CONTENTS OF THE THIRD VOLUME.

THE

CYCLOPÆDIA

OF

PRACTICAL MEDICINE.

JAUNDICE. (Ἴκτερος, *icterus*, *morbus regius*, *aurigo*, *&c.*) Jaundice is a disease of rather frequent occurrence, characterized by a yellow colour of the eyes, skin, and urine, and by the white appearance of the alvine evacuations. In addition to these general symptoms, the malady is frequently attended with extreme depression of spirits, languor, inactivity, and watchfulness; with a bitter taste in the mouth, thirst, loss of appetite, nausea, or vomiting; a sense of fulness or other uneasiness, if not also actual pain, at the epigastrium; occasional shiverings and profuse perspirations; a distressing degree of itching in the skin, and rapid emaciation. The urine soon becomes of a deep mahogany colour, yet gives a bright yellow tinge to substances immersed in it. The state of the bowels is variable, being in some cases relaxed, in other cases confined, but generally acted upon with facility by mild aperients.

The circumstances which *predispose* the system to an attack of jaundice are numerous. The melancholic or leucophlegmatic temperament, under mental excitement, whether of a pleasant or painful nature; an indolent mode of life, sedentary occupations, a full and stimulating diet, and habitual constipation, are among the most powerful. The occasional or *exciting* causes of the disease are chiefly such as either suddenly stimulate the liver to an increased secretion of bile, or obstruct the free egress of that fluid. Thus, a heated atmosphere, strong muscular exertions, sudden and powerful emotions of mind, spirituous or other fermented potations, a large and indigestible meal, fæces impacted in the transverse colon, pressure from a gravid uterus, may induce an attack of jaundice.

The *proximate* cause or essential nature of the disease evidently consists in an obstruction to the passage of bile in its course from the liver or gall-bladder to the duodenum, in consequence of which it either retrogrades into the bloodvessels of the liver, or is absorbed from the surfaces of the biliary ducts. There are many morbid conditions of the liver and its appendages, as well as of the adjacent organs, which may induce such an impediment. Not a few of these have been ascertained by the most conclusive evidence. Others, originally devised by the fertile imaginations of nosologists, and considered as adequate to the production of jaundice, have been successively handed down from author to author, not as merely probable causes, but as legitimate deductions from established facts. Instead, however, of specifying the greatest number of morbid conditions which may *possibly* give rise to jaundice, we shall endeavour to comprise, under a few leading divisions, those phenomena alone which pathology has clearly ascertained. Such, we think, may be conveniently arranged under four general heads.

1. Obstructions arising from biliary concretions or other altered conditions of the bile, as well as from worms, hydatids, or other foreign bodies.

2. Obstructions arising from diseased states of the liver, gall-bladder, or biliary ducts.

3. Obstructions arising from morbid conditions of the duodenum.

4. Obstructions produced by the pressure of enlarged contiguous viscera.

1. The first class of obstructions — *those arising from biliary concretions or other altered conditions of the bile itself*—have received an almost disproportionate share of attention from medical writers. The learned Heberden, for example, scarcely seemed to recognize any other causes of jaundice. There can be little doubt that a highly inspissated state of the bile

may alone produce temporary jaundice. In some instances, after great depression of mind and torpor of bowels, the stools become white, and the skin of a dusky-yellow colour. Under the operation of a brisk mercurial purgative, the patient voids a quantity of dark, pitchy, viscid matter, of sufficient tenacity to be drawn out in threads. He becomes immediately relieved, the skin and the alvine dejections gradually resuming their natural colour. Such cases we may warrantably refer to a thickened and vitiated state of the bile, which, in other instances, has been found of the same pitchy tenacious character while contained in the gall-bladder itself.

Biliary calculi unquestionably form a very frequent cause of jaundice. Their mere presence in the gall-bladder does not usually seem to produce either general or local inconvenience. Out of nineteen instances of biliary calculi, which occurred to Morgagni, besides four to Valsalva, in post-mortem examinations, not one had experienced jaundice. Yet a general failure of health has been observed, where, after death, no morbid appearance could be discovered except that of calculi in the gall-bladder.* Dr. Heberden remarks that, "in nearly twenty persons, a supposed pain of the stomach, which had frequently afflicted them for months or years, was at length joined by a jaundice."† In those cases, it is probable that the occasional pain arose from some change in the position of the calculi in the gall-bladder. That they do not always remain in the bile-receptacle with impunity is clearly proved by the testimony of morbid anatomists. Soemmering repeatedly found the mucous lining of the gall-bladder in a state of ulceration, occasioned by the irritation of the contained calculi; while other pathologists have observed a general thickening of its coats, and disorganization of its whole texture.

The *number* of calculi sometimes contained in the gall-bladder is almost incredible. Morgagni took out of one body 3616; and in the Hunterian museum at Glasgow, 1000 are preserved which are stated to have been extracted from one gall-bladder. The form and size of these calculi are very various. In a few instances they have nearly taken the shape and attained the magnitude of the gall-bladder itself, but, generally, are from an eighth to a one-half of an inch in diameter, and of a polygonal form.‡ The broken or divided portions of the larger calculi have sometimes corresponding convexities and concavities, proving that they were once united. And it is not improbable that the smaller calculi are often subdivisions of a larger mass, formed into distinct calculi before consolidation was completed. The sides of these calculi are often flattened as if from close contact and pressure.

The chemical and physical characters of biliary calculi have been already described in this work under the general title of Calculus. In that condensed but highly-interesting article the distinguished author has given a very perspicuous account of the more frequent forms of biliary calculi; but may not have thought it necessary to allude to one or two kinds of uncommon occurrence, which yet, we conceive, may prove of some importance in a pathological point of view. We, therefore, make no apology for introducing them in this place.

The first of these, as we are informed by Professor Turner, was discovered by M. Bizio, of Venice, in a peculiar fluid, quite different from bile, which was found in the gall-bladder of a person who had died of jaundice. It is of a green colour, transparent, tasteless, and of the odour of putrid fish. It is unctuous to the touch, may be scratched or cut with facility, and has a specific gravity of 1.57. M. Bizio has given it the name of *erythrogen*.*

Another remarkable kind of biliary concretion is described by Dr. Marcet, in the following words.† "Within the last few days, I have seen and analysed a large biliary calculus entirely different in its chemical composition from the above description, and, as far as I know, presenting a new fact in the history of these bodies. This concretion contained no adipocire (cholesterine), and consisted wholly of carbonate of lime tinged by bile. It was of a bright yellow colour. It was heavier than water, and measured two inches five-eighths in length, and two inches and a quarter in its largest circumference." This extraordinary production was found in the gall-bladder of a dead body by Mr. Green, (now Professor Green,) demonstrator of anatomy in St. Thomas's Hospital.

The *formation* of biliary calculi is still involved in much obscurity. Many of the circumstances before enumerated as predisposing to jaundice generally, are found peculiarly to favour the formation of calculous concretion. Such are depressing emotions, deficient bodily exercise, a full diet and frequent constipation. Had biliary concretions been always found to consist merely of inspissated bile, there would have been no difficulty in conceiving how the want of exercise and similar causes, by favouring the retention of bile and the gradual absorption of its thinner parts, should ultimately lead to an actual concretion of the residual mass. And that this has sometimes occurred is sufficiently proved. Van Swieten, in his Commentaries, relates the case of a boy whose gall-bladder contained eight pounds of a thick sort of bile, consisting of a number of concentric strata, each stratum becoming firmer as it approached the circumference. There had, however, been no jaundice, although the stools were of a white colour. Biliary con-

† Marcet on Calculous Diseases, p. 151, Note.

cretions, however, very rarely consist of bile alone; and even where an admixture of bile or a distinct stratum of bile does exist, the central portion is generally of a very different nature. Something more, therefore, than consolidation must take place. Either the original secretion of bile must be faulty, or, in consequence of long retention in the gall-bladder, it must undergo some changes by which its constituent parts become disunited or converted into new products. Probably these different states of bile occur in different cases; inasmuch as calculi are sometimes found in the liver itself, and inasmuch, too, as some kinds of calculi approach nearly to the known constituent principles of the bile, whereas others exhibit characters of a very dissimilar kind. May not also the mucous secretion of the gall-bladder become so altered in its nature, in consequence of the long retention of vitiated bile, as itself to furnish nuclei around which the dissociated constituents of the bile, or new formations from it, arrange themselves? The peculiar nature of some of the nuclei, as well as the effect of long-retained secretions on other mucous surfaces, afford some countenance to this idea; although it must be admitted that the gall-bladder, from the adaptation of its structure to its peculiar function as a receptacle, is less likely to suffer from the detention of its contents than other mucous tissues exposed to the long-continued contact of their secretions.

An inquiry into the power by which biliary calculi are propelled forward necessarily involves some interesting points connected with the structure of the gall-bladder and the biliary ducts, which would lead us into a discussion somewhat foreign to the practical object of this paper. We shall merely remark that the effort of vomiting, whether spontaneous or otherwise, has probably a considerable influence in the extrusion of these concretions. Dr. Pemberton, indeed, does not ascribe any such effect to vomiting, unless where a calculus, from its peculiar size and form, entirely blocks up the duct, and obliges the bile to accumulate behind it, thus forming a kind of wedge which thrusts it further forward. To us, on the contrary, the impulse given in the act of vomiting would promise to be more effectual if the calculus did not very firmly or entirely close up the duct, but rather permitted the fluid bile, when strongly impelled, to slip along its sides; in which case, if the quantity of bile were too considerable to pass off quickly by the portion of the duct anterior to the calculus, it must necessarily swell it out, and thus prepare a way for the freer egress of the descending concretion.

We are not aware that any examples are recorded of very large calculi having passed through the biliary ducts; yet there is ample proof of the great distensibility of these passages. Dr. Baillie has seen both the ductus hepaticus and the ductus choledochus enlarged to the diameter of half an inch. When such a degree of distention takes place, there is generally a proportional thickening; in truth, an actual growth in every direction. Most commonly, however, if not always, when concretions much exceed the diameter just mentioned, they are expelled from the system by a different process; an adhesion is formed between the gall-bladder and the duodenum, and a sufficient opening effected by ulceration. The calculus thus brought into the duodenum is either then propelled along the intestinal tube and evacuated by the bowels, or a further adhesion takes place between the duodenum and the abdominal parietes; an abscess is formed; ulceration proceeds; and, at length, the irritating substance is protruded through the opening in the integuments.

The cases related by Mr. Brayne, to which we have before adverted, afford beautiful and striking illustrations of the former and more perfect mode of extrusion. The patients, in at least two instances, recovered. Of the *latter* mode of expulsion, to wit, that by an external opening, many examples are recorded, from which we may adduce one as related by the venerable Heberden. The patient, after having suffered for years from a discharging tumour near the umbilicus, was seized with acute pain, nausea, and vomiting, "et post paucos dies exiit calculus fellis tres pollices longus, totidemque ambitu, quique pendebat grana ccxlv."*

Jaundice may be presumed to arise from biliary calculi, or other similarly acting obstructions, when its accession is sudden and accompanied by acute pain either in the epigastrium, or shooting towards that part from the back or right hypochondrium; especially if there be also vomiting and occasional shiverings, or profuse perspirations, without any manifest fever or an increased force or frequency in the pulse. Not uncommonly, the pain precedes the appearance of jaundice, returning, perhaps, with great severity for several successive days, and remaining for several hours at each return. Unlike the rigors which forebode an attack of inflammation, the shiverings in jaundice rarely precede the pain, but occur irregularly during a paroxysm, and seem to mark a further propulsion of the calculus along the irritated canal, or its final extrusion through the distended opening of the common duct into the duodenum. The character of the pain is very important; it is acute, and occurs in paroxysms. Sometimes it is intense and excruciating in the highest degree, far exceeding what is felt in the most acute inflammation. The perspiration which sometimes drops from the patient may be ascribed chiefly to the severity of his suffering. The position of the patient also deserves attention. He bends the body forward upon his knees, when not writhing in other directions, and seems to find some relief from pressing upon the seat of pain. Not unfrequently the pain subsides on the appearance of jaundice. The state of the pulse will materially assist in the diagnosis. During the state of simple irritation it is seldom much accelerated or preternaturally firm. When, indeed, it becomes materially harder and quicker, the utmost vigi-

* Commentarii de Morborum Historiâ, &c., p. 213.

lance should be exercised lest irritation should proceed to inflammation; in which case, the pain usually becomes more constant, the tongue whiter, and vomiting more incessant. These symptoms sometimes rise to such a degree as to resemble those of ileus, to which, indeed, they then become nearly allied.

It may be proper here to intimate that the entire subsidence of the pain, vomiting, and other characteristic symptoms, does not necessarily imply the passage of the calculus into the duodenum. Very frequently it slips back again into the gall-bladder, there to remain for a time, with little comparative inconvenience to the patient. We need scarcely add, therefore, that the evacuations from the bowels should be carefully examined, inasmuch as the discovery of a calculus cannot fail to afford relief and comfort to the mind of the patient.

The *treatment* of calculous jaundice should be specially directed to three points:—

1. To facilitate the progress of the inhering concretion.

2. To mitigate the pain and other symptoms of irritation.

3. To guard against the inflammation which is to be apprehended from the irritation of the calculus.

In endeavouring to fulfil these indications, opium may be regarded as our sheet-anchor. The first dose, consisting of one or two grains, or an equivalent proportion of the sulphate or acetate of morphia, may be advantageously combined with five or six grains of calomel. If the pain and sickness do not abate, a grain of opium may be repeated at the end of the first hour, and reiterated, after similar or shorter intervals, until ease be procured. After a few doses have been given, a solution of some neutral salt, particularly the sulphate of magnesia, either with or without the carbonate, or the carbonate of magnesia with lemon-juice in an effervescing form, may be administered, in combination with some aromatic water, and repeated at fitting intervals, until a free evacuation from the bowels is obtained. Soda-water, well charged with carbonic-acid gas, or simple saline draughts in a state of effervescence, are sometimes useful in allaying the urgent vomiting. If opium by the mouth should not procure ease, a drachm of the tincture may be mingled with a few ounces of thin starch or barley-water, and administered as an enema: prior to which, however, it is sometimes advisable to throw up a large quantity of warm water, which alone sometimes proves very soothing to the patient. As soon as possible, recourse should be had to a warm bath, in which the patient may remain until a degree of faintness supervene,—a state of relaxation peculiarly favourable to the passage of the calculus. Should these various methods be unavailing, and the patient be in a state to bear depletion, it will be expedient to withdraw from ten to sixteen ounces of blood from the arm, in a full stream, and, if practicable, while in the bath and in a half-erect posture. Topical bleeding may be also needful if the continued irritation of the calculus indicate inflammatory action, which may be apprehended from the pain becoming more constant, and accompanied with tenderness on pressure.

Emetics have been strongly recommended in calculous jaundice, and are doubtless powerful agents, though not always safe ones. When we consider the structure and the tortuous course of the common bile ducts, as well as the sharp and angular forms of the calculi, we shall not regard, without considerable apprehension, the action of a powerful emetic. In many instances inflammation, adhesion, and actual obliteration of the ducts, have resulted from the spontaneous passage of a calculus. Is it not, then, highly hazardous forcibly to impel these irritating substances against the already irritated mucous lining of the tubes?

Nauseating doses of ipecacuan may, however, prove safer and more availing, if the patient be not already in a state of nausea. Such an exception is, however, very uncommon. The advantage to be expected from nauseating doses is of a two-fold character. We may hope to promote more general relaxation, as well as to augment the biliary secretion; and thus, while relaxing the affected duct, and carrying down an increased flow of bile, nature may be assisted not a little in her efforts to expel the irritating substance.

We have already stated that the bowels are sometimes in a relaxed state. In other cases, however, they are obstinately constipated, and require strong and repeated doses of active purgatives, such as calomel, with the compound extract of colocynth, and an additional quantity of aloes. Even after the expulsion or retreat of the calculus, it will be desirable to exhibit occasionally a mercurial purgative, at the same time supporting the tone and regular action of the chylopoietic organs by small doses of a neutral salt in some mild bitter infusion.

We have mentioned hydatids, worms, and other extraneous matters, as occasionally producing jaundice. In some instances substances may be passed by stool which will enable the physician, in subsequent attacks, to form a reasonable conjecture respecting the nature of the obstruction. But, generally, no such intimation can be obtained. The treatment, however, of jaundice from such causes must be very similar to that recommended for the removal of calculi.

II. *Jaundice arising from diseased states of the liver, gall-bladder, or biliary ducts*, will of course be attended by the symptoms peculiar to each affection, in addition to those which characterise an obstructed state of the biliary passages. General or partial hypertrophy of the liver, (a state not uncommon in great eaters); a tuberculated or scirrhous condition of that organ; with many other forms of disorganization, may so interrupt the egress of the bile as to occasion jaundice. When the disease is dependent on such causes, there is sometimes no pain, or pain of a less acute, though more continued, character. The approach of the supervening jaundice is also generally gradual; and symptoms of hectic

fever too often succeed. It is a remarkable circumstance that, notwithstanding the prevalence of liver-complaints, calculi are rarely found in the interior of that organ. Morgagni affirms, "vix uno in jecinore mihi olim accidit ut invenirem; Valsalvæ autem in nullo, quod sciam."*

Diseased conditions of the ducts themselves form, we believe, more common cases of jaundice than is generally supposed. Of these, inflammation and its consequence are among the principal. The mucous tissue of the ducts may become ulcerated, or so adherent as actually to obliterate the canal. It may, also, be so studded with tubercles as to be no longer permeable to the bile. Jaundice from such causes is often incurable and fatal.

III. Our third general division of jaundice comprises those *morbid states of the duodenum which have been found to occasion the disease.* Of such we may specify the following:—1. viscid mucus adhering to the inner membrane of the bowel, and scaling up the opening of the ductus communis choledochus: 2. a highly turgid or inflamed state of its mucous membrane: 3. a thickened, tuberculated, or otherwise disorganized condition of the duodenum.

"1. Viscid mucus, we are persuaded, is a frequent cause of temporary jaundice. Many of the cases which have been gratuitously attributed to spasm, were probably of this nature.† If we attentively observe the peculiar structure of the termination of the common duct in the duodenum, we shall more accurately conceive how readily its small orifice, in the midst of a papillary projection, may be closed up by a thick and tenacious layer of mucus. Such a cause may be reasonably inferred when the disease has come on rather suddenly, has been unattended by acute pain or other inflammatory indication, yet has been preceded by dyspepsia and a torpid state of bowels. A mucous film upon the tongue, and the absence of the usual marks of chronic visceral disease, will give additional probability to the opinion. A large dose of calomel, followed by a draught containing magnesia and rhubarb in infusion of senna or some other vehicle, will sometimes quickly remove the disease. Much circumspection as to diet, the regular use of active exercise, with an occasional recourse to purgatives, may equally ensure a freedom from relapse.

2. A turgid or inflamed condition of the mucous membrane of the duodenum probably seldom exists without the lower portion of the common bile-duct being similarly affected. This form of disease is characterized by uneasiness or pain in the course of the bowel, which sometimes becomes tender on pressure, the uneasiness being more particularly felt at the expiration of three or four hours after eating, and being often accompanied with vomiting. The tongue has usually a white or yellow surface, and there is considerable thirst. The pulse is also somewhat accelerated. In distinguishing this affection from a diseased state of the pylorus, attention should be paid to the period after eating at which the vomiting occurs. Where the pylorus is alone affected, vomiting generally commences within two or three hours of the meal, and affords almost immediate relief. In the chronic inflammation of the duodenum, of which we are treating, the vomiting seldom occurs until four or five hours have elapsed, and does *not* alleviate the distressing sensations of the patient. He gains, however, sensible relief by taking a tea-cup full of warm fluid, which seems to excite an increased peristaltic action, and thus to liberate the oppressed duodenum from the undigested mass.

It is of extreme importance to overcome this kind of jaundice as soon as possible, lest disorganization of the duodenum, obliteration of the orifice of the bile-duct, or adhesion of its sides should ensue.

Whether simple turgescence or actual inflammation be the cause, the treatment should be essentially the same, varying only in degree. A moderate bleeding from the arm, if the strength of the patient admit of it; repeated local depletion; the warm bath; counter-irritants, particularly in the form of the antimonial ointment; with mild doses of saline aperients, and the most scrupulous attention to diet,—constitute the treatment which experience, no less than general principles, points out as best adapted for the purpose.

IV. *Jaundice produced by the pressure of enlarged contiguous viscera* is of frequent occurrence, although less susceptible of relief from medicine. Cases of simple distention of the transverse colon from a collection of impacted fæces are, of course, to be generally removed by appropriate remedies. Compression, too, by the gravid uterus, obviously admits of a natural cure. But a scirrhous enlargement of the pylorus, or of the round head of the pancreas—two of the most frequent causes of this species of jaundice—are among the most intractable as well as the most distressing disorganizations which human nature can sustain. In these cases, the most deplorable depression of mind, and an extreme degree of emaciation, are often observable. We have already alluded to some points of diagnosis in reference to the enlargement of the pylorus. As the disease advances, the tumefaction will be distinguishable by the hand: so may also, generally, though with more difficulty, the enlargement of the pancreas.

Affections of the head, irrespective of any previous disease in the biliary organs, have been supposed to occasion jaundice. Where, however, a serious injury has been inflicted on the head, such, for example, as is sometimes occasioned by a jump or a fall, it is highly probable that the liver or its appendages received some simultaneous injury, although the

* Ep. xxxvii. Art. xi.

† No special reference is made in this article to "spasmodic jaundice," because we have no evidence of its existence.

effect was not so quickly perceived. This is also the opinion of the judicious Abercrombie. We have, however, long felt assured that the state of the brain and nervous system has been too little considered in the pathology of jaundice. When we regard the influence of the brain and nerves in secretion generally, as well as their influence upon the moving powers, we may reasonably suppose that any considerable deviation from their sound and vigorous condition will be likely to lessen or deteriorate the biliary fluid; and also, by withholding a due supply of nervous energy from the moving forces, retard its transmission through the biliary passages into the duodenum. The remarkable influence which powerful emotions have upon the secretion of bile, and, probably also, on its propelling powers, should lead us more attentively to mark this connexion, and the morbid changes thence resulting; by which attention, we may hope, at some future period, to clear up many obscure points relating to the biliary secretion, both in its healthy and diseased states, and ultimately arrive at more successful methods, not only of removing jaundice, but also, in many instances, of preventing its occurrence.

(T. H. Burder.)

KIDNEYS, DISEASES OF. Notwithstanding the activity with which the kidneys perform their functions, the constancy of their action, and the extraordinary rapidity with which their secretion becomes affected, not only when other parts of the system are suffering under actual disease, but even when they are simply and slightly disordered, these organs are not peculiarly liable to alteration of structure. On the contrary, as it has been well observed by a distinguished pathologist of the present day, "in the greater number of diseases, whether chronic or acute, we cannot discover by dissection any change in the structure of the kidneys."

Of the diseases incidental to the kidneys, the most important, perhaps, are ischuria renalis, nephralgia, and nephritis. To these might be added diabetes, were pathologists agreed as to its primary seat; but though several eminent writers have considered it to originate in the kidneys, there are others of equal name and authority who have referred it to a different source. Ischuria renalis has been discussed in a former article; and it is proposed, likewise, to treat, under their respective titles, both nephralgia and nephritis.

In the present article it will be our object briefly to notice those other renal affections which, on account of the rareness of their occurrence, or the obscurity and uncertainty of their symptoms, or their hitherto uncontrollable nature, may probably be deemed of minor importance so far as practice is concerned; yet which, by those who are truly devoted to medicine as a science, can never be deemed insignificant or uninteresting. The renal affections which we are about to consider may conveniently be arranged, after the plan adopted by M. Andral, under three heads; the first comprising morbid conditions of the circulation of the kidneys, the second lesions of nutrition, the third morbid formations.

1. *Lesions of circulation.*—The kidneys are sometimes found gorged with blood—in that state to which the term hyperæmia has been appropriated, without any other alteration. One or both organs may be thus congested, and the congestion may affect both the cortical and tubular parts, or only one of them. When they are in a high state of hyperæmia, they assume a dark chocolate hue.

The kidneys are also found in a state precisely opposite to that just mentioned, namely, in a state of paleness or anæmia, either partial or general, either complete or incomplete; sometimes existing in a few scattered points only. This is the condition of the kidneys which is frequently observed in persons who have sunk under chronic diseases, especially in dropsical patients, and those who have been the subjects of the affection named by Dr. Good marasmus anæmia. When this paleness exists in an exquisite degree, it may be regarded as in itself a disease, but hitherto it has not been discovered to occasion any functional derangement during life.

The yellow colour, either general or partial, which is occasionally observed in the kidneys, is probably owing, as M. Andral has remarked, to a less advanced stage of anæmia.

It may suffice thus briefly to have noticed that congestion of the kidneys, or extreme paleness of them, may occur without their presenting any other morbid appearance. Such instances, however, are rare: hyperæmia, as well as anæmia, is usually found in connexion with other degenerations of those organs: the former, for example, conjoined with softening, or with induration together with hypertrophy; the latter with softening, or occasionally with induration and atrophy.

2. *Lesions of nutrition.*—The kidneys are sometimes much larger than natural, though otherwise unaltered. Both kidneys may be thus affected, but more commonly the hypertrophy is confined to one only. As was observed while treating of ischuria renalis, great augmentation of volume of one kidney is not unfrequently met with when the other is, by disease or obstruction, rendered incapable of performing its office. The enlarged gland takes upon itself the duty of its fellow. Hypertrophy of the kidney seems occasionally to depend upon its being doubly nourished, by receiving its supply of blood from two renal arteries. This state of kidneys, generally combined with increased vascularity, is the most usual morbid appearance observed in cases of diabetes. An extreme paleness of their tissue, with softening, has indeed been often mentioned as the principal alteration which takes place in them in that disease; but in various cases upon record, and in every instance which has occurred in our own experience, the kidneys have been more vascular, and generally larger than natural.

To this variety of morbid alteration—hypertrophy—may, perhaps, be referred those cases where the kidneys are united by an intermediate substance; a sort of middle lobe, resembling them in its texture, and passing over the vertebral column from the one to the other.

With respect to the nature of those hard, whitish, globular bodies, of various sizes, which are mentioned by authors as existing in the cortical substance of the kidneys, and which, in some few instances, have been detected in the tubular substance also, little is known. Some have regarded them as serving to secrete the urine, while others have supposed them to consist of a mass of vessels interlaced; but it is clear that granulations like these sometimes constitute a really morbid state. They nearly resemble the yellow granulations of the liver, which Laennec thought an accidental tissue, and to which he gave the name of *cirrhosis;* but which, in all probability, are the result of an unusual development of one of its elementary tissues, namely, of its white substance. These granulations in the kidneys are sometimes thinly scattered, sometimes so very numerous as to leave hardly any trace of their cortical portion, and even to occupy the intervals between the cones of the tubular portion of them. Such a state of the kidneys may, it would seem, produce dropsy; for in various cases of dropsical patients no other morbid appearance of importance has been detected. Although, as M. Andral observes, it is difficult to comprehend how dropsy is produced by this affection, the fact is nevertheless certain.

The kidneys, again, are subject to general or partial atrophy. In the former case one or both of them may be diminished in size, without being altered in structure, and without any symptom of disorder of the urinary apparatus having been present during life. Such a condition of kidney may have been coeval with the patient's birth; or the atrophy may have been the result of mechanical compression; of a tumour in the vicinity of the gland; or of a collection of pus formed around it. One kidney may be wholly wanting; and this defect may be either congenital, or the consequence of disease. Of the former occurrence a remarkable example has been given by Morgagni, Letter 31, Art. 25. In the patient there referred to there was no trace of the left kidney, but the deficiency was supplied by the right, which was double the natural size, and furnished with a double pelvis and ureter; and both ureters went to the right side of the bladder. When one kidney has been destroyed by disease, no inconvenience may arise provided the remaining one be sound; but if that be also degenerated, it is obvious that the patient will experience much and severe suffering. An instance is given by M. Andral, where dropsy, of which the organic cause could not be discovered during life, was ascertained to have arisen from great disease of the urinary apparatus; the left kidney was totally gone; the right was enlarged, softened, and studded with those whitish granulations which have been already noticed.

Several curious varieties in the form and the situation of the kidneys are occasionally met with; but they can scarcely be considered as diseases, or, if they be so considered, they are not to be recognized by any peculiar symptoms, nor can they ever be influenced by medical treatment.

The morbid states we are next to mention are softening and induration. The former state is not unfrequently conjoined with turgescence or hyperæmia, and this combination may be regarded as affording strong evidence of inflammation. In patients who during life have suffered under symptoms of nephritis, a very soft state of the kidneys, with intense redness, has been observed. The same condition has also been found accompanying certain chronic affections of the bladder, as thickening of its inner membrane, &c.

There is a peculiar softening of the kidneys which has been described by Dr. Baillie, and by Mr. Wilson in his lectures. The kidneys are converted into a soft loose mass, resembling in appearance common sponge. When shaken in water, the parts all separate from each other, somewhat like the unravelling of the shaggy vessels of the placenta. In one such case small shreds, apparently portions of blood-vessels, had been passed by the urethra; and upon examination after death, Mr. Wilson conceived that they might have come from the kidneys during life. This is one of those lamentable states of disease over which, even if known to exist, our art can exercise no power.

There is another kind of softening in which the substance of the kidneys is extremely pale, or of a grey tint. This alteration has been found where no symptoms of disease of the urinary organs had manifested themselves.

Induration of the kidneys may be attended by congestion or by paleness of their tissue. In the former variety the organs are generally enlarged; in the latter they are also occasionally enlarged, but most commonly diminished in size. In the pale induration the kidneys, though firmer than ordinary, may yet retain their natural structure; or they may be almost as hard and as white as cartilage, their natural structure being entirely lost. This is the state which has been called scirrhus of the kidney. It is very rarely met with, and the symptoms attending it are not to be distinguished from those which belong to other renal affections. When both kidneys are thus diseased, very little urine will be secreted, or there may be complete ischuria renalis. The remedies we must employ must of course be those which have been found useful in nephralgia and in suppression of urine. Opium and hyoscyamus are more likely to afford relief than any other medicines.

3. *Morbid formations.*—Of the diseases belonging to this division of our subject, the most important is that very formidable and intractable malady first accurately described by Mr.

J. Burns, under the title of spongoid inflammation; but more generally known by the appellation of fungus hæmatodes, assigned to it by Mr. Hey. Until of late years it was commonly confounded with cancer, of which indeed it is still reputed a species by some writers of high reputation. In this light it is regarded by M. Roux. Mr. Wardrop has named it soft cancer, and Mr. Langstaff has remarked that sometimes the scirrhous, medullary, and fungoid structures, are so blended in various parts of the same subject that they appear like different stages of morbid growth, and the difficulty the pathologist experiences is in deciding whether the disease is of the cancerous or hæmatodal kind, or *whether they are not of the same class*. The same author refers to Sir Everard Home as stating that the fungoid and the cancerous sore are the effects of one disease, only varying according to the structure of the parts which it attacks. As, however, it is now ascertained that the same structure, the female breast for example, is liable to either disease, and that fungus hæmatodes has been observed in almost every part of the body, the position of the last-mentioned pathologist is no longer tenable. It may be admitted that, in the malignancy of their character, as well as in some other points, fungus hæmatodes and cancer bear a strong resemblance to each other; but at the same time we must maintain that the former disease wants the pathognomonic signs by cancers are which distinguished. (See Fungus Hæmatodes.)

Mr. Wardrop first noticed fungus hæmatodes as affecting the kidney; but he acknowledges that, in the case he relates, the morbid alterations of structure would not have been alone sufficient to warrant him in calling it fungus hæmatodes. He conjectured it to be such because there was fungus hæmatodes over the hip joint. Since the publication of his work, however, several well-marked cases have been given in detail by Mr. Langstaff. In one of these, the subject of which was a man aged seventy, affected by hemiplegia for several years, the symptoms were, for a length of time, difficulty of voiding the urine, which was usually tinged with blood, and afterwards retention; great pain in the region of the left kidney, and uneasiness of the rectum. He died apoplectic.

In another very interesting case, that of a young lady, the symptoms were frequent desire to relieve the bladder, and in the course of a few hours an immense quantity of limpid urine was discharged without alleviation of the urgent propensity to void more: then, the irritability of the bladder increasing, arterial-looking blood was discharged in considerable quantity. Some doubt existed at first as to the source of this hemorrhage; there was some reason for suspecting it might proceed from the uterus, but the introduction of the catheter at once settled the question. After several recurrences of hemorrhage, accompanied by great irritability of stomach and bilious vomitings, the discharge of blood ceased for a time, but then the urine was very turbid, and deposited a muco-purulent sediment. About six weeks subsequent to the first attack, dull pain was complained of in the right side, and upon examination a tumour was distinctly felt in the right hypochondrium, and traced into the iliac region: there was pain upon pressure, and pulsation of the part. The discharge of blood afterwards returned at intervals, and the tumour increased greatly in despite of all the means that could be devised for checking its growth. The patient's general health of course suffered dreadfully, and sometimes she appeared to be reduced to the last degree; yet, in the intervals of the attacks of pain, sickness, and hemorrhage, she rallied in a surprising manner; nor was it until five years and a half from the commencement of her sufferings that she sank under them. Upon examination after death it was found that the right kidney occupied the principal part of the abdominal cavity: the diseased mass, with a portion of the liver which adhered to it, weighed eleven pounds and thirteen ounces. It was almost entirely formed into protuberances of different sizes, and the peritoneal surface was greatly condensed. When that part of the tumour which constituted its chief bulk was cut into, it was found to contain a coagulum of blood, not adhering to the sac, and weighing three pounds, and composed of concentric layers, as in an aneurism which has formed rapidly.

The left kidney, which weighed twelve ounces, was much altered in structure, being chiefly occupied by pulpy tubera, which were rendered red by minute injection.

In the Medical Gazette for May 1831 is related a case of fungus hæmatodes of the kidney, in a subject only four years of age. In this instance the symptoms of renal affection were so trifling that no suspicion existed in the mind of the medical attendant that such affection was the sole, or even the chief cause of the little patient's distress. It had been conjectured, as in Mr. Langstaff's case just mentioned, that the liver was enlarged, but the apparent hypertrophy of that viscus was occasioned by the enlarged kidney, which pushed it upwards and outwards towards the diaphragm. These unhappy cases have hitherto resisted every mode of treatment. When fungus hæmatodes attacks external parts, it is still one of the opprobria medicinæ; what, therefore, can be expected from our art when its ravages are obscurely going on in internal organs?

The formation of hydatids has been stated as being no uncommon disease of the kidney. It would, however, seem that the true hydatid is not often met with in that situation; while those cysts with thin and nearly transparent parietes, and which contain a limpid colourless fluid, very like water, but having some coagulable matter, are of frequent occurrence. These may be dispersed over the surface of the kidney, or be imbedded in any part of its substance. They often attain an enormous size, so as to occupy by much the larger portion of the gland; and they vary in number, from a single one to many

hundreds. Each is a distinct bag, and does not contain others within it. It is probable that these cysts depend upon a morbid alteration of the structure of the kidney.

In the true hydatid the cyst is thicker and much firmer; and, when cut into, appears laminated. Within the bag there is sometimes only one hydatid, but generally there are a considerable number; some attached to its parietes, others loose and floating in the fluid. These hydatids sometimes have numerous others adhering to their inner surface, or floating freely in their cavity. (See HYDATIDS.)

We possess no other distinct evidence of the presence of hydatids than that which their being passed by the urethra with the urine affords. All the other symptoms, such as pain of back, symptomatic fever, nausea and vomiting, belong equally to other renal diseases. Every modification of treatment has been tried, when their existence has been positively known, or has been suspected, but in vain. An artificial outlet cannot be made for them. When they obstruct the flow of urine, as sometimes happens, the bougie or catheter must be employed. Under the steady exhibition of turpentine the pain of the loins has been known to cease, as well as the passing of hydatids; but in many instances the same remedy has totally failed. The muriated tincture of iron has been given, but with no permanent good effect.

Of the remaining morbid formations in the kidneys, tubercle is the only one which merits the least attention. It is very rarely found in them, and, when it is, generally exists in other organs also. The tubercle of the kidney is said by Dr. Baillie to resemble exactly the common tubercle of the lungs.

Fatty matter and gelatiniform matter are now and then observed in the kidneys, and they have been found converted into a bony or earthy substance. But these morbid appearances are of extreme rarity.

We have thus endeavoured to furnish a sketch of those diseases of the kidneys which, though hitherto little understood, could not, in a work like the present, be passed over with propriety. In the actual state of our knowledge our descriptions must necessarily be imperfect. The period may be distant in which their nature and symptoms will be thoroughly comprehended. The most patient attention to the phenomena of certain diseases, the most diligent search into the morbid changes produced in the structure of parts by morbid actions, may for a long time seem to be unproductive of any important practical results; still, patient investigation should never be abandoned. It may be the good fortune of others hereafter to elucidate what is obscure in the affections of which we have just given a brief account; it was our duty to record what is already known respecting them.

(H. W. Carter.)

LACTATION. — Lactation in the human female, when naturally conducted, cannot be called a disease; but even under the most favourable aspect there are often circumstances which require attention and regulation, both for the purpose of alleviating pain and of preventing mischief. There are, moreover, so frequently interruptions to this usually healthy process, and there are so many important questions connected with the flow of milk at various periods, that it becomes necessary, in a work on practical medicine, to discuss them, although somewhat briefly.

The close sympathy between the uterus and the mammæ is evident even in the unimpregnated condition. At puberty the breasts enlarge and their glandular structure is developed; a day or two before menstruation, and during the period itself, the breasts become tumid and more or less painful. There is an affection which may be termed *spurious pregnancy*, described by Dr. Gooch, where, apparently from uterine irritation, the breasts are swollen and affected with shooting pains, and even a serous fluid resembling thin milk oozes from the nipple, being precisely what takes place in real pregnancy, wanting only the darkened areola. In some diseases of the uterus, particularly in hypertrophy of that organ, a similar state of the breasts is often observed. In real pregnancy the alteration in the breasts is strongly marked, and the quantity of milky serum which is secreted is sometimes very copious, especially towards the close of utero-gestation. Sauvages mentions an instance where as much as a pint and a half was daily poured out as early as the fifth month. Many women, however, shew no appearance of milk at all before delivery, who yet have abundance afterwards. After parturition it is usual to place the child to the breast within the first twenty-four hours, partly to draw out and form the nipple before any hardness of the breast occurs to render that difficult, and partly to encourage the flow of milk,—for at a later period the contact of the child's mouth will immediately excite it. With first children there is rarely any quantity secreted before the third day; about that period, but often a day or two later, the breasts become hard and swollen, hot and painful; the pulse is quickened, the skin above the natural temperature, the thirst urgent, the sleep broken and troubled with unpleasant dreams, and the sensorium disturbed, so that the patient, whilst yet awake, will fancy strange objects about the bed. The process goes on, more or less rapidly, till the milk is at the height, as it is termed, when the breasts are extremely hard, and the gland is felt knotted and loaded, and is at the same time very tender; the swelling may extend quite to the clavicles and under the arms, the axillary glands being similarly affected; a small quantity of milk will often ooze out from the nipples, particularly if the breasts be fomented, or gently pressed with the hand. If the child be put to the breast, the action of suckling is attended with great pain to the mother, but followed by much relief. As the milk flows, the hardness diminishes, and the swelling subsides. After a few hours, if the milk be freely and frequently drawn off, the sensations become more comfortable, the pain

is removed, the breasts are only distended when the child has been long away, the pulse and skin are restored to their natural state, and the process of lactation is then fairly established.

In the management, up to this period, much may be done for the relief of the patient. As soon as the symptoms begin, a purgative may be administered with great advantage, and one which contains the neutral salts in combination, as it will promote watery discharges from the bowels, is preferable: this should be repeated in twenty-four hours, or earlier, if the case is severe. There is distressing thirst, but if we allow a too free indulgence in liquids, the distention of the breasts is increased; it is therefore better to allow only a small quantity of drink at a time, and perhaps nothing is so effectual in a small bulk as an effervescing saline draught frequently repeated. As a newborn infant will often experience much difficulty in drawing out the nipple of a hard and swollen breast, or in extracting the thick milk itself, it is often advisable to have this done by an older child or a grown person, or by artificial means. These consist of various sorts of breast-pumps, where a smooth-edged glass tube is placed over the nipple, and a vacuum being produced by suction or by syringes, or by heat, the milk is thus drawn off, and the buried nipple made to project. Great benefit may be obtained by fomenting the hardened breasts with hot water, or by applying mild poultices, which promote the easy flow of the milk and relieve the distention. This is also often effected by small wooden bowls soaked in boiling water, and wrapped up in flannel, which are then placed over each breast. As a more permanent application, hare-skins are often used; cabbage-leaves were also formerly much in vogue to promote a copious perspiration over the surface; the smell, however, is very unpleasant, and the same advantage may be gained by oiled silk.

