the early period of life has felt the full influence of vaccination, is altered or modified, as well in its primary aspect as in its subsequent developement and progress. No reasonable doubt can be entertained, from the abundance of facts now before the world, that such modification is the *law* of the animal economy, and that the regular or normal progress is the *exception*.

It does not appear, however, that the modifying power of vaccination displays itself in the incubative stage. In the modified as in the natural disease, the same interval of time elapses between the reception of the variolous germ, the first developement of symptoms, and the subsequent appearance of eruption. The same pain of back attends the initiatory fever. The same constitutional disturbance, as well in kind as in degree, precedes the eruption. But though the primary fever rages uncontrolled by vaccination, its influence is often perceptibly seen at the very first appearance of the papulæ. The eruption is both less in quantity, and more limited in extent than in the common forms of the disease. It shows itself in the face and breast, and not at all, or very scantily, on the extremities.

In many cases, indeed, this description does not apply. The eruption is profuse, and equals, both in extent of surface affected and in quantity, the worst cases of natural confluent small-pox. The modifying power, however, begins to show itself almost immediately afterwards. The feverish excitement, which with such a state of surface might be expected to run high, subsides entirely. Some of the papulæ never advance at all towards maturation, while around others an imperfect attempt to form areolæ may be observed as early as the second or third day. The course of the disease is then so rapid, that by the fifth day the pustules on the face have maturated. The pocks are horny and speedily desiccate, leaving however, for a considerable time afterwards, tubercular elevations of the skin surrounded often by a mottled redness. During the progress of this imperfect maturation the patient is generally able to walk about. He enjoys a good appetite and sound sleep. The unsightliness of the eruption alone disturbs him. No inflammation of the cellular membrane interrupts the period of convalescence. No pits remain to attest the violence of the disorder.

We are warranted, as well by etymology as by the custom of old authors, in applying to this mild form of small-pox the term varicella; but to distinguish it from another disease which has received the same name, (the genuine or infantile chicken-pox,) we may with propriety call this the *varicella variolodes*. It resembles the true chicken-pox in the mildness of the external inflammation and the absence of all severe constitutional excitement. It differs from it, however, in its undoubted origin from the variolous germ, and in its power of communicating the most perfect small-pox to others, as well by inoculation as by infection.

In some cases, especially where the interval from the date of vaccination has been short, small-pox in the vaccinated shews itself in a form so singularly mild that the real nature of the disorder can be with difficulty ascertained. In fact, none but those who are in the constant habit of seeing such cases, of tracing them to their source, and observing the minute gradations by which the several kinds of small-pox run into each other, could recognize them. A few scattered pimples perhaps are all that exist to attest the fact, but these pimples, in their progress to maturation, will be found to exhibit (with or without the aid of the microscope) that great and undoubted criterion of variolous origin, *depression of their centres*. The diagnosis is aided by carefully inquiring into the history of the initiatory fever, and observing if forty-eight hours have elapsed between the occurrence of rigor and the developement of papulæ. It is put beyond dispute by tracing the source of the disorder to some case of undoubted variola, at the distance of eight to fourteen days, or by its simultaneous occurrence with other cases in which the character of the disease is unequivocally displayed.

Such are the phenomena of small-pox as it usually presents itself in those who have undergone regular vaccination in early life. It remains to state that every intermediate degree between the thoroughly confluent and the mildest varioloid will sometimes be seen. It is seldom, however, that any severe affection of the bronchial passages is witnessed. A few vesicles may be observed on the tongue and soft palate, but they seldom extend to the larynx. Affection of the brain and nervous system is more common. Intense delirium may often be found accompanying a very modified aspect of

eruption, giving rise to much anxiety and some real danger. The cause of this anomaly generally exists in the peculiar habit of the individual. He will be found to be a person of an irritable or nervous temperament, and who has probably displayed, on some former occasion, a similar occurrence under the pressure of acute disease.

Small-pox after vaccination very rarely exhibits dissolution of the fluids, hemorrhages, and the other phenomena of malignancy. Such an occurrence has been witnessed, and followed too by a fatal result, but it must be looked upon as the most rare of all observed deviations from the ordinary course of the modified disease.

Inoculated Small-Pox.

Small-pox existed in the world, and had been studied by physicians for at least a thousand years, before any idea prevailed that its course could be controlled and its virulence assuaged by any artificial means. When, where, and by whom this great discovery was first made is not accurately known. It has been conjectured that it had its origin in the countries bordering on the Caspian sea, Circassia and Georgia, but the opinion rests upon no adequate authority. Nor can we place much more reliance on the statements which have been made as to the antiquity of inoculation in China and Hindostan. Our first accounts of it are derived from Constantinople, and there, towards the close of the seventeenth century, inoculation must be considered as having had its origin.