The milk first drawn has a purgative quality, and thus serves to carry off the meconium which is loading the large intestines. On this account, when a child does not get the first draught of the breast, from being nursed by a wet-nurse, or from being brought up by hand, a gentle purgative should always be given; diarrhœa of an irritable character, and even convulsions, often being produced from retained meconium. In this country it is usual to give a purgative under all circumstances, but it is not customary in many parts of the continent, and it is doubtful whether it be not often superfluous. By the experiments of Dr. Robert Lee, it would appear that the meconium is an excrement, and does not contribute to nourishment; but that above the situation of the meconium a quantity of highly nutritious albumen is found in the intestines, serving for the sustenance of the infant till lactation is established. A purgative given before that period will therefore carry off this substance, and artificial nourishment must be given to make up for the loss of the natural provision.

The milk varies considerably in condition during lactation. At first it is thick, yellowish, and having a very large proportion of cream; several days elapse before it possesses its natural appearance, which should be thin, bluish, and sweet. The quantity of cream varies very much according to the diet, and the frequency with which the breasts are drawn. Some milk has a decidedly saline taste; and at other times it has been distinctly bitter, so that the child will turn away from the breast in disgust. Its taste and qualities may be easily affected by articles of diet, by passions of the mind, repletion, hot rooms, &c. and the child is more or less disordered by the alteration. Medicines will often affect the milk in a very striking manner; a purgative given to the nurse will frequently act violently upon the child, without in the last affecting the individual herself; in the same way, alkalies given to the nurse will relieve acidity in the child's stomach; and mercury given through a similar medium will cure syphilitic symptoms in the infant at the breast.*

Milk has been said to be sometimes black or green, but there is in such cases most probably a mixture of blood, from the exterior or interior of the nipple. The writer has seen four instances where it was of a golden yellow colour, and where, upon standing, a thick layer of bitter cream, as yellow as pure bile, floated on the surface. In neither of these cases was the patient jaundiced; but a very copious flow of bile being kept up from the intestines by mercurial purgatives, after a few days the yellowness gradually disappeared; the child, till then, having been much griped and affected with diarrhœa. In no cases where wet-nurses have been jaundiced, has the writer seen the milk yellow; and it is no uncommon thing for them to become thus disordered, upon a sudden transition from poverty and a scanty diet to a full and luxurious mode of living. Milk will disorder an infant from merely being too rich, without its being otherwise altered in character. The remedy here will consist in purging the nurse, making her take plenty of active exercise, and putting her upon a more spare diet. The properties of the milk will also be considerably influenced by pregnancy or by menstruation.

There are some popular errors upon this point, which it is not difficult to expose. One is, that women will not become pregnant during lactation. This is far from being the case, and Mr. Roberton of Manchester† has taken the trouble to enquire minutely into the result of 160 cases, in which he found that eighty-one women had become pregnant once or oftener during suckling. Mr. Roberton has stated "that the appearance of the catamenia during

* On the authority of Mr. Keate, it may be here stated that a foreign gentleman, a patient of his, was in the habit of regulating his hepatic system, when there was a deficiency of bile in his motions, by taking asses' milk medicated by giving the animal a certain quantity of a mercurial preparation (the nitrate of mercury.) The effect was very marked, and he could bear mercury in no other shape.

† Vide Edinb. Med. and Surg. Journal, No. 110.

lactation does not appear to have any influence in disposing to conception." In this respect the writer's experience leads him to a different conclusion: he is decidedly of opinion that those women who menstruate during pregnancy will more readily conceive than those who do not; and he has also remarked, as Dr. Hamilton has done, that both these occurrences are more common with first children; hence women under such circumstances are not, *cæteris paribus*, so eligible for wet-nurses. Dr. Mason Good has recommended cohabitation with the husband during lactation, as likely to increase the quantity of milk; arguing upon the fact that the Tartars are accustomed to irritate the vagina of their mares for a similar purpose. The objection to his proposal will only apply to hired wet-nurses, lest they should become pregnant. Wet-nurses have very frequently recommended themselves to the writer on the plea that they have still continued to menstruate, by which they believe that their milk is *renewed*, as they term it, every month, so as to be rendered fit for much younger children than it would otherwise have been. This occurrence, however, much impairs the milk, in its probable duration, and in its properties at the period itself. The infant becomes unusually fretful, brings up the milk by vomiting, and has frequent watery motions of a spinach-green colour. These symptoms are so peculiar, when arising from no very obvious cause, that it may be generally safely guessed that the nurse is either menstruating at the moment, or will do so on that day month; for it is not uncommon to find the effects on the child brought on, although the alteration in the uterine condition of the nurse is not complete.

One of the most early and most troublesome attendants upon suckling is soreness of the nipples, as the pain recurs as often as the infant is put to the breast. Very few escape some degree of tenderness, with first children especially, but the inconvenience is soon obviated, and the delicate skin becomes callous, like the fingers of a harp-player—an effect which may be hastened by some slightly astringent or gently stimulating lotion, as green tea, brandy, weak solutions of the sulphate of zinc or of alum. If more severe and intractable, a solution of one to two grains of nitrate of silver in one ounce of rose-water will be found of service. Should the skin become excoriated, or should a crack take place at the junction of the nipple to the areola, a shield of glass, wood, ivory, or silver, should be used, with an artificial or prepared cow's teat, through which the child may suck without biting or much disturbing the nipple. The surface of the sore may then be freely touched once a day or oftener with the lunar caustic, and in the intervals the part may be kept well smeared with ointment containing honey, or a minute quantity of Peruvian balsam. Preparations containing lead or mercury in any form are scarcely advisable, as they may be swallowed by the infant. Where the surface of the nipple is not chapped, but unusually hot and dry, and very tender to the touch, all astringent lotions and stimulating applications aggravate the mischief; the simplest ointments, of wax and oil alone, will be found to agree best, or the part may be covered with powdered gum arabic or a bread-and-water poultice. The dress should, in all cases, be carefully kept from irritating the sore nipple, by means of wax cups, shells, or glasses for the purpose.

There is one species of sore nipple not often noticed by practitioners, (who are too apt to leave these cases to the management of the nurses,) which the writer has found more intractable than any others, and the means frequently of inducing the mother to give up suckling entirely, from the constant torture to which she is exposed. There is little or nothing to be seen but a small spot at the orifice of the nipple, which is elevated and irregular in appearance, extremely painful to the touch, and exuding a sanious ichor. When the child is put to the breast, the pain is most acute, and seems to come from the interior of the nipple and breast; and the first and last milk is generally mixed with blood. It would appear as if the interior or lining membrane of the lactiferous tubes was in a morbid condition. Little or nothing can be done for this affection. The free application of caustic to the external orifice, and poulticing the breast, has now and then effected a cure, along with careful attention to the stomach, bowels, and general health, which is highly essential. Those who have uniformly suffered from sore nipples on former occasions have frequently seemed to prevent them by using, previously to parturition, for several weeks, either an astringent or demulcent lotion, according to the state of the skin.

Inflammation will occasionally attack the breast itself at any time during lactation, but most frequently at a very early period, when there has been exposure to cold, much trouble in the first management of the milk, or soreness of nipples; it does not so frequently happen where the milk is at once driven back without suckling the child. If not immediately treated by leeches, by fomentations, and poultices, hot and frequently changed, or, as some prefer, by cold lotions, abscess will take place, accompanied by great pain and much constitutional disturbance. The treatment of this state comes within the immediate province of the surgeon; but there are one or two circumstances respecting *milk* abscess deserving of notice in this place. It is very customary, when abscess is threatened, to persevere in keeping the child to the breast, or otherwise drawing the milk off; partly to enable the patient to continue suckling, and partly to prevent the milk collecting in and distending the inflamed breast. If the inflamed portion be not extensive, there is no objection to this, as a small abscess will not much interfere with the functions of the remaining sound parts; but if the whole, or nearly the whole, of the breast be implicated, the pain of suckling will be very violent indeed, and the frequent disturbance and irritation will contribute to increase the inflammation, and diminish or

entirely obviate the chances of preventing the formation of matter. Should abscess be formed, and matter be felt fluctuating, the most experienced practitioners agree upon the propriety of puncturing early and freely; otherwise in such a peculiar structure most extensive mischief will take place, and the surface remain disfigured afterwards in the most unsightly manner. It is curious to notice in subsequent confinements how little the real glandular apparatus has been destroyed, even where large collections of pus have formerly been evacuated, so that the patient will sometimes be enabled to nurse with but little trouble; although from some partial obliteration of the ducts, there is always rather more difficulty in the flow of the milk.

Milk fever.—What is called *milk fever*, is an aggravated and morbid form of the healthy and natural excitement which takes place at the onset of lactation. The febrile symptoms are much more severe; there is a well-marked precursory rigor; there is great pain and throbbing of the head; a flushed countenance; intolerance of light and sound; the pulse is full, hard, and rapid; the thirst excessive; the skin hot and dry, and the tongue covered with a thick fur. These attacks may be usually traced to a too stimulating diet, a heated atmosphere, much exertion and disturbance, or mental agitation. They are much less frequent than formerly, when great fires, loads of blankets, and brandy caudle, were the usual appendages to a lying-in chamber. If the flow of milk be encouraged, and gently yet freely drawn off; if the room be kept cool; agitation soothed or avoided; purgatives duly administered, and perhaps diaphoretic medicines; a remission of the symptoms will usually take place in a few hours, accompanied by a copious perspiration and tranquillity of pulse. On the contrary, by bad management phrenitis may supervene, of a very dangerous character; when the milk will be entirely suppressed, and nothing but the free use of the lancet will save the patient.

A very common expression is, that in such cases *the milk flies to the head.* In phlegmasia dolens the milk was also supposed to fly to the leg, and hence the French writers formerly called it, "depôt du lait." It has several times happened in the writer's experience, that where bleeding has been had recourse to in inflammatory diseases with sudden suppression of milk, the serum of the blood, when separated by rest, has been white, opaque, and bearing nearly all the characters of milk, except the formation of cream on the surface. It may here be observed, also, that where the milk is driven back artificially, and active purgatives are employed, a great quantity of milk-like fluid may be generally seen in the motions. Depressing passions, fear, and anxiety, will suddenly drive off every vestige of milk; but the only genuine *translation* may be said to be those extraordinary instances where the milk has receded more or less rapidly from the breasts, and a vicarious discharge has taken place from other parts, the general health remaining but little affected. The most common example of this is where the discharge has taken place from the vagina in the form of leucorrhœa; but it has also occurred from the fauces, the navel, the eyes, the kidneys, the whole surface of the mammæ, &c.

Where the child is to be weaned, or where a mother does not wish to suckle, or is not able from constitutional debility or local defect, or where the death of the child has taken place, it becomes necessary to "*backen*" the milk, as it is vulgarly termed. This may be done the most safely for the mother by her not being too impatient. If cold evaporating lotions are applied to the breasts, there is a more rapid dispersion of the milk, but there is more risk of fever, phrenitis, &c. It so happens, however, that these cold lotions rarely are allowed to act as such, for nurses in general are so particularly careful to cover up the patient's neck with the bedclothes and wrappers, that the lotions very rapidly become warm fomentations. In the writer's opinion, the best and safest applications consist of stimulating liniments, applied warm and also constantly, by means of layers of lint or flannel. The breasts should also occasionally be gently pressed and rubbed with warm oil; and if they are very hard and distended, a small quantity may be now and then squeezed out or drawn off artificially. The bowels are to be actively kept open by saline purgatives; the diet is to be low, and the quantity of drink lessened. It will be but a few hours before the extreme distress is mitigated, but it will be often several days before the milk is thoroughly dispersed, or the remedies can be discontinued. The sensation of "draught of milk" in the breasts will sometimes be felt two or three times a-day for weeks afterwards. In weaning a child, however, it is often the plan to do it so gradually, by accustoming it to partial feeding for some time previously, that little trouble is at last experienced in dispersing the milk. It is still very desirable that opening medicine should be plentifully given, even under such circumstances; as from this discipline being neglected, patients will often suffer for months afterwards, with great depression of spirits, loss of appetite, feeling of weight and lassitude, and general ill health,—sensations which are soon relieved by having recourse to opening medicine.

An excessive secretion of milk will sometimes be met with; but in nearly all these cases there is apparently some defect in the organization of the nipple, or the lactiferous tubes have lost their elastic property of retention, for in the intervals of suckling a constant and very copious discharge of the milk takes place. The daily waste and drain cannot exist long without materially affecting the health and strength; and unless the flow can be kept in check, there is no remedy except weaning the child and repelling the milk altogether. Various plans have been proposed, but the trial is not often successful. Local strong astringent applications, as lotions of alum, oak-bark, zinc, &c., sometimes do good, but they are apt to

effect too much, and drive away the secretion entirely. The astringent tonics internally, particularly the mineral acids, steel, kino, and alum, have occasionally been of service. Belladonna has been advised, both locally and in small doses internally. The breasts should be kept as cool as possible, and cold bathing be daily had recourse to.

The period of lactation is generally one of the most healthy of a woman's life; but there are many exceptions to this; and many who have begun with success, by continuing to suckle too long, by a too limited diet, by much loss of rest, or by other causes, have had their own health and that of their infants considerably and even fatally impaired. A recent writer has attempted to define the exact period to which suckling should be limited, as far as the advantage of the infant is concerned; but all such definitions are constantly contradicted by experience. There is much fallacy also in the arguments to prove that protracted lactation is the cause of various infantile diseases, especially hydrocephalus. Putting aside altogether the striking fact that the dangerous disturbance of dentition is proceeding at the same time, it may be allowed that hydrocephalus and the other diseases mentioned may and often do occur after or during protracted lactation; but they happen quite as frequently, and indeed more so, where a child has been brought up by hand, without the breast at all; or where it has been badly fed, or over-fed, whilst still suckling. In all the cases of mothers who have nursed their children for two years and upwards, in the class of life alluded to by Dr. Morton, it may be, perhaps, fairly assumed, from the known habits of the parents, that the children have been fed at the same time, and generally fed upon exactly the same sort of food as would be more adapted to older children. "The child eats whatever we eat" is the common expression, though the child is still allowed to apply to the breast at pleasure, to prevent the chance of a fresh pregnancy. Many children, particularly in the higher classes, where hired wet-nurses are employed, are kept for a long time at the breast because they are backward with their teeth, have had their bowels disordered by a premature attempt at weaning, or because they are in delicate health; but if hydrocephalus supervene in such instances, it is quite as likely that the previous disordered health may have been the cause, as the protracted lactation. In savage nations, in many parts of America, the east, and the polar regions, it is the constant custom for mothers to suckle their infants for two years at least, and without any of the pernicious consequences which Dr. Morton has imagined.*

It is certainly true, that if the mother's health be impaired by undue lactation at either an early or a late period, the child will suffer from defective nutrition, but in no other manner.

Dr. Marshall Hall has well described the state of disorder of the general health in females, which is induced by exhaustion of the frame, arising from protracted lactation, or from the original powers not having been equal to the continual drain on the system. One of the earliest symptoms of failure is a dragging sensation in the back, when the child is in the act of sucking, and an exhausted feeling of sinking and emptiness at the pit of the stomach afterwards. The appetite fails gradually, but entirely; there are thirst, a dry tongue, a quick feeble pulse; costive bowels, headach, with giddiness, lightness, and failure of sight. The skin is hot and cold alternately; there are profuse night-perspirations; generally leucorrhœa, great debility, and emaciation. The memory is impaired; the spirits are weak, irritable, and depressed. Symptoms resembling phthisis will sometimes come on, and mania is not an unusual result. Though much may be done in the first instance by the proper use of tonics, cold or sea bathing, change of air, a regulated diet, and local applications, to restrain the leucorrhœa; and though we may now and then effect a portion of good by partially feeding the child, yet the quickest and most effectual remedy is to wean the child. The different symptoms resulting from the exhausting process require appropriate treatment, according to circumstances; but all treatment will generally fail, unless we remove the cause of exhaustion.

Before leaving the subject of lactation, it may be remarked that males have also the organs for supplying milk, in a dormant state, which under peculiar circumstances have been excited into action, and have supplied milk in abundance, sufficient to suckle children. Instances have been given in recent times by Humboldt and Captain Franklin, and many others are on record. Very old women* and virgins have also had milk in considerable quantities, the nipples in all these cases having been frequently stimulated by the contact of the child's mouth purposely applied. It is by no means uncommon to meet with newly born infants, of either sex, who have their breasts turgid with a milk-like fluid, which is dispersed with difficulty.

(C. Locock.)

LARYNGITIS.—Of inflammations of the larynx there are many varieties, to which we mean briefly to allude before we enter upon a description of that formidable disease which has of late years obtained the title of laryngitis, and is the proper subject of this article.

Beginning with the slighter inflammations, we may, 1st, advert to that affection of the

* See Edinburgh Medical and Surgical Journal, No. 110.

* A very interesting account is given (in the Medico-Chirurgical Review, for July, 1832) by Dr. Kennedy of Ashby-de-la-Zouch, of Judith Waterford, of that place, and now alive, with milk still in her breasts at the age of eighty-one: the summary may be given in Dr. Kennedy's own words. "Here, then, are the remarkable circumstances of a woman who menstruated during lactation, who suckled children (many not her own) *uninterruptedly* through the full course of *forty-seven* years (three years of which time she was a widow), and who in her eighty-first year has a moderate but regular secretion of milk."

membrane lining the larynx, which is distinguished by hoarseness, or complete loss of voice, and by slight cough, an affection which, arising from exposure of the body, or part of it, to a current of cold or damp air; from partial or general wetting; or from an incautious laying aside of some article of dress, especially during changes of the weather, is so slight, as seldom formally to be brought under the observation of the physician.

2dly. Similar symptoms not unfrequently occur in connection with common sore throat (cynanche tonsillaris), and for the most part they also form a case for domestic prescription, unless the inflammation is so considerable as to threaten suppuration.

These two affections are chiefly prevalent about the beginning of winter and in the spring, and for the most part yield to confinement to the house for a day or two, and the antiphlogistic regimen. The latter affection, like the former, is of little importance, unless considered in connection with laryngitis, which has sometimes commenced like an ordinary sore throat attended with hoarseness; or unless it give rise to chronic disease of the affected part; for it is observable of both these slight inflammatory attacks, that when neglected, or when, from exposure to frequent vicissitudes of temperature, to foggy and cold weather, or to the night-air, they are from to time renewed, a state of permanent irritation is sometimes produced which is indicated by hoarseness, slight muco-sibilant inspiration, and cough, and by some difficulty of swallowing; symptoms which, especially in persons advanced in life, end in chronic laryngitis, a disease always intractable and often fatal. In these attacks, relief, if sought in time, may in general be obtained by bleeding, especially topically, and blistering; by a course of calomel and ipecacuanha; or calomel and antimonial powder, one grain of each given three times a day, and continued until the gums become slightly affected by the mercurial; by pure air of moderate and equable warmth; and rest and quiet.

3dly. Sometimes the membrane of the larynx is inflamed in gastric fever, and in various fevers of the exanthematous order, especially in small-pox, measles, scarlatina, and erysipelas, fevers which we apprehend are all essentially gastric. In small-pox, the epiglottis and larynx are often inflamed and beset with pustules, from which very great distress arises. In the beginning of measles, inflammation of the upper part of the windpipe is so considerable as to give rise to an attack which, for a short time, advances with all the violence of croup. In the winter of 1807, and more especially in the spring of 1808, when measles were epidemical in Edinburgh and the neighbourhood of that city, and of so unfavourable a kind that we witnessed the death of more than 100 patients in the course of a few months, the disease corresponding with the putrid measles of Watson,* not only was the larynx often affected before the efflorescence took place, but in several instances after the rash had disappeared it became inflamed; in all which cases, to the best of our recollection, the patients died. In one dissection which we procured, of laryngitis after measles, the following were the appearances discovered. The investing membrane of the epiglottis was considerably thickened, particularly at its edges; such also was the state of the membrane of the glottis; the sacculus laryngeus was nearly obliterated, and, below the sacculus, ulceration had taken place. When the epidemic commenced, bleeding was often useful, but after it had continued for some time, and had become more fatal, the attending fever being typhoid, bleeding appeared injurious; indeed we then observed that scarcely a child recovered which had been bled, so that bleeding was not had recourse to when the larynx became inflamed. Nor were blisters applied, most blistered surfaces having a strong tendency to run into ulceration and gangrene. Were we again to be called to such cases, we would recommend immediate change of dwelling, a remedy not yet duly appreciated in acute diseases; an emetic and calomel, with small additions of opium.

We have frequently known inflammation in scarlatina and in some forms of cynanche to affect the fauces, whereon perhaps a plastic membrane was formed, and to ascend into the nares and descend into the windpipe. Several soldiers of a militia regiment, stationed at Woolwich, were daily brought into the general hospital with scarlatina. The disease was unusually fatal. One of these patients, who had been only a few hours in the hospital, died after symptoms which the surgeon on duty thought proper to investigate by dissection. He cut out the trachea, and found it lined with a membrane as in croup. The preparation was preserved, and afterwards presented to the writer of this article by his late friend Dr. Rollo, surgeon-general to the artillery: an engraving of it was given by the writer in his work on the "Pathology of the Membrane of the Larynx." At page 37 of the same work, will be found an account of two cases of inflammation of the larynx, one occurring about the eighth or ninth day of fever in a girl eight years of age, who was relieved by bleeding; the other in a girl of eleven, in whom an attack of bilious remittent fever was ushered in by laryngeal inflammation. A fatal case of laryngitis occurring during apparent convalescence from remittent fever, published in the first volume of the Transactions of the Physico-Medical Society of New York, was republished in the Medico-Chirurgical Review for April 1827.

In erysipelas the fauces are often inflamed, and the inflammation extends to the larynx, in which case the respiration resembles that of croup, and the disease is generally fatal. A female thirty-four years of age, had been in the hospital Cochin for disease of the heart, when, on the 23d of February, she was seized with violent rigor; 24th, erysipelatous eruption of the face with febrile reaction; 25th, 26th, the erysipelas was extended to the hairy

* Med. Obs. and Inquiries, vol. iv. p. 132.

sealp and to the neck, eyes closed; 27th, acute pain in the throat, difficult deglutition, respiration impeded; 28th, swelling and inflammation in the anterior part of the throat; inability to expectorate; suffocation threatened. March 1st, swelling of the neck enormous—asphyxia—death.

Dissection. The mucous membrane lining the mouth, larynx, and pharynx, red and inflamed. The epiglottis and its ligaments thickened; the rima glottidis nearly annihilated by the swelling and by tough mucus. The cellular tissue of the larynx, face, and neck injected, red, and œdematous; the lungs sound.*

4thly. The larynx is often inflamed in those diseases in which the inflammation extends over the whole of the mucous membranc of the lungs. In common and also in epidemic bronchitis, the inflammation, apparently commencing in the Schneiderian membrane and fauces, often affects the larynx in its descent into the bronchi. The membrane of the larynx is also liable to be affected in those varieties of chronic bronchitis, which, according to the season or age at which they occur, or according to the symptoms of the attack, have been termed winter cough, catarrhus senilis, suffocative catarrh, or peripneumonia notha. In pertussis, inflammation often obtains in the mucous membrane of the larynx as well as in that of the trachea and bronchi. Lastly, in croup, the symptoms referable to inflammation of the larynx are so obvious and remarkable as to have exclusively engrossed the attention of most observers, leading them to overlook proofs, scarcely less equivocal, of an inflamed condition of the bronchi.

5thly. We have known many cases of inflammation of the glottis arising from an accident, to which the children of the poor are liable. Slatternly mothers often permit their children to drink from the spout of the tea-kettle, and the children are thus led to a habit which, if the kettle should happen to contain boiling water, may prove fatal. The symptoms produced by this accident are inflammation and vesication of the fauces, difficult breathing, audible inspiration, whispering voice, leaden countenance, watery eyes, and cold extremities—symptoms which we were wont to think were as much dependent upon bronchitis as upon inflammation of the glottis; but a dissection published by Dr. Marshall Hall, in his satisfactory account of this affection in the twelfth volume of the Medico-Chirurgical Transactions, would lead to a conclusion that the inflammation does not extend even to the trachea. We have been accustomed to treat this affection by bleeding, blistering, and a preparation of calomel and ipecacuanha. Our confidence in bleeding is not, however, very great. The children soon acquire that peculiar expression which livid paleness with œdema imparts, when asphyxia, in an advanced state of bronchitic inflammation, is impending, a state which contra-indicates free bleeding. Bronchotomy is recommended by Dr. M. Hall, and this operation his view of the case would amply justify. He also recommends scarifying the epiglottis. Probably small doses of opium, given at an interval of two or three hours, would be useful, as they generally are in burns attended with much suffering. In the third volume of the Dublin Hospital Reports there is a case given by Dr. Burgess, of a girl of three years of age, who drank boiling water from the pipe of a tea-kettle, by which great swelling of the parts immediately ensued, thereby preventing deglutition and impeding respiration. In about two hours after the accident, in looking into the mouth, it appeared as if a large piece of raw flesh had been forced into the fauces, and had completely filled up the passage. Respiration was performed with very great difficulty, and was rapidly becoming more laborious,—in fact the child appeared to be dying, when bronchotomy was performed, by which life was saved.

6thly. Inflammation of the mucous membrane of the larynx sometimes arises when the system is under the influence of mercury. We think we have seen inflammation extending to the windpipe in severe cases of mercurial glossitis, and hence we are unwilling to reject, as one of the species of laryngitis, that caused by mercury. But we are not satisfied that the cases of alleged mercurial laryngitis, which have been recently published, did not owe their origin to other influences, such as lues venerea, or exposure to cold, rather than to the mercury.

7thly and 8thly. There are yet two inflammatory affections of the membrane lining the larynx which must be briefly described, in order to complete this part of the subject: these are scrofulous inflammation of that portion of the mucous membrane, and inflammation symptomatic of secondary syphilis.

Scrofulous inflammation is an affection of a very dangerous nature, not, as we apprehend, generally accompanied with tuberculated lungs. This affection is not confined to youth or adolescence; sometimes it appears at or after the meridian of life, as the commencement of a very chronic variety of phthisis, which some physicians have imagined depends upon indigestion, and is to be cured by blue pill, &c. We have frequently witnessed this affection in an acute form in persons who had abandoned themselves to the habitual use of ardent spirits, in *muddlers*, as they are called, who drink at all times, but seldom to complete intoxication. Such patients lose their appetite; become emaciated; usually have a patchy purplish complexion; gradually acquire a dry hard cough, which at first appears nothing more than an aggravation of that cough observable in drunkards, which is attended with white and scanty expectoration, and is followed, especially in the morning, by retching or even vomiting of a little clear ropy fluid. If we examine these patients, we shall find the pulse accelerated, the tongue and fauces florid, the former glazed. This disease is always fatal,

* *Bouillaud.*

but generally not until purulent expectoration, colliquative diarrhœa, and night sweats, have existed for some time. It often is to be met with in publicans, and such as are engaged in the occupation of vending ardent spirits. It is attended with a sense of exhaustion, a depression of mind, a fear of death, and a consciousness of the disease being self-produced, which it is most painful to witness. The patient may, in the commencement, derive some advantage from change of air, exercise on horseback, very small topical bleedings, not more than three or four leeches being applied, followed by counter-irritants and light bitters. The bowels must be properly regulated, avoiding all medicines which lower the strength; and a mild alterative pill may be given for ten days or a fortnight, namely,

℞ Pilulæ hydrargyri, scrupulum.
Pulveris conii, scrup. ii.
Ipecacuanhæ, gr. xv.

Ammoniaci contriti, sesquidrachmam, M. et divide in pilulas xl. Sumat duas mane et meridie; superbibendo poculum lactis asinini.

Milk, shell-fish, broiled, tender but lean meat, and vegetable jellies will form the most suitable nourishment.

The more common form of scrofulous inflammation of the larynx and trachea belongs to youth, and occurs in those families of which the members are liable to consumption. It has seemed to us often to arise from night-air and fatigue, especially when these causes operate during a season of mental anxiety and over-exertion. This is a frequent disease with those wretched females who frequent the streets of our cities in the night, and their obscene haunts during the day. The hue which may be observed on their cheeks is not always the glow of intemperance or of shame, nor yet the factitious blush of effrontery, but is often the crimson of a consuming hectic, which is rapidly hurrying them from misery to misery. It is little known how large a portion of the tenants of the brothel actually labour under consumption, but the subject is too horrible to be pursued.

At first the disease is attended with a dry barking cough, a single bark, often supposed to be a stomach cough; but the symptom which is most distinctive of this very treacherous complaint, and which in consumptive families ought ever to excite the liveliest apprehension of danger, is a change in the sound of the voice, which the patient can no longer extend without difficulty. It is slightly raucous, and acquires that hollowness which, both as if proceeding from a vault and in reference to its tendency, is not unaptly called sepulchral. When, the attention being arrested by the cough and the sound of the voice, which often have existed for many weeks or even months before they become objects of regard, we more closely examine the patient, we shall find that there is some uneasiness in the region of the larynx, or in the superior part of the thorax; a degree of quickness of the pulse is discoverable, as also some emaciation and decay of the strength, but the latter so slight as to have escaped notice. Indeed so insidious is this disease, that in many instances it has passed undiscovered until some acquaintance, who had not for a considerable time seen the patient, discerning a great change in his looks, expresses his apprehension. Then the truth, in all its nakedness, flashes on his alarmed relatives, and a physician is obtained who detects the nature of the disease by discovering that there are irregular chills followed by heats and perspirations, and confirms all their fears. The patient soon loses the power of extending his voice; he can only speak in a whisper; his cough becomes stridulous, his expectoration purulent, and laryngeal or tracheal consumption is incurably established. If a patient, fortunately for himself, should in the commencement of his disease be visited by a person possessed of medical skill, his life may sometimes be saved. In the treatment of this complaint, if the disease should not have reached the suppurative stage, we must disregard the diathesis, and address ourselves to the local affection. First, we must apply leeches to the upper part of the sternum; we prefer three or four leeches every third or fourth day to a greater number; secondly, the tartar emetic ointment (taking care that it does not reach the leech-bites) to the sides of the larynx, first to one side and then to another; thirdly, we must give the solution of tartar emetic (so as to excite slight nausea) with the addition of nitre.

℞ Antimonii tartarizati, gr. duo.
Nitratis potassæ, scrup. ii.
Aquæ distill. unc. sex: M. et divide in haustus sex. Sumat unum, ter, quaterve de die.

Lastly, a diet consisting of milk, farinacea, and fruits, will be necessary. This plan may be followed for eight or ten days; if without efficacy, new measures must be tried, as change of air and scene, and restoratives, such as a return to the use of animal food, a glass or two of claret, and sponging the surface with very diluted nitro-muriatic acid, which may also be taken internally. If the expectoration be considerable, a drachm of Riga balsam in a glass of water may be taken three times a day, or the following draught:

℞ Tinct. benzoini compositæ, ʒi.
Mucilaginis acaciæ, ʒii.
Syrupi papav. albi, ʒi.
Aquæ cinnamoni, ʒvi. M.

together with such treatment as would apply to impending laryngeal or tracheal phthisis.

There are certain cases of scrofulous inflammation of the windpipe that are invariably overlooked in the first stage, of which the first symptom detected are round and pretty deep ulcers in the fauces. The affection of the larynx so commencing, according to our observation, always ends in phthisis.

The syphilitic inflammation of the larynx, like the last variety, is seldom discovered in its very beginning. This disease is introduced by anomalous symptoms of constitutional dis-

order, and an obscure febrile state. The patient's expression appears altered and anxious, his complexion pale or mixed, his skin opaque and, as it were, dirty, his eyes hollow, the tarsi slightly inflamed; some degree of emaciation takes place; then the voice becomes husky. These symptoms will naturally suggest that line of inquiry which we adopt when we are endeavouring to detect a syphilitic taint; and here it will not be irrelevant to observe that a change in the sound of the voice, whenever it accompanies a cachectic state of the body, demands the utmost attention,—attention which will sometimes be rewarded by enabling us to discover the approach of a disease that would shortly assume a hopeless expression. In syphilitic inflammation of the larynx, when the head is suddenly turned to a side, uneasiness will be felt in the organ, which, when pressed, feels tender. The patient suffers much from a stridulous cough, attended with little or no expectoration. These symptoms being neglected, ulceration of the membrane of the larynx next ensues, which may be discovered by difficult and suffocative inspiration and cough, by purulent expectoration, and by unequivocal hectic, attended with great irritability of the nervous system, and, lastly, by permanent loss of voice. In the commencement of this affection we must endeavour to subdue the inflammation by means of leeches, blisters, and the antiphlogistic regimen. Then we must give the muriate of mercury in decoction of sarsaparilla, and employ mercurial fumigations.

In this manner, with the help of change of air, a remedy often of surprising efficacy in specific inflammations, a cure may sometimes be accomplished; but syphilitic inflammation of the larynx, which we apprehend will be most likely to occur in strumous habits, will, in general, like the proper scrofulous inflammation, terminate in laryngeal consumption, unless a termination should take place in the inflammatory stage, such as was exemplified in one of Bouillaud's patients, who died of suffocation so early as the fifth day, the cellular membrane being so thickened, infiltrated, and gorged, as almost to obliterate the rima glottidis; and on the left side of the larynx an ulceration being formed with the characters of chancre.* When syphilitic ulcers exist, they will generally be found in the sacculi laryngis. We have, in a specimen of diseased larynx, seen fimbriated excrescences in the glottis, which were probably syphilitic, but we were not able to obtain a history of the preparation.

As we learn from an ably written paper by the late Mr. Wood, in the seventeenth volume of the Medico-Chirurgical Transactions, on the effects of inflammation of the larynx, that a patient lately died in St. Batholomew's Hospital, of a disease of the larynx, which was discovered after death to be cancerous; and as Dr. Monro, in the 2d volume of his Outlines of Anatomy, informs us that he has seen in some cases the arytenoid and thyroid cartilages thickened and covered by a scirrhous substance, by which the glottis was straitened; it is probable that our successors in pathology, when facts accumulate, will add a *ninth* species, viz. scirrhous inflammation of the larynx, to the foregoing catalogue of diseases of that organ.

We proceed to the consideration of laryngitis, which is a more suitable designation for the disease now under review, than angina œdematosa, as applied to it by some authors: it has been well observed that "the term *œdematosa* is unnecessary, as œdema constitutes no fundamental character of laryngitis, but is an effect or consequence of inflammation of the affected organ,"* in what manner soever excited.

Of laryngitis, it is true, notices and cases were previously published, but the disease was not generally understood prior to the publication, by Dr. Farre, of a valuable paper on cynanche laryngea in the third volume of the Medico-Chirurgical Transactions.

Our knowledge will often be advanced by examining a specimen of a disease before we apply ourselves to the study of its general history. We therefore beg to call the attention of the reader to a case of laryngitis in every way interesting, but especially so to the pathologist, as being the first accurately reported history of that disease which, as far as we know, is to be found in the annals of medicine.

"Some time on the night of Friday, the 10th Dec. 1799, having been exposed to rain on the preceding day, General Washington was attacked with an inflammatory affection of the upper part of the windpipe, called in technical language cynanche trachealis. The disease commenced with a violent ague, accompanied with some pain in the upper and fore part of the throat, a sense of stricture in the same part, a cough, and a difficult rather than a painful deglutition, which were soon succeeded by fever and a quick and laborious respiration. The necessity of bloodletting suggesting itself to the General, he procured a bleeder in the neighbourhood, who took from his arm in the night, twelve or fourteen ounces of blood. He could not by any means be prevailed on by the family to send for the attending physician till the following morning, who arrived at Mount Vernon at about eleven o'clock on Saturday. Discovering the case to be highly alarming, and foreseeing the fatal tendency of the disease, two consulting physicians were immediately sent for, who arrived, one at half after three, and the other at four o'clock in the afternoon. In the mean time were employed two pretty copious bleedings, a blister was applied to the part affected, two moderate doses of calomel were given, and an injection was administered, which operated on the lower intestines, but all without any perceptible advantage, the respiration becoming still more

* Med. Chir. Journal for July 1825, p. 206.

* Med. Chir. Journal for July 1825, p. 206.

difficult and distressing. Upon the arrival of the first of the consulting physicians, it was agreed, as there were yet no signs of accumulation in the bronchial vessels of the lungs, to try the result of another bleeding, when about thirty-two ounces of blood were drawn, without the smallest apparent alleviation of the disease. Vapours of vinegar and water were frequently inhaled; ten grains of calomel were given, succeeded by repeated doses of emetic-tartar, amounting in all to five or six grains, with no other effect than a copious discharge from the bowels. The powers of life seemed now manifestly yielding to the force of the disorder; blisters were applied to the extremities, together with a cataplasm of bran and vinegar to the throat. Speaking, which was painful from the beginning, now became almost impracticable; respiration grew more and more contracted and imperfect, till half after eleven on Saturday night, retaining the full possession of his intellect, when he expired without a struggle. He was fully impressed at the beginning of his complaint, as well as through every succeeding stage of it, that its conclusion would be mortal; submitting to the several exertions made for his recovery, rather as a duty than from any expectation of their efficacy. He considered the operations of death upon his system as coeval with the disease; and several hours before his death, after repeated efforts to be understood, succeeded in expressing a desire that he might be permitted to die without further interruption. During the short period of his illness, he economized his time, in the arrangement of such few concerns as required his attention, with the utmost serenity; and anticipated his approaching dissolution with every demonstration of that equanimity for which his whole life had been so uniformly conspicuous."*

The violent ague with which this case commenced was doubtless the rigor of incipient inflammation; the pain in the upper and fore part of the throat, the sense of stricture in the same part, and the labour of respiration, showed that inflammation was seated in the larynx. The difficult deglutition arose from the state of the tonsils, in which probably the inflammation commenced. The inflammation did not descend into the bronchial vessels of the lungs, wherein we are told there were no signs of accumulation. It may be inferred, therefore, as will be apparent from the sequel, that this was a genuine specimen of laryngitis.

Laryngitis generally arises from exposure of the body, or a part of it, to cold or wet, or from sudden transitions of temperature. It affects those persons who are liable to cynanche tonsillaris, and often commences as one of their accustomed attacks; and hence the patients are seldom alive to danger until a feeling of suffocation convinces them that their illness is one of unusual severity. In the Richmond Surgical Hospital, House of Industry, Dublin, we saw a case of inflammation of the larynx, which commenced in the tonsils, and was by malepractice extended to the larynx. The patient was a robust young man; his face was much flushed, his pulse quick. He was completely hydrophobiac. When he tried to swallow, the effort was followed by extraordinary difficulty of inspiration, and every attempt to articulate was productive of a sense of strangling. There was pain and great tenderness on pressure on either side of the pomum Adami. He was attacked, two days before he entered the hospital, with cynanche tonsillaris, when an old woman, partial to stimulants, as such practitioners generally are, rubbed the inflamed tonsils with pepper and salt, and immediately difficult deglutition came on, which was followed by constriction of the glottis. He fell under the care of an excellent surgeon, the late Mr. Todd, who soon restored him to health by copious general and local bleeding.

If, when the throat first becomes sore, the patient is examined, probably the uvula will appear inflamed, and the tonsils and arch of the soft palate redder than natural; and in some few instances exudations of coagulable lymph will be seen on those parts; the tongue perhaps is swelled; the face flushed; the pulse frequent, full, and hard; and the skin hot. The breathing soon becomes affected; the inspiration "is long in being completed," audible, and as if the air were drawn through a dry and narrow reed; the patient points to the larynx as the seat of uneasiness; he frequently coughs, and the cough is very peculiar in sound, not so ringing as that of croup, but harsher and more stridulous, and attended with scanty, viscid, and transparent expectoration. Pain is sometimes complained of in the chest. The voice, at first acute and piping, gradually becomes thick, then hoarse and whispering, and at last it is completely suppressed. There is sometimes great difficulty in swallowing, from the epiglottis ceasing to perform its valvular office, whence it happens that, when the patient begins to drink, a portion of the fluid escapes into the larynx, and produces a fit of coughing, which seems to threaten instant suffocation.

Laborious respiration and an inadequate supply of air before long affect the appearance of the patient. His expression becomes full of anxiety; his countenance pallid; his lips leaden; his eyes protruding and watery; his pulse is quick, feebler, and less uniform; and the surface of his body colder. Sometimes the integuments which surround the larynx, especially in the fore part of the neck, are swollen. In a case operated upon by Mr. Macnamara of Dublin, the trachea was laid bare at a depth of two inches and a half below the surface, to such an extent had the integuments of the neck become œdematous. The patient is restless and apprehensive, often changing his position, in the vain hope of obtaining relief; walking or rather staggering to and fro, or from one room to another, in

* This account is dated Alexandria (Virg.), Dec. 21, 1799, and signed by Dr. James Craik, attending physician, and Dr. Elisha E. Dick, consulting physician.

great distress: feeling that he is on the point of suffocation, he cannot be ignorant of the danger to which he is exposed; hence he is willing to submit to any means of relief, and is impatient of delay.

In this stage of the complaint the patient seldom sleeps for many minutes at a time; when he begins to dose, he starts up in a state of the utmost agitation, gasping for breath, every muscle being brought into action which can assist respiration, now a convulsive struggle. He is quite enfeebled, becomes delirious, drowsy, and at last comatose, the circulation being more and more languid, and he dies on the fourth or fifth day of the disease, or even earlier. Instances have come to our knowledge in which the disease has terminated fatally within twelve hours, (one of Dr. Armstrong's patients died in eight hours, and another in seven;) and therefore, if a person dies suddenly in the night, who had complained on the foregoing day of sore throat, laryngitis may be suspected as the cause of his death. Instances have also come under our observation, in which the disease has lasted three or four weeks, of which the following case is an example.

We have inserted the first recorded case of laryngitis, that of General Washington; and we beg to insert the first case of the disease recorded as such.* In so doing, the reader will obtain a glimpse of the second Monro, who, at a time when the most eminent of his contemporaries in England were ignorant of its existence, perfectly understood and explained to the writer of this article the nature of laryngitis.

Mr. A. æt. forty-three, robust and corpulent, in the spring and summer of 1805 was for three months under a mercurial course for secondary symptoms of syphilis. In spring 1806, he was affected with fever and pains in his limbs. In July 1806, he laid aside his flannel shirt, and thought he caught cold. July 10th, severe fits of coughing in the night; 11th, 12th, 13th, troublesome nights from the cough. V. S. ad ℥xvi. 14th to 19th, emetic, squills, opiates; 20th, respiration not quickened, but difficult, constriction felt in the larynx; long-continued fits of stridulous cough; tongue white and swelled; pulse 120; by an effort he can completely inflate the lungs without raising a cough. On this day the patient was first seen by the writer of the case, at whose request Dr. Monro was called into consultation, whose opinion was *that the symptoms arose from inflammation and thickening of the mucous membrane of the windpipe.* Twelve leeches to the left of the windpipe, and a blister to the right, pulv. jalapæ comp. ʒiß. calomelanos gr. v. July 22d, during the night he slept not many minutes at a time; cough threatening suffocation; expectoration of clear ropy mucus; hissing inspiration; tongue furred and swelled; evident fulness as well as tenderness on the left side, and in front of the thyroid cartilage, which is painful when the head is turned. When in bed his head is low, and thrown to the left side; when sitting, his chin is projected; countenance anxious. Opinion: *as the disease appears to be confined to the upper part of the windpipe, it was resolved, should suffocation be imminent, to perforate the larynx between the thyroid and cricoid cartilages.*

* Abridged from the Pathology of the Larynx and Bronchia, by J. Cheyne, M.D. Edin. 1809.

May we be permitted to introduce Dr. Monro to the student of pathology as a physician worthy of the closest imitation. In his writings we have somewhat too much of the ardor of controversy, into which he was betrayed in support of his reputation as a physiologist, ungenerously assailed; but in the common intercourse of professional life he was scrupulously correct in conduct, and in his manners urbane. He was a strict economist of time,—a man of industry and order. His mind was unceasingly occupied in the acquisition of knowledge, so that no allurement, not even the pleasure of his garden, for which he had a genuine relish, was permitted to seduce him from his daily task of recording the results of his observation, by carefully arranging and registering the facts which he judiciously collected; and hence, after he had passed the common period of life, when between his seventieth and eightieth year, he was still to be found in his study, with his case-book before him, adding to his stock of pathological knowledge. In the investigation of disease he could not be viewed without admiration. His digested experience, his keen observation, and the excellent method of inquiry which he pursued, rendered him a personification of medical sagacity, and enabled him, in consultation, to tower above the great competitors of his youth and age, the one a man of genius, the other of talent—Cullen and Gregory, who were children compared with Monro in the power of discovering the nature and predicting the course of an obscure and uncommon disease. He was remarkable for the possession of tact, employing the term not merely as expressive of discrimination, but also of that quality which, in the exploration of diseases in the thorax, abdomen, and pelvis, enables the physician, by manual examination, to detect the nature of the altered structure of the organs contained in these cavities. Monro, in his inquiries, brought not merely his touch, but all his senses to his aid in an extraordinary manner. Long before the time of Laennec he availed himself of the aid of auscultation (immediate) in ascertaining the existence and nature of diseased conditions of the heart. We have known him sit for a long time, with his ear applied to the thorax, deriving information from a mode of inquiry at that time peculiar to himself. Finally, though remarkable for caution, he possessed great decision of character, of which his practice, never rash, but often extremely bold, afforded sufficient evidence. The therapeutic agents which he employed were skilfully combined, and while mere effect was despised by him,—while

> "His vigorous remedy displayed
> The power of art without the show"—

nothing was omitted in weak compliance with the prejudices of his patient. This sketch will be pardoned by all those who think that, even with advancing age, there ought to be no abatement of zeal in the cultivation of professional science; that improvement in all things is promoted by placing models of excellence before the eyes of the student; and that an expression of gratitude is seemly. The writer, having derived many useful lessons from studying the character of Monro, has never lost an opportunity of paying an humble tribute to his memory. It appears surprising that this great pathologist should have been allowed to retire from the theatre of his usefulness without receiving one valedictory plaudit.

Leeches, blister, steam of warm water and vinegar. July 24th, miserable nights; often on the point of suffocation; pain on pressure in every part of the trachea, pulse 128; tongue more swelled. July 27th, in the last three days a pound of blood was drawn each day. The first blood sizy and cupped. Laudanum produced sleep, but he awoke gasping, dyspnœa being then more severe. Sometimes he started from his chair, and staggered from one room to another; then his face was quite livid; his pulse, an hour after a paroxysm, was 136. Tongue swelled, and indented from the impression of the teeth. Emetic of ipecacuanha proved nearly fatal. When he began to vomit, his inspiration was interrupted and crowing; his face was pale, and his lips livid. Gr. ii. calomelanos ter quotidie. Evening, haustus cum tinct. opii et vini ant. gutt. x. August 4th, sickness after the evening draught, which lasted all night. At 7 A. M. breathed with great difficulty; extremities cold. He was taken out of bed and seated on a sofa, supported with cushions and pillows, after which his head fell upon his breast, and he ceased to respire. When his head was raised, respiration was resumed, but it was stertorous, and his complexion was changed from the purple of imperfect respiration to the paleness of a cadaver. Bronchotomy was performed without effect; he died in about two hours after the operation. We were not permitted to examine the body, but concluded that death arose from closure of the rima glottidis, owing *to thickening of its lining membrane*.

At one time it was conjectured that this case was connected with syphilis; but if such complication had existed, it is probable that the inflammation would, in four weeks, have reached the ulcerative stage, of which the expectoration afforded no evidence. This case, with several others which fell under our care, induced us to attempt a definition of the disease in the following terms. "Pain in the larynx not very acute, unless on pressure; some degree of fulness externally; a change in the sound of the voice, difficult and even crowing inspiration, but slow rather than quick; an altered, sometimes stridulous voice; fits of suffocative coughing; and all those symptoms which arise from obstructed circulation in the lungs."*

Causes.—Persons advanced in life are more liable to laryngitis than the youthful; and of the former the disease most frequently occurs in such as are liable to indigestion, connected with a disordered condition of the liver. Several of our patients had been habitually intemperate. The exciting causes of laryngitis, as we have already mentioned, are such as usually are productive of common cynanche or catarrh, the principal being exposure to cold.

Prognosis.—In some few cases of laryngitis the inflammation recedes, and the disease terminates favourably. This favourable change we may presume is taking place when we discover that the swelling of the epiglottis is subsiding, that the difficulty of breathing and pain of the larynx are abating, and when freedom of expectoration is restored, and deglutition becomes easy. On the other hand, the danger increases with an increasing struggle of breathing. Paleness and lividity of the complexion, a prominent watery eye, and lethargy or stupor, are symptoms which indicate great urgency of danger. It may fairly be affirmed that laryngitis is the most fatal of the phlegmasiæ; consequently the prognosis, in every stage of the disease, must be delivered with the utmost caution. "Of seventeen cases of laryngeal angina observed by Bayle during six years, only one ended favourably."

Diagnosis.—The diseases which are most liable to be mistaken for laryngitis are—

1. Ossifications and caries of the cartilages of the larynx. This state of these bodies gives rise to extensive ulceration, of which the diseased cartilage is the centre. This affection is often of slow growth, beginning with uneasiness in the region of the larynx, followed by hoarseness; then occur cough, difficulty of breathing, which is croaking, sibilous, and in paroxysms; and difficulty of swallowing; purulent expectoration, which is often of extraordinary fetor; sometimes diseased portions of cartilage on which the fetor depends, being expectorated. We learn from Dr. Monro's Outlines of Anatomy, that the cartilages of the larynx, especially the thyroid, and sometimes even those of the trachea, are occasionally found ossified. In examining the body of an old man, who for the last six years of his life had been subject to a severe and almost unremitting cough, "I found," says Dr. Monro, "the cartilages of the larynx ossified, a considerable quantity of viscid mucus within the trachea, and its internal coat thickened, spongy, and red. In such cases, the mobility of the different component parts of the larynx being lessened or destroyed, the voice becomes much feebler; and there have been instances, as I have been informed by my father, of these morbid ossifications exfoliating internally, and portions of the bony matter expelled by coughing." By a patient labouring under disease of the cartilages of the larynx, who was under the care of Dr. Colles of Dublin, one of the arytenoid cartilages was expectorated; and Dr. Hunter, as we learn from Dr. Baillie, "knew an instance in which the cricoid being converted into bone was separated by exfoliation, and afterwards coughed up." Abscesses thus formed sometimes burst into the œsophagus, sometimes into the cavity of the windpipe, and sometimes they open externally. When the patient escapes sudden suffocation, this disease, which admits of treatment similar to that of simple laryngitis, usually ends in hectic fever. In general it is not attended with inflammation of the epiglottis, and instead of terminating within four or five days, its course is tardy. To this disease, rather than to simple laryngitis, we apprehend belonged the case of the Right Hon. Isaac Corry, as detailed by the late amiable and accomplished Dr. Edward Percival, in the fourth volume of the Medico-Chirurgical Transactions. In Mr. Corry's case,

* Vide Pathology of the Larynx, p. 161.

as we learn from Dr. Colles, who was one of his attendants, the epiglottis was in a natural state, and the rima glottidis little if at all reduced in its capacity. Of the same nature appears to have been the first of Mr. Lawrence's cases, published in the sixth volume of the Medico-Chirurgical Transactions, and the case furnished by Dr. Latham, and published in the same paper, in which, on dissection, there were found two distinct ulcerations through the substance of the thyroid cartilage, which contained pus. Mr. Goodeve's case, published in the London Medical Journal, July, 1825, was probably of the same nature, as the patient's voice and respiration improved after the expulsion of a piece of bone from the glottis.

2. Abscesses in the vicinity of the windpipe, compressing that tube, are sometimes formed in the neck, under the fascia, and are discoverable by hardness, swelling, and pain on pressure, œdema, and inability to open the mouth widely; they are often accompanied with fever of a typhoid nature, which we have more than once considered as the primitive disease;* but as, by an incision, relief may occasionally be obtained, the treatment chiefly belongs to surgery. The usual situation of these abscesses, according to Mr. Porter, is behind the broad portion of the cricoid cartilage, where it presses on the rima glottidis. The progress of this disease is sometimes rapid; sometimes the abscess bursts behind the rima glottidis, and hectic ensues.

3. It will be necessary to recollect that aneurismal tumours have given rise to symptoms resembling those of laryngitis, of which there is an example in Mr. Lawrence's paper. We learn from that eminent surgeon that a patient laboured under great difficulty of drawing air into the chest, coming on in fits, which Mr. Lawrence supposed might be relieved by bronchotomy, and therefore he desired that he might be sent for on the occurrence of a fit. After the patient's death, her disease was found to be an aneurism of the arteria innominata, situated between the first bone of the sternum, and pressing on the trachea. Mr. Wood knew an instance, in which tracheotomy was performed, which was attended with bursting of the aneurism into the trachea, and he refers to several such cases.

Pathology.—In several dissections which we have superintended, we have observed appearances corresponding with those described by Drs. Farre and Baillie, and Mr. Porter. Swelling and other remains of inflammation of the tongue, velum, arch of the palate, and fauces, may occasionally be seen. The following appearances are always visible. The epiglottis thickened and erect, by which it ceases to protect the aperture of the windpipe; the mucous membrane of the glottis and larynx, as well as the epiglottis, thickened and vascular; underneath the mucous membrane an infiltration of serum. This thickening of the mucous membrane and distention of the submucous tissue, from inflammation and effusion, bring the sides of the rima glottidis nearly into contact, and thus at length almost obliterate the passage.

Coagulable lymph has occasionally been found on the free surface of the mucous membrane. In the second case related by Dr. Farre, in the third volume of the Medico-Chirurgical Transactions, coagulable lymph was effused from the inflamed surfaces about the glottis and epiglottis, and thus assisted in closing the rima. The tumefaction of the mucous membrane generally ceases at the junction of the larynx and trachea, but increased vascularity may sometimes be discovered in the trachea and bronchi.

The two phenomena which invariably characterize the anatomy of laryngitis, (the latter a consequence of the former,) are—1st, inflammation and some thickening of the mucous membrane; and 2dly, œdema underneath, which latter state, although it cannot be called peculiar to this affection, is a very unusual attendant upon any other disease of the mucous membrane.

That laryngitis is an inflammatory affection, we have abundant proof. The fever which belongs to the disease is attended with increased heat of surface, and frequent and strong pulse. The blood is sizy. The parts affected are swelled and painful, and we may sometimes obtain a view of a portion of the affected organ in a state of intense inflammation. When the tongue is not much swelled, by depressing its root, by pushing the root downwards and forwards by means of a spatula, elevating at the same time the handle of the spatula, we can discover the epiglottis erect, florid, swelled, and rounded. One writer on the disease has well described the epiglottis as being enlarged, red, glossy, and nearly of the size and appearance of a plum:* inflammation, thus denoted by swelling and glossy redness, is, doubtless, the state of the glottis as well as of the epiglottis.

Mere inflammation of the membrane will be productive of uneasiness and occasional difficulty of breathing from spasmodic stricture. But effusion into the submucous tissue must render the difficulty of breathing permanent, and lead to asphyxia, when, from narrowing of the glottis, the supply of atmospheric air becomes insufficient to effect the removal of the venous character of the blood during its passage through the lungs, and when, consequently, those functions which depend upon the arterial properties of the blood being restored, and more especially the function of the brain, are interrupted.

In laryngitis, asphyxia may take place under a variety of circumstances. 1st. We have known asphyxia take place, in the course of the first night of the disease, from strangulation, the patient being found in the morning quite dead. 2dly. Asphyxia much more generally

* These abscesses are frequently fatal, as in a case related by Dr. Tweedie, which occurred during convalescence from fever. Dr. Tweedie has also met with cases of symptomatic laryngitis, both in continued and scarlet fever, which generally rapidly destroys life by causing œdema of the glottis.—*Clinical Illustrations of Fever.*

* *Mr. Wilson,* vol. v. Medico-Chirurg. Transactions, p. 158.

arises from gradual depravation of the circulating fluid. 3dly. Death may also take place after the obstruction has been removed by means of a surgical operation, as in the case of Mr. A. In such case the brain, in consequence of the transmission to it of blood in a state of imperfect oxidation, receives a shock from which it never recovers, even when the lungs are again abundantly supplied with air. This is like the shock from submersion, which we have known to be fatal after the pulse and respiration had been restored. In the two latter cases the patient dies from disease of the brain, and not from strangulation. Œdema productive of death may be the work of one night; yet, generally, the morbid process is prolonged for four or five days; the difficulty of breathing, at first often remitting, we apprehend must be referred partly to spasm caused by inflammation of the membrane. In the progress of the disease, however, the dyspnœa becomes unremitting, which cannot be accounted for unless on the supposition of a permanent narrowing, the effect of œdema. If we had any certain means of ascertaining when the membrane is merely inflamed, and when it is œdematous as well as inflamed, much of the difficulty which attends the treatment of the disease would be removed.

Treatment.—But as we have no certain means of establishing the condition of the windpipe, we must be guided by the symptoms of the disease in deciding the question of bloodletting, which is one of the most difficult points in therapeutics. Although bloodletting may be expected to remove the inflammation of the mucous membrane, it cannot be expected to remove the effusion from the tissue beneath it: as well might we expect that bloodletting would remove phlegmon after matter is formed, as that it will remove laryngitis after œdema is established. It may prevent the further deposition of serum, and render it easier for the absorbents to act upon that which has been already effused; but more than this we are not to expect.

The practice of the physicians who attended the great American President during his last illness, was, we conceive, very unfairly decried by some of their professional brethren on this side of the Atlantic; and this is the more remarkable, as medical criticism was not so grossly vituperative thirty years ago as it is now. In a medical journal of 1800 we find the following specimen of gratuitous illiberality:—"Think of a man being, within the brief space of little more than twelve hours, deprived of eighty or perhaps ninety ounces of blood, after swallowing two moderate American doses of calomel, which were accompanied by an injection; then five grains of calomel, and five or six of emetic tartar; vapours of vinegar and water frequently inhaled; blisters applied to the extremities; a cataplasm of bran and vinegar to his throat, upon which a blister had been already fixed: is it surprising that, when thus treated, the afflicted general, after various ineffectual struggles for utterance, at length articulated a desire that he might be allowed to die without interruption! To have resisted the fatal operation of such Herculean remedies, one should imagine that this venerable old man ought at least to have retained the vigour of his earliest youth. A British physician may be deemed not competent to ascertain the propriety of transatlantic practice; the current of blood in the inhabitants of the new world may bear some proportion to the current of its rivers; in that case the medical treatment ought likewise to be conducted on a larger scale," &c. In answer to this rhapsody, in which the writer has tried to destroy the character of two respectable physicians, it may with truth be affirmed, that when these gentlemen pronounced the disease of which their illustrious patient died to be cynanche trachealis, they proved that they were not ignorant men. They shewed that they were not ignorant of the seat and nature of the disease; they knew it to be seated in the upper part of the windpipe, and to be of an inflammatory nature. We venture to say that their critic would not have been nearer the mark. Perhaps there was not in Britain more than one individual, namely Monro, who was acquainted with the true nature of the disease of which General Washington died. The late Dr. Pitcairn, a physician in London, of deserved reputation and character, ten years after the death of General Washington being attacked with the same disease, when no longer able to articulate, "wrote down with a pencil on a slip of paper that his complaint was to be considered as croup." Nay more; Dr. Pitcairn's case was the first which the late Dr. Baillie, then at the head of the medical profession in England, had ever witnessed; and that great physician, with his characteristic candour, admits that he was ignorant of the nature of the disease of which his friend Dr. Pitcairn was dying. Dr. Pitcairn, the day before he died, did not consider himself in danger, but thought that he was suffering under an attack of cynanche, such as he had often experienced, with a little more than its usual severity; and this, adds Dr. Baillie, was so much impressed on my mind, "that I did not even examine his throat, nor did he seem to wish it." Moreover, four hours before his death, when drowsiness was coming on, Dr. Baillie "thought him somewhat better." Hence it is probable that the best informed physicians in England, prior to the publication of Dr. Farre and Dr. Baillie's papers on cynanche laryngea, would have pronounced General Washington's case to be one of cynanche trachealis. This being admitted, the American physicians ought not to have been charged with ignorance, nor their practice so mercilessly impugned. What are the most approved remedies for croup? Bleeding, tartar emetic, blisters, and, according to many, calomel: these were the remedies which General Washington's physicians prescribed, and which they administered, it must be admitted, with boldness. Whatever injury the patient sustained from the measures employed ought to be charged, not to the account of the intelligent physicians who attended him, but to the less perfect state of pathology at the end of the eighteenth century than at present.

General Washington died within twenty-four hours of the commencement of his illness; and we cannot deny that in this supposed case of croup, the remedies employed, however justifiable in the then state of medical information, probably shortened the general's life. If bleeding fails to subdue an inflammatory disease, it will be hurtful "by depressing the power by which the muscles act;" and on the vigorous action of the muscles which expand the chest, depends a continuance of that struggle by which the lungs are supplied with air sufficient for the arterialization of the blood.

We acquire a juster view of laryngitis by contrasting that disease with croup. They are both truly inflammatory diseases, but in that point alone do they resemble each other. Croup is a disease occurring before puberty, generally affecting, not merely the larynx, but the whole of the bronchial membrane, ending in an effusion of lymph on the free surface of the membrane, to be cured, probably, in ninety-nine cases of a hundred, by emetics and bleeding timely employed; and it is a disease in which a surgical operation will only add to the danger, to which in the second stage the patient is exposed. Laryngitis, on the other hand, is a disease which rarely occurs before puberty; is confined to the upper extremity of the windpipe; ends in a serous effusion into the cellular tissue beneath the mucous membrane; will probably terminate unfavourably in a great majority of cases under any method of treatment, in which emetics aggravate the danger and bleeding is often a doubtful remedy, and in which, when the patient is *in extremis*, bronchotomy will afford the only reasonable hope of safety.

Bloodletting has been successfully practised in this disease, as the reader may be convinced by several recorded cases: for example, by a case to be found in a paper on laryngitis, published by Dr. Beck of New York, in the twelfth number of Dr. Beck's Journal. The case occurred in the person of Dr. Francis, one of the editors of the journal, who, having for three days had soreness of the fauces and thirst, was attacked with pain, difficulty of breathing and swallowing, and a sense of strangulation, for which symptoms 152 ounces of blood were abstracted.* For three or four days after, the patient was still in a precarious condition, and required a repetition of the bloodletting. Other cases are published, in which the lancet was successfully employed: in one of these, to be found in the sixth volume of the Medico-Chirurgical Transactions, viz. that of Sir J. Macnamara Hayes, as reported by Dr. Roberts of Bishop Stratford, we learn that the first bleeding "was attended with considerable relief," the second "with manifest advantage," by the third "his safety appeared to be ensured." In the case of a young woman who earned a pittance by gathering cockles on the strand at ebb-tide, and afterwards hawking them through the streets of Dublin, who, on the 13th of July 1813, presented herself at the county of Dublin Infirmary on the second day of laryngitis, pale, scarcely able to articulate or swallow, the effort producing a convulsion as when a crumb enters the windpipe, the voice sounding as if she were throttled, inspiration being slower than natural and sibilous, the following treatment proved successful. At noon, she was bled ad deliquium, which by the way had nearly proved fatal. The venesection was repeated twice in the course of the evening. On the following day respiration was rendered difficult by the least exertion; hitherto unable to swallow. She was again bled, and a purgative enema and blister prescribed. Next day she began to expectorate yellow mucus, and could swallow fluids. On the 16th July convalescent.

It is observable that the lividity of complexion which, especially in the more advanced stages of laryngitis, arises from imperfect arterialization of the blood, did not exist in any of these cases.

On the other hand, bloodletting has been unsuccessfully practised in laryngitis, not only in the case of General Washington, but also in many others. In the second attack of laryngitis, that to which Sir John Hayes fell a victim, he was three times bled from the arm on the second day of his illness, and the result of his case and the other cases reported by Dr. Baillie, in which also bloodletting was practised, led Dr. Baillie to affirm that "venesection, even when employed strenuously and early, was of no real use." But the most remarkable instance of the inefficacy of bloodletting may be found in Dr. Armstrong's Practical Illustrations of Typhous Fever, p. 393. The loss of one hundred and sixty ounces of blood within six hours gave temporary respite to the difficulty of breathing, yet was so far from arresting the inflammation that death took place within twenty-four hours. As, then, there are cases in which bloodletting is salutary, and cases in which it is hurtful, let us try to ascertain when and to what extent that remedy ought to be practised; and let us be permitted to premise that cases will occur in which it may be difficult to come to a satisfactory conclusion with respect to bloodletting—in which the considerations for and against that remedy will be balanced, so as to make the most skilful and experienced physician pause. In such a dilemma, however, it will be well that the physician should not allow his doubts to transpire; as doubts which may be the result of an accurate weighing of indications against contra-indications, and which prove that he is a pathologist, will, perhaps, by the world and by his unreflecting brethren, be thought to proceed from inexperience and perplexity.

We conclude, first, that bloodletting will be more clearly indicated in youth than in age: it may be observed that the same means by which Sir John Hayes was relieved during his first attack which took place in the meridian of life, failed fifteen years after:—and, secondly, that we may bleed with most hopes of success when the symptoms of inflammatory fever are

* On the 17th Nov. 1823, V.S. ad ℥xl.; evening, ℥xx. 18th Nov. ℥xvi.; evening, ℥xvi. 19th Nov. ℥xvi.; evening, ℥xvi. 20th Nov. ℥xvi. 22d Nov. ℥xii.—Total ℥clii.

most evident: in Sir John Hayes, during the first attack, the face was swollen and flushed, the eyes were protruding and bloodshot; there was fulness about the neck, the muscles feeling very turgid, and the breast being suffused with a purplish colour; whereas in the second attack, we find that his skin was not hot, nor his pulse more frequent than in health.

"At the beginning of the attack, it may be advisable," says Dr. Baillie, "to take as much blood at once as to produce fainting. We beg to submit to the reader, that blood in laryngitis is sometimes so imperfect a stimulus to the heart, that if the action of that organ is interrupted, it is not improbable that it will never be resumed. In certain conditions of the circulation in this disease, I have found bloodletting a very dangerous measure. I think it was fatal to a patient who came to the County of Dublin Infirmary about twenty years ago, when I was one of the physicians to that hospital. By my orders he was let blood, not till he fainted, but till he became pale and fainty; very shortly after the operation, which sensibly reduced his strength, he was seized, upon slightly exerting himself, with a paroxysm of difficult breathing, not more violent than many from which he had emerged during the two or three previous days, and expired." In Dr. Beck's paper, already referred to, we learn that Dr. Hoffman of the United States Navy was called to a patient in laryngitis whose countenance was anxious, flushed, and covered with sweat; eyes staring, and dyspnœa insufferable; that a vein was opened in each arm, which bled freely, and that death took place in a few minutes after. Mr. Porter, in the eleventh volume of the Medico-Chirurgical Transactions, after drawing a very lively and accurate portrait of laryngitis in a man about thirty years of age, who came to the Meath Hospital with his face pale and swollen, his lips livid, his mouth closed, his nostrils widely extended, his eyes protruded and starting from their sockets, but at the same time with the conjunctiva very white and covered with a watery suffusion, and with an expression of indescribable anxiety; his pulse hurried, and his breathing very laborious, making two or three or even more attempts at inspiration for one expiration, and his convulsive struggles for breath truly painful to behold, breathing with a hissing or whistling sound, while the utmost endeavour at speech was only an indistinct whisper;—tells us that he ordered from thirty to forty ounces of blood to be taken from both arms, and adds that in about two hours afterwards, when he returned to the hospital to perform bronchotomy, there was scarcely a pulse to be felt at the wrist; the extremities were cold; the patient lay on his back almost insensible, and seemed sinking with amazing rapidity. Knowing the candour of the intelligent and skilful reporter of this case, we are not afraid to observe that this was a combination of symptoms in which bloodletting was not likely to improve the condition of the patient, for whose sufferings the proper remedy was the knife, which was afterwards successfully employed. Indeed, Mr. Porter, in his valuable remarks on the case, has affirmed that it presents a strong illustration of the inefficacy, in laryngitis, of bleeding, blisters, and the various internal means usually resorted to for the purpose of subduing inflammation. We conclude, that although we may bleed in certain states of the disease so as to influence the pulse, it would be unsafe under any circumstances to bleed usque ad deliquium.

The question of bleeding may with most safety be determined by the condition of the circulating fluid. We may, with comparative safety, bleed while the complexion is good, or, in other words, so long as the quantity of atmospheric air admitted into the lungs is sufficient to produce that chemical change by which venous blood, in passing from the right ventricle to the left auricle, is converted into arterial; but when the alteration in the appearance of the patient takes place remarked in the advanced stages of the disease, which indicates that the blood is no longer arterialized in its passage through the lungs; when the face and lips, especially the latter, become livid, the expression anxious, the eyes protruded and watery, and when these appearances are established permanently, we may conclude that the stricture of the glottis is of a nature not to be relieved by bloodletting, and if so, that the patient will be injured thereby.

In the early stages of laryngitis, would not the application of leeches to the palate and tonsils be deserving of a trial? This question the reader will be better able to answer after he shall have read a short but valuable paper by Surgeon General Crampton, in the third volume of the Dublin Hospital Reports, on the application of leeches to internal surfaces. Mr. Crampton informs us, that in no instance in which leeches have been applied to the tonsils within the first twelve hours of the attack of inflammation, has the disease proceeded to suppuration.

We would bleed the patient freely during the first twenty-four hours; we should be disposed to do more—so long as the complexion of the patient is good, we would have recourse to venesection, keeping a finger on the artery while the blood flows, and closing the orifice when the pulse is reduced; we would have leeches applied, or blood removed from the nucha by cupping; and should be disposed to bleed again, or even a third time, so as to abstract forty or fifty ounces of blood, and at the same time let the patient have a powder containing two or three grains of calomel, three or four of pulvis Jacobi veri, and one-half or one-third of a grain of opium, every third or fourth hour, till the gums become affected. This we prefer to an exhibition of tartar emetic, not wishing to expose the patient to the danger of vomiting, which is productive of a frightful struggle in laryngitis. Blistering the neck is of very questionable efficacy, and by the inflammation, stiffness, and soreness which it occasions, adds much to the sufferings of the patient, and, when bronchotomy becomes necessary, to the inconveniences which attend that operation. If the physician reposes much confidence in the antiphlogistic power of a

blister, let it be deferred till bleeding has been carried as far as is expedient, and then let it be applied to the upper part of the sternum.

"From bleeding and opiates," says Dr. Baillie, "if no substantial advantage is produced in thirty hours, it might be advisable to perform the operation of bronchotomy at the upper part of the trachea, just under the thyroid gland." We apprehend, however, that a consideration of the mere duration of the disease will lead us astray; thirty hours may be too long to wait, or it may be too short. If the circumstances of the patient, especially the condition of the circulating fluid, be such as to contra-indicate bleeding, and to show that asphyxia is imminent, it may be improper to put off the operation for thirty minutes. If the complexion is good, if asphyxia is not threatened, the operation may be delayed for thirty days.

In Dr. Baillie's second case already referred to, it is stated, "in the night time, the patient becoming much worse, Mr. Tegart, who scarcely ever left him night or day, went for Mr. Home and Mr. Wilson to perform the operation of bronchotomy. Mr. Wilson was out of town on professional business, but Mr. Home came about four in the morning. The patient, however, was beginning to sink, so that no advantage from an operation was now to be expected." It is, indeed, probable that bronchotomy would not have saved the patient; but as that operation in an adult can be performed without difficulty, and as there are instances of its having been successful even when the brain was oppressed, which is the most alarming symptom in this disease, we humbly think that no patient who is not in the article of death ought to be deprived of the chance of escape which it affords. The patient operated upon by Mr. Goodeve, surgeon to the Clifton Dispensary, was quite insensible when the operation was performed; "no pulse could be found at the wrist, his face was suffused with blood and his lips livid, and it was hard to say whether he breathed or not," and yet he recovered.

There can be little doubt but that in most cases the aperture ought to be made between the thyroid and cricoid cartilages, but in this matter the surgeon must be the arbiter.* The operation has often proved perfectly successful, and a canula has been worn for a long time without much inconvenience. Thus the patient operated upon by Mr. Goodeve wore a tube for more than six months; he was then able to lay it aside, and his voice was quite restored. In the fourth volume of the Dublin Hospital Reports, we learn from Mr. White that one of his patients was wearing a tube without being prevented from working at his trade, which was that of a cabinet-maker, two years after the operation; the sides of the opening, which was of an oval shape, and one inch in depth to the trachea, being perfectly healed, smooth, and covered with a thin cuticle. But the most remarkable proof of the relief which the canula is capable of affording, is that which is supplied by the case of Mr. Price of Portsmouth; we learn in the twenty-ninth number of the Medico-Chirurgical Review, in which journal there is much valuable information to be found on laryngitis, that Mr. Price had been breathing for about fifteen years through a canula.

Laryngitis sometimes is more of a chronic than acute affection, in which case the affected organ probably undergoes a considerable change of structure; in the case in Mr. Lawrence's paper, which we have already alluded to, which continued for nearly four months, the mucous membrane had assumed a thick and puckered condition, and had partially thrown out coagulable lymph of a stringy and fimbriated texture, which obliterated the ventricles of the larynx. In one of our cases which had lasted four months, the membrane lining the glottis, and arytenoid cartilage, was like a thin layer of flexible cartilage. In chronic laryngitis, *mutatis mutandis*, the same principles of treatment are applicable as in the acute species. Bronchotomy may be necessary to prevent that fatal exhaustion arising from continued disturbance of the respiratory function, as it was in the case related by Dr. M. Hall in the tenth volume of the Medico-Chirurgical Transactions; but medical means alone will often prove sufficient for the removal of the inflammation if it be unaccompanied with ulceration. The remedies chiefly to be relied on in chronic succeeding acute laryngitis, are, change of air—this remedy we again specify, even at the risk of being thought to harp a little too much upon one string;—the establishment of a discharge from both sides of the larynx by means of small caustic issues; and mild mercurials, with the infusum sarsaparillæ compositum of the Dublin pharmacopœia.

(J. Cheyne.)

LEGITIMACY. See Succession.

LEPRA.—Λέπρα: from λεπρὸς -ρα, *scaly; th.* λέπις, or λέπος, *a scale.* A scaly disease of the skin, occurring generally in circular patches. At a very early period of medical literature, the

* On this subject consult Mr. Lawrence's paper in the sixth vol. of the Medico-Chirurgical Transactions.

The writer of this article many years ago recommended the introduction of a trocar and canula, without previous incision. This operation is justly condemned by Mr. Wood in his valuable paper published in the seventeenth vol. of the Medico-Chirurgical Transactions. Mr. Wood observes: "Dr. Cheyne has advocated an operation equally reprehensible with that of Pessault, (who recommended the introduction of an elastic tube through the nostril into the trachea,) *that of introducing into the trachea a trocar and canula without previous incision.* The reflection that the canula must irritate by being moved up and down with the larynx, which does not move in association with the skin, combined with the danger of wounding a large bloodvessel irregular in its course, the œsophagus and contiguous important parts, and the depth it may be necessary to penetrate in consequence of the unusual depth of the trachea from the surface, ought to preclude this use of the trocar," &c. This quotation is introduced as an *amende* for the inconsideration that led to the proposal of an operation which is so objectionable.

confusion, which afterwards became "worse confounded," began to reign concerning the terms *lepra* and *leprosy*. The Arabian physicians had described the tubercular elephantiasis, the elephantiasis of the lower extremity, and some varieties of scaly disease, under distinct appellations, which became frequently misapplied. When, at the revival of learning, their works were rendered into the European languages, the Latin translator multiplied the perplexity by interpreting the Arab word *juzam* by the term *lepra*, which the Greeks had applied to designate the scaly disease defined above. In the middle ages the term leprosy was indiscriminately applied to the different forms of elephantiasis, the scaly diseases, and, in fact, to any form of chronic skin-disease which was bad enough to entitle the subject of it to admission to the lazar-houses which were established over Europe at that time, where the indigent were glad to get the subsistence they provided at the expense of being called lepers. This confusion has been a subject of complaint with writers from age to age, yet it became perpetuated. Hensler's learned treatise,* written with a view to elucidate the subject, left it nearly as complicated as ever; for he and Sprengel treated under the term leprosy the various forms of elephantiasis, the Greek leuce, and the proper scaly lepra. Many modern writers do not appear to desire the removal of this obscurity, as they persist in describing the former of those under the name of leprosy. We trust, however, that medical men will now see the expediency of adhering to Willan's correct nomenclature in this instance, which restores to the term lepra its proper and original signification, namely, the scaly disease, the subject of this article.

History of the disease.—Lepra generally begins on the extremities, below the larger joints, where the skin covers but thinly the tibia and ulna respectively. It commences by small, roundish, smooth points, slightly prominent above the surface of the skin, which soon become red and shining from being overlaid by minute transparent scales. These become soon detached and replaced by others. The eminences by degrees enlarge; the scales become thicker, and are chiefly formed on the circumference of each spot. They observe the circular form in spreading, and attain the size of a shilling or a half-crown piece; and as they increase, the circular border becomes raised and encloses a red area, which is free from the squamous development. A red areola is also perceived external to the raised circumference where the scales collect. These orbicular patches, in spreading, touch and intersect one another; and though in this stage the circular form is lost, we may still trace the segments sufficiently well to shew their original conformation. They unite usually first at the elbows and knees, the parts, as we have said, where the disease first shews itself. In the progress of the affection, while the existing patches are enlarging in this manner, new ones arise; the abdomen, the back, and the chest become affected; and in some cases it spreads to the head, face, and hands.

The scales fall off and are renewed very frequently. Sometimes they are so easily detached and form so rapidly, that the patient's clothes and bed are filled with scales, which cause some irritation: in other instances they adhere more firmly, and accumulate in such quantity as to impede the motions of the joints,—a still greater source of troublesome annoyance.

By their multiplication the scales become aggregated apparently in an irregular manner; yet each one is propagated from a centre, and is attached by a pulp to the dermoid tissue: this fact is proved by tearing one off, when a slight red speck is seen to project from the middle of the inferior surface, corresponding to a depression in the spot whence it has been displaced. When the disease has lasted long, or is in process of cure, the scales, as they fall, present the reticular eminences proper to the cuticle, and leave the surface red, smooth, and marked by corresponding reticulations.

The description here given will apply to the great majority of cases of lepra, but it presents varieties derived from its extent, duration, and treatment. The accidental circumstances of situation and colour also impart to it certain peculiarities.

It sometimes covers the whole body, commencing for the most part from the extremities; it begins usually on the two arms and legs at once, and propagates itself, as described, to the trunk; it rarely spreads to any extent on the face: the forehead, the temples, and the external angles of the orbits are, however, often the seat of some scaliness spreading from the hairy scalp. When the scalp becomes affected, the scales are very minute, and generally cover an exudation derived from the inflamed bulbs of the hair; a moisture is also remarked to accompany the scaliness when the disease invades parts where there is a necessary friction, or places furnished with many sebaceous follicles,—as the nates and inside of the thighs, the axilla, the verge of the arms, &c. These form exceptions, however; for it is one of the essential characters of the disease that the desquamation is quite dry.

In cases of a very chronic nature, where the disease is of such extent as to spread over the hands and invade the root of the nails, these become much altered in structure, curved, and of a dirty yellow colour. It has been observed in some rare instances that the dermoid tissue which secretes the nail has become inflamed and furnished a sanious discharge (*Rayer*). In the cases which are complicated by any of those accidental secretions, the lymphatic glands sometimes inflame and swell, as Richter remarks; but we cannot admit into the description of lepra the rhagades and ulcerations which are mentioned in his excellent work.*

* *P. G. Hensler.* Vom Abendländischen aussatz im Mittelalter, nebst einem Beitrag zur Kentniss und Geschichte des Aussatzes. Hamburg, 1792.

* Specielle Therapie, vol. vi. p. 440.