About the year 1703, rumours of the great success of this operation attracted the attention of Dr. Emanuel Timoni, a Greek physician, who had studied and graduated at Oxford. He subsequently settled in Constantinople, and being convinced of the importance of the discovery, wrote an account of it in 1713 to his English correspondent Dr. Woodward, which, in the following year, was published in the Philosophical Transactions. In 1715, Dr. Pylarini, the Venetian consul at Smyrna, having also learnt the success of this Turkish practice, published an account of it at Venice. A notice of this work appeared in the Philosophical Transactions for 1716, and these favourable accounts were fully corroborated by the reports of Mr. Kennedy, (an English surgeon, who had travelled in Turkey) in his "Essay on External Remedies," published in London in 1715.

No notice, however, was taken of these important facts by any English physician, and the idea of transplanting or engrafting small-pox (as the process was called) was well-nigh forgotten in London, when the celebrated letter of Lady Mary Wortley Montague appeared, which described the practice in so lively a manner as to attract public attention.* "The small-pox," she writes, "so general and so fatal amongst us, is here entirely harmless by the invention of *engrafting*, which is the term they give it. There is a set of old women who make it their business to perform the operation. Every year thousands undergo it, and the French ambassador observes pleasantly that they take the small-pox here by way of diversion, as they take the waters in other countries. There is no example of any one that has died in it, and you may believe I am well satisfied of the safety of the experiment, since I intend to try it on my dear little son. I am patriot enough to take pains to bring this careful invention into fashion in England." She kept her word, and to the spirit and enterprize of this lady the introduction of inoculation into this country is altogether due. It was not until her return to London that any attempt was made to profit by a discovery which had been announced for five years; and her own daughter was reserved to be the first example of inoculation in England. This event occurred in April 1721, and as its success was complete, Dr. Keith, who had been witness to the experiment, submitted his child to the same process, and with a like happy result. Several months elapsed, but the medical profession in London still remained sceptical; some, because the practice originated with ignorant old women, and others from inability to understand the rationale of the process.

The next step was to obtain a pardon from King George I. for six condemned criminals, on condition of their submitting, by way of experiment, to inoculation. This was effected through the agency of the Princess of Wales, who was anxious to follow Lady Mary's example, and to secure her own children by the new process. These and some other trials having been deemed satisfactory, the Princesses Amelia and Caroline were inoculated on the 19th April, 1722, the former being then eleven and the latter nine years of age. Both of them passed through the small-pox favourably; but the new practice, begun under such brilliant auspices, received a severe check in the death of three persons, (one of them a child of the Earl of Sunderland,) which happened within a few days afterwards.

Cotemporaneous with these experiments in London were those performed at Boston in North America, by Dr. Boylston, on the authority of Timoni and Pylarini. 244 persons were inoculated by him in Boston and its neighbourhood between June, 1721, and January, 1722, of which number six died. The subjects, however, were ill chosen, and the operator betrayed both ignorance and rashness. Dr. Boylston, however, deserves credit for having been the first to remark that the period of incubation is shorter in the inoculated than in the natural small-pox, and that the former may be employed to supersede the latter.

When these occurrences at Boston became known in London, the clamour against inoculation increased. Objections were made to it both in a medical and moral point of view. By Dr. Wagstaffe it was declared to be unsafe, and by the Rev. Mr. Massey impious. Under these discouraging circumstances, it is hardly to be wondered at that the practice of inoculation advanced but slowly. Prejudice and mismanagement combined to throw obstacles

* Vol. ii. Letter 31, dated April 1, 1717.

in its way. It was calculated that during the first eight years only 897 persons were inoculated throughout the whole of Great Britain, of whom seventeen died.

By slow degrees the medical profession became convinced of the advantages of inoculation, but it was not until the middle of the last century that it was practised in England to any considerable extent. Several circumstances contributed about this period to bring it into repute. In the year 1746 the Small-Pox and Inoculation Hospital of London was founded, for the express purpose of extending to the poor the benefits which had hitherto been almost exclusively confined to the rich. The results of the practice in the hospital were eminently favourable to the cause of inoculation. In 1747 Dr. Mead, then in the zenith of his fame, published his work *De Variolis et Morbillis*, and in a chapter expressly treating of inoculation, adduced many cogent arguments in support of it. In 1754 the Royal College of Physicians of London put forth a strong approbation of inoculation; but the popularity which it ultimately acquired is mainly attributable to the improvements which, in 1763, the Suttons introduced in the mode of conducting the process.