A remarkable appearance which lepra sometimes assumes has induced accurate observers to recognise in it a peculiar species of the disease. It has been observed on parts of the trunk that a complete desquamation over a considerable surface takes place without being followed by any reproduction of scales in this particular place: it remains red and smooth, and still affects the circular form; and not only is the whole area round and bordered by a slightly raised margin, but it contains within it some patches, either circular or obviously shewing a disposition to that form, yet without scales either on the centres or the raised borders—their usual nidus. What makes this variety more remarkable is, that whilst the patches exhibit this feature probably on the back, it is as scaly as ever on the extremities. We must not, however, suppose that this partial absence of scaliness in such rare cases makes any exception worth notice in the history of lepra; in some instances it probably depends on idiosyncrasy, but we think it is more frequently a partial curative effort of nature, or the effect of medicine, which from some unaccountable cause is arrested after having proceeded only so far as to check the morbid secretion of the cuticle, the vascularity still remaining. This explanation is rendered the more plausible if we consider the locality of the phenomenon, and the manner in which the disease usually advances towards a cure in the cases where we can trace its disappearance under the influence of medicine. Its situation, as we have said, is on the trunk, almost invariably on the back; and it is here that, when lepra begins to yield to any of the methods of treatment to be mentioned afterwards, the effect is first visible.*

The constitutional disturbance attending on lepra is for the most part very trifling, particularly when we consider the large cutaneous surface which is frequently engaged; sometimes a slight fever, accompanied with gastric symptoms, coincides with its first attack; but when established, it goes on for months and years without constitutional symptoms of any import arising from it. Its most troublesome accompaniment is a disagreeable pruritus, which attends its commencement and increase. This occurs particularly when the circulation is excited by exercise or full diet, and when the warmth of bed exalts the cutaneous action: it is sometimes aggravated to a burning heat which is almost intolerable. This itching and tingling is not peculiar to lepra, but is met with in most diseases of the skin attended with inflammation, and is often present in a greater or less degree as a symptom of internal disease. Mr. Plumbe's explanation of this phenomenon is too mechanical, and, though ingenious, inadmissible. He thinks that it is to be referred to the raising up of the scales by the increasing development of the "inflamed margin, and fresh growth of scales, the centre which was attached to the cutis being thus forcibly torn from such attachment." He supports this opinion by the observation that the pricking occurs most constantly at the commencement, when the new scales are oftenest detached, and seldom happens when the disease is subsiding. We consider this pruritus to be a morbid sensation, depending probably on an altered secretion in the skin, and the reason appears to be very obvious why it happens in the commencement. The morbid secretion which forms the scale affects the sensibility of the skin more strongly at first, when the impression is new, than afterwards, when the squamous deposits become an accustomed stimulus to it, and besides at this period the cutaneous sensibility becomes somewhat impaired: the subsidence of the disease is of course not marked by pruritus, as the vascular irregularity producing the scaly secretion is now returning to the physiological state. This explanation is applicable to the itching and tingling of other cutaneous affections, and to that which is symptomatic of hepatic and other visceral derangement.* Hippocrates remarked that the pruritus increased before rain.

Although much constitutional disturbance be rare, yet if lepra spread over the whole body, and is severe in degree, it often produces some anxiety and febrile excitement, partly from the general extension of the subinflammatory state of the skin, and partly from the mere mechanical annoyance that the scaly incasement gives rise to by obstructing the free motion of the joints, which become sometimes painfully tense, and so stiff as to oblige the patient to keep his bed.

Willan and Bateman, endeavouring to systematise different terms used by the Greek writers, divide their genus lepra into three species, a division which is considered unnecessary by the most judicious writers. Their lepra vulgaris is the disease we have described here, and comprehends all the varieties.

Lepra alphoides is a mere variety of the common lepra, possessing the same essential characters, and requiring similar treatment. It is a form in which there is less redness of the skin and elevation of the circular margins: the scales also are smaller and of a more pearly whiteness. It seldom reaches the trunk, and it generally attacks children, aged persons, or those

* It appears to be a law in pathology that the resolution of a disease commences from the place to which it has last extended: of this pneumonia is an instance familiar to stethoscopists, yielding first where it is most recent. It also sometimes affords an example of a state which we think is analogous to the appearance of lepra which we are discussing,—we mean those cases which will, no doubt, present themselves to the memory of accurate observers, where the pneumonia, after proceeding a certain way towards resolution, remains stationary, neither going backwards nor forwards. This appears to us to be the nature of the appearance adverted to particularly by MM. Cazenave and Schedel.

* There is an analogy between those morbid sensations of itching, pricking, tingling, &c. and the muscæ volitantes, flashes of light, and tinnitus aurium. They are all irregular impressions on the sentient extremities of the nerves; in the latter on those of vision and hearing, in the former on the nerves of touch. Diseases of the chylopoietic viscera and the brain give rise to both class of vitiated sensations.

of a weakly habit of body. It appears to be a variety of the disease in which the morbid action is less energetic, modified probably by some constitutional peculiarity.

Lepra nigricans is confessedly a rare form. M. Biett insists that this has invariably a syphilitic origin, and we agree with him in this view of it.

Secondary syphilis, as it assumes almost every form of cutaneous disease, appears sometimes under that of lepra. It is a question with pathologists whether the syphilitic diseases of the skin are to be separated from the others in nosological arrangement: they agree in anatomical characters, put on the same form, and in many instances yield, temporarily at least, to the same treatment. Notwithstanding these points of agreement, however, the most esteemed authors consider that they should form a separate class. Their venereal origin furnishes a much more important reason for distinguishing them than any consideration arising from their agreement in form affords for keeping them together, as it is an indication for a special line of treatment, the disregard of which might be attended with disastrous consequences.

Lepra more commonly affects men than women, but the difference as to sex is inconsiderable. Youth and middle life are more liable to it than infancy or old age; but no age is exempt from it, after the first dentition to the latest period of life. It appears to be less affected than the other skin-diseases by the influence of seasons; but it is observed to be most common in autumn. Differences of condition and circumstances in life have not a decided influence on it, except so far as they favour the development of the predisposing cause. Willan considered cold and moisture to be a frequent cause of it, and says that it is often excited by external irritants and dry sordes on the skin. Bateman differs with him in this, as he has seen it frequently in persons whose respectable rank and circumstances precluded these causes, while he has not observed that certain classes of workmen, necessarily exposed to them, were particularly affected with it. Like the other cutaneous diseases, it has been known to succeed to a disordered state of the digestive tube and of the biliary organs; but we must consider in these cases that there has been a great predisposition present; and it is one of the diseases where the latter acts a principal part. Where a predisposition prevails, the slightest causes are sufficient to give rise to it; thus it has been produced by highly seasoned food, spirituous potations, violent exercise, and strong emotions of the mind; anger is said to be a frequent exciting cause of it: mental depression also produces it, especially that arising from unexpected poverty and the bad diet accompanying it, as in the interesting case narrated by Dr. Mackintosh.*

It is quite certain that lepra is not contagious; and discussions on the subject could only have been entertained when a total disregard of precision permitted diseases of the most distinct nature to be classed under this most abused term.

Pathology.—It is sufficiently obvious from the enumeration of occasional causes, that we are not aware of any determinate conditions in its origin. That lepra is an inflammatory disease there can be no doubt; but as the term inflammation does not convey any very defined notion as to proximate causes, this is but a vague account to give of its etiology. We cannot in fact conceive any change taking place in the organization of the skin without a change in the organic action of its ultimate tissue or capillary vessels; and wherever this takes place, it constitutes a phenomenon which has hitherto been denominated inflammation. Observation of the mottled arms of healthy infants shews that the cutaneous capillaries in their physiological state affect something like an orbicular arrangement; and this might be in some measure connected with the fact, that most inflammations of the skin originally observe a rounded form. Further than such a simple step, however, our knowledge does not permit us to advance in the etiology of this, or indeed of any other skin-diseases. In Mr. Plumbe's work an attempt is made to ground the pathology of cutaneous diseases on the part of the dermoid tissue affected, and to specify the class of vessels diseased in each morbid alteration. This would be very desirable, but is wholly unattainable in our present state of knowledge. Anatomy teaches us hardly any thing about the arrangement of the capillaries of the skin. We are totally ignorant as to whether there be separate vessels for the secretion of the tissue of the corium, the rete mucosum, and cuticle; and whether the transpiration and sebaceous matter are furnished by these, or have separate vessels for their elaboration: it is gratuitous, therefore, to say that the seat of the inflammatory action which constitutes lepra is in the vessels which secrete the cuticle, merely because cuticle is the product of the inflammation; for this is to assume that the different tissues are formed by different vessels, a conclusion which has never been proved, and which modern physiology gives reason to suspect is untrue. If the argument were admitted, it would infer a separate set of vessels for every product of inflammation of the skin. It is, however, unsuitable to proceed with a discussion of this nature in this place.

Diagnosis.—The disease which most resembles lepra is psoriasis. The earliest observers of squamous diseases marked the difference which exists between them. Paul of Egina marks the distinction which depends on their form, in these words: "λέπρα per profunditatem corporum cutem depascitur *orbiculatiori modo*, et squamis piscium squamas similes dimittit. Ψώρα (psoriasis of the moderns) autem magis in superficie hæret, et *varie figurata est;*" but if no other difference existed than their configuration, we might be induced to follow the example of some respectable authorities, and to describe them together as mere varieties of the same disease. They differ,

* Practice of Physic, vol. ii. p. 217.

however, in more essential respects. Lepra is a more chronic disease than psoriasis, both as to duration and effects; it does not excite the same amount of sympathetic disturbance in the constitution, and is less affected by the relations of temperament, seasons, climate, &c.: in fact when it once sets in, it appears to become more inveterately wedded to the constitution than its congener, which, although it produces greater local and general irritation, is yet more amenable to the resources of medicine. Its general aspect, indeed, sufficiently distinguishes it from every species of psoriasis except one. The circular margins enclosing the central red part free from scales are quite contrasted with the irregular scaliness of psoriasis, cracked often by rhagades and ulcerations. The psoriasis guttata, however, appears to be a near approach to the character of lepra, and to constitute a natural alliance between them: the same round spots, gradually increasing and becoming covered with scales, characterise both, but it is only at the very first stage and at its declension that they are very similar; for when it is fully formed, the patches are much larger, and have assumed the annular form mentioned above, whereas the smallness of the patches, their *whole* surface being covered with minute furfuraceous scales in psoriasis, is sufficiently characteristic, so that whilst their agreement in some things shews them to belong to the same family, yet there appear to be sufficient points of peculiarity in each to enable a careful observer to make a tolerably confident diagnosis. Several eminent writers are strenuous advocates for their being united on the grounds of similarity, and lean much on the fact that sometimes in psoriasis there are present some patches which have all the characters of lepra. We acknowledge this fact, but we do not think it a valid argument, as it would hold good for uniting many cutaneous diseases which all agree to separate, as, for instance, eczema and impetigo, because the vesicles of the former are frequently intermixed with the pustules of the latter. While, therefore, we acknowledge their affinity, and that their treatment is similar, yet, from the differences detailed above, and these as particularly affecting their prognosis, we are for maintaining them distinct, and the weight of authority is on our side.

There is a possibility of confounding some other diseases, which affect a circular form, with lepra. In the state of the ringworm of the scalp, when the purulent incrustations are detached, a red ring remains, which is sometimes covered with a slight scaliness. This might be mistaken for a lepra of the scalp, and the more so if the porrigo be a little developed on the body; but a little attention will detect the difference between the aspect of the ring-worm and the leprous patches; the former is covered over with a small laminar scab rather than a semi-transparent scale: the hair, which falls in the ringworm, is preserved in lepra, and a few days' watching will develope the favous pustules from which the scab is secreted. If contagion can be established, as it generally can in the porrigo scutulata, it decides the question at once; but the chief element in the diagnosis is derived from considering that it is much rarer for the porrigo to be found on the trunk and extremities, than for lepra to be seen on the head, and that respectively they for the most part spread in contrary ways, the lepra from the extremities and trunk to the head, the porrigo from the head to the body.*

With respect to the syphilitic eruptions which assume the guise of lepra, their diagnosis is not difficult, and this fortunately, as it is of more importance to be positive in this case than the former, the consequences of mistake being much more serious. The syphilitic squamous disease, called by Willan and others lepra *nigricans*, represents the figure of lepra; but the violet, coppery, or black colour, which is its essential characteristic, is quite sufficient to stamp its origin. The round, flattened, circumscribed concretions constituting the tubercular syphilis, called sometimes by us incorrectly pustular eruption, might impose on us also for lepra; but here the coppery colour, which is happily for our diagnosis an inseparable companion to the venereal taint, comes again to our aid. But even if we had not this unerring distinction, a little examination evinces that the tubercular spots, although disposed in rings, are very different from the circular patches; and the thin squamous lamina, which is sometimes observed on the tubercles, is disposed just the reverse of the leprous scales: it spreads from the centre, and is only a partial covering, never large enough to conceal the circumscribed induration which projects beneath.

Prognosis.—Lepra is to be reckoned, under the most favourable circumstances, as a disease very difficult of cure, and in many cases incurable. In old or debilitated subjects, scarcely any means are sufficient to eradicate it; but in those of an opposite habit success is never to be despaired of, as there are many cases on record of its being quite removed after twelve and sixteen years standing. It is not dangerous when it is a primary disease; for even when nearly the whole skin is encased by its scaly concretions, the injury of its function seldom involves the system in general disorder. This is a statement of a general rule, to which, of course, exceptions will be found in those whose organization is bound together by a greater sympathy—idiosyncrasies† of constitution, which it is impossible to foresee as it is to explain when developed. The obstinacy with which it adheres when once engrafted on the system, shews itself sometimes by the inefficacy of every means to prevent it spreading over the whole body; and again, in other cases it disappears spontaneously or under the influence of medicine, in one place, and while the patient is congratulating himself on its departure, it sud-

* *MM. Cazenave et Schedel,* Maladies de la Peau d' après M. Biett.

† We owe an apology for the use of this word, which is, indeed, but a confession of ignorance, although cloaked by so learned a term. It really means that the fact which is referred to it cannot be explained by any recognised law in pathology.

denly appears in another part of the body. On the other hand, it has been known, after lasting for months, or even for years, gradually to subside of its own accord under the influence of some of those inexplicable changes to which the human body is liable. It appears to have sometimes gone on to a fatal termination; and the description of its ultimate encroachment on the vital functions, while it suggests phthisis, presents some singular features. "The local disease having reached its highest degree, a remarkable constitutional affection appears. The patient now becomes very languid; asthmatic, particularly at night-time; smothering fits seize him; he coughs violently and spasmodically, and spends the night in perfect sleeplessness, falling into excessive, colliquative, clammy sweats, which give an intolerably fetid odour. His voice becomes weaker and hoarser; the appetite for food and drink is preternaturally increased; and the temper becomes gloomy. Finally, various nervous symptoms arise, faintings, convulsions, paralysis of some parts, and death arrives preceded by the highest degree of exhaustion."*

Treatment.—The history of the treatment which has been from time to time employed presents a picture of the prevailing medical dogmas, and at the same time indicates the obstinate nature of the disease; for where so many various remedies have been lauded for their success, it only proves that experience has not established that any one has been generally successful. It would take up a large space to furnish a mere catalogue of the various substances which the three kingdoms of nature have been ransacked to supply for the cure of this disease in different ages. Empiricism, aided by superstition, was, in the early times, perpetually devising something new from the animal kingdom; from the flesh of the harmless ass, recommended by Hippocrates and mentioned with applause in the writings of T. Bartoline, and the bull-frogs of Myzaldus, to the poisonous viper, which Galen hails as one of those great discoveries which accident has furnished to mankind.† In the vegetable and mineral kingdoms almost every article used as a drug has had, at one time or other, its favourers, from the most innocent herb to arsenic; and each has been extolled as a specific. In describing the treatment, however, we shall only take notice of those remedies of which the efficacy has been proved by the experience of men who have made their therapeutic virtues the subject of investigation since cutaneous diseases have been studied after the modern improvements in pathology.

One great reason why remedies have been extolled beyond measure by some as certain specifics, and denounced unmeritedly by others as quite useless, is, that former writers have mostly neglected to mark the particular features of each case in which their remedy succeeded or failed. Having determined that it was *the leprosy* they had to do with, they appear to have gone to work with their favourite nostrum, without taking into account, or at least without recording, the most important therapeutical indications of the affection.

The first grand consideration in a rational treatment has respect to the cause. Can we trace its dependence on any internal disease? If so, it is vain to expect its cure until the primary disorder be successfully attacked; while it is unpathological to make it the object of *chief* attention: we say chief, because, although only a symptom, yet it is not, even in this case, to be entirely neglected, as its reaction may have a powerful influence on the original focus of the disease, and this in two ways, which it is highly important to distinguish. Its appearance on the skin may afford a salutary natural derivation, and in this case it would of course be injurious to endeavour by treatment to repel it: in another instance the disease of the skin may be only an additional source of morbid action, and react on the primary affection in a prejudicial manner; so that here, although but a secondary phenomenon, it must become an object of treatment. It is only tact and much observation that can discern these different circumstances; they do not often, however, fall under consideration, as lepra is one of the cutaneous inflammations least frequently complicated with organic disease of the viscera.

It needs scarcely to be mentioned that if the skin affection can be traced to any external cause, whether it be mechanical irritants peculiar to any trade or locality, or endemic agents operating through the atmosphere, the patient must be withdrawn from their influence. Thus, if it occurs from the influence of a cold and moist climate, or that it can be imputed to sordes on the skin, (both which circumstances Willan reckoned as common causes,) in the first instance the patient should remove to a dry atmosphere; and in the latter he should change his occupation to some that would not necessarily expose him to the exciting cause; and it is the medical man's duty, if he have ascertained any of these sources, to insist upon the absolute necessity of taking this step, being aware that the comfort which flows from health may be taken from the patient for the remainder of his life if he neglect of it.

The cause being investigated, and the treatment with respect to it having been considered, the age and constitution of the patient, and the extent and duration of the cutaneous affection, are the circumstances upon which we ground our judgment in proceeding to apply remedies for its cure. If the patient be young and strong, (and lepra usually occurs in such patients,) general bleeding must be performed; and if the disease has not become very widely extended, and inveterately chronic, the abstraction of blood by the lancet will frequently be attended with great benefit. The application of leeches in the neighbourhood of the leprous patches is also very effectual; and the disease in some instances yields to a few general bleedings, accompanied by leeching. The local bleeding by leeches is inadmissible

* *Richter*, Specielle Therapie, vol. vi. p. 440.
† De Simpl. Med. Facult. lib. xi.

when the malady has extended over the whole or a great part of the body; but when it is confined to one or both arms or legs, we can speak in the most decided manner of the great benefit derived from their use. In the comparatively recent cases the application of leeches two or three times, preceded by abstraction of blood from the arm, will be generally followed by a great diminution of the central and external redness and of the desquamation; in fact, sometimes by a speedy disappearance of the disease without the use of any other measures of importance.

The circumstances which peculiarly demand the abstraction of blood are, an active irritable state of the patches, and the existence of feverishness or great uneasiness from the prickling sensations; but it has of late years been proved that bloodletting is an excellent adjuvant to other means. In fact, a great improvement in the treatment of skin-diseases generally has taken place since the utility of bloodletting has been recognised in reducing the inflammation from an active to a passive state. It will much facilitate the cure of even the smallest extent of the disease to begin by a good bleeding; but it is in cases where it has spread very generally over the body that the bleeding is to be mainly depended on, at least at the outset of the treatment.

Dr. Duffin, whose large experience of this remedy is very favourable to its use, after pointing out its striking usefulness in the circumstances adverted to above as peculiarly requiring it, adds, "but supposing that there exist no general symptoms, still this mode of treatment is very often proper, were it had recourse to with no other view than to subdue the irritability of the skin or its extreme susceptibility to disease. But it has another good effect—it induces a state of the system that admits of being much sooner affected by the use of arsenic, when the active symptoms have been so far subdued as to allow of the employment of that medicine." Its effect as a preparative is, indeed, the chief improvement we alluded to; and since it has been so employed, many remedies whose efficacy was much debated are now found decidedly useful, their exhibition being preceded by a bloodletting, and recourse being had to it during their use occasionally, if any symptom of the active inflammation re-appear. It would be obviously improper to employ it if the patient be in a debilitated state, the effects of a bad constitution, of the long duration of the disease, or of old age.

Amongst the external remedies the bath is indisputably the most effective, and most generally used. The simple tepid water is very much employed, and is not superseded by the many new methods of bathing or vapourising the surface. The painful stiffness and irritation is almost always relieved by a twenty minutes' immersion in water at 90°: it appears to us to promote cleanliness, and a softening and falling off of the scales, just as well as the vapour-bath; but the latter is preferred by many experienced practitioners. The tepid salt-water bath is still more effectual as a stimulant to the skin; but it is to be used only when the inflammatory state has been entirely removed by the antiphlogistic measures.

Much expectation had been raised as to the efficiency of medicated vapours in this and the other squamous diseases; but their superiority to the ordinary baths has not been demonstrated. The sulphur vapour-bath is the most powerful stimulant amongst them, and it has certainly been used successfully in some obstinate cases; it must, therefore, be kept on the practitioner's list, to be employed where other remedies are inapplicable or have already failed. The vapours of tar and of acetic acid have been much used, but they are not so highly esteemed as those of sulphur; but, indeed, experience has not established for any of those fumigations the virtues which were proclaimed at their first trials. Bathing in the medicinal waters containing sulphur, such as Harrowgate, Lucan, Leak, St. Gervaise, &c. is decidedly a means of great power in scaly diseases, and many extraordinary cures are attributed to their use. When they are recommended, and the patient cannot remove to any sulphureous spring, a useful substitute may be readily made by dissolving six ounces of the sulphuret of potash in ten gallons of tepid water, and adding a small quantity of the sulphate and muriate of soda (eight ounces of each). Bathing, however, whether it be local or general, and medicinal fumigations, are only to be relied on as a secondary remedy; they are not to be used till the active irritation be removed by depletory measures; and it follows from this that they are particularly applicable in the chronic cases, and in patients of a debilitated habit, where the disease is but little energetic: they must be persisted in for some time to produce a beneficial effect, and the vulgar opinion that they weaken the constitution is to be entirely disregarded, for the contrary is the fact, as the patients will be found to derive strength from every means that exerts a salutary influence on the cutaneous disease. In many states of the skin where tepid bathing is advisable, its action will be much aided by gentle friction with a soft flesh-brush, the use of which is deservedly extolled by some writers.

Topical applications in the form of ointments and lotions are very useful in many cases. They are intended either to allay irritability, or, from their stimulating effects, directly to attack the disease by altering the action of the skin. In the former kind is reckoned the Carron liniment, which, spread over the leprous patches, has been found to cool the skin, and keep it soft and comfortable; the addition of two drachms of oil of turpentine to eight ounces of it, renders it a gentle stimulus which can be borne in almost all cases, and adds much to its good effects; it is one of the simplest applications, and can be used over a greater surface than others of a more powerful nature. Dr. Duffin prefers an ointment composed of equal parts of diluted citrine ointment and tar ointment to any

other topical remedy in the chronic cases, and states that it may be applied very extensively over the body without dreading its affecting the mouth, or producing any other of the effects peculiar to mercury. The patient is to be directed to remove the old ointment perfectly previously to laying on a fresh application, and to use for this purpose an alkaline lotion, made of two drachms of liquor potassæ to six ounces of water. The ointment adheres with great tenacity, and he "thus unconsciously submits the parts to a very perfect ablution and considerable friction, two agents of the utility of which no person can doubt in the case of lepra."

M. Biett, who thinks that ointments in general are of but little service, yet places confidence in one composed of the ioduret of sulphur and lard, twelve or fifteen grains of the former to the ounce of the latter. It is a very valuable remedy in recent lepra, occurring in a weakly individual who could not tolerate active internal medicines: it should be applied by a gentle friction to a few patches at a time, after a tepid bath: the skin's activity increases under its use; the circular elevations are reduced to its level, and the scales fall; and when the natural state is nearly restored in one part, new patches are to be attacked, until the resolution becomes complete.

Besides the Carron liniment mentioned before, the smearing of the patches with cream or with fresh butter has been extolled as very efficacious in allaying irritation from the rigidity of the skin; and we can recommend with confidence the use of these emollients as excellent adjuncts to the general means of bleeding and purgatives, (which must be the chief reliance as we have mentioned before,) when the heat, itching, and stiffness give great annoyance.

A lotion that was held in much repute for detaching the scales when they adhere tenaciously, is a decoction of the stalks of dulcamara with some alkali: it is said even to bring the skin to a healthier condition. We should remark that benefit from these external applications, liniments, ointments, &c. is to be looked for chiefly when the disease is confined to the extremities, and shews little disposition to spread.

The most effectual means for combating lepra are, however, to be sought for in the internal medicines; and the experience of able observers has proved a great number of these to possess undeniable power.

The use of different medicated waters, as those of Harrowgate and Leamington in England, and of the different waters on the continent which contain sulphur, has been a long time established as very beneficial; we have of late had occasion to know of several cases that have been cured by drinking the water of Lucan Spa, which resembles the Harrowgate, but is not so strongly impregnated with sulphuretted hydrogen. This is a much better way of administering the sulphur internally than either the simple flores sulphuris, or in combination with antimony, the golden sulphuret of which was once a very favourite remedy in cutaneous diseases. The mineral waters should, if possible, be drunk at the source, or at least be procured from it; as it is a fact that their imitations are not so efficacious as the waters of the springs.

The dulcamara has certainly properties which entitle it to notice. Dr. Crichton's testimony was very strong in its favour, and brought it much into use in the treatment of lepra. He states that out of twenty-three cases in which he employed it, only two resisted its action; two or three ounces of the decoction of the twigs and leaves were used by him thrice a-day; but we cannot help being inclined to attribute his success rather to the other means which he used, as the experience of other physicians who have used it still more extensively does not corroborate its virtues: it is still used, however, as an adjunct, in chronic cases.

Decoctions of the acrid stimulant plants, daphne mezereon, d. enidium, and of guaiacum, have been used with success in different instances. The compound decoction of sarsaparilla has also enjoyed much reputation, and may be recommended for its stimulant effects on the skin: its use should alternate with some of the more powerful remedies to be mentioned.

A remedy which at one time was extolled to an extravagant degree, and has fallen in late times into as undeserved disrepute, is the tar-water; but we are persuaded on the grounds of experience that it does possess real efficacy. A case has been communicated to us, which had been treated by some of the most eminent practitioners with the most powerful remedies; but no effect was produced on the disease till tar-water was tried by a physician whose experience of it led him to place much confidence in it; and under its use the patient got quite well. Half-a-pint of it should be drunk three times a day. In the case alluded to the patient was made to walk rapidly until he began to perspire, and then to sit for a time in a warm room, and much importance was attached to this manner of exhibiting it. Pitch pills are also to be mentioned as a remedy to which experience bears a very satisfactory testimony; six or eight of them, each five grains, should be taken for a dose three times a day, and this will have to be increased by degrees according to circumstances.

Some English writers praise very highly the treatment by mercurial preparations; and in some cases minute doses of corrosive sublimate have proved of unquestionable utility, salivation by mercury being, however, seldom undertaken in the cure of lepra. The naïve relation which that respectable writer, Dr. Turner,* gives of its effects in two cases where he employed it, would answer for its history in most cases; and as a purgative, indeed, calomel will be very beneficial in occasional doses, no matter what plan of treatment be preferred; and in children particularly it is a very useful means.

* A Treatise of Diseases incident to the Skin, by Daniel Turner, of the College of Physicians, London. 3d edit. 1726, p. 30, et seq.

We come now to speak of arsenic, a remedy that has been of late years much investigated as to its effects in squamous diseases. While some have found it to possess uncommon virtues, others have decried it as not only useless but dangerous. It is without doubt a very dangerous remedy in the hands of incautious practitioners, and will never prove useful if it be employed where circumstances contra-indicate it. But we must express our suspicion that where it has failed, it has been for want of discriminating between the states which are favourable to its action, and where its administration is improper. It is superfluous to say that its exhibition requires the most cautious attention on the part of the practitioner; and we are confident that where it is judiciously employed, it is not only a safe but a very valuable remedy. It seems to be peculiarly applicable in those cases which are seldom benefited by other medicines—we mean those instances in which the lepra has lasted for several years, and has invaded nearly the whole skin, so that it has taken on such a diseased habit, that nothing less than the most powerful means will restore its original state. In cases which have not run on to a very chronic state, the other means will prove as effective, and probably should be tried before we should have recourse to the arsenic, although some able practitioners advocate its propriety in almost every case. In the inveterate cases, however, when all other means have failed to produce any salutary effect, its well regulated exhibition has been frequently known to effect the dispersion of the disease.

Having determined on its use, we must watch its effects, and persevere so as to give it a fair trial. Fowler's solution of arsenic is the preparation most approved of. It is best to commence with the small dose of three drops to be taken three times a day in a glass of water; or it may be deemed advisable to use the decoctions of dulcamara, mezereon, or of sarsaparilla as a vehicle, as Dr. Duffin recommends. The dose must not be raised beyond eight drops three times a day, or at the very highest ten. When it first affects the system, the pulse becomes quickened, smaller, and hard; and there arises a prickly soreness about the eyelids, accompanied by some puffy swelling, particularly of the lower one. The gastric symptoms which are the signals for suspending its exhibition, are, sickness of the stomach, griping pains all over the abdomen, headach and whitish tongue, with a peculiar taste in the mouth. When there comes on a pain in the chest, accompanied with anxiety of the præcordia, and a certain consciousness of serious constitutional disturbance, which is indicated by uncommon gravity of the countenance, the medicine has been either given in too large doses or continued too long. When the pain in the chest and any of the latter symptoms occur shortly after its commencement, it is probably a case which will not bear its administration at all, and other means should at once be substituted. It will generally be found that an impression has been made on the disease when its effects are recognized in the constitution, and often before this. At first the patches become less indolent, and a long-unaccustomed sensation of heat and activity is felt; the scales first clear off in the centre, (for in those inveterate cases the whole patch is overgrown with scales); by degrees the circular eminences sink and clean; and thus a disease which had become engrafted on the habit for years, retires under the influence of this powerful medicine.

Some of the favourable symptoms ought to shew themselves by the time that the medicine has affected the pulse, or when the stiffness and puffiness are perceptible under the eyelids. If the skin do not discover its action when these characteristic signs appear, there is no necessity, indeed it would be improper, to continue its use. In others, nausea and loss of appetite, with some epigastric soreness and oppression, are the first signs of its operation; but we should not consider these latter symptoms as unequivocal reasons for laying aside its use altogether; a few days' intermission will often remove this gastric disorder, when a further trial may be made; and it has frequently happened that the good effects have begun to shew themselves soon after its being resumed. But in deciding how far it may be pushed, the discretion and tact of the practitioner must guide him: we only wish to lay down as a principle that the arsenic is not so unsafe a means in judicious hands as it has been vulgarly thought; and that after its use is commenced, ill-grounded fears should not deprive the patient of the steady trial of a remedy which experience has proved to be so valuable. Dr. Duffin states that he has prescribed it in very near four hundred cases, and has never yet seen it do any mischief; and his testimony and that of M. Biett, (two gentlemen who have investigated its effects the most assiduously amongst modern observers,) agree that it is a most important remedy in this intractable disease.

The tincture of cantharides is another very energetic medicine in lepra. It was brought into notice by the eulogy of Mead, although it is nearly certain that it was against the tubercular elephantiasis that he employed it.* However that may be, it has been used ever since in the scaly disease, and it has been found of great effect, particularly of late years. It is applicable in the same inveterate description of cases as the arsenic, and requires quite as much caution in its administration. Four or five drops three times a day should be the utmost dose for the first month of its use, and at the same time the patient should use demulcent drinks of gruel, barley-water, flax-seed tea, &c. When given at an improper stage, or in too large a dose, it is very prone to produce serious disturbances in the alimentary canal and the genito-urinary organs, so that when we perceive painful heat at the epigastrium, vomiting and purging, or strangury and

* Medical Works of Richard Mead, M.D. Dublin, 1767; of the Leprosy, p. 455.

erections to follow its use, it must of course be intermitted; but unless these symptoms shew an unusual degree of violence, it may be often advantageously resumed. By a cautious gradation of the dose (very small at first), and the use of the demulcent drinks, with an occasional dose of purgative medicine, those sinister consequences may in general be avoided.

In some remarks on the use of tincture of cantharides in hooping-cough by Dr. Graves, in the fourth number of the Dublin Journal of Medical and Chemical Science, Dr. G. states that it produces its good effects without causing urinary irritation when given in the formula recommended by Dr. Beatty, which we here subjoin:—R. Tinct. cinchonæ compositæ ℥ v; tinct. cantharidis; tinct. opii camphoræ *aa* ℥ß. M. There is nothing in the other ingredients of this mixture which should preclude its trial in lepra; and it would be very desirable if this combination would allow of its free use, by averting its ill effects on the urinary organs. Bateman's disparaging notice of cantharides kept it out of use for some time; but its value has been confirmed by the experience of the Hôpital St. Louis, where it is esteemed as only second to arsenic in the chronic cases. Where either of these two remedies is found to create constitutional disorder forbidding its continuance, it may advantageously be replaced by the other: but we repeat, to derive good effects from either of them, the greatest care must be taken to use them in the proper stages; for if they be given whilst any activity of inflammatory action remains, instead of benefit we must only expect to aggravate the whole disease.

A course of purgatives is at the present time a favourite practice in the less severe cases of lepra with some French practitioners, who speak with much applause of the good effects of calomel, jalap, sulphate of magnesia and of soda, aloes, &c. in its removal. We rather suspect that this may arise from the novel introduction of catharties into their practice, and the reaction in their favour which naturally follows on the apprehension and horror they had of this valuable class of medicines up to a recent period. It is, doubtless, of the highest importance to keep the bowels free by the occasional use of laxatives; and for this purpose a few grains of calomel will be generally found the most suitable. Much purging, however, as far as our experience goes, is decidedly injurious, excepting probably in children, where we can have recourse to scarcely any other class of remedies, and where purgatives answer very safely and conveniently.

The external and internal means of treatment have been noticed separately for the sake of arrangement, but in practice they are almost always employed together; and, when judiciously combined, they mutually assist each other's action. The tepid bath may be used in almost every plan of treatment, and will be found a useful adjunct. In those cases which have not spread extensively nor lasted long, the treatment should be commenced by an abstraction of blood, which is to be repeated either generally or by leeches, whenever the inflammation shews any signs of having resumed an active state: at the same time the patient should use some one of the internal remedies, and probably daily the bath. With those it will be often judged advisable to apply some of the unguents or lotions already mentioned, so as to conjoin the operation of the different classes of remedies; and it is in such cases that this combination is most effective. In the inveterate cases our reliance must be placed in the steady use of the internal medicines. We can go no farther on these points; each particular case will doubtless present its peculiarities, which must be considered. Having adverted to the most approved principles, and mentioned the remedies whose virtues have been best confirmed by experience, it remains for the judgment of the practitioner to guide him in each particular instance in the application of the former, and the choice and conjunction of the latter.

(J. Houghton.)

LEUCORRHŒA, from λευκὸς, *albus*, and ῥέω, *fluo*. Properly this name ought to be restricted to a *white vaginal discharge*, but every sort of discharge, not sanguineous or menstrual, has been at various times considered as leucorrhœa, whether mucous, serous, purulent, or of a mixed description.

Besides "leucorrhœa" and "vaginal discharge," this complaint has been called "fluor albus," "fluor muliebris," "les fleurs blanches," "sexual weakness," or "a weakness," and vulgarly "the whites." All these are more or less objectionable, and the one chosen for the title of this article as much so as any other; but it is one which is so well known and universal, that it can scarcely lead to error in practice, and is, therefore, the most convenient. It would, no doubt, be very useful in practice to discriminate between the different discharges, because very frequently their character will depend upon, and therefore be a guide to the knowledge of, the nature of the disease which produces them, or the particular part which has become disordered or disorganized. Sir Charles M. Clarke has classed the diseases of the female genital organs by the nature of the vaginal discharges which are peculiar to them; and although there are many serious objections to such a mode of classification, yet it proves how important it is to note their several and distinguishing peculiarities. Of the diseases to which females are liable, there is none more common than vaginal discharge, of one sort or another; it attends most of the uterine diseases, and it is extremely common as the result of either local or constitutional disturbance, or of general debility. It is looked upon by the patients themselves as the cause of ill health, or of the symptoms under which they may happen to labour; whereas, in the majority of instances, the discharge itself can only be considered as a symptom, the effect and result of local or general disorder. By practitioners in general vaginal discharges have been carelessly attended to; there has been one common

routine of treatment without investigation; and it is only when the complaint has been obstinate, that at a later period more minute inquiry has been made, and more rational and scientific plans adopted. So many of the vaginal discharges depend upon uterine disorganization, or some alteration in the position of that organ, that it is advisable in every case, where possible, to make a minute examination *per vaginam*, so as to ascertain the exact condition. It is foreign to this article to enter upon the question of the numerous uterine diseases which give rise to vaginal discharges; we must here only consider idiopathic leucorrhœa, a simple vaginal discharge, unconnected with any alteration of structure.

The simplest form of leucorrhœa is a mere increase of the natural secretion from the mucous membrane of the vagina. As this membrane is continued to the interior of the uterus and the fallopian tubes, it is easy to suppose that now and then the lining of these organs may become affected, and the leucorrhœa have a more extensive seat. Frank has mentioned a case of unusual obstinacy, where, after death, the fallopian tubes were found to be the origin of the disorder; and numerous cases are on record, where, in prolapsus uteri, the leucorrhœal discharge was found to proceed from the os uteri itself. By many of the older writers it was thought to be merely a variety of menstrual discharge, and hence the term "menstrua alba," &c. Hoffmann, Cullen, and others, considered that the discharge issued from the same vessels which secreted the menstrual fluid in their healthy condition. Dr. Jewel, in his recent work on this disease, states his impression to be that it seldom issues from the uterine cavity, and proposes a test to ascertain that point in individual cases. Dr. Jewel assumes that in the night-time, when in bed, the discharge from the interior of the uterus is suspended, which is not the case when it arises only from the vagina or the cervix uteri; and hence he advises that a piece of sponge be introduced into the vagina at bed-time, and if the uterus only is affected, the sponge will be withdrawn *dry* in the morning. The accuracy of this test must depend upon the assumption being correct. That is, however, by far the most common form of the complaint which takes place from the vagina alone, or, perhaps, as this gentleman states, from the cervix uteri. There is an altered action of the mucous lining of the parts, and in what that particularly consists depends the peculiarity of the cases. It has been by far too common to consider all such cases as arising from debility, local as well as constitutional, and hence the remedies have most frequently been merely strengthening. In general we shall find great symptoms of debility accompanying long-continued leucorrhœa, but the debility is nearly always the consequence and not the cause of the disease. It is the acknowledged fact, that whenever the general health has been broken down and much constitutional weakness occasioned, local disorder is often the result, and such disorder may attack the uterine organs or vaginal passage, though it is not debility which affects them, but through debility a diseased action arises. This diseased action is sometimes acute inflammation; in others, and more commonly, sub-acute; whilst, in chronic cases of long standing, a relaxed condition of the secreting apparatus may take place from habit, as we see in the diseased discharges from other sources: this Dr. Dewees has called the "leucorrhœa of habit." Besides inflammatory action, a very large proportion of cases of leucorrhœa depend apparently upon irritation, different from inflammation, and yet easily running on into it—a state easily recognised, but difficult to be described. The irritation which excites leucorrhœa is very often remote from the vaginal membrane itself, so that, upon alleviating or removing the distant irritating cause, the complaint will cease.

The discharge of simple leucorrhœa is mucous—merely an increase of the natural moisture of the part; it becomes more abundant than in health, but retains its character of mucus, being clear, transparent, colourless, and glutinous to the touch. This rarely goes on to a great extent without being altered in its appearance, and much more watery. In general this sort of discharge is accompanied with but moderate symptoms, is more gradual in its progress, and is unattended by pain; there is little or no inflammatory action present. In other cases the discharge is whitish and opaque, becoming creamy when rubbed between the fingers, and rendering water turbid. This sort of discharge has been considered by Sir C. M. Clarke and others to depend chiefly on an inflamed condition of the cervix uteri; it is rarely abundant, but occasions much disorder of health, and local pain. A watery discharge resembling serum is a very common result of more acute inflammatory action in the mucous surface, and in general appears suddenly, as the effect of cold or any active excitement. It occasionally becomes very abundant, is attended with much local heat and soreness, and soon becomes puriform, or mixed with purulent matter, and sometimes with bloody streaks. When it is fetid, brown, or coming away in violent gushes, organic disease of the uterus is to be feared, the nature of which can only be detected by an examination per vaginam. Purulent discharge from inflammatory action may also take place from the vagina, independent of gonorrhœa from impure connection; and this may be said to form one variety of leucorrhœa, as, although it may often arise from organic disease of the uterus, it is not unfrequently met with in a perfectly healthy condition of that organ. Many will hesitate, perhaps, to class either the watery or the purulent discharge under the term leucorrhœa; but it is quite certain that all the above-mentioned discharges arise from the mucous surface of the vagina alone, without organic disease, and solely from a diseased condition of the natural secretion of the part.

Patients in general content themselves with stating the existence of a weakness, and too many medical men are satisfied with such a slight

description, and neglect to inform themselves more accurately of the nature of the discharge.

The symptoms vary, as will be supposed, and there is a marked connection in general between the symptoms and the character of the discharge.

The mildest form of the disease is often of long standing before a practitioner is consulted; it is generally found that it has been preceded by what is called "delicate health." The countenance is pale and sallow, the frame weak, the pulse feeble and easily quickened by the least exertion, the appetite impaired or capricious, the spirits are languid, and exercise is taken with difficulty; menstruation is either scanty or too profuse, the digestion is disordered, and the bowels are irregular; there is pain in the back when the individual is fatigued, or when she remains long in the erect posture; but it is a pain of debility, relieved by rest, and not permanent. The discharge, which has been referred to weakness, is a disordered action of the mucous membrane, and is the effect of a state of indifferent health. The discharge in these cases is mucous only, is never very abundant, and is unattended by local pain, except in the back. It may easily be altered in character, and then the symptoms are also changed, as in such cases a very slight cause will increase the disordered local action.

The most acute form of leucorrhœa is most commonly the effect of cold, of metastasis, or of some local irritating cause, and consists of a profuse watery or purulent discharge, accompanied with local soreness and pain: the vagina is hot, very tender to the touch; there is much fever, heat of skin, quickness of pulse; these symptoms being often preceded by a distinct rigor. When the discharge is more scanty and glairy, like the white of an egg, or creamy and opaque, the cervix uteri is considered to be principally affected, and may be felt by the finger to be hot and tumid, the pulsation of the minute arteries being easily distinguished. In these cases there is much pain of the back, extending round the hips and down the thighs, and, though relieved, not removed by the recumbent posture. This description of leucorrhœa may occur in the most debilitated or in the most healthy frames, and may be considered accidental. All of these forms may end in chronic leucorrhœa, where the discharge is more or less profuse and constant, mucous or purulent, or a mixture of both; it may become green and offensive, and yet be the result only of functional disorder. The quantity poured out is sometimes very abundant, even to the extent of a pint and a half in the twenty-four hours; it will then be expelled in gushes on any change of posture. There is in these cases a very relaxed vagina, often accompanied by prolapsus of the uterus; the mucous surface appears smooth and glossy, and has lost its natural rugæ; there is great emaciation and debility; the eyes are hollow, the face pale or chlorotic, the pulse feeble and rapid, the feet often anasarcous, the respiration short and laboured, to which succeed palpitation of the heart, dragging pain in the back, inability to exertion, profuse nocturnal perspirations. Unless remedial measures be successful, after a protracted scene of much general suffering the patient dies exhausted.

The causes of leucorrhœa are either those which induce inflammation of the parts or irritation, or which weaken the action of the secreting vessels, although by far too much stress was formerly laid upon the latter. Catching cold, as it is commonly termed, is a very frequent cause of the acute leucorrhœa; so also is metastasis of a discharge from some other part, though of a different character. The suppression of the menses, the repelling of milk in the breasts, the sudden checking of catarrh, and perhaps any sudden check to the perspiration, may be considered as causes of acute leucorrhœa; a severe labour, in which the vagina has been kept long upon the stretch, or where it has been injured by officious manual interference or the use of instruments, will often cause the inflammatory leucorrhœa. Violent exercise, particularly dancing or riding on horseback, the excessive use of venery, or pollution, have the same effect. Of the irritating causes, we may mention local displacements of the uterus, especially prolapsus; local tumours of the vagina or uterus, and of the latter polypus in particular; stone in the bladder, disease of the urethra, a loaded state of the rectum, the presence of hard scybala, or of ascarides. A pregnant uterus may act in this manner, and also by the increased local determination of blood which pregnancy produces. The impaction of a pessary, or of a piece of sponge introduced for other purposes into the vagina, has sometimes been the unsuspected cause of a long-standing leucorrhœa. Of the debilitating causes, may be mentioned frequent child-bearing, repeated abortions, profuse menstruation, and in general all the usual tendencies to disordered health, such as hot rooms, luxurious habits, indolence, poverty of living, protracted lactation, over-exertion, &c.

Treatment.—It is in this point that the greatest errors have prevailed, from the disposition to follow carelessly an established routine. Astringent tonics, bark and acid for instance, are prescribed in the majority of cases, and perhaps an astringent injection, which would aggravate many of the forms of leucorrhœa we have been mentioning. The plan of treatment ought to be regulated solely by the character of the complaint. It must be recollected that it is not always safe to check suddenly a long-standing leucorrhœa, if profuse. Many instances are on record of mischief resulting from such a course, and the following case is a striking illustration. We were consulted by a soldier's widow several years ago, for a complete prolapsus of the uterus, produced by violent exertion during the retreat from Corunna, within a few days of her confinement, and which had never been reduced. There was profuse semi-purulent discharge from the inverted vagina. After some difficulty the uterus was replaced within the pelvis, and a pessary worn, consisting of sponge soaked in an astringent lotion. The discharge from the

vagina ceased, and in twenty-four hours a quantity of muco-purulent fluid began to be copiously expectorated from the bronchial membrane, which amounted after a few days to nearly three pints in the twenty-four hours; and in less than a fortnight from the replacement of the uterus, the patient sank from exhaustion.

In the leucorrhœa from constitutional debility or disordered health, of the first class described, the usual remedies for restoring the vigour of the frame are required. Tonics of every description are admissible, according to the circumstances of the case; but those containing or combined with the mineral acids have most efficacy. The vegetable bitters, or the sulphate of quinine or the bark itself, may be given three times a-day, combined with from ten to twenty drops of the diluted sulphuric acid, or double that quantity of the old vitriolic elixir. From one to two grains of the sulphate of zinc, or any of the preparations of iron, will often agree exceedingly well, and as the health improves, the discharge becomes less and less abundant; the diet should be nourishing, the air good and occasionally changed. Besides these remedies, the shower-bath or cold bathing may be used, and especially hip-bathing, or sponging the back and loins freely with cold vinegar and water or salt water. Local remedies are rarely required in these milder cases. In the acute form of the complaint, it is often necessary to apply leeches to the neighbourhood, to the groins, labia, or back; and if the cervix uteri is particularly affected, to the os uteri itself, by means of a proper tube. This is much more easily effected than is supposed, and the liability of the leech remaining at the lower end of the tube instead of crawling up to fasten upon the uterus, may be prevented by inserting a piston to push the leech higher up the tube. Bleeding from the arm is rarely necessary, though in plethoric habits it may now and then be desirable. A low diet, perfect rest, and antiphlogistic general treatment are necessary; the bowels should be kept fairly open with saline purgatives or castor-oil, avoiding aloes, scammony, or others of a drastic character; warm hip-bathing is very useful, and injections into the vagina of warm water, decoction of poppies, or solutions of the superacetate of lead. Dr. Jewel advises, very confidently, weak solutions of the nitrate of silver as injections, in the proportion of one to three grains of the salt to an ounce of distilled water, or even the application of the caustic itself to the cervix uteri. We doubt, however, whether this treatment is applicable to this very acute form of the disease.

When more chronic, when there may be said to be subacute inflammation only present, or perhaps only irritation, the general health must be attended to, according to the nature of the general symptoms; but in such cases the greatest benefit will arise from local treatment, or from remedies more especially directed to the local mischief. It is this form of the disease which is most obstinate, and for which it is advantageous to possess a variety of remedial measures. Of the internal medicines which have been found serviceable, the balsams, particularly the copaiba, have been mentioned; but their efficacy is not nearly so marked as in the gleet or gonorrhœa of the male: the cubebs has also much about the same remedial powers. The cicuta has been found of service by some practitioners. The tincture of cantharides has been perhaps more successful, pushed to as large a dose as can be borne without producing irritation of the bladder. Astringent medicines are also found occasionally serviceable, particularly the mineral acids with the infusion of roses and alum; the latter may be given in doses of from five to twenty grains three times a-day. The acetate of lead has been often successful, catechu, kino, uva ursi, powder of galls, which may be given in large doses. At the Lock Hospital, Mr. R. B. Walker is in the habit of giving ten to twenty grains of the latter in decoction of tormentilla. Dr. Copland recommends small doses of the sulphate of copper. Emetics are said to have been of use, but perhaps in the more acute form of the complaint. The local remedies, however, are most to be depended upon in these cases, and may be applied freely and several times a-day, either by means of the female syringe, or of a piece of sponge or lint introduced carefully into the vagina, and occasionally withdrawn for a fresh supply of lotion. Most of the female syringes are too small, and produce irritation by the frequent necessity for withdrawing the pipe for the purpose of refilling the instrument. The writer has been in the habit of obviating the inconvenience by a gum-elastic tube of three to four inches in length, and about half an inch in diameter, perforated with several holes at the apex, which is rounded off, and the tube made to fit to the stomach or lavement pumps, which are now so common; in this way any quantity of fluid may be injected into the vagina without withdrawing the tube. The applications may be classed into the irritating, the sedative, and the simple astringent; and as a general rule, it may be stated that the first are most applicable to the chronic states of subacute inflammation, rousing the vessels into a more healthy action. These consist of solutions of nitrate of silver (as just mentioned), of the sulphate of copper, of oxymuriate of mercury, &c.; injunctions of mercurial ointment, fumigations of cinnabar, or the local application of copaiba or turpentine. Dr. Jewel limits his lotions to the strength of three grains to an ounce of water, preferring the application of the lunar caustic itself to a stronger solution; but at the Lock Hospital, solutions of the strength of half a drachm, or even two scruples to the ounce, are not unfrequently employed. The sedative injections consist of decoction of poppies, of solutions of opium or belladonna, and of the superacetate of lead, the last being by far the most efficacious. The writer is in the habit of using the common Goulard's extract in the proportion of two or three drachms to the pint of distilled or rain water, warm or cold according to the sensations of

the patient, and he prefers as much as half a pint to a pint to be used at a time, three or four times a day. The sedative lotions are most serviceable where there is an acrid discharge, with heat and excoriation, or where there is much inflammatory action with local pain. In some severe cases he has seen benefit from introducing a piece of lint soaked in a liniment consisting of equal parts of Goulard's extract, Battley's laudanum, and mucilage. The astringent injections are applicable to the cases which appear to be attended by great relaxation of the vagina and its mucous membrane, with chronic discharge of a mucopurulent or simply thin mucous character. All the vegetable astringents are then occasionally serviceable, as well as the mineral. Alum, the sulphates of zinc, iron, or copper; the acetate of zinc; decoctions or infusions of oak-bark, galls, green tea, kino, catechu, rose-leaves, &c. may be alternately used, or some may be combined together; but a great deal depends upon their being used freely and frequently. In using astringent injections, particularly alum, it is advisable to wash out the vagina directly afterwards with cold water, as the discharge will sometimes become coagulated, and, remaining in the vagina, produce irritation and an increase of the symptoms. Leucorrhœa has been said now and then to be owing to want of cleanliness, and no doubt this may cause it, but it would be difficult to prove that no other cause existed. The remedy is obvious.

When there is reason to believe that the leucorrhœa depends upon a loaded state of the rectum or the presence of ascarides, a soap or a turpentine clyster will readily remove both cause and effect. In the leucorrhœa of pregnancy more caution is to be observed. In the early months it is desirable to check it, as an excess of it will be very likely to bring on abortion; but it must be done gradually, and the lead injections are the safest. Where the discharge arises principally from the uterus, conception rarely takes place; and when it has occurred, the ovum is easily separated by the slightest causes, so that extreme quiet is always necessary for the first few weeks. In the latter months of pregnancy, leucorrhœa may be looked upon rather as a relief, unless excessive; the pressure of the gravid uterus and the greater determination of blood to the neighbourhood frequently producing symptoms of heat, weight, and discomfort, which are alleviated by the escape of the discharge. Rest and cooling laxatives, with a spare diet, are generally all that will be required.

Very young children are liable to leucorrhœa. It occasionally occurs in infants shortly after birth; in these cases it is more or less purulent, and attended by a redness and tumefaction of the orifice of the vagina. It is very apt to occur also during dentition, and not only when the first set of teeth are in progress, but at the time of the second set, and even when the dentes sapientiæ are irritating the system at a more mature age. Young girls are also sometimes affected with leucorrhœa, attended with debility, disordered health, and pain in the back. This usually arises from intestinal irritation or from gravel, though probably the latter may be equally the effect of the visceral disorder. It must be borne in mind that the appearances above described are not unfrequently the effects of improper habits. The curative measures are simple; the portion of the vagina affected is usually very limited, generally near the external orifice, so that the Goulard lotion is readily and effectually applied. Alkalis and gentle purgatives, with a mild diet and rest, will in most cases be sufficient to remove the complaint. An epidemic vaginal catarrh has occasionally existed, as mentioned by Professor Capuron to have prevailed in Paris. It has also been observed in this country among children, but attended by much local inflammation and constitutional disturbance of a typhoid character, and which, unless treated very early, has ended in ulceration, sloughing of the pudenda, and death. These cases have been described by Dr. Percival of Manchester, as having occurred there in 1791. Again, in 1815, the attention of the profession was called to them by Mr. Kinder Wood, who had then seen twelve of them, all occurring at Oldham, or the immediate neighbourhood of Manchester. Dr. Mackintosh, of Edinburgh, has described four cases, of which two followed immediately after measles; and it is not uncommon to find a milder sort of leucorrhœa making its appearance after the subsidence of that eruptive disease. Except those mentioned by Dr. Mackintosh, it is curious that nearly all the others have been noticed in the neighbourhood of Manchester; for Dr. Ferriar, who practised there also, states, in his "Medical Histories and Reflections," that he had "met with several instances" of a similar nature. The cases related by Dr. Percival are important on another ground, as the first instance which fell under his notice led to the committal of a youth for a supposed rape, the appearances on the pudenda of the child having led to the suspicion that violence had been committed. The rapid occurrence of several similar cases alone saved the youth from trial and probably execution. The recollection of such facts is of real consequence when an opinion is required upon supposed instances of defloration.

There is one material point connected with cases of leucorrhœa, and especially those where the discharge is purulent or of an acrid character. In such instances it is well known that sexual intercourse will often bring on a train of symptoms very much resembling gonorrhœa in the male. This, when occurring between husband and wife, has often led to much domestic unhappiness, from the supposition of one party or the other having contracted gonorrhœa from impure connection. It is important to be able to distinguish between gonorrhœa and common leucorrhœa to remove or confirm the suspicions, but it is very doubtful whether any very accurate diagnosis can be formed. It has been stated that in a recent gonorrhœa there is ardor urinæ,

which does not accompany leucorrhœa, unless unusually acrid. But how are we to distinguish in a case of this unusually acrid leucorrhœa, or where a gonorrhœa is not recent? The redness and tumefaction of the labia, nymphæ, &c. only can be seen in a recent gonorrhœa, and they may be seen in severe cases of leucorrhœa, particularly in those following local irritation, or possessing more acute inflammatory action. One other test is mentioned by authors, that in leucorrhœa the discharge ceases during menstruation, but does not in gonorrhœa. This, however, is denied by other authors, and, as Dr. Jewel observes, "this is a point which cannot easily be decided, as from the colour of the menstrual secretion, that of the leucorrhœal or gonorrhœal must necessarily be in a great measure obliterated." From what has been stated, it is quite evident that it is extremely difficult to distinguish between the two diseases, and particularly when we recollect how ready the party in fault will be to conceal or distort the facts. In all such cases it becomes the duty of the medical man to give his assistance not only in curing the disease, but in preserving domestic harmony.

(C. Locock.)

LICHEN, λειχήν. The cutaneous affection known formerly under this term was supposed to be, with several others, a mere modification or symptom of the lepra Græcorum (about which disease we have seen what confusion reigned—see LEPRA); and we find that this improper notion was still held by writers at the beginning of the last century. It was also erroneously represented to be synonymous with impetigo. All this originated in its not being quite clear what was intended by the term λειχήν in the Hippocratic writings, and in a misconception of Celsus. The latter describes, under the name of *papulæ*, a form of cutaneous eruption which the best authorities consider to be the same as the λειχήν of Hippocrates, and it is quite evident that he means a perfectly different disease by the term impetigo. Able commentators assert that the λειχῆνες of Hippocrates (Aphorism. sect. iii. aph. 20.) signify what they denominate "pustulæ siccæ," —an expression which accords in sense with the papulæ of Celsus, and the same term (or pimple) which is adopted in modern nomenclature from the Roman author. Since the time of Willan, indeed, his application of lichen has been in universal acceptation, and it now always signifies an eruption of small, solid, reddish papulæ, which terminate with a scurf, and are very liable to recur.

The papulæ of lichen usually occur in adults, and are often connected with internal disorder, but not so exclusively as to be admitted into the definition: they are accompanied always with more or less pruritus, and are situated on the arms, face, or legs, and sometimes are developed all over the body.

But the closer description of the disease and its course requires that we notice its varieties; and here we may remark that we differ from those authors who deny the utility of entering into more minute distinctions than are necessary merely to denote the generic relations of the cutaneous affections. It is true that multiplying terms *uselessly* would only tend to embarrass the student of those diseases; but it is equally certain that classifying phenomena according to the various relations of form, colour, situation, extent, and other conditions, and thereby establishing *real* varieties, not only is highly conducive to the advancement of the pathology of those affections, but very much facilitates the attainment of a practical acquaintance with them. It appears to us to be as indispensable to the study as it is to the description of them, to have specified varieties fixed in the mind by distinctive appellations; and we confidently affirm that students who were really interested in acquiring a knowledge of skin-diseases have ever found material aid from the division into species accomplished by Willan. Their imperfections are, of course, manifold, but it is a proof of their utility to observe that every systematic writer, whatever his sentiments be with regard to them, whether he admire them or call for their abrogation, is obliged to notice them. The fact is, that they burden the memory of those only who make the vain endeavour to learn skin-diseases by books, while they assist in a very efficacious and pleasing manner the labours of the patient observer of nature.

The principal species, or rather varieties, of this affection are the following.

1. *Lichen simplex.*—This is the species most commonly met with. It consists of small red papulæ, more or less elevated and acuminated, which contain no fluid of any kind, and are quite opaque and solid. It mostly commences on the face and the back of the hands, and, when more generally extended, it affects in preference the posterior and exterior parts of the arms and thighs. It may be stated generally, that it occurs most frequently in those parts of the skin which are most delicate and exposed to external influences. The eruption of papulæ is accompanied with a tingling formication, which is very disagreeable, particularly during the night, or when the person becomes heated by exercise or otherwise.

This variety is either acute or chronic in its course and character, but much oftener the latter.

In the *acute* form the papulæ are very red, and the inflammatory action accompanied with much heat and itching. After three or four days their redness diminishes, and having thrown off a minute furfuraceous scurf, they disappear. They are, however, at the same time followed by others. In about a fortnight, after four or five successive eruptions, it genetally subsides altogether. This acute form of the affection mostly occurs on the face and trunk.

The *chronic* form is generally situated on the limbs, and prefers, as before mentioned, the posterior and exterior surface of these. The papulæ have scarcely any inflammatory

character, and the pruritus with which their manifestation is preceded or accompanied gives but trifling annoyance. While some are sufficiently red, it requires that we pass the fingers over the great majority which stud the surface to distinguish them, so little do they differ from the rest of the skin in colour. The papulæ remain from a week to a fortnight, and leave the branny desquamation behind on waning; but the duration of the affection in the chronic form is quite indefinite, as fresh successive crops of pimples protract it often to many months. It manifests its tenacity sometimes by breaking out in a different part of the body after disappearing from its original situation, and it is liable to recur from the slightest cause, when the patient thinks that he is at length clear of it; such as changes of weather, errors in diet, or unusual exercise.

2. *Lichen circumscriptus.*—This variety is distinguished by a marked peculiarity of form. The papulæ, which in the former species are scattered without order, assume in this a circular arrangement. At the first view nothing may be observed beyond a ring of red papulæ, but on closer inspection these are found to enclose areas covered with a minute farinaceous desquamation, which is detached from small papular eminences beneath. The external papulæ alone manifest any inflammatory redness, or if those inside the circles differ from the rest of the skin in colour, it is only by a light pinkish hue. The circumference of these circles, at first so small that the papulæ lie clustered in contact, soon spread by new eruptions, while the old borders fall into the desquamating centres. They seldom enlarge beyond the size of a shilling, and when the eruption is extensive, they mingle their circumferences, yet not so intimately but that it is always easy to recognize their circular form. This variety occurs as frequently on the trunk and face as on the extremities. From its tendency to spread and to propagate by forming new patches, it is not to be speedily eradicated. We have observed it occurring most frequently in early youth: it is called by boys at school *wildfire*.

3. *Lichen pilaris.*—This differs from the *lichen simplex* probably in no pathological character save that the papulæ are developed at the root of the hairs, which perforate their centres. This variety is remarked to be more chronic in its duration, and to be accompanied with greater irritability of the skin, than any of the preceding. Bateman's observation accounts for this: he states that it is often connected with derangement of the digestive organs, produced by ardent spirits.

4. *Lichen lividus.*—This is a kind which almost always occurs in persons with constitutions broken up by misery and privation. It consists in dark violet pimples scattered here and there on the legs and thighs; they are flat and broad, and are generally mixed with specks, which differ in nothing from purpura, to which disease this form of lichen is evidently allied. It is not so rare as some authors assert, but it is of little importance in a medical point of view, as in most cases its cure is to be promoted rather by the charity than the professional services of the physician.

5. *Lichen agrius.*—This is the severest form of this disease, as its name implies.* The papulæ are smaller than in the lichen simplex; they occur in congregated masses, and are very numerous. Their colour is deep red, and the skin where they arise is affected with a vivid erythematous inflammation, which spreads between them and beyond them. The heat or pruritus which accompanies their eruption is of the most violent character, and often deprives the patient, night after night, of rest: he cannot avoid scratching the pimples, and often employs a hard brush for this purpose. This proceeding, although rendered irresistible by the intolerable burning and itching, only tends to make matters worse; it aggravates the inflammation, and encourages the development of new patches. Besides this, where the papulæ become forcibly abraded, small ulcerations ensue, and a liquid oozes from them which forms thin crusts or scaly concretions. In some rare cases the affection appears to be relieved by the discharge, and having soon thrown off the soft incrustation which the latter formed, the cutaneous inflammation and its effects subside. The general course of the disease is, however, very different; painful exacerbations and new eruptions take place for many weeks; and at length it falls into a chronic condition, in which the inflammation nearly ceases, and the pruritus becomes much mitigated. In this condition it remains for an indefinite period, the serous secretion being checked, and the scaly crusts becoming dry, and diminished to a farinaceous exfoliation. After a severe attack of this affection the skin remains for a long time thickened and rough, and retains a morbid sensibility, which persists for a considerable space.

This aggravated form of lichen is sometimes produced from the lichen simplex by causes, general or local, which determine a higher inflammatory action. In such a case the inconsiderable itching which accompanied the pimples of the original species is changed into a burning pruritus; the papulæ become in some places apparently confluent, and surrounded with a deep red inflammatory areola; and thus it proceeds in the course described. It more generally, however, commences as a distinct form, putting on its characteristic severity from the very beginning. In that state where the lymphy fluid which exudes from the abraded and ulcerated papulæ concretes into crusts, it approaches very nearly to the character of eczema. If it persist without shewing any tendency to heal, after some time a purulent secretion forms, and may become, as Celsus remarked, really converted into impetigo.

The situation of this species is uncertain. It occurs with about equal frequency on the face, trunk, and extremities. It is not peculiar to any period of life, as it happens at all times

* Ἀγριὸς, *ferus, agrestis.*

from childhood to old age, but it appears to be more frequently and easily excited in those vitiated habits of body produced by addiction to spirituous liquors. This is more particularly the case among the poor, who, in addition to the injury done by the drinking itself to their organization, deprive themselves of a wholesome nutrition to indulge this miserable propensity. It is always preceded or accompanied by some fever and gastric derangement, sometimes of a serious nature; such as headach, nausea, vomiting, and loss of appetite, also general soreness and pains. Internal disorder is also very apt to occur if the eruption be repelled by the unseasonable application of cold.

6. *Lichen urticatus.*—This is a variety which well deserves to be separately specified. It consists of an eruption of large red papulæ, like the wheals produced by the stinging of nettles. They are found on the neck and arms of young persons, and those of a delicate skin, in spring and summer. It disappears with a slight exfoliation after a short time, and recurs again generally several times before it is finally removed. The pruritus which accompanies it is not of the acrimonious character of the last species, but it gives considerable annoyance, particularly at night, when it also is accompanied by a slight feverish access.

M. Biett describes a variety distinguished from any other by the papulæ displaying a spiral or circularly twisting arrangement. He has given it the name of *lichen gyratus.*[*]

Lichen tropicus is a species which appears to differ in no respect from the other varieties except in the rapidity of its invasion, and the greater intensity of the itching, which are caused by the high activity of the cutaneous action, and the general exaltation of sensibility which the solar heat gives rise to in the torrid zone. It is appropriately called the "prickly heat" in the tropical countries. "The sensations arising from it," says Dr. James Johnson, "are perfectly indescribable, being compounded of pricking, itching, tingling, and many other feelings." It is usually, but not invariably, accompanied by an eruption of vivid red pimples, not larger in general than a pin's head, which spread over the breast, arms, thighs, neck, and occasionally along the forehead, close to the hair. This eruption often disappears in a great measure when the patient is sitting quiet and the skin is cool; but no sooner does he use any exercise that brings out perspiration, or swallow any warm or stimulating fluid, such as tea, soup, or wine, than the pimples become elevated, and but too sensibly felt. As would be anticipated, the new comers are much more liable to this unpleasant affection than natives or long residents, for the susceptibility of the skin is greater while the contrast between the cold and hot climate is still sensibly present; but even natives are not exempt from it. The fears which Hillary and Mosely express about dangers accruing to the patient from repulsion of the eruption by cold bathing are ungrounded; but Dr. Johnson states "that the cold bath rather aggravated than appeased the eruption and tingling, especially during the glow which succeeded the immersion." "The only means," says he, "which I ever saw productive of any good effect till the constitution got assimilated to the climate, were light clothing, temperance in eating and drinking, avoiding all exercise in the heat of the day, open bowels, and, last not least, a determined resolution to resist, with stoical apathy, (the temptation to scratch,) its first attacks." Mr. Plumbe remarks with justice, "that the prickly heat is not confined to the climates from which it derives its name. In fact, the lichen *urticatus* occasionally occurs in these countries with an intensity of itching and tingling that must be quite as tormenting as the tropical affection. The writer knew a person who for several successive nights was obliged to jump out of bed from the sudden supervention of an intolerable heat and itching, produced by an eruption of this nature. The pimples which arose on the head in particular produced such irritation, that the patient felt as if they would make him mad. After remaining in the cool air for a while, and taking a draught of water, they subsided, and allowed him to go to sleep at an advanced period of the night, leaving him quite free till the next night. It is often brought on in spring and autumn, in young persons, by violent exercise, and it is a penalty not unfrequently paid for dancing in these seasons. Mr. Plumbe mentions a case where a public performer was obliged to forego this manner of obtaining a livelihood from the severity of its attacks."[*]

Diagnosis.—To some of the foregoing varieties may be referred every example of lichen; but these papular eruptions are so manifold, and pass so readily into one another, that it may be difficult to assign its proper place to individual cases: this, it will be conceived, is not of essential importance. Although we have adopted this division into species because we are convinced of its convenience and exactness, and think that it tends to forward the study of cutaneous pathology, yet it is not intended to impose a notion on the student that we derive at present much assistance from them in the treatment. Their diversity consists, at least chiefly, in the degree of inflammatory action, and is much influenced by the previous constitution of the person, their circumstances and habits, local relations, &c. The causes which produce them afford, also, a proof of their agreement. They may be comprised under two general heads:—1st. heat, either of the atmosphere or artificial. This is a common source of them, from the slightest summer rash (lichen simplex) to the prickly heat. Blacksmiths and glasshouse-men are very constantly affected by some form of it, from the heat of their furnace and forge. 2d. Derangement of the digestive organs, either from improper diet and spirituous liquors in excess, or defective and unwholesome aliment. To this head are often

[*] *Cazenave et Schedel*, Maladies de la Peau d'après M. Biett, p. 269.

[*] Practical Treatise on Diseases of the Skin, p. 251, third edition, 1832.

to be traced cases of lichen agrius, lichen urticatus, and to the latter cause particularly the lividus.

An accurate diagnosis of lichen is not always easily made. It is of considerable importance in practice, however, to be able to distinguish it, more indeed for the sake of determining what it is not, than for establishing its own identity. We must be particularly cautious not to confound it with any of the exanthematous eruptions, with measles or scarlatina for instance; but it is only necessary to point out here the possibility of this mistake: if the description of the varieties above given be fixed in the mind, it cannot occur.

From scabies, prurigo, and eczema, the lichen simplex is not so easily distinguished. We will observe, in drawing the distinction, that scabies comes out in vesicles which discharge a fluid on breaking, that it occupies the intervals between the fingers, and the flexures of the wrist and finger phalanges; on the other hand the solid red papulæ of lichen are very different from the transparent vesicle of scabies; they are situated, as we have seen, on the exterior parts of the arms and thighs; and if they appear on the hands, where scabies almost universally begins, they occupy the dorsal surface, and do not affect the joints or the intervals of the fingers. The contagion of scabies would settle the question if this were ascertained, but this is never the case where there is a doubt as to the diagnosis. It is, in fact, to procure information as to the contagious nature of the eruption under consideration that diagnostic marks are valuable between scabies and lichen, in order that proper precautions may be taken, in case it be the former, to prevent it spreading. Lorry sums up the difference between them with conciseness and accuracy. "Primo a scabie differunt, quod papulæ illæ (lichenis scil.) vulgo magis confertæ sint et elatiores: 2°. quod rubicundæ magis et minus aridæ sint: 3°. quod sanatis febribus superveniant: 4°. quod latiores sint, et sæpius recidivam patiantur quam vera et legitima scabies; 5°. quod in furfur abeant notabile; 6°. demum quod remediis sanentur a scabiei curatione alienis."*

The papular nature of prurigo comes nearer the external character of lichen simplex, but the pimples of the former are larger, much more separated, and seldom differing in colour from the surrounding skin; they are not acuminated as in lichen, and are covered generally with a speck of dark blood: this is produced by abrasion in scratching, the pruritus being of a peculiarly acrimonious nature; whereas in lichen simplex it is comparatively mild. Lichen may simulate eczema so closely as to require much tact and consideration to decide between them. When the eruption of lichen simplex is very vivid, there often appear, here and there, some vesicles; and when with this occurrence it happens that the patient abrades the summits of the papulæ, the excoriations give out a fluid which concretes and forms soft crusts; in this state many of the features of eczema are present. On inquiry it will be ascertained that at first the eruption was entirely papular, and that the few stray vesicles are merely adventitious. They generally come out after the excoriations have been made, and in their immediate neighbourhood.

The lichen agrius is still more difficult to distinguish from eczema. We must rely on the history of the eruption, and the character of the elevation of the skin, which is vesicular in the latter case, and papular in the former. This can generally be determined by examination after the crust which covers it is removed. Besides this, the irritation which the real eczema causes is strongly contrasted with the burning itching of the papular eruption; but this distinction may fail after a long duration of the latter disease, and the others become so confounded, that it is often impossible to distinguish between them.

It has been already stated that lichen agrius sometimes takes the characters of impetigo, but the reverse never takes place; the latter ought never to be mistaken for the former. The small psydracious pustules of impetigo are manifest from the beginning, and the coarse crusts which form on their breaking are different from the thin layer which the excoriations of lichen furnish.

When lichen agrius subsides into a very chronic state with a tendency towards cure, it is often so much overlaid with furfuraceous exfoliation as to be taken for a scaly disease. Some authors, indeed, assert that it is not uncommon for it and for the lichen simplex to be converted into psoriasis. The writer has lately seen a gentleman who had on the arms and chest an eruption of lichen simplex, which in the axillæ and the folds of the buttock was changed in character so as to resemble pityriasis more than any other cutaneous affection.

Lichen circumscriptus has often been mistaken for herpes circinnatus; we have lately seen a skilful observer make this oversight. It is to be borne in mind that the circular patches of the papular eruption are smaller, and shew no vestiges of vesicles or their remains, which are always discernible on closely inspecting the rings of herpes circinnatus. Moreover the central space of the latter is quite untouched, but in the lichen the papulæ are still recognised, paler than the external circle, and overlaid with the farinaceous scurf. It is proper to remark that the psoriasis guttata has been also mistaken for lichen circumscriptus.

The difference between lichen urticatus and urticaria will be ever easily recognized by any one that has seen both affections. Besides the exanthematous character of the latter, the form is quite distinct. The papulæ in the lichen are large, elevated, distinct, and are more or less permanent. The wheals of nettle-rash are confluent, flat, and scarcely ever remain beyond a few hours at a time. This lichen may also be mistaken for the venereal eruption called by some authors lichen syphiliticus. The latter disease is marked by its coppery hue; besides it is destitute of the pruritus

* Bateman's Synopsis, (note) p. 8.

which accompanies all proper lichens, and it is more steadily persistent than lichen urticatus. Again, it is seldom found alone, almost invariably accompanied by some of the other attendants on secondary syphilis.

Prognosis.—In none of its varieties can lichen be considered as a dangerous disease, and in the less scarce forms almost the only importance that attaches to its presence is the troublesome itching which the pimples occasion. When it arises from merely local or temporary causes, such as the directly irritating action of the spring or summer heat, it is of little consequence and of short duration; but if its origin be more deeply seated in the constitution, if it be liable to frequent recurrence and exacerbation, it leads to more unpleasant consequences. It is in such instances that it gives rise, after a long duration, to a thickened rugous state of the skin, which completely obstructs its function of exhalation. At other times, as we have before stated, under similar circumstances it becomes complicated with eczema and impetigo, and, according to Biett, sometimes degenerates into ecthyma. The lichen agrius, as it is the most severe of all the varieties, so is it also the most difficult of cure; when situated in the face, it more particularly resists with uncommon obstinacy all therapeutic means. It may be stated as a general rule, that this and the other varieties are difficult of removal in proportion as they are of long duration.

Treatment.—In the lighter forms of this eruption the treatment is simple. It demands, indeed, but little interference from the physician. His services here are seldom required further than in making an accurate diagnosis, tracing the eruption to its true cause, and laying down principles of treatment. As they generally occur in warm weather, and depend more or less on it, the individual should keep the house for some time, and thus abstract himself from the direct heat of the sun and from exercise, which last is one of the most common exciting causes of it. It will be useful to employ every day towards evening the tepid bath. Some even prefer the cold bath; the warm bath is too stimulating to the skin. To coincide with these cooling means, it will be requisite to adopt a diet in which the allowance of animal food is diminished. It will rarely be necessary to inhibit it altogether, but the greater proportion that vegetable and farinaceous matters make in the meals, the better. Wine and spirituous drinks should be laid aside, but there is no objection to a moderate quantity of table-beer. As to medicines, it will be sufficient to give a saline laxative occasionally, so as to keep the bowels open: sometimes it will be judicious to use a few grains of calomel or blue pill for this purpose; potions of lemonade are much used in France. Bateman extols the success of dilute sulphuric acid where a grateful tonic is called for. For allaying the itching, various topical applications have been used. Mucilaginous decoctions, as that of marsh-mallows, are said to have a soothing effect. A lotion with two drachms of prussic acid to a pint of water has been also recommended highly. We believe that one of the best applications for this purpose is milk of almonds, in the composition of which a few bitter almonds have been mixed; with this the skin should be gently moistened three times a-day, or whenever the pruritus become troublesome.

In some of the acute cases where a good deal of fever accompanies the eruption, or where much sympathy is evinced in the digestive organs by vomiting, loss of appetite, or pain in the head, it will be highly advisable to take away some blood from the arm, and to pursue a more decidedly antiphlogistic plan. Stimulating applications, such as sulphur fumigations, or ointments with camphor, &c. are not to be used in the acute forms; but when much of the activity of the eruption is subsided, and the harsh chronic state of the skin, mentioned before, supervenes, then baths of the sulphuret of potash or of the sulphureous mineral waters will be very proper. In this state the ointment of the proto-ioduret of mercury, mentioned in the article Lepra, has been used with decided benefit.

In lichen agrius it is advisable to commence the treatment almost always by a venesection. Nothing tends so much to allay the vehemence of the burning pruritus. This practice will be more pointedly indicated if the patient be young and vigorous, but we consider that it is not less useful in an opposite condition. The application of leeches in the neighbourhood of the inflamed papulæ will also prove a very effectual sedative for the painful itching, but in their use it must be carefully observed to place them exterior to the inflammatory area. Every thing said with respect to the necessity of an antiphlogistic diet it is still more indispensable to observe here while any fever remains, or while the inflammation displays any activity. Under these conditions, every local stimulant must be avoided as worse than useless. Emollient poultices, with some Goulard's extract sprinkled in them, will sometimes be found to assuage the irritation, but if used more than barely lukewarm, they will only increase it. The almond-milk embrocation will answer this end probably as well as any other. Dr. Elliotson recommends, as the best means for allaying the tingling and itching, a lotion of chloride of lime or soda, to be used very dilute.

If under depletory means the eruption loses much of its intensity, then the exhibition of tonics will often prove highly serviceable. The decoction of cinchona with sulphuric acid is preferable to any other. This is especially useful in the cases of broken-down, dissipated subjects, and where the constitution has been brought rather low by antiphlogistic measures. It is not to be imagined that there is anything contradictory in this practice of first reducing the system by depletory means, and then administering tonics as it were to restore it; on the contrary, the practice is found not only compatible with theory, but experimentally

good. In fact, where we have to do with impaired constitutions, the abstraction of blood will be useful, as the tonics will act with greater certainty and efficacy after it, than if they be trusted to without it. With respect to the diet in this stage of the affection, it should be still kept of a very light kind; but it is to be borne in mind, that where the disease has supervened in an individual whose digestive organs and system generally have been greatly impaired by habitual drinking, it is expedient to allow him a small portion of his accustomed stimulus. This is another fact confirmed by experience and reconcileable to pathological principles.

Where it has fallen into an inveterately chronic state, lichen is a very intractable malady. Sulphur fumigations, sulphur and alkaline lotions, have in this case been found beneficial. Mercurial preparations have also been recommended. If obliged to have recourse to this mineral, we would prefer trying the proto-ioduret of mercury to any other preparation, from what is known of its effects in some other cases; one grain twice a-day is a sufficient dose for an adult. With its internal use, might be properly joined the local application of the ointment of the same preparation. We believe, however, that Fowler's arsenical solution is the best internal remedy in those inveterate cases; it is to be given in doses of from three to eight drops thrice a-day, and continued for at least a month. The cautions usual in its exhibition are of course to be strictly observed.

(J. Houghton.)

LIVER, INFLAMMATION OF. Hepatitis, from Lat. *hepar*, Gr. ἧπαρ, *the liver*.

The history and symptoms of inflammations of the liver have been peculiarly dwelt on in all works on medicine from the earliest periods. In fact, until very recent times, when the attention of physicians was more especially called to the diseases of the gastro-intestinal mucous membrane, — heretofore a comparatively unexplored field,—this affection and its subsidiary diseases were more studied than any other lesion of the digestive apparatus. (See Gastro-Enteritis.)

Pathology.—The liver may labour under the effects of increased quantity of blood in its parenchyma from several causes. Of these the two most important are, 1. *active congestion*, the result of irritation in its tissue, either primary or the consequence of some other lesion originating in its own substance, or some other organ with which it sympathizes; and, 2. *passive congestion*, induced by mechanical obstruction to the exit of its venous blood. This obstruction may be seated in the hepatic veins, the heart, lungs, or even in the aorta, *(mechanical hyperæmia of Andral.)* In addition to these, two other sources of congestion are mentioned, one a stasis of blood similar to that which occurs in organs attacked with scorbutic disease, and the other the congestion which occurs so remarkably in intermittent fever; a congestion sometimes so intense as to induce hepatic apoplexy.*

The results of inflammatory action on the liver vary according to the intensity, length of duration, and situation of the disease. In general, the first visible effect is the production of increased vascularity of the parenchyma, which may be either general or partial; but we believe that in the majority of cases the latter is most frequent. This is accompanied with tumefaction of the part, and is the first stage of acute inflammation, as far as this can be demonstrated by the knife: under these circumstances the hepatic tissue is extremely red, and blood flows copiously when it is divided by the scalpel.

In a still more advanced stage, in addition to the vascularity, we observe a remarkable softening of the part, sometimes so great that a slight pressure will reduce it to a mere pulp. This state is analogous to the second stage of acute pneumonia, and, like it, may be accompanied by the formation of pus or lymph on the serous surface. In this respect, however, there is a great difference between the liver and lung, as we seldom meet with pneumonia without serous inflammation, while the reverse often obtains in hepatitis. This is a point of great importance in the surgical treatment of the disease, and one to which we shall recur.