Robert and Daniel Sutton were sons of Mr. Robert Sutton, surgeon, of Debenham in Suffolk, who had acquired some celebrity as an inoculator. Both followed their father's profession. The former established himself as a professed inoculator at Bury St. Edmund's, and the latter at Ingatestone in Essex. The success which attended Daniel (the cleverest of the family) at Ingatestone was unparalleled, but he fairly earned it by the boldness and dexterity of his management. The peculiarities in his system of inoculation were chiefly the following:—he reduced the preparatory process from a month to a week; he employed very freely, during the whole period, a strong purgative powder, containing calomel and emetic tartar; he inoculated by means of a single puncture; he exposed his patients freely to the coldest air prior to and during the eruption, and prescribed cooling drinks and a spare diet. There was nothing new in the plan. Lady Mary Wortley Montague had stated that the Turkish children were suffered to play about in the open air during the period of eruption; Sydenham taught the value of the cool regimen; and the purgative powder had been introduced from North America. The merit of the inoculator consisted in the skill with which he selected what was beneficial in the several plans already known.

The system of Daniel Sutton was ably followed up by Baron Dimsdale, who enjoyed a high reputation and extensive practice, and whose admirable treatise on inoculation* (1779) contains everything then known on the subject. Nor was any further improvement attempted. For twenty years the mode of practice recommended in Dimsdale's work was adhered to, and the result was, that in every succeeding year inoculation became both more popular and more successful. The close of the century, however, which saw the rise of inoculation was destined to witness its fall. In 1798 Dr. Jenner announced the discovery of vaccination, almost immediately after which the general practice of inoculation declined, and has never since been revived.

Theory of inoculation.—The object of inoculating is to secure a mild form of the disease, and this result follows in a very large proportion of cases. No adequate explanation has ever been offered of the singular fact, that mildness of the disease should be occasioned by the germ being received into the system by means of the cutaneous vessels. Something, it has been said, may be attributed to the influence of the preparative process, but this explanation will not go far when we reflect that the same means applied during the incubation of the natural disorder are not productive of the same effects.

The beneficial influence of inoculation is displayed not only in moderating the quantity of eruption, but in determining the whole force of the disease upon the surface. In a very large proportion of inoculated cases, the eruption is of the distinct sort, and moreover widely scattered. An efflorescence (roseola exanthematica) frequently precedes for one or two days the developement of the true variolous papulæ. Sometimes a full and confluent crop is produced, but under these circumstances it is very seldom that the mucous membrane of the pharynx and larynx become implicated to any dangerous extent. The cellular membrane, in like manner, is rarely involved in the inflammatory action, so that the disease is then properly characterized as *confluent superficial*. Secondary fever, therefore, is rarely met with in the latter stages of inoculated small-pox; and further, that affection of the fluids which constitutes the leading feature of acute malignancy is almost or altogether unknown as a consequence of inoculation. The result of all this is, that the mortality by inoculated small-pox is very small indeed, and bears no sort of proportion to that of the casual disease. The average number of deaths at the Inoculation Hospital was only three in a thousand. In the wards appropriated to the casual disease the deaths were (and continue to be) three in ten!

Practice of inoculation.—According to the statement of Lady Mary Wortley Montague, the old women of Constantinople "opened with a large needle one or more of the veins of the arm or leg, and put into the wound as much matter as would lie on the head of the needle, afterwards binding it up with a hollow bit of shell." This simple mode was first followed in England, but it was afterwards supposed more desirable to have large wounds, which might ensure a more plentiful discharge of matter. For this purpose incisions were made three quarters of an inch in length, and deep enough to penetrate through the skin; and some cotton charged with variolous matter was laid on them for twenty-four hours, and retained

* The present Method of Inoculating for the Small-Pox, by Thomas Dimsdale, M.D. seventh edition, 1779.

there by means of a plaster.* Another mode of giving the small-pox, said to have been first practised in China, consisted in inserting crusts or cotton charged with variolous matter in the nostrils. These rude practices were very injurious to the cause of inoculation, and they have long since yielded to the simple expedient of making a *single* wound with a lancet armed with fresh variolous matter in any convenient part; and by a sort of general consent, the arm, at the insertion of the deltoid muscle, has been selected for the purpose.

It is of little moment at what period of the disease the matter for inoculation is taken, but thin, limpid, or *crude* lymph of the fourth and fifth days is generally preferred to the purulent or well-concocted matter of the eighth and ninth days. It is of as little importance whether the matter be supplied by a distinct or a confluent, a casual or an inoculated case. The Suttons preferred the crude lymph of a *primary* inoculated vesicle. Common sense would dictate the propriety of rejecting a case of extreme malignancy.