On this subject Mr. Annesley makes the following remarks: "When the surfaces are the seat of inflammatory action, the adjoining internal structure of the organ generally participates in it to a greater or less extent, and likewise, when morbid vascular action commences in the parenchymatous structure, it sometimes extends to the external surface; but this more rarely occurs in India than the former mode of extension, the internal structure appearing to us to be more frequently the seat of the inflammatory state than the surfaces, which seldom participate in it till the more advanced stages of the disease. We frequently observe in India the internal structure of the liver inflamed to the greatest possible extent without any effusion of lymph from its surfaces, and the inflammation of structure may go on to the production of several abscesses in both its lobes, or of one very large abscess in the eighth lobe only, without any decided marks of inflammation of the envelop of the organ, except some alterations of colour merely, which are usually occasioned by the states of the parts immediately underneath; nay, even abscesses of the liver may proceed to the utmost extent, and ultimately break into the abdominal cavity, without having induced inflammation of the serous surface where they point, and consequently without forming adhesions to the parts with which they are in immediate and close contact."†

In the report of the Meath Hospital, by

† Annesley's Diseases of India, vol. i. p. 406.

Dr. Graves and the writer of this article,* the important fact of the rarity of adhesions in cases of hepatitis, even after the formation of abscess, is noticed. This is a fact which we had observed long before the appearance of Mr. Annesley's work, and one from which it would appear that both in the warm and temperate climates acute inflammation of the liver is much more seldom complicated with serous inflammation than a similar state of the pulmonary parenchyma. It is not easy to explain this singular but most important difference; but it is obvious that the only mode of arriving at a solution of the difficulty is to compare the physiological relations of the two membranes.

It has been long admitted that the peritoneum is less liable to the adhesive inflammation than the pleura, as, in our examinations after death, we commonly meet with adhesions of the pleura, while those of the peritoneum are comparatively rare. This fact, however, may, to a certain degree, be explained by the greater fatality of abdominal inflammations, a greater portion recovering from pleuritis than from peritonitis. The more frequent affection of the pulmonary serous membrane in cases where the subjacent parenchyma is engaged, may be explained partly by the greater degree of motion which, in consequence of the function of respiration, the two pleural surfaces are exposed to; as in this way the parts are not only predisposed to inflammation, but a slight effusion of lymph may become an exciting cause of disease by its mechanical action over an extensive surface. Again,—if, as there is great reason to believe, the air-cells are in reality white tissues, the propagation of inflammation from them to a similar structure ought more readily to take place than from the glandular acini of the liver to an essentially different tissue.

The next stage of hepatic inflammation which has been described is that of purulent formation or abscess; but we believe that between this condition and the red softening of the liver there is an intermediate stage, in which the hepatic tissue is found of a yellow colour, exceedingly soft, and leaving a puriform exudation on the scalpel. Between this state and the third stage of pneumonia there appears to be a great analogy, as it is an interstitial suppuration immediately preceding the formation of abscess. In several instances we have observed this alteration to extend to some distance around an hepatic abscess, and in cases where numerous small purulent collections existed, the hepatic tissue which separated them had undergone this change. The tissue thus altered varies considerably in consistence, in some instances being almost semifluid, in others possessing a certain degree of firmness. As yet this condition does not appear to have been recognized in the systematic works on pathology.

Lallemand, in his "Lettres sur L'Encéphale," speaks of a softening of the liver, in which, in consequence of severe inflammation, its tissue is reduced into a diffluent sanies of the colour of wine-lees; but this condition is obviously different from that we have just described.

Abscess of the liver, so common in India, is of rare occurrence in these countries. A few isolated cases are to be met with in medical records, but no series of cases was published as occurring in Europe until the appearance of Louis's researches on this subject.* Subsequently, the writer of this article, in conjunction with Dr. Graves, published several examples of this lesion.†

Puriform matter, as the result of inflammation, is met with in the liver under several forms. We may find it, as it were, infiltrated into the hepatic tissue, as described above,—a condition to which the name of yellow softening of the liver may be given; it may occur in numerous minute abscesses; or, lastly, it may form one or more large collections of matter, in some cases encysted, in others bounded only by softened and yellow hepatic substance. These collections of matter are generally isolated, though in a few cases they have been found to communicate by fistulous passages.

As yet we are not fully aware of the circumstances which dispose to the formation of a cyst around these puriform collections. The more chronic the abscess, the greater will be the likelihood of a cyst existing, but it will often be found even in recent cases. We have seen these cysts under very opposite circumstances. Thus, in a case which occurred in the Meath Hospital, where, after acute hepatitis, the patient sank with suppuration of the liver, we found numerous abscesses, some the size of an orange, others that of a hazel-nut, the smaller being encysted, the larger not so. In another case, however, the reverse of this was observed. A patient had laboured under gastro-enteric fever for some time, when attention was directed to his liver, from his complaining of pain in that situation. The organ was then found enlarged, and it soon became evident that matter was forming. The patient died, and on dissection, a vast abscess in the right lobe, capable of containing several pints, was discovered: this was encysted, while in the remainder of the liver were numerous small abscesses, only separated by softened hepatic tissue. In another case, the particulars of which we shall detail hereafter, a very chronic abscess, communicating with the duodenum, existed in the right lobe, while a recent one, which had opened into the peritoneal cavity, was found in the left. In the first abscess, which had existed under our observation for two months, we found the cavity empty, and lined with a strong semi-cartilaginous membrane, of a dark greyish colour; while in the second there was no cyst whatever, its parietes being formed of yellow softened hepatic tissue. The last case which we shall notice on this subject is that of a woman who sank under a very chronic abscess of the liver. Here the cavity was of enormous dimensions, and presented an im-

* Dublin Hospital Reports, vol. v.

* Recherches Anatomico-pathologiques. Paris, 1826.

† Dublin Hospital Reports, vol. 5.

perfectly formed cyst, most developed where the parietes of the abscess were thinnest—that is to say, immediately under the serous covering of the convex surface. In the more deep-seated parts it could hardly be detected.

The appearances of structure of these cysts are various. In some cases we only observe a pseudo-membranous layer, of a line or two in thickness, yellowish white, and resembling semi-concrete pus. In other cases the cyst appears organized, and may strongly resemble a mucous membrane; presenting villosities more or less completely developed, which we can easily demonstrate by immersing the part in water. A third variety presents the lining membrane of a reticulated structure, for which the name of fibro-mucus has been proposed; while in the last species the membrane is semi-cartilaginous, of an iron-grey colour, and very similar to the investment of chronic tuberculous cavities in the lung.

Nothing can be more various than the size of these abscesses. We have seen them so large as to be capable of containing four pints, and, on the other hand, they may be so minute as to represent suppurated tubercles, from which indeed it is sometimes difficult to distinguish them. The surrounding hepatic tissue is generally in a state of red or yellow softening, but cases are on record where it has been found perfectly unaltered; in these the disease was generally chronic. The same variety is observable in the nature of their contents. In all our cases, with but one exception, the matter was healthy, though sometimes mixed with portions of softened hepatic substance. In the case of exception, in which the operation of opening the abscess was performed successfully, the matter was of a dirty green colour, and mixed with sanious fluid. Andral states that in all the cases in which he found puriform matter in the liver, it was white and consistent, like the pus of a phlegmon, and that those who have described it as similar in colour to the lees of wine have confounded other diseases, particularly the occurrence of encephaloid matter, with the inflammatory suppuration. In warm climates, however, great variety is observed in this respect. "The matter," says Mr. Annesley, "contained in an abscess presents various appearances. In some it is a thin, watery pus; in others it is thin, watery, and with thick curd-like clots floating in it; in many cases it is perfectly purulent, and of varying degrees of consistence. As respects colour, there is also considerable difference; most frequently the matter is of the usual yellow colour. Sometimes it presents a yellowish-brown or sanious tinge, and occasionally a greenish-brown or greenish-yellow hue; sometimes it is watery or reddish brown; at other times it is observed of a creamy consistence, and nearly white."*

It is to be regretted that the relations which exist between the vessels of the organ and these collections of matter have not as yet been made the subject of any accurate investigation. We cannot find any instance recorded, where, as in tuberculous and other cavities in the lung, vessels were found traversing the puriform collections. They have been observed, however, forming projections on the internal surface of the cysts; but when we consider the vast size to which hepatic abscesses may attain, the inquiry as to what has become of the vessels becomes a matter of extreme interest, and in the present state of pathological anatomy offers a new field for inquiry.

The abscess once formed may open in a great variety of situations both internally and externally. Of the internal openings we have witnessed the following examples:—1. perforation of the diaphragm and communication with the lung; 2. communication with the duodenum; 3. perforation of the peritoneum, and effusion into the abdominal cavity.

The first of these terminations appears to be a not unfrequent and perhaps the most favourable of the internal openings of the abscess. Many patients have recovered where this lesion undoubtedly occurred, as indicated by the fact of their presenting all the symptoms of hepatic abscess, both constitutional and local, which subsided upon the occurrence of a sudden and copious expectoration of purulent matter, which had not been preceded by any symptoms of pulmonary disease. We have known of cases where pressure exercised on the hepatic region was immediately followed by a free expectoration of pus. The easy exit of the purulent matter, the result of its entrance into the bronchial tubes, is in all probability a principal reason why this termination of the disease should be so often favourable. The abscess may open either into the right or left lung; and though there are some cases where the pulmonary pleura was not perforated, yet the communication with the pulmonary parenchyma and bronchial tubes is much more frequent than the formation of an empyema,—a circumstance explicable by the great tendency to adhesion presented by the pleura.

Dr. Smith, an American writer, details a case where the hepatic abscess opened into the pericardium. The liver, which was almost entirely occupied by an enormous abscess, adhered closely to the upper portion of the diaphragm, through which the opening between the abscess and the pericardium existed; the pericardium was inflamed, and contained about two pints of a purulent liquid similar to that which existed in the liver.

It would appear, then, with respect to the thorax, that the abscess may open into the lung, pleura, or pericardium. Of these, the first is by far the most frequent. With respect to the abdomen, the abscess may communicate with some portion of the gastro-intestinal tube, the peritoneal cavity, the gall-bladder, the vena cava, or kidney. In the cases where the opening has taken place into some portion of the digestive tube, its seat has been in the stomach, duodenum, or colon.

Lastly, the abscess may open externally in a great variety of situations upon the abdomen, and also on various places on the side and in

* Op. cit. p. 533.

the axilla. When the opening takes place externally, it is seldom by a direct, but commonly by a sinuous and fistulous passage. Louis, in his *Recherches Anatomico-Pathologiques*, declares that he has never yet known of the occurrence of a cicatrix in the liver the result of a cured hepatic abscess. We feel satisfied that this is a pathological appearance rarely observed in the dissecting-room,—a circumstance to be explained by the rarity of the disease in this country and its general fatality. In one case, however, we have witnessed this rare appearance. A patient who had been a soldier in the East-India Company's service, and who had, while in India, suffered from an attack of hepatitis, accompanied, as he described, by great tumefaction of the liver, died in the Meath Hospital of a chronic enteritis. On dissection, the right lobe of the liver was found greatly diminished in volume; while in the centre of its convex surface existed a very deep stellated depression, around which the hepatic tissue was puckered, rising in the form of crests with intervening sulci of nearly an inch deep. From the centre, which was occupied by a mass of cartilage nearly the size of a walnut, emanated prolongations of thin plates of cartilage, answering in number to and forming the base of the sulci which appeared on the surface. In this case we were not able to determine by what aperture the contents of the abscess had been evacuated, but in all probability it was through the duodenum. The appearances on dissection in this case were almost identical with those in a case of cicatrices of the liver, of which Mr. Annesley gives a beautiful drawing, (see plate 15 of his book.) This gentleman states that he has met with several cases of these cicatrices in India. There is a form of disease which is very liable to be confounded with hepatic abscess, as it has many symptoms in common with this affection; we allude to a circumscribed inflammation and suppuration in the parietes of the abdomen, immediately over the liver. The disease sets in with fever, pain, tumefaction, and tenderness in the affected part; and, in addition, we have many of the constitutional symptoms of hepatitis. In one case, which occurred in the Meath Hospital, a slight jaundice existed for several days, analogous, in all probability, to that arising from diaphragmatic pleurisy. These cases are generally of little severity as compared with true hepatitis. Matter forms speedily under the integuments, and, on this being evacuated, the patient rapidly recovers. In a case, however, which we have witnessed, the disease proved fatal under very remarkable circumstances; we shall therefore notice it at greater length. A woman aged twenty-three, who had laboured under amenorrhœa for twelve months previously, was attacked with cough and hemoptysis, followed, after some days, by fever, pains in the back and limbs, and prostration of strength. Soon after this she complained of pain in the right side of the chest and hypochondrium, increased by coughing, pressure, or motion. She had a distressing short cough, with yellow tenacious expectoration. The inferior portion of the right side of the chest sounded dull, and the respiration in this situation was almost inaudible, except when she made a forced inspiration. The symptoms having continued for about a fortnight, an uncircumscribed puffy tumour made its appearance over the lateral portion of the liver; the hemoptysis returned, with a hard teazing cough, but the fever disappeared; poultices were diligently applied to the tumour, which rapidly enlarged and presented evidences of extensive suppuration. On the thirteenth day after its appearance it was opened by means of an abscess-lancet, when a great quantity of matter mixed with blood was discharged; at this time the spitting of blood ceased. In about three weeks, however, the abscess again appeared, and rapidly increased to a size much greater than its former dimensions; it was again opened, and a large quantity of purulent matter given exit to. On the next day the abscess presented the appearance of an enormous anthrax, with edges about two inches high, from which a quantity of whitish slough could be detached by pressure; the patient was now emaciated, had diarrhœa, with cough and sanguinolent and puriform expectoration. We endeavoured to trace the extent of the disease by introducing a probe; but although this was found to pass extensively under the muscles and cellular substance, yet it could not be introduced either into the thoracic or abdominal cavity. After some time it was found that when the patient coughed, or took a deep inspiration, air escaped with great violence from the base of the ulcer, towards the upper portion of which a circular fistula, through which a probe could be passed, was observed; through this the probe passed for about three inches, when it met with a solid resisting body. The infra-mammary region sounded clear on percussion. Examined by the stethoscope, the respiration was cavernous, and accompanied during inspiration by a sound like the tick of a watch. When the patient coughed or made a forced inspiration, a loud guggling was audible. There was no metallic tinkling, *bourdonnement*, or pectoriloquism; but the voice resounded strongly from the sixth rib upwards, while anteriorly and posteriorly the respiratory murmur appeared natural. She died on the following day.

Dissection. — Great emaciation. The external sore extended from the sixth to the tenth rib; it was about four inches in breadth. Between the eighth and ninth ribs the fistula was plainly observable. On opening the abdomen, the serous membrane was found healthy, with the exception of that portion which covered the liver laterally and superiorly. Here the liver adhered to the diaphragm.

On the centre of the convex surface of the liver we found the base of the abscess formed by a circular portion of thick false membrane, of about two inches in diameter, *external* to *the hepatic peritoneum*, but producing a depression on its surface. The costal portion of the diaphragm, for an extent corresponding to the base of the abscess, was destroyed, but adhered round its edges. This abscess communicated

with the lung by a perforation through the diaphragm of about the same size as the external fistula, which led into an abscess in the lower lobe of the right lung. This was narrow, elongated upwards, and presented many of the characters of a pneumonic abscess. It had no lining membrane, and communicated with numerous bronchial tubes. Around it the pulmonary tissue was of a greyish-white colour, softened but not granular. The diseased portion did not terminate by any distinct line, and occupied about two-thirds of the lower lobe, which was universally adherent to the diaphragm, and for about three inches to the costal pleura; the remainder of the lung was healthy. The mucous membrane of the stomach was pale and soft, the lower portion of the ileum red, and presenting some aphthous ulcerations; the mucous membrane of the colon was covered with fungous elevations and numerous aphthous ulcerations.*

In this case the diseased action had in all probability a double seat from an early period, namely, the lower portion of the lung and the integuments over the liver; it is remarkable for the double perforation of the diaphragm through its costal and thoracic portions, and for the direct communication made by the latter with the substance of the lung: the pleural and peritoneal adhesions prevented the escape of the matter either into the thoracic or abdominal cavity, a circumstance illustrative of the powers of nature in availing herself of diseased action to promote an ultimate cure.

Some authors have described gangrene as a result of hepatic inflammation; but facts are still wanting for the elucidation of this subject, and there can be but little doubt that, if it ever does occur, it must be a circumstance of extreme rarity. On this subject we shall quote from Mr. Annesley:—

"Gangrene has been remarked by many writers and teachers as one of the terminations of acute inflammation of the liver; but although we have observed this disease, and made post-mortem examinations of it, the number of which certainly has not been exceeded by any other inter-tropical practitioner, we have never seen a single case of gangrene of this viscus. We are inclined to believe that the appearances that have been taken for gangrene have been merely that black congested and softened state of the organ which is sometimes observed in the more acute attacks of the disease, supervening to congestion, or at least this state of the viscus having speedily run into gangrene after the death of the patient; and therefore, if gangrene had actually existed at the time of dissection, it is to be considered as a consequence of death rather than a termination of the disease."†

In the works of the modern pathological anatomists of Europe, the same infrequency of gangrene of the liver is observed; so that we may conclude that both in warm and temperate climates the termination of hepatitis by gangrene is of extreme rarity. Andral relates one decided case of gangrene of the liver, where the disease surrounded an abscess of the left lobe, and states that this is the only instance he has seen of gangrene of the liver. When we reflect on the vast number of dissections which this great pathologist has made, the fact of his having seen the disease but once is a decided proof of its rarity. Here is another circumstance in which the pathological relations of the liver differ remarkably from those of the lung, as, in the latter viscus, gangrene is a not unfrequent occurrence; but when we consider the greater liability to a stasis or effusion of blood in the pulmonary parenchyma as compared with the hepatic, and also that in the lung the diseased portion is exposed to the action of air, we may find in these circumstances an explanation of the fact.

The effects of chronic inflammation on the liver are exceedingly various, and its results greatly influenced by the constitution or habit of the patient. Among them may be enumerated the different forms of hypertrophy, either partial or general, either of the red or white substance, or of both; induration; scirrhous or tuberculous tumours; and hydatids. We are far from believing that these latter lesions are always the result of an inflammatory process; as there is undoubted evidence that these new tissues may be the result of a lesion of secretion and nutrition, not induced by any previous irritation of the part; while, on the other hand, cases are on record where these different diseases appear to have been first brought about by an acute or chronic hepatitis. The following observations by Andral on this subject are highly philosophic:—

"There is scarcely one of the alterations of the liver which have been described which has not been designated by the name of hepatitis. In my opinion there is hardly one of them which may not be the result of an irritation whose first effect was to cause an hyperæmia of the liver. For example, four individuals receive an external injury on the same region of the liver; in one an abscess is developed in the liver; in the second this organ becomes cancerous; in the third it becomes filled with hydatids; and in the fourth it is atrophied. In all these four cases irritation has been manifestly the point of departure: but what has been its mode of action?—it has deranged the normal nutrition of the organ; there its influence is confined: the predisposition of the individual has done the rest. On the other hand, I do not know an alteration of secretion or nutrition of the liver, not even a collection of pus in its parenchyma, that can be considered as necessarily arising from an antecedent process of irritation. I do not know one of which we can say that its formation has been necessarily preceded by a hyperæmia. What, then, does the word hepatitis express? nothing more than the common link by which the different lesions of secretion and nutrition of the liver are often united. But this link is neither constant nor necessary; and if we have seen a case where an hyperæmia of the liver by ex-

* Meath's Hospital Reports.
† Op. cit. vol. i. p. 435.

ternal violence has been followed by the formation of hydatids, I may cite many other cases where nothing has demonstrated a similar point of departure, and where, from analogy, we would arrive at an opposite conclusion, and admit that the development of these entozoares is found connected with a diminished activity of the normal nutrition of the liver."*

Observations are still wanting to establish the exact relative frequency of suppuration as the result of hepatitis in its acute and chronic stage; there can be little doubt, however, that this lesion is much more frequently the result of an acute than of a chronic inflammation.

With respect to the frequency of peritoneal adhesions it may be stated that these, which we have seen to be by no means constant in the acute disease, are commonly met with in chronic hepatitis. In this disease the convex surface of the liver is generally found adherent to the parietal peritoneum by strong and organized adhesions. On its concave surface we may also meet adhesions with several portions of the abdominal viscera, though, as far as we have seen, these are not so frequent nor so general as those of the convex portion.

Symptoms of hepatitis.—Inflammation of the liver has long been described as occurring under two forms, the *acute* and *chronic;* but although numerous cases will be met with where it would be difficult to declare to which of these species the disease belongs, yet in a practical point of view the division is convenient. Let us examine the symptoms, progress, and termination of the first or acute species.

Acute hepatitis.—In the different elementary works on the practice of physic, the symptoms of this disease are described as occurring in a manner much more constant than the state of the science can permit us to believe, and in this way the student is misled, and gets a very false and contracted view of the affection. In fact, there is no one symptom mentioned that may not occasionally be absent; and, on the other hand, all may arise from other causes besides hepatitis. The symptoms may be considered as local and general, the *local* being, principally, pain, tenderness, and tumefaction; the *general*, fever, and lesion of the digestive and in some instances of the nervous and respiratory systems. Of these, the first two, namely, fever and lesion of the digestive function, are by far the most frequent, a circumstance to be expected when we recollect the general complication of hepatitis with gastro-intestinal disease. (See GASTRO-ENTERITIS.)

Acute hepatitis may be generally described as commencing with that group of symptoms indicative of inflammation in the digestive system; in other words, the patient at first appears to be attacked with gastric or bilious fever, to which succeed, sooner or later, symptoms of the hepatic disease. There is often then high fever, the type being generally more inflammatory and less typhoid than that which results from a simple gastro-enteritis. The pulse is more frequently strong and full; there is thirst, a furred and yellowish tongue, and frequently vomiting, sometimes of a bilious, at other times of a dark-coloured matter. The bowels are commonly irregular or costive, and the discharges present a great variety of appearances according as the biliary secretion is more or less affected, and also according to the degree of complication with gastro-intestinal disease. The urinary secretion is also affected, being almost always scanty and very high coloured.

In addition to these symptoms we have the local indications of hepatitis, which are, principally, pain, tenderness, and tumefaction. The pain is felt in various situations, and occurs with various degrees of intensity. In some cases the patients describe it as a stitch in the side, aggravated by respiration or motion; in others the pain occurs about the cartilages of the lower ribs, or it may be felt in the lumbar region. Much has been written about the occurrence of pain in the right shoulder in cases of hepatitis; from our experience we would say that this is an extremely rare symptom, and one by no means pathognomonic of the disease, an opinion borne out also by the experience of Dr. Mackintosh* in these countries, and of Andral in France.† There can be no doubt that practitioners are often misled from attaching an unmerited degree of importance to the presence or absence of this symptom. Generally speaking, the pain is more acute when the inflammation is superficial,—a circumstance illustrative of the general law, that in parenchymatous inflammations the pain is more severe when the disease approaches or involves the surface of the organ.

The symptom which we regard as next in importance to the pain is the tumefied and tender condition of the organ. When the belly is flaccid and the intestines are empty, there is seldom much difficulty in detecting the hepatic enlargement. We then generally observe the right hypochondrium and the epigastric region full, and the edge of the liver can be felt descending more or less below the costal cartilages. Sometimes the ribs appear tilted out, but the intercostal spaces preserve their relative positions with respect to them; a point of great importance in the diagnosis between hepatic and pulmonary diseases. But where the belly is distended by either fœcal matter or air, it becomes extremely difficult to ascertain the enlargement of the liver. In such a case we would always recommend that a dose of opening medicine should be given, followed after some time by a purgative injection, after the operation of which the examination of the hepatic region will be greatly facilitated. We shall also derive important information by the use of mediate percussion by means of the pleximeter, as recommended by M. Piorry, from whose recent work we shall quote.

"In some acute cases of hepatitis, or rather in sanguineous congestions of the liver, it has

* Précis d'Anatomie Pathologique, tom. ii.

* Elements of Pathology and Practice of Physic, vol. i.

† Clinique Médicale, Maladies de l'Abdomen.

been easy to demonstrate, at the Salpêtrière, the Pitié, and at the Hôtel Dieu, that the liver is susceptible of great increase of volume, and that the dimensions of this gland diminish rapidly after a copious bleeding, and sometimes also by strict regimen, which by itself produces a loss of blood. The diminution of the hepatic organ varies from one to three inches, from above downwards, in the twenty-four hours; this is still greater in proportion as the blood drawn is more considerable. Not only has this fact been observed with old men in whom the venous circulation, embarrassed by disease of the heart, and particularly its weakness, explains the tumefaction of the liver, but also in adults, in cases of plethora and acute fevers. I could easily accumulate twenty observations to support this proposition. M. Vidal, one of the house pupils connected with my attendance, has just related to me three most remarkable facts taken most carefully. I shall confine myself to the following:—A young man discharges a loaded pistol direct against the region of the liver; the ball, however, does not penetrate, which singular fact may be attributed to the presence of air between the muzzle of the piece and the ball, the pistol being applied to his clothes so firmly as to stop up the muzzle: his clothes are, however, torn, and the foreign body, after having violently contused the skin, falls at the feet of the wounded man. The first few days no accident of importance occurred; the circumference of the liver was bounded by a black line. The fourth day there was fever, flushed face, and dyspnœa very intense: this was referred to the liver; this organ above and below exceeded by an inch or more the former line of demarcation. A copious bleeding was tried; the next day the liver had resumed its former dimensions, and the severe symptoms disappeared. The cure was rapid."*

In using the pleximeter we should employ it over the epigastrium and hypochondrium, and also over the lower portion of the chest both anteriorly, laterally, and posteriorly. By this means the extent of the hepatic tumefaction can be generally determined with ease. In some instances the tumefaction is more evident in the superior, in others in the inferior portions of the liver; when, however, the belly is much distended, this mode of observation is liable to many difficulties: thus, when the intestines contain much solid and fluid matter, we cannot estimate the extent of dulness inferiorly; and on the other hand, when they are distended by flatus, the liver is pushed upwards, under which circumstances the dulness of the lower part of the chest ceases to be a measure of the hepatic tumefaction.

Jaundice has been described as an attendant on hepatitis, but it is not a constant symptom. The patients have generally a slightly yellowish tinge, particularly in the face, similar to what is observed in gastric or bilious fevers, but very different from true icterus. In none of the cases observed by us at the Meath Hospital was there jaundice; and Andral relates numerous cases of hepatitis where this symptom was absent: it may, however, occur in acute hepatitis; but facts are still wanting to explain its absence in some cases, and its presence in others. Of one fact we are certain, that jaundice, when induced by inflammation, is much more frequently the result of a duodenitis than of an inflammation of the liver. From the known effect of a duodenitis, simple or complicated with gastric inflammation, in the production of icterus,* it becomes an interesting question to determine how far the complication of gastro-intestinal inflammation in hepatitis may act in producing the symptom of jaundice. The following table of cases, taken from the writings of Andral, Louis, and from the report of the Meath Hospital, may assist in throwing some light on the subject. The first column states the condition of the liver, the second that of the gastro-intestinal apparatus and ducts, and the third that of the skin.

State of the liver.	*Digestive tube and ducts.*	*Skin.*
Acute hepatitis	Healthy; ducts free	Jaundice.
Red softening	Healthy; ducts free	Jaundice (slight).
Red induration	Ditto ditto	Jaundice.
Numerous abscesses	Ditto ditto	Jaundice.
Abscess	Ditto ditto	Jaundice.
Ditto	Ditto calculus	Jaundice.
Ditto	Ditto healthy	Jaundice (slight).
Hepatitis with tumefaction	Chronic gastritis	Jaundice.
Hypertrophy	Chronic gastro-duodenitis; ducts free	Jaundice.
Vast abscess	Gastro-enteritis; ducts healthy	Jaundice.
Numerous small abscesses	Slight enteritis; ducts free	Jaundice (slight).
Ditto ditto.	Gastritis; gall-bladder atrophied; calculus in cystic duct	Jaundice (deep).
Numerous abscesses	Colitis; ulcerations of gall-bladder	Jaundice.

* *Piorry*, du Procédé Opératoire, etc. Paris, 1831.

* *Marsh*, on Jaundice, Dublin Hospital Reports. *Broussais*, Commentaires, &c.

State of the liver.	*Digestive tube and ducts.*	*Skin.*
Hypertrophy	Chronic gastro-duodenitis ..	No jaundice.
Numerous abscesses	Chronic gastro-enteritis; duodenum healthy	No jaundice.
Ditto ditto.....	Gastritis	No jaundice.
Vast abscess	Ditto	No jaundice.
Abscess and gangrene.....	.....	No jaundice.
Abscess	Duodenitis	No jaundice.
Chronic abscess in right .... Acute ditto in left lobe	Chronic gastro-duodenitis ..	No jaundice, (slight yellowness at the commencement).
Vast hepatic abscess	Healthy	No jaundice.
Numerous abscesses	Colitis	No jaundice.
Red softening	Gastro-enteritis.....	No jaundice.

It is obvious, from the inspection of this table, that we cannot arrive at any explanation of the presence or absence of jaundice in cases of hepatic inflammation, from the consideration of the circumstance of gastro-intestinal complication. We see here cases of hepatitis with jaundice, in which the digestive tube was free from disease, and the same symptom with gastro-intestinal inflammation; and, in the cases of hepatitis without jaundice, the tube was healthy in some, and diseased in others.

We may remark, while on this subject, that in hepatitis the biliary secretion is variously affected. In some it appears to be suspended, while in others, even after extensive suppuration of the liver, the gall-bladder has been found filled with healthy bile. We have observed these facts repeatedly in the Meath Hospital. Thus, in a case where a great number of abscesses were formed, the gall-bladder contained a perfectly transparent viscid fluid which did not coagulate by heat or the addition of nitric acid; the fluid was perfectly colourless, and in short presented all the characters of pure mucus. Notwithstanding this appearance of the contents of the gall-bladder, it is most remarkable that the intestines contained a quantity of yellow mucous and fœcal matter. In this case the mucous membrane presented indications of inflammation.

In two other cases, where the most extensive destruction of the liver had taken place, the gall-bladder was found to contain a bile healthy to all appearance. In the first of these a chronic abscess existed in the right, and a recent abscess in the left lobe. In the second, the organ was completely burrowed by numerous abscesses. In the different cases of hepatic abscess recorded by Louis, the greatest variety in the contents of the gall-bladder occurred. From these facts we seem justified in concluding that in acute hepatitis, and probably also in the chronic disease, we cannot form any exact diagnosis of the state of the liver from the appearance of the biliary secretions in the stools, inasmuch as in one case it is altered in its quality in a variety of ways, while in another, apparently the same condition of the organ, no perceptible change is observable. The truth is, that neither its presence, absence, nor alterations, give us any data to enable us to conclude as to the stage, extent, progress, or termination of the inflammation; and it is plain that under these circumstances the state of the stools will but little assist our prognosis. It is probable, however, that a very copious secretion of bile is more favourable than the contrary, as the inflammation of secerning organs is generally more inveterate when their secretion is arrested.

When hepatitis is once formed, it may terminate by resolution or by suppuration; or the irritation may continue in a modified manner, so as to be classed among chronic diseases of the liver. The indications of resolution are, in the first instance, the subsidence of the fever, the gastric symptoms, and the pain: this is followed by the disappearance of the tumefaction, which, though generally the last in the order of symptoms, often occurs with great rapidity. The infra-mammary and postero-inferior portions of the chest recover their clearness of sound on percussion; the dilatation of the side is no longer observed; the right hypochondrium and epigastric region lose the tension and fulness which occurred during the acuity of the disease. Although a few cases of suppuration without perceptible tumefaction of the organ have been met with, yet from our own experience we would say that the subsidence of the swelling is one of the most certain indications of the resolution of the disease, certainly more so than the disappearance of the fever and pain.

But when suppuration is to occur, we often find that the tumefaction, so far from diminishing, becomes increased, and this at a time when the fever is frequently changed in character and assumes a hectic type. Shiverings, more or less severe, are observed, with or without perspirations; the pulse becomes small and rapid; the countenance is pale, and a sour smell of the surface is perceptible. In one case we have observed a miliary eruption. There is generally a constant sense of weight and uneasiness in the right hypochondrium, and the pain has in some instances been found as it were to concentrate itself on a particular spot, probably corresponding to the principal collection of pus. After some time a fluctuating tumour may appear generally in the epigastrium or some part of the right hypochondrium, which is followed by discoloration of the integuments; but in other cases no such occurrence takes place, and we must be guided by the history of the case and the constitutional symptoms in forming the diagnosis of suppuration. Should the tumefaction persist,

with a fever either of the continued or remittent type, we may suspect the formation of matter. When, however, the abscess forms so as to be perceptible by manual examination, we may observe the following conditions:— 1. a generally enlarged state of the organ, in which, though no perceptible fluctuation exists, a doughy or boggy feel is communicated over a greater or less portion of the tumour; 2. distinct tumefaction below the margin of the rib; 3. a tumour in the epigastrium; and, 4. a bulging of the false ribs, with more than usual fulness of the intercostal spaces.

But it must be always borne in mind that, although the constitutional symptoms frequently undergo a remarkable change at the moment of suppuration, yet there are abundance of cases in which the change is scarcely if at all perceptible. To this we shall recur in speaking of the difficulties in the diagnosis of this disease.

The constitutional symptoms which are of most value are, the supervention of night perspirations, shiverings, cold sweats, clamminess of the skin, and frequent fainting sensations. If this state has arisen in a case where it has been found impossible to affect the system with mercury, the diagnosis of abscess may be made with a great degree of certainty. In this last and most important statement, the best East-India practitioners agree, and we have heard one gentleman, who occupies a high rank in the service, declare that he never yet knew a case of abscess of the liver in which ptyalism was induced, even although the largest quantities of mercury had been exhibited. Mr. Annesley says, "that there can be no doubt that the system will not be brought under the full operation of mercury, or that ptyalism will not follow on the most energetic employment of this substance, when abscess exists, although a slight tenderness of the gums will be produced by it." As far as our experience in the Meath Hospital has gone, we should say that the same circumstance holds good in the case of hepatic suppuration in these countries; but it is not peculiar to inflammation of the liver, as it is observed in other cases of intense visceral inflammation, in which, when ptyalism is induced, it is obviously the effect and not the cause of the reduction of the visceral disease; and we have no doubt that, from not properly estimating this circumstance, practitioners have erred with respect to the curative powers of mercury, and have done injury by the introduction of enormous quantities of this mineral into the system at a time when the violence of the local action prevents its specific and sanative effects on the economy.

The terminations of these cases of hepatic abscess are various. We have already alluded to the internal openings of the abscess in describing the pathological anatomy of the liver in a state of inflammation. In these cases the diagnosis is to be made on the same principles which Louis has laid down in speaking of peritonitis from perforation of the intestine: there is a sudden appearance of a new train of symptoms, accompanied in almost all cases by subsidence of the hepatic tumour. Thus, when the matter makes its way into the lungs by the mechanism which we have before described, a sudden and copious expectoration of puriform matter has been commonly observed; this is accompanied by a remarkable diminution in the hepatic tumour. Should these symptoms arise in a case where previously there had been no evidence of disease in the pulmonary parenchyma, the diagnosis may be still more certain. We had once an opportunity of making a stethoscopic observation of this most interesting lesion: the patient had recovered from an attack of that violent gastric fever accompanied by yellowness of the skin which we have described in the article Enteritis, when he again came under our care, labouring under symptoms of hectic fever, which proved ultimately to proceed from hepatic suppuration. This patient had a constant dry cough, which led us to make repeated stethoscopic examinations without our being able to detect any disease whatsoever in either lung: in less than twelve hours after the last stethoscopic observation the patient was suddenly seized with a feeling of suffocation, and began to expectorate large quantities of perfectly formed pus, of which in the course of the night he discharged upwards of a pint and a half. On the following morning the left lung, which the day previously had presented no morbid sign whatever either by the stethoscope or percussion, was found completely dull over the whole region of the lower lobe, with complete extinction of the respiratory murmur: there was no bronchial respiration, no resonance of the voice, dilatation of the side, nor displacement of the heart; nor was there any constitutional symptom indicative of either pleuritic or pneumonic inflammation. The patient continued to expectorate copiously for some days, and after the second day the morbid phenomena of the chest began to subside. We had, first, a mucous rattle audible at the root of the lung, which gradually extended over the dull portion, and was followed by a return of the respiratory murmur and resonance of the voice.

This stethoscopic observation, for the accuracy of which we pledge ourselves, is explicable only by the sudden filling of all the bronchial tubes with purulent matter. Let us observe, first, the sudden supervention of dulness and absence of respiration in a patient whose chest a few hours before presented no morbid phenomenon; this is accompanied by a copious expectoration of purulent matter, and there are no constitutional symptoms of pleurisy or of pneumonia. The absence of these symptoms is of great importance, because if the disease had proceeded from either of these lesions, it must have been of extraordinary violence, and would have certainly been accompanied by high constitutional and local symptoms. There was no dilatation of the side, or displacement of the heart, so that the diagnosis lay between hepatization of the lung and the sudden filling of the tubes with pus;

but there was no bronchial respiration nor resonance of the voice, which would have occurred had it been hepatization, but which were absent because the large tubes were completely filled; and further, during the recovery of the patient the phenomena of the voice were exactly the reverse of those in pneumonic resolution. Thus, in the latter the resonance *decreases*, while in this case it *increased*;—in hepatization, because the air-cells recover their permeability, and the morbid subsides into the natural bronchophony;—in the case under consideration, because the emptying of the tubes permitted the return of the natural resonance of the voice. The resolution of pneumonia is accompanied by *decrease* of bronchophony, while in the case before us it was accompanied by *increase*.

In the majority of cases the matter discharged from the chest consists of well-formed pus. In a case, however, recorded by Annesley, the opening of an hepatic abscess was followed by a violent purulent and bloody expectoration; the patient experienced a great sense of suffocation when he lay on his back, and on dissection a vast hepatic abscess was found communicating with the posterior portion of the lung. We have witnessed a case of the same lesion, in which, whenever the patient turned on the left side, a large quantity of purulent matter was discharged from the trachea.

It is hardly possible to confound this accident with any disease of the lung, properly so called, particularly if by stethoscopic observation we have been satisfied of the previously healthy condition of the organ. The only cases which might possibly be confounded with it are the rare instances of the opening of an empyema into the lung, or the sudden secretion of purulent matter in quantity by the bronchial mucous membrane, of which a few instances are recorded.*

We have already spoken of the rarity of hepatic abscess opening into the general cavity of the pleura—a circumstance explicable by the adhesions which are formed between the two surfaces of the pleura, and which have the effect of directing the matter into the substance of the lung. From the rarity of these cases it is difficult to state the symptoms of this lesion; yet in a case where a sudden occurrence of the signs of effusion into the pleura, accompanied by the disappearance of those of the hepatic abscess, were observed, the diagnosis might be made with a great degree of probability.

A not unfrequent termination of hepatic abscess is by the establishment of a communication with some portion of the digestive canal. The stomach, duodenum, and colon, are the parts in which the communication has been most commonly observed; and the circumstances which appear to influence the point of communication are principally the situation of the abscess and the general volume of the hepatic tumour. When the matter makes its way into the stomach, a sudden vomiting of purulent fluid, with subsidence of hepatic tumour, has been observed. When, on the other hand, it opens into the intestine, we have a sudden diarrhœa, followed by the same phenomenon. From instances of recovery under these circumstances, it seems fair to infer that a cure by cicatrization of the opening is not unfrequent; but the opening may become fistulous, and continue until the fatal termination of the case. This occurred remarkably in a case the particulars of which we shall just now detail, and which we before alluded to.

Rupture into the peritoneal sac seems to be more frequent than the opening into the pleura, a circumstance to be expected from the smaller degree of liability of this membrane to form adhesions. When it does occur, we have violent peritonitis supervening; but the full evacuation of the abscess is not a necessary consequence. The following unique case is highly instructive, as illustrating the rupture of hepatic abscesses both into the digestive canal and peritoneum.

A man, aged 39, was admitted into the Meath Hospital in August, 1828, labouring under hectic fever, with cough and nausea. He complained of great soreness from the fourth rib on the right side downwards. The hypochondrium was full and tender, and the side dilated one inch and a half, without distention of the intercostal spaces. Having recognized that the disease was hepatic, and suspecting that an abscess, deep-seated, had formed, we determined on performing the operation, first proposed by Dr. Graves, of dividing the abdominal parietes as far as the peritoneum, and keeping the wound plugged with lint. This was done, yet after six days had elapsed, no matter made its appearance. Soon after this a circumscribed tumour, evidently containing fluid, suddenly appeared between the median line of the epigastrium and the termination of the wound. It is important to remark that this tumour was not preceded by any local induration, but at once presented fluctuation. In consultation, however, it was determined to open it cautiously by means of a lancet, when, in place of matter, there was a gush of dark-coloured bile: the tumour disappeared, but fulness of the side continued. About four hours after this operation the patient expressed a sudden desire to go to stool, and passed two copious discharges of purulent matter, with bilious fæces. This was followed by remarkable improvement, and the tumefaction rapidly diminished, so that in a few days all swelling of the right hypochondrium had disappeared. A diarrhœa, however, continued from the time of the disappearance of the tumour, and resisted every attempt to check it. Twenty-three days after the subsidence of the first tumour, a small hard swelling was observed in the epigastric region, about the size of an egg: this increased daily, and soon became fluctuating. On the thirteenth day after this, sudden and violent peritonitis set in, with subsidence of the epigastric tumour. He lived

* See *Van Swieten*, Comment. vol. iv. p. 60. Les Ephemerides des curieux de la Nature. *Baumes*, Traité de la Phthisie. *Hippocrat.* de morbis vulgaribus. *Andral*, Clinique Médicale.

eight days longer, the diarrhœa continuing until his death.

From considering the various symptoms in this case, we made the following diagnosis publicly, before dissection: viz. 1. that the gall-bladder would be found to have been punctured, but that from peritonitis not having set in on that occasion, it was probable that its fundus was adherent: 2. that a chronic abscess would be found in the right lobe of the liver, which was the cause of the first symptoms, and in all probability of the persistent diarrhœa, from a communication remaining open between it and some portion of the digestive tube: 3. that a recent abscess would be found in the left lobe, which had opened into the peritoneum, and had caused death by peritonitis.

On dissection, the peritoneum was found of a deep-red colour, containing a quantity of serous fluid, in which was a large quantity of flocculi forming masses having the consistence of jelly; the liver was generally adherent to the diaphragm and abdominal parietes, the adhesions of the right lobe being strong and ancient, those of the left soft and recent. In the left lobe an abscess of the size of an orange was discovered a little above its lower edge, and communicating with the peritoneal cavity by a fistulous opening sufficiently large to admit a quill. In the right lobe we found a cavity of the size of an egg, empty, and lined with a semi-cartilaginous membrane of a dark iron-grey colour: this communicated with the duodenum by an opening large enough to admit the finger with ease. The gall-bladder presented superiorly a spot exactly corresponding to the size and form of a lancet puncture, which was covered by a thin transparent membrane.*

But hepatic abscess frequently proves fatal without any rupture internally or externally. In these cases, as Broussais has well observed, the diseased action is seldom confined to the liver, but commonly occurs in some other organ, such as the gastro-intestinal mucous membrane, the lungs, or brain; of these the first is by far the most frequent. The actual state of pathology, however, does not permit us to adopt the opinion of Broussais as to the constancy of this complication, but the fact of its frequency is well established, and becomes of great importance in practical medicine. In all the cases of abscess of the liver recorded by Andral, there is but a single instance where the disease occurred without complication with lesion of other organs.

Suppuration of the liver has occurred without any of the characteristic symptoms of hepatitis. Thus, in the twenty-sixth observation of Andral, numerous abscesses, with redness and softening of the hepatic tissue around them, were found, yet the patient never had pain or tumour in the region of the liver, nor was he jaundiced: in this case there was complication with acute pneumonia and gastritis. In another case, where a scirrhous state of the stomach existed, numerous partial inflammations of the liver and an abscess were discovered; the patient never had either icterus or pain either in the hypochondrium or right side of the chest. The same author details a case where an hepatic abscess with gangrene was discovered after death, and in which all the characteristics of an hepatic affection were absent. This patient laboured under a chronic bronchitis and gastritis. We have known two cases where numerous abscesses were found in the liver, and in which the symptoms were merely those of continued fever, without any indication which could lead to the suspicion of the disease. Other instances might be quoted, but such cases are comparatively rare, and should not discourage the student, or render him too sceptical as to the powers of diagnosis.

In certain cases the gall-bladder becomes distended with bile so as to form a tumour in various situations along the margin of the liver, representing in many particulars the phenomena of an hepatic abscess so completely that the most eminent practitioners have been deceived in their diagnosis. It is extremely difficult to lay down rules by which this affection can be distinguished with absolute certainty. The obstruction of the ducts in most cases has been preceded by more or less of indications of hepatic disturbance, which it is impossible to say did not proceed from disease of the parenchyma of the liver. In the case which we have recorded, there was actually an hepatic abscess at the time when the distention of the gall-bladder occurred, and which was evidently its cause, so that in this case we had the local and constitutional symptoms of hepatic suppuration preceding the tumour caused by the gall-bladder. In this case, then, the previous symptoms could only mislead us as to the nature of the tumour. We are not, however, aware of any other case where the tumefaction of the gall-bladder was preceded by an hepatic abscess.

In the first volume of the Dublin Hospital Reports a most interesting case of enlargement of the biliary duct is recorded by Mr. Todd. The patient, a delicate girl, had been in bad health for some months previous to her death, during which she had had severe fever with several relapses. When she was first seen by Mr. Todd, she was nearly insensible; she moaned incessantly, and frequently screamed, as if seized suddenly with acute pain; the skin was of a deep orange colour, and she was greatly emaciated. On examination, it was found that the abdomen was distended with fluid, and that the epigastric and right hypochondriac regions were occupied by a tense swelling, which could be traced extending even below the umbilicus. A distinct fluctuation was perceptible at the most prominent point, a little below the ensiform cartilage, and a little to the right of the linea alba. This part was extremely sensible, and hence it was thought probable that a large abscess of the liver was here approaching the surface. With this impression, and anxious to afford immediate relief, Mr. Todd made an opening into the most prominent part of the tumour, when a thin fluid coloured with green bile escaped; a

* Dublin Hospital Reports, vol. 5.

canula was then introduced with a view to prevent the escape of the fluid into the peritoneal cavity, when upwards of two quarts of a viscid green bile were discharged. After the operation all the tumefaction of the abdomen had subsided, and no enlargement of the liver nor any other swelling could be detected. In the evening, however, the belly became swollen, painful, and tense, and the patient died on the following day. On dissection, the peritoneum was found inflamed, and containing a serous and bilious fluid; the liver was perfectly healthy, and the gall-bladder was found empty and contracted; but the hepatic and common ducts were found to be enormously distended, forming a sac, which still contained more than a quart of bile, and extending from the porta of the liver to the os sacrum, lying behind the duodenum, pancreas, and root of the mesentery, and stretching in a transverse direction, so as to cover the anterior surface of the right kidney, and the greater part of the left.

Andral relates several cases of distended gall-bladder forming an evident and fluctuating tumour in various portions of the abdomen. He has seen it, 1st, immediately below the cartilaginous portions of the right ribs; 2dly, lower down in the hypochondrium; 3dly, in the iliac fossa; and, 4thly, in the epigastric region. In a case of aneurism of the hepatic artery, which we have lately observed, the gall-bladder formed a fluctuating tumour very near to the right ileum, and the biliary ducts were found in a similar state to that described by Mr. Todd, only distended to a less degree. We believe that in all the cases, with the exception of that which we have recorded, there was jaundice; and it is probable that if the gall-bladder had not been punctured, and that the abscess had continued to press on the ducts, this condition would ultimately have been induced. In this case, also, it is very important to compare the appearance of the two tumours with a view to their diagnosis. That of the gall-bladder appeared suddenly, without being preceded by local pain or induration, but was at once fluctuating: that arising from the abscess of the left lobe was preceded by pain and induration; and fluctuation did not appear until some days after its occurrence. This observation may be of utility in determining the point in future cases.

Chronic hepatitis.—A great number of affections of the liver have been classed under this general term; such as induration, scirrhus, tubercle, hypertrophy, atrophy, &c. &c. In fact, we cannot say with certainty what the condition of the liver will be on dissection in a case where symptoms of chronic irritation have existed. We may, indeed, recognize an enlargement or an induration, but it appears rash to go farther than this. The liver, like other organs, however, being subject to chronic inflammation, we may recognize this condition, although we cannot say what particular alteration it may have induced.

The disease may set in with an attack of acute hepatitis, or may from the commencement preserve a slow insidious character. In some cases there is more or less of fever, while in others the patient is apyrexic. The principal phenomena are various derangements of the digestive function, and it is often next to impossible to pronounce on the actual condition of the gastro-intestinal mucous membrane. In fact, chronic disease of the liver and of this surface are commonly combined. If, in addition to pain, long continued in the region of the liver, increased by excitement, and accompanied by tenderness and tumour, we observe a sallow countenance, a dry skin, foul tongue, scanty and high-coloured urine, with occasional attacks of jaundice, we may safely make the diagnosis of chronic hepatitis.

In the less acute forms of the disease the local symptoms of an hepatic affection are often very indistinct, and the case presents many of the usual phenomena of a chronic gastro-enteritis. In addition to these, the pain about the right shoulder, when it does occur, the distention and oppression in the epigastrium and right hypochondrium, the bitter taste in the mouth, the sallow appearance of the countenance, the elevation of the shoulders, and the wasted state of the body, are the circumstances which in warm climates are relied on as indicative of hepatic disease.

It is stated that, when the surfaces of the liver are the seat of disease, the pain is more decided, and that, as the superior or interior surface is chiefly affected, so in the first case the symptoms will be referred to the chest, and in the second to the stomach and bowels. An eminent writer says, that when the superior and exterior part of the right lobe is the seat of disease, the patient reclines with most ease on the right side, a dragging sensation being felt on turning to the left. From this sensation it is supposed that we may infer the existence of adhesions between the lobe of the liver and the right side.

Nothing can be more various than the terminations of this disease which have been observed. In fact, every one of the known organic changes of the liver has been found in cases where the patient laboured under symptoms of chronic hepatitis. Most of these certainly may be looked on as the results of the inflammatory action, the modifications in their nature being probably connected with the constitutional dispositions of the patient. In fatal cases death is induced by various circumstances. In some cases an acute hepatitis supervenes upon the chronic, but in the majority the patient is cut off in consequence of disease of other organs. He may be attacked by peritonitis, either in consequence of the rupture of an abscess or of the gradual extension of disease to the serous surface: he may be attacked with enteritis or dysentery, which is a common termination in warm climates: pulmonary or cerebral disease may set in; and dropsy, with or without an affection of the heart, is not unfrequent.

The diseases with which chronic hepatitis has been confounded are principally the following: chronic gastro-duodenitis, scirrhus of the stomach, chronic pleurisy of the right side

with empyema, and a neuralgic affection, of which the seat appears to be in the hepatic plexus.

In the articles Enteritis and Gastro-Enteritis we have alluded to the great frequency of the error of confounding the affection of the gastro-intestinal mucous membrane with that of the liver, and have dwelt on the injurious consequences of this mistake. With respect to the diagnosis between this disease and chronic pleurisy with effusion, we would say that there is hardly a case where the tact of the practitioner is more requisite than in this. We will suppose that he is called to see the case for the first time after considerable enlargement of the organ has occurred. He will often find that the history of the case gives him but little assistance, as the two affections are often accompanied by very similar symptoms; neither will he derive decided assistance from the stethoscope and percussion. In both cases we may have extensive dulness of the side, absence of respiration, resonance of the voice, or bronchial respiration. The side will be dilated in both, and the decubitus generally on the affected side. Neither will the existence of a tumour in the abdomen be unequivocal, as in the one case it may occur from hypertrophy of the organ, in the other from displacement.

From our experience we should say that the indication which is the most unequivocal is drawn from the state of the intercostal spaces. When the side is dilated by a fluid, as in empyema, the spaces are raised either to a level with the ribs or even protruded beyond them, and the side has generally a smooth and rounded appearance. On the other hand, when the dilatation is produced by a solid tumour, such as an enlarged liver, the reverse of this occurs; the pressure being exercised on the ribs, these are pushed outwards, but the intercostal spaces preserve their relative positions with them, and the side does not present any thing of the smooth and rounded appearance which we have described.* There are certain cases, however, where even this diagnosis is not applicable, such as where the patient is fat, the integuments œdematous, or the belly distended by fluid. Under such circumstances the difficulty of diagnosis is extreme.

It appears to us that the attention of British practitioners has not been sufficiently called to the frequency of the neuralgic affection of the liver which is commonly seen in hysterical subjects, and has been noticed by Andral in his Clinique Médicale. "We sometimes observe in the region of the liver severe pain, which cannot be accounted for after death by any lesion of the viscus or its excretory ducts. These are cases of hepatalgia or hepatic colic. The circumstance just mentioned, and, moreover, the nature of the pains, their intermission, and the state of good health which often exists in the intervals,—all lead us to believe that these pains have their site in the numerous nervous filaments which are distributed in the liver, and which are derived either from the pneumogastric or the great sympathetic."*

The persons in whom we have witnessed this affection were females. In some of these a decidedly hysterical tendency existed, while in others this disposition was scarcely if at all indicated. In one case the condition of the spine lately denominated "spinal irritation" was present. The principal symptom in these cases was a constant pain in the region of the liver, which lasted for years, and was subject to occasional and violent exacerbations from various causes, such as mental emotion, fatigue, over-excitement, derangement of the bowels, or the occurrence of menstruation. During the exacerbation the pain is excruciating, to all appearance more violent than that in the most intense inflammation, and is generally accompanied with exquisite tenderness of the right hypochondrium. It has been stated to have been sometimes accompanied by a slight jaundice, but of this we never witnessed an instance, as, in the cases which we have observed, none of the usual symptoms of hepatic irritation, with the exception of the pain, existed. There was never fever, nor tumefaction, nor a bilious state of the urine, foulness of the tongue, thirst; nor were the alvine evacuations apparently affected, although the disease had been present for months or even years. Further intervals occurred during which the patient enjoyed a respite from pain, and presented no local nor general symptom of hepatic derangement. The diagnosis of this disease is then to be drawn from the violence of the pain, which is greater than that of inflammation, combined with the absence of fever, tumour, and the other indications of structural disease of the liver. We may also remark, that in several cases which have occurred under our observation the patients were subject to neuralgic affections in other situations, as the face or extremities: in one severe dysmenorrhœa had long existed.

It is now some years since we were consulted in the case of a lady of luxurious habits and highly nervous temperament, who, while in India, had been attacked with pain in the region of the liver, which was supposed to arise from acute hepatitis. For this she was largely bled, both generally and locally, and brought under the influence of mercury, without relief. She was ordered to return to England, and on the passage was several times bled and twice mercurialized with the same intention. Some time after her arrival in this country the pain became again severe, and occurred with violent exacerbations. Each attack had been treated as if it had been one of acute hepatitis, she having been repeatedly bled, leeched, blistered, and mercurialized. Temporary relief used to be afforded by the bleeding, but the disease constantly recurred; her constitution had become shattered, and she was constantly subject to the most violent hysterical paroxysms: the stomach had become so irritable that every

* See Dub. Hosp. Rep. vol. v.

* Maladies de l'Abdomen, t. ii. p. 26.

thing was rejected, and the patient's sufferings were indescribable. Such was the condition of this lady when we were first called to see her; it was plain that the disease had resisted the most rigorous and long-continued antiphlogistic treatment. We found that there never had been any fever, that the right hypochondrium was perfectly supple, the lower part of the chest sounding clear, the tongue clean, the eyes and complexion clear, and the patient subject to neuralgic affections in other parts of the system. Under these circumstances we determined on treating the affection as a neuralgia. Further bleedings were inhibited, contrary to the wish of the patient, who, as before stated, experienced temporary relief from them. She was put on a generous diet, sent to the country, and directed to use free doses of the carbonate of iron. This treatment proved perfectly successful, and in the course of a few weeks the lady was in the enjoyment of a state of health and comfort to which she had been a stranger for more than two years previously. We know of another case of a lady who had been actively treated for supposed hepatitis in the country without success. She was advised to come up to town to place herself under the care of physicians, for the purpose of undergoing a course of mercury. On examination, her medical attendant could find no evidence of hepatic disease except the pain. She was also treated by the carbonate of iron with complete success. Since then we have known several cases where the error of confounding this affection with inflammation has been committed,—an error always full of danger, but in Great Britain peculiarly unfortunate from the empirical and almost universal employment of mercury in all hepatic affections. We have at this moment under our care a most deplorable example of the effects of this error, where the most profound lesions of the nervous system have been induced by the long-continued use of mercury.

Causes of hepatitis.—The exciting causes of hepatitis may be enumerated as follows: residence in a tropical climate, intermittent or continued fever, gastro-intestinal inflammation, suppression of habitual fluxes, abuse of spirituous liquors, injuries of the side, wounds of the head, congestion from venous obstruction, suppression of cutaneous eruptions, exposure to cold, gall-stones, &c.

Treatment.—When a patient has been attacked with symptoms of acute hepatitis, the disease being still in its early stages, and no evidence of suppuration present, the treatment should be commenced by a free bleeding from the arm, which, if the subject be robust and the inflammatory fever high, should be pushed so as to produce some effect on the circulation. It would be always well to see the patient again in the course of from four to six hours, when, if the pain and oppression should have returned, and the inflammatory fever again be lighted up, the bleeding should be repeated without hesitation; a less quantity of blood, however, will generally answer the expected purpose. The bowels should be opened by a free dose of calomel, followed by saline medicine, and assisted by a purgative injection. The patient will thus be brought into the state best adapted for deriving advantage from local bleeding; and we would impress strongly on the mind of the practitioner, that, although the exhibition of mercury is sometimes indispensable, he must place his chief reliance on general and local bleeding, both as the surest means of arresting the disease, and of ensuring the beneficial action of mercury should its exhibition become necessary. In warm climates it has been observed that in some cases the operation of bleeding is followed by faintness before a sufficient quantity is taken, and the blood is dark and grumous. In this case, as has been observed in other violent inflammations,* the bleeding is soon followed by more violent excitement of the circulation, when a second bleeding is indicated, and the patient will bear the loss of a much greater quantity of blood; and this will then be found to present the buffy appearance in a much higher degree. This second bleeding also gives much greater relief to the patient.

From our experience we would say that general bleeding has not the same marked influence over hepatitis that it has over peripneumony, but appears principally useful in preparing the patient for local depletion, which seems to have the most direct influence on the disease. We have seen a case where upwards of a hundred ounces of blood were drawn at different times, and in which no apparent effect was produced on the inflammation until local bleeding was performed. In a robust adult not less than thirty leeches should be applied after the general bleeding, to the most painful part of the side, a measure which will be followed by still greater advantage if the bowels have been previously opened; and to ensure this result, purgative injections should be used to assist the action of the medicine administered by the mouth. When the patient can bear it, the greatest advantage will be derived from the application of a cupping-glass, fitted with an exhausting syringe over the leech-bites, by which means a much greater quantity of blood is obtained, and the subsequent oozing from the leech-bites generally prevented. As the blood flows, the exhaustion should be gently continued until the cup is full, when, if it is thought necessary to obtain more, the cup should be re-applied, and its margin surrounded with a cloth dipped in warm water; this causes a copious flow of blood.

In all cases it will be well to avoid, as far as possible, the oozing hemorrhage of leech-bites, as this exhausts the patient without any corresponding influence on the disease, and keeps him in an uncomfortable state. It is much better to make several applications of leeches successively, and to arrest the hemorrhage after the leeches have fallen off, either by the cupping-glass or the application of stypties, of which the best appear to be the solid nitrate

* See Rush on the Yellow Fever.

of silver, or the muriated tincture of iron. In the Meath Hospital the application of powdered alum has been found very beneficial. After the hemorrhage has been completely arrested, the patient will derive great advantage from the application of warm poultices of linseed-meal or bread and milk over the affected organ; these, however, must be made light, as their weight in some cases proves distressing.

It has been the practice on the continent, and lately in Great Britain, to apply leeches to the anus in cases of hepatic irritation, on the principle of depleting the system of the *porta* through the hemorrhoidal veins. We believe that the only cases in which this practice would be decidedly beneficial are those where the hepatitis is complicated with dysentery, or where it has supervened on the suppression of a hemorrhoidal flux; but in no instance should we be content with this mode of local depletion, as it is decidedly inferior to the application of leeches over the affected organ itself. In the dysenteric complication to which we have alluded, which is frequent in India, Mr. Annesley has found decided benefit from the application of leeches to the os coccygis.

The circumstances which point out that the general and local depletions have exercised a salutary influence on the suffering organ are the following:—the diminution of the inflammatory heat and of the oppression in the epigastrium and hypochondrium; the subsidence of the pain and tenderness; and, lastly, of the tumefaction, which is to be ascertained by the touch and by percussion of the lower part of the thorax and abdomen.* Blisters may be now employed, but their use must never be resorted to while the inflammatory fever continues high, and they must be removed as soon as the patient begins to feel their stimulus. (See Derivation.)

When the disease occurs in persons of a broken-down constitution, and particularly in those who have long indulged in ardent spirits, it is scarcely necessary to observe that we must be much more cautious in the use of the lancet, and trust principally to local bleeding and counter-irritation.

After the employment of general and local bleeding, the production of ptyalism appears to be the most powerful means of subduing the disease; but, as we stated before, the practitioner must consider this treatment as secondary to that which has now been pointed out. There can be no doubt that the establishment of a free salivation is commonly followed by a rapid subsidence of the local disease, but it is also true that the accomplishment of this is commonly difficult, and often impossible. The more severe the disease, the greater will be the difficulty of inducing ptyalism; and the best mode of insuring the kindly action of mercury will be to reduce the inflammatory condition of the organ as far as possible before its exhibition. We have before stated the remarkable fact that in cases of suppuration of the liver it has been found nearly impossible to induce salivation.

It would appear that the safest mode of using mercury in this disease is by the exhibition of large doses of calomel at long intervals of time; as it is stated upon high authority that the remedy is thus much less apt to irritate the bowels, and that a less quantity of mercury, when thus exhibited, will sooner affect the system than a greater quantity given in divided doses. Ten grains of calomel, combined with one or two of opium, may be given twice in the day, or a scruple dose at bed-time, as recommended by the East-India practitioners. It is stated that the combination of the calomel with some antimonial, such as the antimonial powder or James's powder, assists in the speedy production of ptyalism. But of one fact we feel certain, that if after the use of mercury for three or four days free ptyalism be not induced, the remedy should be omitted.

In the acute stage of the disease the patient must be kept on a strict antiphlogistic regimen. Effervescing draughts may be allowed, and will often be found to be of great benefit when they act on the skin or kidneys. Mild saline purges with emollient injections should be employed; and the patient may drink a solution of cream of tartar or tamarind tea; and if there be much restlessness, an anodyne draught or twelve grains of Dover's powder should be exhibited at night.

But if, notwithstanding these means, the tumefaction continues, and the fever assumes a remittent or hectic type, the formation of abscess is to be dreaded. Under these circumstances we can no longer push the strict antiphlogistic treatment. The patient's strength must be supported by farinaceous and gelatinous foods, and the exhibition of wine in moderation, with vegetable tonics, will be advisable; poulticing must be diligently employed over the region of the liver, and we must endeavour to bring forward the abscess towards the surface as much as possible; when, in the event of a perceptible and fluctuating tumour being formed, it will be advisable to give exit to the matter as speedily as possible. This, however, is an operation of the greatest importance, and must never be undertaken without a full knowledge of the pathological relations of this disease.

We have already alluded to the rarity of adhesions between the surfaces of the peritoneum in cases of acute hepatic abscess. It is obvious that for the success or safety of the operation the adhesions of the peritoneum is a necessary condition; for in the event of their not existing, the matter will make its way into the peritoneal cavity, defeat the object of the operation, and almost inevitably destroy life. To obviate these difficulties, Dr. Graves has proposed a mode of proceeding which has been repeatedly acted on with success in the Meath Hospital. It is, without question, a most important addition to the surgery of the abdomen. In the fourth volume of the Dublin Hospital Reports this eminent and scientific physician has published a case of hepatitis, in which, notwith-

* See article Abdomen, Exploration of.

standing the employment of active measures, evidences of suppuration occurred. There was no distinct pointing of abscess, so that it was judged impracticable to perform any operation which could reach the contained matter. Under these circumstances Dr. Graves, reflecting on the fact that certain deep-seated collections of matter may be induced to point towards a situation in which the resistance of the integuments and fascia is removed, proposed that an incision should be made over the most prominent part of the tumour, and carried through the abdominal muscles, so as to reach without dividing the peritoneum. This wound was kept open by plugs of lint, and poultices were applied over it. In a few days after a fit of sneezing by the patient, puriform matter in great quantity broke through the wound. The discharge continued copiously for a number of days, and the patient recovered perfectly.

We have since witnessed two instances where this operation proved successful. It would appear that it not only acts on the principle of removing resistance in a particular point, but also by inducing adhesions immediately below the wound, in all probability the result of its immediate irritation. In a case where numerous abscesses existed, and in which this operation was performed over the most prominent part, we found on dissection that the only point of adhesion of the whole peritoneal surface was that immediately below the wound, and corresponding exactly to its extent. Here recent coagulable lymph was effused, so that there can be no doubt that, had the patient lived longer, the contents of this abscess at least would have been evacuated through the external opening. The operation has every thing to recommend it; it is perfectly safe, productive of no distress to the patient, prevents the chance of effusion into the abdomen, and has been *proved* to be efficacious.

In a case of extensive and chronic hepatic abscess with great attenuation of the integuments, we proposed the performance of this operation; but it was determined by the attending surgeon to try the operation of a caustic issue in place of that proposed by Dr. Graves. After the separation of the slough, the matter did not shew any disposition to escape. A small valvular incision was then made through the ulcer, which gave exit to a few ounces of puriform matter. This operation was immediately followed by excruciating pain in the abdomen and the most violent peritonitis, evidently arising from the escape of matter into the cavity, and proving that in this case the operation of the caustic had failed in producing adhesions.

When the abscess makes its way either externally or into the lungs or digestive tube, the strength of the patient must be carefully supported by light and nutritious diet, wine and tonic medicines, according to the circumstances of the case. The mineral acids may also be exhibited in the different tonic infusions, such as gentian, calumbo, or cinchona. Attention must be paid to the bowels; and it seems not impossible but that a gentle and graduated pressure on the organ might accelerate the cure by inducing a closure of the opening after the matter has been evacuated. The opening of the abscess into the serous cavities appears at first sight a necessarily fatal occurrence; and we believe that it has been so in every recorded case, with a single exception. In the report of the Meath Hospital before alluded to, a case is recorded in which death from the peritonitis was apparently prevented by the opiate and stimulating treatment first proposed by Dr. Graves in certain cases of peritonitis. In the case also of double abscess of the liver which we have recorded in this article, the patient lived for eight days after the rupture of the second abscess into the peritoneum, and it was evident on dissection that the process of cure had commenced, the gelatinous effusion in many places having assumed an appearance of layers, and presenting large bloodvessels in its interior.

In the treatment of *chronic hepatitis* the first great indication is to remove all unnecessary stimulation of the liver or gastro-intestinal surface. Fermented liquors and all kinds of stimulating food must be inhibited, and the diet of the patient must consist of the simplest and most bland articles. The bowels are to be diligently but mildly acted on by gentle laxatives combined with mercurials, such as the hydrargyrum cum creta or the blue pill. In the commencement of the treatment we should apply every third or fourth day a dozen of leeches to the region of the liver, until we remove as far as possible the pain and tenderness of the organ. When this is effected, we should resort to counter-irritation, which must be persevered in for a considerable length of time. The best mode of proceeding is by the repeated applications of blisters over different parts of the organ, and by keeping up an eruption with a mild tartar emetic ointment. If these means do not succeed, and if there is no contra-indication, it will be advisable to affect the system gently with mercury, which may be done either by the exhibition of a small dose of calomel and blue pill combined with Dover's powder, at night, or by mercurial inunctions practised over the region of the liver.

Where it is thought unadvisable to use mercury, from the constitution of the patient, the nitro-muriatic acid and the nitrous acid have been strongly recommended. It would appear that the best mode of using these remedies, particularly the first, is by the external application, either by sponging the surface, or by the foot-bath. The following is the mode in which this remedy is recommended to be used by Mr. Annesley. A mixture is made of eight ounces of pure water with four ounces of the nitric and four of the muriatic acid, of the strength of the London Pharmacopœia. Of this solution from two to five ounces are to be mixed with about three gallons of water at the temperature of 96°, in a high and narrow vessel, and the feet kept immersed in it for about half an hour every night before retiring to rest. If the bath does not cause a pricking sensation in the parts, the next is to be increased in

strength. Advantage has also been obtained from sponging the trunk with a similar solution every night. The dilute nitrous acid drink has also been strongly recommended in cases of chronic hepatic affections. It possesses the property of producing a slight salivation, but is much slower in its operation than mercury. Taraxacum is a favourite remedy with many practitioners in these cases, but we are sceptical as to its efficacy.

After the disease has been subdued, vegetable tonics may be given to restore the digestive powers. The patient should wear warm clothing, and carefully avoid any error of regimen that may cause a return of the hepatic disease. In some obstinate cases we have known decided benefit from the use of the seton; and it is scarcely necessary to observe, that where the disease has supervened in a warm climate, removal to a more temperate region will be always advisable.

(William Stokes.)

LUMBAGO.—See Rheumatism.

LUMBRICI.—See Worms.

MALARIA AND MIASMA. The first of these words, and that which is now generally employed to designate a certain effluvium or emanation from marshy ground, we have adopted from the Italian. It is framed from the coalescence of the words *mala* and *aria (bad air.)* Miasma is a Greek word (μίασμα, from μιαίνω, *inquino, polluo,)* signifying originally contagion or pollution, but now with the occasional adjunct, marshy, not unfrequently applied to the same effluvium or emanation.

We infer the existence of the matter designated by one or other of these terms, as we do that of contagion in cases of disease which do not furnish a material transferable by inoculation, from certain effects on the animal economy; and we trace its origin to marshes from its having been observed, for a series of ages, that such effects are produced only in the vicinity of marshes, or at least are more abundant where vegetable matter and water are so situated with respect to each other, that a chemical reaction between them is possible. The observation of centuries having rendered us well acquainted with certain effects of malaria, we now reason conversely; and when we perceive the more familiar of them, particularly intermittent and remittent fevers, we infer its existence, and endeavour to discover its sources, which may not be very manifest.

The chemical and physical properties of malaria are unknown to us; the experiments which have been hitherto performed to illustrate its nature, or even to discover its presence, having furnished very unsatisfactory results. The air collected above the marshes of fort Fuentes was found by Gattoni as pure as that at the summit of Mount Leguone, if not more so; and M. Deseye obtained in the most confined marshes as on the most exposed hills, 78 parts of azote, 21 of oxygen, and one of carbonic acid, from an analysis of the air. It is true that MM. Thénard and Dupuytren found that the carburetted hydrogen gas disengaged from marshes left in the water through which it was passed a peculiar and very putrescible matter; and M. Julia discovered that dew gathered in the neighbourhood of marshes contains, likewise, a matter capable of fermentation; but there is no evidence that these substances are malaria; nor, were they proved to be so, do we know any thing of their chemical properties but their capacity of undergoing the putrefactive process. Even the very obvious question, whether malaria is always one and the same, or a multiplicity of marsh-poisons exist, is one which the present state of our knowledge does not enable us to answer decidedly. It has been argued, that as the existence of such a poison is known only by its effects on the constitution, a variety in these effects should be deemed evidence of a difference in the poison. But it may be remarked that the diseases which are reputed to originate from malaria pass in the same subject into each other,—intermittents, for instance, into remittents, and inversely; and that, of a certain number of individuals residing in or merely visiting the same place at the same time, and consequently exposed to the same morbific cause, some are attacked with one form of fever, others with another. And we know that diseases certainly derived from one and the same poison, such as small-pox, exhibit great diversity of character in different persons. These circumstances favour the opinion that there are no differences in the effect of this poison which may not be explained by a difference in the dose, or of the constitution on which it acts, or by the influence of certain agents, such as temperature, which modify its operation. The fact most in favour of a multiplicity of poisons is the occasional prevalence of one form of malarious disease, yellow fever for example, in the same situation for months, to the exclusion of all others. But as this occurs only under high temperatures, which at once promote the evolution of the poison, and modify the individual habits on which it operates, we would not consider it to furnish conclusive evidence, that the poison acting in this case is specifically different from the malaria which produces other forms of marsh-fever.

From what we have said on this obscure branch of our subject, it will be tolerably manifest that on the questions of the nature and simplicity or variety of malaria we possess no satisfactory information whatsoever; and that the legitimate objects of our present investigation are its sources, the laws of its propagation, the extrinsic circumstances which modify its influence, its effects on the animal economy, and the measures to be adopted to guard against these effects.

Though marshes, whether salt or fresh, are prolific sources of malaria, especially in a certain stage of the drying process under a hot sun, this poison is the product besides of various sorts of soil, to which the term marsh is by no means applicable. In the warmer regions of the earth those collections of low and dense brushwood, or of reeds and grass, which are

called *jungles*, are so familiarly known to be productive of malaria, that jungle-fever is as common a name for malarious disease in southern latitudes as marsh-fever is in Europe; and in the warmer regions of Asia, Africa, and America, even the larger and more open woods generate the poison under certain circumstances. Grounds which are alternately inundated and drained for the cultivation of rice, whether in India or Europe, are found so injurious to the health of the cultivators and the neighbouring inhabitants, that by some governments, that of Russia for example, this species of cultivation has been prohibited. Wet meadow lands, especially in warm climates, and in temperate ones during seasons of unusual heat, have been proved to be sources of malaria; at least agues have been observed to prevail in districts in which no assignable cause for them existed but lands of this description. That the half-wet ditches of fortifications may produce malaria was shewn by the result of filling up those of Bourg-en-Bresse, by which process those fevers ceased which had previously so affected the inhabitants, that one-half of them were incapacitated from any occupation for a third of the year. The mud which is left by the drying of extensive ponds or marshes by the summer's heat, though invested at the time with no growing vegetation, but probably containing vegetable and likewise animal recrements, is capable of furnishing this poison. Lakes, especially if situated in flat countries, are indirectly sources of it, not by the moisture of their immediate margins only, but likewise by imparting a degree of the same quality to the adjacent country. Considerable portions of Hungary and tracts of land in France are rendered insalubrious from this cause. The mud left by the retiring tide in sea-ports and estuaries is productive of malaria in hot climates, as is evinced by the fevers with which the crews of boats are attacked in such situations; and we have seen reason to think that in certain seasons they are not perfectly salubrious in our own. The felling of woods, by which process land previously shielded from the sun's rays (and consequently damp) is exposed to their influence, is often followed by the prevalence of malarious disease in the district in which it is performed. Turning up lands which have long lain in pasture for the purpose of cultivating them is mentioned both by Volney and Rush as productive of malaria and its consequences. In the West Indies this has been found to be a very dangerous operation, Cassan describing it as sometimes producing fevers which resemble an absolute plague, the labourers even dying on the spot if they attempt to remain at night on the ground which they have broken up during the day.*

The decomposition of vegetable matter in other circumstances than in connexion with soil has frequently proved a prolific source of malaria. This is often exemplified by the very pernicious effects of steeping flax and hemp; and Rush and others mention examples of fevers originating from the decomposition of coffee, potatoes, pepper, and other vegetables. The sickliness of ships from the leakage of sugar in a damp hold, and the occurrence of a fever which committed fearful ravages on the crew of the Priamus frigate from the action of bilge-water on chips and shavings left in the hold from the repairs of the magazine, as mentioned by Burnett, may be referred to the same class. Neglected sewers and drains have proved under a high temperature to be productive of fever by generating this poison.

If the preceding enumeration of circumstances under which the production of malaria takes place be examined, it will be found that vegetable matter and moisture are present in all the examples, and that animal matter is so occasionally. It is a proper subject of enquiry, and one which has given rise to some controversy, which of these elements are essential to the generation of the poison, and under what conditions those which are essential should exist to possess the power of producing it.

With regard to water, it seems ascertained that its presence is necessary, if not at the surface, certainly below it; but that the quantity in the former situation should not be large. Many circumstances tend to prove that for the production of malaria only a small proportion of water should exist in any situation. It is remarked by African travellers, that in that country the evolution of malaria commences immediately on the falling of rain, and that of this the inhabitants are so conscious that they then retire to their houses, and endeavour to exclude even the least access of air. As the rains continue and the ground becomes thoroughly wetted, the sickness abates, to be renewed with greater violence on the retiring of the rains, and the ground becoming dry. In the case of inundations, it is at their subsidence that sickness prevails, as was exemplified by the mortality among our troops under such circumstances during the Burmese war. In temperate climates, a marsh, the whole surface of which is thoroughly wet, is comparatively innocuous; but if partially or entirely dried by the summer's heat, it becomes extremely pestilential in autumn. Dr. Ferguson, a writer whose extensive opportunities have been aided by great power of observation, has furnished us with many instances, we cannot so justly say, of the small degree of moisture as of the excessive dryness which produces malaria in its most intense degree. "The army," says this writer, "advanced to Talavera through a very dry country, and in the hottest weather fought that celebrated battle, which was followed by a retreat into the plains of Estremadura, along the course of the Guadiana river, at a time when the country was so arid and dry for want of rain, that the Guadiana itself and all the smaller streams had in fact ceased to be streams, and were no more than lines of detached pools in the courses which had formerly been rivers; and there they suffered from remittent fevers of such destructive malignity, that the enemy and all Europe believed that the British army

* Macculloch on Malaria, p. 112.

was extirpated. The aggravated cases of the disease differed little or nothing from the worst yellow fevers of the West Indies; and in all the subsequent campaigns of the peninsula, the same results uniformly followed, whenever, during the hot season, any portion of the army was obliged to occupy the arid encampments of the level country, which at all other times were healthy, or at least unproductive of endemic fever."* The writer can vouch from personal observation for the accuracy of this description; and he has repeatedly observed that cases of fever and ague abounded in parts of Estremadura so remote from the Guadiana or any stream, that no influence from visible water or dampness could be supposed to have a share in their production.

The following example taken from Dr. Ferguson's paper is strongly illustrative of the same facts, the effects of concealed water in producing the poison. The approach to the town of Ciudad Rodrigo is through a bare, open, hollow country, that has been likened to the dried-up bed of an extensive lake. Upon more than one occasion, when this low land, after having been flooded in the rainy season, had become as dry as a brick ground, with the vegetation utterly burnt up, there arose fevers among our troops, which, for malignity of type, could only be matched by those before mentioned on the Guadiana.

It will be readily understood, that though the surface of the soil which produces fever may appear dry or even burnt, yet as its occurrence takes place after rains, there is no proof that the presence of moisture is not necessary, but evidence of the very reverse, though it is shewn that the dampness need not exist on the surface. The nature of the subsoil,—its being, for instance, a dense clay, which by preventing percolation may detain the water within a short distance from the ground,—has probably some influence in engendering sickness; but there are many facts which prove that an impermeable subsoil is by no means essential to the production of the poison. The leeward shore of Guadaloupe, Dr. Ferguson informs us, so far from being impermeable, is a remarkably open and pure one, being mostly sand and gravel, altogether without marsh in the most dangerous places; yet it is inconceivably pestiferous throughout the whole tract. The soil of Walcheren, too, of the pestilential nature of which we have had such melancholy experience, is sandy, or a mixture of clay and sand.

These examples tend to confirm, so far as the water is concerned, the law of Dr. Ferguson, that the only condition indispensable to the production of the marsh poison on all surfaces capable of absorption is the paucity of water where it had previously recently abounded; a rule, to which he assures us there is no exception in climates of high temperature. It ought at the same time to be remarked, that though the formation of malaria is perfectly compatible, as the writer can testify from personal observation, with the degree of superficial dryness described by Dr. Ferguson, it may likewise consist with a degree of manifest moisture.