The best age for inoculation is from the third to the sixth month from birth, and again, after the period of dentition is passed. Adult persons in the middle periods of life may be inoculated with perfect safety, due attention being paid to the habit of body. Season has but little influence upon the results of inoculation, but, *cæteris paribus*, the extremes of heat and cold should be avoided. The spring season was generally preferred by the professed inoculators in England. At Constantinople the month of September was the period usually selected.

The circumstance chiefly to be dreaded in inoculated small-pox is an inflammatory state of the blood. Hence it is that the only preparatory measures of any importance are such as have for their object to repress this tendency. A dose of purgative medicine should be given prior to the operation, and two or three more during the period of *incubation*. The purgative should consist of calomel, combined either with antimonial powder, emetic tartar, or powder of jalap. The patient is to be restricted to a spare vegetable diet. He should sleep in a large airy apartment, without a fire, and during the day should be exposed freely to the cold air. The influence of cold in repressing the quantity of eruption was strikingly manifested in the practice of the Suttons, and constituted, in fact, the principal peculiarity of the Suttonian system.

Phenomena of inoculation.—On the second day after the operation, if the part be viewed with a lens, there appears an orange-coloured stain about the incision, and the surrounding skin seems contracted. On the following day a minute papular elevation of the skin is perceptible, which on the fourth day is transformed into a vesicle with a depressed centre. The patient perceives an itching in the part. On the sixth day, some pain and stiffness are felt in the axilla, proving the absorption of the virus into the general mass of blood. Occasionally on the seventh, but oftener on the eighth day, rigors occur, accompanied sometimes with faintishness, sometimes with pain of the back, headach, or vomiting. The patient complains of a disagreeable taste in the mouth, and the breath is offensive, soon after which the eruption shews itself.

The incision in the arm, when viewed through a glass, now appears surrounded with an infinite number of small confluent papulæ, which daily increase in size. On the tenth day an areola or circle of inflammation forms around the inoculated point, now distended with matter. This areola is irregular in shape, and in its progress becomes interspersed with numerous minute vesicles. By the fifteenth day the primary pustule has scabbed, and the eruption on the body generally has begun to maturate. By the twenty-first day, in the great majority of cases, the disease is wholly at an end. The number of papulæ dispersed over the body is subject to great variety. In some cases not more than two or three are perceived. It is important to know that an eruption is not indispensable to the success of inoculation. In some cases the full change has been produced upon the frame, and a complete insusceptibility to future attacks given, by means of the single pustule excited artificially upon the arm.

Treatment of inoculated small-pox.—In mild cases nothing is required but one or two doses of simple aperient medicine, such as the infusion of senna, with manna and Epsom salts. In cases of greater severity we are to proceed in the manner already directed for the natural small-pox.

The objections which have been urged against inoculating for the small-pox, and which have caused the abandonment of the operation, are the following. Although in many instances the subsequent disorder be slight, still it is sometimes severe, and occasionally brings life into hazard. It often proves the exciting cause of other disorders, and more especially calls into activity the scrofulous taint. But more than all, it is urged against small-pox inoculation that it adds to the danger of the public by multiplying the foci of variolous contagion,—that it preserves one life at the risk of many. This objection to inoculation, which has been so strongly insisted on of late years by almost all writers, was long since fully appreciated. Dr. Watkinson, Dr. Schwencke, and others, in the year 1777, attempted to obviate it by shewing that the diffusion of variolous contagion takes place only in certain epidemical states of the air; that when such a condition of atmosphere prevails, the disease would propagate itself quite as widely, independent of all cases artificially excited; and when it was not present, inoculation would be perfectly harmless. The argument is ingenious, and certainly calculated to shew that this charge against inoculation has been overstated. It might seem easy to determine the point at once by reference to the Bills of Mortality, where a gradual augmentation of deaths, in proportion as the

* Woodville's History of Inoculation, p. 99.

practice of inoculation extended, will at first sight appear. Dr. Adams, however, very justly remarks* that this argument is more plausible than solid, for in the first place, admitting the fact to be as stated, there has been a corresponding increase in other diseases, not communicable by inoculation; and, secondly, the statements may be so put as to shew a diminution rather than an increase. Thus, in the thirty years between 1741 and 1770, there died of small-pox, according to the Bills of Mortality, 63,308; whereas in the next thirty years (viz. from 1771 to 1800) there only died 57,268.

Although, then, it would be difficult to support this objection against inoculation by a reference to statistical tables, it is obvious that it must necessarily contribute to diffuse the contagion, and so far therefore is an evil. Notwithstanding this defect, however, and others already adverted to, inoculation must still be viewed as a most valuable discovery, and a merciful provision of nature against the ravages of a dreadful pestilence.