The necessity of the presence of vegetable matter has hitherto constituted an important part of the creed regarding malaria, but this necessity is questioned in the paper in the Edinburgh Philosophical Transactions, to which we have so often adverted. We have already mentioned Dr. Ferguson's opinion, that the only essential requisite for the formation of the poison is, that water should be absorbed by soil and then exposed to speedy evaporation; and the following example is given of the apparent absence of vegetable matter from a situation abundantly productive of malaria. "In Spain, during the month of May 1809, which was cold and wet, the army remained healthy; but in June, which was remarkably hot and dry, marching through a singularly dry rocky country of considerable elevation, several of the regiments bivouacking in hilly ravines which had lately been water-courses, contrary to the advice of officers who had served in the Mediterranean, several of the men were seized with violent remittent fever, (the first that had shewn itself in the march,) before they could move from the bivouac the next morning; and this portion of the troops exclusively were affected with this disorder for some time. In this instance, the half-dried ravine having been the stony bed of a torrent, in which soil never could be, the very existence of vegetables, and consequently of their humid decay or putrefaction, was impossible, and the stagnant pools of water still left among the rocks by the watercourse, and near which these men encamped, were perfectly pure. Yet this situation proved as pestiferous as the bed of a fen." Even in this situation, which furnishes the strongest argument that could be adduced for the author's departure from the established creed, it would perhaps be difficult to prove the total absence of vegetable matter, not only from the surface of the ravines, but beneath the rocky surface; and certainly there exist many facts which prove that vegetable matter is in the highest degree favourable to the production of malaria, if not essential to it. These are, the universal presence of such matter where the poison is generated, the cases adduced by Dr. Ferguson and similar ones excepted, if they are to be regarded as exceptions; the pernicious effects of the steeping of hemp and flax, for we presume it will not be argued that in this case the mere evaporation of the water, independently of the vegetable matter, would produce the poison; a similar result from the leakage of sugar and the decomposition of coffee, potatoes, pepper, &c., and the fever which committed such ravages on board the Priamus frigate from the action of bilge water on the chips and shavings left in the hold. A similar argument may be deduced from the wholesomeness of peat-bogs, which seem as well calculated as any marsh to produce malaria, excepting that the vegetable

* On the Nature and History of Marsh Poison, by William Ferguson, M.D., &c. (from the Transactions of the Royal Society of Edinburgh), Edinburgh, 1821.

matter they contained being in a subcarbonized state, is not susceptible of decomposition. Since there is no reason to think that the evaporation of mere water will produce the poison, we are compelled to conclude that, if there was no vegetable matter present in the cases mentioned by Dr. Ferguson, some influence from mere terrestrial soil gave rise to the effects which are usually owing to the presence of such matter.

The necessity of the putrefaction of the vegetable matter present when malaria is produced, is a different question from that which we have just considered. In by far the greater number of cases in which this poison is generated, there is no offensive smell whatever; it is true that a marsh or other source of malaria may be at once noisome to sense and pestilential, but it is frequently the latter without being the former. Although it has been shewn that vegetable decomposition is instrumental in the production of the poison, if not strictly essential to it, yet the circumstance of its being generated in abundance without there being any perceptible smell, and in situations so dry that vegetable putrefaction in the ordinary sense of the term seems impossible, appears to prove that this decomposition is either in degree or kind different from putrefaction, though the two may coexist.

Malaria is generated in so many instances in which animal matter does not exist, that we must conclude that the presence of such matter is not essential to the formation of the poison; whether, when present, it increases the quantity or modifies the nature of the miasma, does not appear to be ascertained.

Heat is the extrinsic agent most influential in favouring the production of malaria in soils and situations capable of engendering it—an influence attributable probably to the effect of a high temperature in favouring the chemical action between organized recrements and humidity, and likewise to its accelerating the formation of the aqueous vapour which appears to be the vehicle of the diffusion of the poison. Hence even the milder forms of malarious disease are observed only in seasons of a certain degree of warmth, rarely, for instance, arising in this country before the vernal or after the autumnal equinox; whilst the more intense degrees occur only in the higher latitudes, or, if seen in climates ordinarily temperate, it is during seasons of unwonted heat; and wheresoever they exist, their prevalence is terminated by the cold of winter. It has often been observed that a summer of unusual warmth, especially if occurring after a wet spring, causes intermittent and remittent fevers to reappear in districts whence they had long been banished by the improvement of agriculture,—an occurrence, of the possibility of which medical men should be aware; for when the malarious disease has made its visitation in the form of remittent, it has not always been discriminated from typhus, and confusion and controversies have hence arisen not very creditable to all parties concerned.

The branch of our subject now to be considered, the propagation of the poison, is one regarding which we possess a considerable degree of irregular knowledge, consisting rather of detached facts presenting various unexplained anomalies, than of groups of corresponding facts from which the medical reasoner can deduce fixed and determinate laws. As might be supposed, the effect of the poison is in general more intense in proportion to the proximity to its source. This is probably owing to the more condensed state in which malaria exists near to the spot where it is generated; and it is remarked that circumstances which favour its condensation add to the intensity of its effects. It appears to be on this principle that the vicinity of swamps is so much more pernicious in the evening or night than during the day. The influence of a high temperature in favouring the production of the poison has already been pointed out; but it appears that during the portion of the day when the temperature is at its highest, the mobility of the atmosphere is so great, and favours so much the diffusion of the poison, that it is comparatively innocuous near the spot where it is generated; but in the more quiescent state of the air in the evening, though it is less abundantly formed, it is infinitely more pernicious. Its effect at these times is aided probably by its finding a powerful vehicle in the mists which at night are observed to rest over low and marshy grounds. The more pernicious effect of the night-air in a pestilential country and season, however it is to be explained, is familiarly known, and is often exemplified by the fatality to soldiers of certain night-guards.

But to this general law, that malaria is more pernicious in proportion to the proximity to its source, there are important exceptions. In some instances it is found to affect places at some distance, especially if they are situated on an eminence, with the same if not greater intensity than those in the vicinity; thus the neighbourhood of Versailles is powerfully influenced by the marshes of St. Cyr; and at Neuville-des-Dames, above Chatillon on the Indre, fevers are more prevalent than close to the marshes where the malaria is produced. The stagnant water of Lake Aguano, we learn from M. Monfalcon, exhales deleterious effluvia, which are carried backwards to the north-east to two or three villages, and even to the convent of Comaldules, a league distant, and situated on a high mountain. But the most extraordinary instance of this kind is mentioned by Dr. Macculloch, as occurring in Malta; the malaria which is produced on the beach beneath a cliff producing no effect on the spot itself, while it affects, even to occasional abandonment, the village situated above.

In explanation of circumstances of this nature, of which it were easy to multiply examples, M. Monfalcon supposes that the aqueous vapours in which the marsh poison is dissolved are raised during the day by the heat and consequent expansion of the air, and are condensed and precipitated on the adjacent hills during the evening; whilst Dr. Ferguson conceives that so far from rising into the atmosphere, malaria has a peculiar attraction for the earth's

surface, along which it creeps so as to concentrate and collect on the sides of the adjacent hills. We doubt whether either of these explanations is very satisfactory, and think it probable that the explanation of these facts is to be found simply in currents of air which sweep the surface of the marsh so as to prevent the accumulation of the emanations there, and convey them in a state of condensation to the more elevated spots situated in the line of the atmospheric movements. The situation of certain elevated places, which have been powerfully influenced by marsh emanations, has frequently been observed to correspond with the direction of a manifest current of air which passed over the surface of a swamp. Chains of hills in Corsica and Italy, very far from morasses, but placed in their line, and in the face of a wind which carried to them their emanations, were entirely depopulated and rendered uninhabitable. Orlandi cites an analogous example:—the south winds passed over stagnant waters before arriving at some hills, the air of which they infected: these heights became salubrious only when Pope Paul V. had caused the marshes to be drained.

The distance to which marshy emanations may extend by gradual diffusion has been calculated by Monfalcon to be 1,400 or 1,600 English feet of elevation, and from 600 to 1000 in a horizontal direction. In Europe these limits, he supposes, cannot be exceeded; but in equatorial regions the activity of the poison is much more extended; and in the West Indies, vessels at the distance of 9,000 feet from the marshy coast have felt their baneful effects. But when winds are in operation, their influence may extend to much greater distances than those mentioned. The case of the convent of Comaldules, which was infected at the distance of three miles, has already been quoted: but we know not any facts which teach us the extreme limits to which the poison may be transported. The distance will probably be influenced if the ground be such as to preserve the poison in a state of condensation instead of allowing it to be diffused; thus, a current of air sweeping up a valley, at the mouth of which the surface is swampy, will convey the poison to a greater distance than it could reach in a more open situation. An instance of this kind occurs in Ceylon, where the poison is conveyed many miles inland up a valley, whenever the sea-breeze blows in such a direction as to cross the swamps on the shore and enter its mouth.

We should take but an imperfect view of malaria did we consider intermittent and remittent fevers its sole results. Besides these its more familiar effects, organic affections of the spleen, liver, and mesenteric glands; similar affections of the stomach and intestines; dropsy, apoplexy, palsy, and idiocy, as manifested in the marshy districts of Tuscany, and in the cretinism of the valleys of Switzerland, are the effects of its long-continued application. Cholera, dysentery, and diarrhœa are by many writers referred to its more brief agency, and there is reason to think occasionally with justice; intermittent neuralgia, there seems little doubt, is one of its effects, and to this formidable list some are disposed to add rheumatism, but the propriety of this seems doubtful. It is observed that the natives of marshy districts, who permanently reside in them, lose their whole bodily and mental constitution, contaminated by the poison they inhale. Their aspect is sallow and prematurely senile, so that children are often wrinkled, their muscles flaccid, the hair lank, and frequently pale, the abdomen tumid, the stature stunted, and the intellectual and moral character low and degraded. They rarely attain what in more wholesome regions would be considered old age. In the marshy districts of certain countries, for example Egypt, Georgia, and Virginia, the extreme term of life is stated to be forty; whilst we learn from Dr. Jackson, that at Petersburgh, in the latter country, a native and permanent inhabitant rarely reaches the age of twenty-eight. In the portions of Brittany which adjoin the Loire, the extreme duration of life is fifty, at which age the inhabitant wears the aspect of one of eighty in a healthier district. It is remarked that the inferior animals and even vegetables partake of the general depravation; they are stunted and short-lived.

By the progress of civilization, and consequently of agriculture, the domain of malaria is diminishing throughout the more enlightened portions of the earth. This is manifest in our own country, from many parts of which, where they formerly prevailed, agues have been banished. The draining of swampy lands; preventing in ponds or other damp situations the accumulation of putrid or putrescible vegetable or animal matter; and, in marshes situated near the sea, preventing by embankments the mixture of salt water with fresh, from which combination most pestilential emanations have always been observed to proceed, are the most efficient means of reclaiming malarious tracts, and consequently of preventing the production of the poison. But some lands are of so incorrigible a nature, the Pontine marshes for example, that the hand of man has hitherto been employed upon them in vain; and it is desirable to know, since we cannot prevent such districts from generating the poison, how its diffusion and pernicious influence may be in some degree checked. It is remarked that malaria has a peculiar attraction for certain surfaces, and that it is not disengaged from those to which it adheres, at least not in a noxious form; in other words, they do not constitute fomites. The attraction of the poison for trees is great; and it has repeatedly been observed that not merely a few individuals, but the population of whole cities, situated in the most swampy districts in the world, have owed their security to a screen of woods interposed between them and the marshes. Facts of this nature suggest very obviously the propriety of planting trees in the vicinity of irreclaimable swamps. The floors of dwellings are supposed to have a similar attractive power over the poison; and hence, in malarious districts, the second stories of houses are found to be more salubrious than the first; and if from circum-

stances the first floor must be occupied, some security is afforded by having the bed a few feet elevated from it.

Nutritious diet, and that kind of general regimen which is most conducive to good health, should be observed by individuals exposed to the operation of malaria; and they should be especially careful to avoid, if possible, the vicinity of swamps in the evening.

(Joseph Brown.)

MALFORMATIONS OF THE HEART.—Under this head we comprehend all those deviations from the natural mechanism or form of the heart which are developed in its original conformation, or in the progress of its early growth. They arise, for the most part, from an arrest or interruption in those successive changes which the heart undergoes from its first formation until it is adapted to support the double circulation of post-natal life; but, as in the case of other monstrosities, they sometimes consist of an irregular, and sometimes of a superfluous, development of parts.

1. *Defective malformations.*—As there is a period in fœtal life in which the heart does not exist, so there have been instances in which the constructive process has been at this period interrupted with respect to this organ; so that, whilst other parts of the body were more or less perfectly developed, the heart was entirely deficient; its place being sometimes occupied by a mere sac or a net-work of vessels, as in the zoophytes, and in other cases the communication between the arterial and venous system being direct. In nearly all the cases of *acardia* on record, the brain and spinal marrow were also wanting; but Andral* quotes an instance from the second volume of the *Répertoire d'Anatomie*, in which the nervous centres were nearly entire, but there was neither heart, nor lungs, nor large vessels. As these are cases more of physiological than of practical interest, we need not dwell longer upon them.

It has not been distinctly ascertained by observation that the heart of the embryo is ever quite of the simple structure of the heart of fishes: in the early stages of its existence, however, it differs only in having the rudiments of a septum at the apex of the ventricle, and probably at a more remote period it is quite simple, consisting of a single auricle and ventricle; and this condition remaining stationary until birth, constitutes a variety of malformation of the lowest order. Of this description we find the record of eight instances.† In these cases the aorta gives off one or more pulmonary arteries, and the pulmonary veins terminate either in the auricle or in the vena cava. Some of these infants lived for several days without any *apparent* irregularity or defect in the performance of their functions, except some dyspnœa and blue discoloration of the skin, which varied considerably in different instances and at different times. In Dr. Farre's case the skin was very pale, and with but slight lividity, while the action of the heart and diaphragm was excessive; and these symptoms are explained by the fact that the orifice of the aorta was much contracted, so that, while the system was ill supplied with blood, the heart and lungs were kept constantly engaged. Of the two cases related in the Philosophical Transactions, one lived ten days with no other uncommon sign than a purple skin; in the other this only occurred shortly after birth and again just before death, which happened on the eighth day.

The next gradation of malformation is that in which there are two auricles with one ventricle. Of this we have found only two examples recorded, the subject of one of which, quoted by Laennec from Kreysig,* attained the age of twenty-two years. This fact proves that, great as the anomaly in this case was, the body can better adapt itself to this sort of reptile-like circulation than to those malformations which greatly obstruct the course of the blood.

Nearly allied in effect to the preceding, although their more perfect structure would entitle them to a step higher in the class, are the cases of imperfections or perforations of the septa between the ventricle, and between the auricles.† Many of this kind have been described, in a considerable variety of combination. There is commonly a contraction of the orifice of the pulmonary artery, and in the fœtus born with this malformation the ductus arteriosus is either totally wanting, or imperforate. Some subjects of this malformation have survived for several years, (one reached twenty-seven,) but always in a state of great disorder, being affected with blueness of skin, faintings, &c. The foramen in the septum of the ventricle is always nearest to the base of the heart, and it is often so near the origin of the aorta or of the pulmonary artery, that the vessel communicates freely with both ventricles. These all appear to be instances of arrest of development, corresponding with the state of the fœtal heart in the early stages of its existence; and the disorder which they occasion in post-natal life is generally in proportion to the extent of the imperfection, but it is always greatly augmented wherever there is a contraction of the arterial orifices.

The last order of malformations from simple interrupted development or adaptation are those in which the heart retains, after birth, one or both of the peculiarities naturally destined

only for the fœtal state, the open state of the foramen ovale and of the ductus arteriosus. As the occlusion of these channels of auxiliary circulation is essential to the well-being of the perfect breathing animal, nature admirably contrives that the first respiratory act shall in normal cases effect this change, and the means by which it fulfils this end are worthy of attention. According to Meckel, there is little difference in thickness between the two ventricles of the heart at the time of birth, the left scarcely presenting any of that superiority which is so evident in after-life. In fact, it appears that before birth the right ventricle, through the ductus arteriosus, assists the left in the systemic circulation; and when the post-natal change takes place, there must be not only an additional outlet given to the blood from the right ventricle, but also an increase of power to the left ventricle, to maintain the aortic circulation, which now depends solely on it. A full and perfect respiratory act fulfils both these objects; by expanding the lungs it gives a free outlet to the blood from the right ventricle, and, by arterializing the blood which returns to the left ventricle, it stimulates it to such an increased energy of contraction as enables it, unaided, to supply blood through the system. This increased energy is soon followed by an increased thickness of the muscular walls of the ventricle, which gives a permanency to the greater power required in its important function. The ductus arteriosus, thus freed from the current of blood through it, contracts, as in the case of all obstructed or empty arteries, into an impervious cord. The progress of this contraction has been minutely described by Bernt as a test applicable to the investigation of cases of supposed infanticide.*

The obliteration of the foramen ovale is probably a much slower process, and one of less consequence, for its ordinary state at the time of birth is such that, unless there be considerable inequality of pressure between the auricles, it is sufficiently closed by its valves to prevent the passage of blood through it.

From these circumstances we are inclined to consider patescence after birth of the foramen ovale in most cases, and of the ductus arteriosus in every case of its occurrence, to be the result of loss of balance between the effective forces of the two sides of the heart at the time of birth. The ductus arteriosus stands in the same relation to both ventricles, that is, it communicates with the great artery proceeding from each: as long as these two arteries are filled with equal force, there will be no current in the duct; and such is the state under which, in natural cases, it contracts into an impervious tube. But if there be greater pressure on one end, whether from the pulmonary artery or from the aorta, a current must then pass from the stronger to the weaker side. Now the causes of such an inequality of pressure are various; and it will be worth while to point out a few of them, as we shall thereby gain a clearer understanding of the complicated pathology of several kinds of malformation. In several cases on record the open state of the ductus arteriosus has been found in conjunction with a manifestly contracted state of the orifice of the pulmonary artery, and in some with its total obliteration. Dr. William Hunter relates the case of a child born in the eighth month of gestation, which, after exhibiting a livid skin, dyspnœa, and violent palpitations, died of convulsions on the twenty-third day from its birth. On dissection, the pulmonary artery was found reduced to an impervious cord, whilst the foramen ovale and ductus arteriosus were both open. Dr. Farre gives the history of two similar cases, one of which died in a week, the other lived six months. In all these the muscular power of the right ventricle had become useless; in Dr. Hunter's case its cavity was nearly obliterated, and in both of Dr. Farre's a perforation of the inter-ventricular septum made the right a mere appendix to the left ventricle. The part which the ductus arteriosus bore here was important, for, open to pressure only at its aortic end, it must have supplied the place of the pulmonary artery, by conveying the blood in a retrograde course from the aorta to the lungs. The same thing occurs in a minor degree when the pulmonary artery is merely contracted at its orifice. If, on the other hand, the aortic orifice is contracted, so that the artery does not receive the due influence of the systole of the left ventricle, the pressure on the right end of the ductus arteriosus will be greatest, and a current will flow from the pulmonary artery to the aorta. Any obstruction to the circulation through the lungs would have a similar effect, and for the reasons which we have already observed to obtain in fœtal life.

Openings in the septum of the ventricle, when combined with decided contractions of either of the arterial tubes, we cannot but view as in most instances the effects of the latter; for it is a simpler idea, and one more consistent with the laws of development, to suppose that an obstruction, which, pathologically speaking, is of frequent occurrence, retains the current of blood in the course which it held in the early period of its formation, than to ascribe a perforated septum to some specific and inexplicable arrest in its natural development.

The most common combination of an open ductus arteriosus is, however, with considerable patescence of the foramen ovale; and we would still view this latter in the light of a cause. Any considerable direct communication between the auricles must, to some extent, frustrate the longer intercourse through the lungs; and from the blood passing thus directly in a venous state to the left side of the heart, two things affecting the balance of the circulation must result: 1. the left ventricle, not receiving its proper stimulus of pure arterial blood, does not contract with increased energy, as at the moment of birth it ought to do; 2. this defective force in the left ventricle occasions some stasis of blood in the pulmonary vessels; whence the pressure of the aortic extremity of the ductus arteriosus continuing to be less than at the

* Handbuck der Gerichtlich. Arzneikunde.

right end, the blood persists to flow through it as before birth, and its canal is kept permanently open.

2. *Irregular malformations.*—The next description of malformations are those which consist of a misplaced or erroneous position or attachment of parts in the heart, constituting the *qualitative* malformations of Meckel. Examples of transposition of the aorta and pulmonary artery are described by Farre,* Langstaff,† and Baillie.‡ The subject of one lived five months and died of small-pox; the surface was cold and extremely susceptible, and the skin blue, with incessant cough in any posture but on the right side. During the eruptive fever there was increased heat only in the head, the limbs and body remaining cold. The valve of the foramen ovale was found perforated with five holes; the aorta sprung from the right, and the pulmonary artery from the left ventricle. In Mr. Langstaff's case the child lived ten weeks with similar symptoms, and here both the foramen ovale and ductus arteriosus were open. In two cases related by Sir Astley Cooper, the pulmonary artery communicated with both ventricles, and gave off the descending aorta; the ascending aorta rose from the left and divided into the innominata, and the left carotid and subclavian; the foramen ovale was also open.

A remarkable instance of malformation is described by Dr. Holmes in the first volume of the Transactions of the Medico-Chirurgical Society of Edinburgh. The subject was a young man aged 21, who had from childhood been affected with palpitation, dyspnœa, blueness of skin, pain about the heart, and frequent faintings, with cold limbs. The foramen ovale was found open, and the right auricle, instead of opening into the right ventricle, communicated with the left by a large aperture, which was furnished with a tricuspid valve. The auricle was enlarged to the capacity of a pint. The right ventricle gave off the pulmonary artery as usual, and must have received blood only through an opening in the left ventricle, immediately beneath the aortic valves.

The valves of the heart have been found in an unnatural state, which many pathologists have considered to be congenital. Laennec describes a union of the laminæ of the tricuspid and of the mitral valves at points near their extremities, but leaving apertures through which a finger might be passed. In the same case the semilunar valves of the aorta and of the pulmonary artery were also adherent to one another. Small, smooth, round, or oval openings are occasionally met with in the different valves, which may be regarded as congenital; and Laennec met with a case in which holes of this kind had converted the tricuspid valve into a mere net-work. There have been noticed other irregularities in the valves, such as an inequality in their size, and a superfluity in their number.

3. *Superfluous malformations.*—The last order of malformations to be noticed are those consisting of excessive development. Well described examples of these are not numerous, nor do they bear any remarkable feature. The heart has been found with supernumerary auricles and ventricles, and even double the natural number. Meckel describes instances of these double hearts, all having occurred in double monsters.* Winslow met with one in a fœtus which was defective in the œsophagus and trachea. Andral has seen a heart with three auricles, and another with four ventricles. An appendicular auricle or ventricle is not uncommon: we have met with an instance of the latter. Supernumerary septa, partially or entirely separating portions of the different cavities, have likewise been described. The foramen ovale has been found closed in the fœtus;† and in one case of this kind there existed an unusual communication between the vena cava and pulmonary veins. Bertin quotes a case of a double arch of the aorta.

The pathological effects of malformations of the heart depend on two physical causes, an obstruction to the circulation, and an intermixture of venous with arterial blood. The first of these is probably the most important; for the latter, although decidedly injurious, does not appear to encroach so seriously on the functions of a body accustomed to its effects, as to prove fatal, unless when conjoined with material obstruction to the circulation. These two, moreover, produce and react on each other in a manner sufficiently interesting to merit a little consideration.

Some cases of single heart already noticed, prove that the free admixture of venous blood in the arteries is not incompatible with life, as the subjects lived for several days. There was in these cases, besides, some obstruction to the circulation, in the aorta, or in the pulmonary artery; the one being characterized by pallor, and the other by a blue discoloration of the skin: and it is a question whether, but for these impediments, life would not have been considerably prolonged; for the simplicity of the moving power would prevent any of that loss of balance which is so frequent a cause of obstructed circulation in the double heart. This loss of balance, or undue action of one compartment of the heart, is an almost inevitable consequence of any malformation which causes a mixture of venous with arterial blood; and if it be great, it will generally aggravate the evil effects of the malformation; whence, in such cases, the obvious tendency to progressive disorder. In the greater number of instances the right side of the heart suffers more especially. Naturally its task may be said to be lighter in post-natal life than that of the left side, but the various congenital irregularities of mechanism fall heavy upon it; whence, according to the observations of Louis, it is almost always affected with dilatation or hypertrophy. Thus in perforation of the septum of the ventricles, as well as in the open state of the ductus arteriosus with a free pulmonary artery, the

* Op. cit. p. 29.

* De Monstrosa Dupl.
† Vieussens sur la Structure du Cœur.

right ventricle has to contribute to the aortic circulation as well as to maintain the pulmonary, whence it gradually assumes a more muscular structure than the left ventricle. The right auricle may suffer in a similar way from an open foramen ovale; but as the contractile power of the aurieles is but trivial in force, this malformation will scarcely produce great disorder without the addition of another cause, Such a cause is any obstruction to the circulation through the lungs; for example, a contraction of the pulmonary artery. Where this exists, the blood will not proceed so fast as it arrives; there is consequently an accumulation in the auricle, with an unequal pressure and a flow through the foramen ovale. But in the history of cases described, we find the worst complication of this malformation is with an imperfection in the tricuspid valve. This is illustrated in Corvisart's case of the postilion.* The man, aged 57, said to have been previously healthy, was attacked with blueness of skin, palpitation, dyspnœa, &c. after injuries from a carriage passing over him, and a violent blow on the epigastrium. From this time he suffered in various degrees, and in four years sank under the usual symptoms of valvular disease of the heart, accompanied by discoloration of skin. The right auricle and ventricle were found greatly dilated and thickened; the left auricle was also dilated, but the left ventricle was both thinner and smaller than natural. The foramen ovale was more than an inch in diameter, and the right auriculo-ventricular opening so much dilated as to admit four fingers, whilst that on the left side only admitted one; the mouth of the aorta was likewise contracted. Laennec ascribed the open state of the foramen ovale to this accident; but we think it more probable that this was congenital, and, as is often known to be the case, harmless in its effects until the period of the accident. The violence may have occasioned a rupture or dilatation of some portion of the tricuspid valve, so that it ceased to close the auriculo-ventricular orifice, whence regurgitation into the right auricle, and such pressure as to drive the blood through, and in time greatly to dilate the foramen ovale. We have said that an imperfect state of the tricuspid valve is the worst disorder of the mechanism that can complicate itself with an open foramen ovale; and the reason is, in addition to what we have just remarked, that the impulse of the right ventricle is propagated through the foramen ovale to the left auricle, and there opposes the course of the blood, which, during the systole of the ventricle, ought to flow into it from the lungs. It may be thus seen why in the above and in all similar cases on record, there has been an excessive oppression of the respiratory function. The contraction of the left ventricle and aorta was obviously the effect both of the small quantity of blood which the disordered mechanism of the right ventricle could propel into it, and also of the unstimulating quality of that blood.

We may remark, in conclusion, that every kind of malformation which leads to a mixture of venous with arterial blood, must, as we have before explained, occasion an obstructed circulation through the lungs, and consequently add to the labour of the right ventricle. Bertin ascribes the frequent occurrence of hypertrophy in the right cavities of the heart, in cases of malformation, to the more stimulating influence which arterial blood, obtaining entrance through the unnatural opening, exercises upon them.* Laennec thinks, however, that the pathological change results from the necessity imposed on the right cavities (naturally the weakest) of a more energetic action, in order to resist the impulse of blood flowing from the left side.† This opinion is more clearly supported by Dr. Hope, in his valuable work on Diseases of the Heart,‡ who remarks on the opinion of Bertin, that the obstructions in the pulmonary artery which so frequently prevail, would throw the current too much in the opposite direction, from right to left, to permit the entrance of arterial blood into the right cavities; and he considers that the greater labour thrown on the right ventricle in supporting the weight of the aortic circulation, is a sufficient cause for the changes in question. The dilatation in the same cavities is the generally acknowledged effect of over-distention; and Dr. Hope considers that this always depends on some obstruction to its course on the left.

M. Louis gives the following numerical comparison of the pathological changes in nineteen cases of congenital malformations.§

Contraction of the orifice of the pulmonary artery in ten; of the aorta in only one. Dilatation of the right auricle in eighteen, five of which were with hypertrophy, and two with attenuated parietes. Right ventricle simply dilated in five; simply hypertrophied in six; dilated and hypertrophied in four. Left auricle dilated in eight; hypertrophied in three. Left ventricle dilated in four; hypertrophied in two. Tricuspid valve more frequently diseased than the mitral, but neither often.

Symptoms. — Malformations of the heart sometimes give rise to very prominent and well-marked symptoms, whilst in other instances they have only been discovered by the scrutiny of the anatomist after death. When the disease is extensive, and particularly when combined with hypertrophy of one of the cavities or obstruction in some of the orifices, some or other of the following signs are always present:—discoloration of the skin, varying from a slight reddish purple tinge to a deep purple or livid colour, especially affecting those parts which are naturally red, as the lips, tongue, fauces, and nails, which are sometimes almost black;—considerable diminution of the superficial heat, with great sensibility to cold;—palpitation of the heart coming on in paroxysms, especially after exertion or mental emotion;—the pulse very variable, but generally irregular;—occasional syncope;—in children con-

vulsions;—respiration habitually short and difficult, with fits of severe dyspnœa, which sometimes occur periodically, and after tormenting the patient for a variable period, are terminated with sighs and yawning;—torpidity of bodily habit, with irritability of temper;—severe pain of the head, vertigo, and defective vision;—atrophy, and a disposition to hemorrhage.

It was, until lately, a general opinion that the blue discoloration of the skin, or *cyanosis*, as in its greater degrees it is termed, is a characteristic sign of malformations of the heart which occasion the mixture of venous with arterial blood. This has been called in question in consequence of some cases described by Fouquier, Meckel, and Breschet, in which there existed malformations of this description without cyanosis; and on the other hand an example of cyanosis reported to the Academy of Medicine by Dr. Marc, where no organic disease of the heart, congenital or otherwise, was discovered on dissection. Another opposing argument has been urged by Fouquier, founded on the alleged fact that the blood in the arteries of the fœtus is dark without there being any blueness of the skin. Bertin* and Ferrus† have accordingly taken up the idea that the mixture of venous with arterial blood has no necessary connection with cyanosis, but that a stagnation of blood in the capillaries, generally dependent on an obstruction to the circulation in the heart, is the universal cause of the blue discoloration in question; and that the presence of this sign in malformations arises only from the impeded state of the circulation which generally attends them. This view appears to us at least quite as inconclusive as the former one; for we know that the circulation is impeded in almost every considerable disease of the heart or lungs, often without any cyanosis, and never (except, according to Laennec, in emphysema of the lungs) with that degree which is seen in congenital malformations. Moreover, the cases before quoted (from Farre, Langstaff, and Baillie) prove that in some most remarkable examples of constant discoloration of the skin, there were no apparent obstructions to the course of the blood.

We confess that we are still inclined to prefer the old opinion, modified in some degree according to the objections which the foregoing facts bear against it. With respect to Fouquier's argument, it may be stated that the fact of the blood in the fœtal arteries being dark is denied by later writers;‡ and it is familiar to accoucheurs that a newly-born infant is often livid or purple till it cries; crying is a proof of complete respiration, and then this colour gives place to a general redness. The absence of cyanosis in the cases of malformations before named was conjoined with a general pallidity of the surface; and it would seem, therefore, that defect of blood in the capillaries was the reason of the absence of a dark colour. It must be remembered that in many cases we often see the countenance and surface so pale that the colour of the blood obviously does not affect them; and it is not to be expected that blueness of the skin should be apparent in a greater proportional number of cases of malformation with free communication between the cavities than is the redness of the same parts visible in other subjects. Dr. Paget well observes that, "as the colour of any organ is partly derived from the blood it contains, a change of the colour of the blood must affect the colour of the organ;" and we can conceive no cause of this change more efficient than one which throws black blood into vessels which naturally contain it of a visible red. To assert that malformations are the only source of cyanosis would be to take an occasional for a proximate cause: in the collapsed stage of cholera, in asphyxia, and in emphysema of the lungs, we find a similar discoloration of the skin; and in these the same proximate cause must be recognized, the presence of black blood in vessels which ordinarily convey red. In these cases, as in the former, and as also in the healthy state, an additional obstruction, the effect of posture, exposure, or exertion, will be followed by a still further injection of the capillaries, and where an ordinary subject would become florid and flushed, these assume a deeper and more livid hue.

In most of the cases accurately described, a diminished temperature with chilliness of the surface has been remarked in those malformations that are attended with blueness of the skin. Dr. Farre submitted some of these to the test of the thermometer, and found the internal heat to be as usual, but that of the surface depressed in various degrees according to the exposure of the part. In some instances, when a limb has been exposed, it has been observed to become quite cold and livid. The patients commonly like to approach the fire at all seasons, and require an unusual quantity of clothing; when exposed to cold, especially if accompanied with wind, they sometimes become quite torpid and incapable of exertion. This is well instanced in a case described in Dr. Hope's work.*

The palpitation, syncope, and dyspnœa may generally be said to be more frequent than in any ordinary disease of the heart; but the paroxysms are not often so severe as in the advanced and aggravated forms of valvular disease: nevertheless, when verging towards a fatal termination, they scarcely differ in symptoms from valvular disease, with which in fact they are frequently complicated. The greater blueness of skin, when present, is the most decisive distinction. It would appear that the intermittent form of the dyspnœa depends here, as in other diseases of the heart, in some measure on a sympathetic spasm, excited in the bronchial tubes by the engorgement of the right cavities of the heart. The relief of these exacerbations by deep sighing and yawn-

* Op. cit. p. 470.

ing, which favour the oxygenation of the blood and its transmission through the lungs, is more remarkable than in other asthmatic diseases. The torpidity of habit, as well as the vertigo, acute headach, and defective vision frequently present, must be ascribed to the influence of the venous blood circulating through the brain; and the same circumstance renders the nutritive process inactive, whence the subjects are commonly thin and slender.

We have no reason to think that malformations of the heart are characterized by any distinctive physical signs; but the accompanying organic changes may be recognized by their usual signs, which are ably stated elsewhere. (See Auscultation, Hypertrophy, Dilatation, and Diseases of the Valves of the Heart.) Contractions of the arterial orifices would be attended with a hissing, grating, or bellows murmur during the first sound; and a similar sound, more profound or remote, would probably accompany regurgitation into either auricle. In a case related by Dr. Hope, in which there was a perforation through the septum of the ventricles with a contraction of the pulmonary artery and open foramen ovale, there was a loud, superficial, hissing, bellows murmur accompanying the first sound. Dr. Hope considered the superficial character of this sound to indicate an obstacle in the passage of blood from the right ventricle. It is probable that a free communication between the ventricles might occasion a murmur with the first sound; but an open foramen ovale can scarcely be expected to have any such effect, as the flow of blood through it, if there be any, would scarcely be forcible enough to become sonorous. Corvisart* perceived, in one instance, a peculiar *bruissement* in the region of the heart, sensible to the hand. One of the aortic valves was absent.

Treatment.—Although it is obvious that the cure of malformations is beyond the reach of art, yet, as we have seen that their fatal tendency depends greatly on their complication with other pathological conditions, the treatment which is adapted to retard the progress of these will generally delay the fatal subversion of the functions to which both, when united, inevitably proceed. Anything which causes an additional embarrassment to the breathing, or in any way injures the balance of the circulation, will not only produce a temporary disorder in fits of palpitation or asthma, but will permanently aggravate the organic mischief by increasing the attendant dilatation or hypertrophy, and by favouring the habitual passage of blood through all devious and unnatural channels. Hence it becomes of the utmost consequence to watch those patients who are supposed to labour under congenital disease of the heart, and to keep their functions as near as possible on a balance; forbidding every sudden or violent exertion or mental excitement; enjoining a moderately nutritive but light diet of the most easily digestible kind; carefully excluding from cold a frame so susceptible to its effects; and, if necessary, aiding the excretory functions by the occasional cautious administration of appropriate medicines. The defect of the proper arterial quality of the blood is probably more or less felt by all the organic functions; in none, perhaps, more than in the secretion of urine, which is generally turbid and scanty. Hence the artificial aid of diuretics, especially colchicum, with nitre and other salts, may prove serviceable. Dr. Farre supposes that the skin may be made in some measure to compensate for the defective action of the lungs in the process of arterialization; and although the experiments of Majendie and others scarcely permit us to believe that the process of oxygenation goes on at this surface, it is probable that, by keeping it in a more perspirable state, more relief may be afforded to the pulmonary and cardiac congestion than by any other measure. The warm bath, partial or general, has been found of great effect in relieving the paroxysms of palpitation and dyspnœa occurring in these complaints; and the application of warmth by gentle frictions with hot flannels is a measure of some utility, and one which may very often be resorted to. In individual cases relief may often be procured during the paroxysms by particular postures; it is important to try to discover these in each case, but no general rule can be laid down.

From what we have before remarked, it may be deduced that malformations may occasionally take their origin at the time of birth from a defective state of the respiration; and we do not deem it quite useless to suggest the expediency of watching this function in the newborn infant, and of exciting it, if any lividity of the skin should show it to be imperfect, through the various channels of sympathy that are familiar to physiologists, such as by sprinkling the face and neck with cold water, or tickling the nostrils with a feather; or, if these fail, by artificial inflation of the lungs.

MEDICINE, PRACTICAL, PRINCIPLES OF.—In the article Disease was necessarily presented to the reader a long catalogue of evils, which, however, man has not been left unprovided with the means of meeting or of combating; some of them he has been enabled to mitigate, and others have quite disappeared before his increasing knowledge and skill. In the same manner as beasts of prey and venomous and offensive reptiles lose their ferocity, or recede in all parts of the earth, and finally disappear, before the advancing civilization of mankind, so, also, it would seem, do the diseases which prey upon health and life become modified by the resources of man's ingenuity, or disappear before his discoveries and growing wisdom; and when philosophers perplex themselves concerning the origin of evil, they little suspect how many of the physical as well as moral ills of humanity are destined to disappear before the sagacity, the research, and the enlarged virtue of the species. The great king-

* Op. cit. p. 276.

doms of nature have each already and amply contributed to reward human industry by remedies for the maladies of men; placing within man's power various substances which, taken in certain quantities, or externally applied, produce beneficial effects on the frame when it is labouring under disease; that is to say, when its functions are disordered, or the structure of its parts is changed or impaired. Experiencing the effects, also, man has learned how to avoid many of the causes of disease. His reason to a great extent protects him; and would do so more effectually but for the force of habits formed before his reason acquires strength. By regulating the impressions made on the body and mind by some of the actual agents of disease, he has even converted them into occasional remedies; and, the practice of medicine becoming more comprehensive in its scope, and no longer confined to the administration of drugs or to the mere *cure* of maladies, has so far advanced as to include the means of preserving health unbroken in a great variety of circumstances, by which the mind and body are liable to be temporarily affected in the course of life.

These agents of disease have already been spoken of, as being external to the body or inherent in it: the air which surrounds it; the food which supports it; the exercise which promotes all its actions; the sleep which, after labour, refreshes it; the mind which governs and directs its voluntary actions and ennobles it; and all the inherited or congenital peculiarities to which it is liable, as well as all the accidents to which it is exposed in its progress from the helplessness of infancy to the second helplessness of old age.

When by the undue impression of any of these agents their morbid effects are produced, such effects consist of disorder in some of the corporeal actions, of which the secondary results have been pointed out as very various. If there is, first, some increase or some decrease of the energy of the nervous or of the vascular system, exhibited in one function, in more than one, or in all, there follow changes in the structural condition of the parts affected; whilst new formations seem produced by peculiar modifications of action, distinct from mere depression or augmentation of vital power. Certain laws of sympathy, of relation, and of conversion, have also been detected, which were comprehended in our general notice of disease; and by reasoning from the evident object of some morbid actions, an attempt was made (professing, certainly, little novelty) to establish the probable final cause of all.

If any endeavour to attain to general principles in medicine be thought worthy of encouragement, they must be sought, it appears to us, by pursuing the route thus marked out; by a review of the causes of disease, and of the forms which it assumes; of the results to which it leads, and of the general objects to which it tends. It is agreeable to believe that medicine is now cultivated by many labourers in a spirit so philosophical, that the young student who falls into the vulgar error of considering such a general view superfluous, may confidently be told that he will live long enough to see and to regret his mistake.

Before the forms and products of disease had been so minutely investigated as to admit of being detailed with any approach to exactness, the ancients were led, by the simple observation of the *causes* of disease, to adopt natural measures for restoring the equilibrium of a function disturbed. If a man became ill from exposure to a hot sun, he was cured by a cool regimen; and if from exposure to cold, a return to health was promoted by warmth, and sometimes by mere insolation. If too much food disordered him, he was relieved by abstinence; if too much exercise or labour had exhausted him, he was renovated by rest. Thus *contraria contrariis medentur* became one of the first maxims, or one of the first general *principles* in medicine. As knowledge advances, the general principles of treatment acquire a wider and a firmer basis; but this first principle, to which the ancients in their regulation both of treatment and regimen paid especial regard, has in some periods of medical history been departed from with disadvantage, and sometimes, and even recently, been utterly denied. The wise physicians of Greece saw nothing unreasonable in the belief that when the system was disturbed by a burning fever, the body was struggling to produce coolness; and when they beheld the frame shaken with a chilling ague, they concluded that an effort was making for that restoration of bodily warmth which they found to follow the cold fit: nor, probably, was their conclusion incorrect. Without neglecting these observations, the modern physician has much more to do. He endeavours to ascertain in what consist the first movements of nervous or vascular disorder, and, in any disease presented to him, what actual change is already produced, and what further is threatened; so that his measures may be properly directed, and with a promptness proportioned to the occasion; for he has not only to remove effects obviously induced and existing, but to check, suspend, and stop the less palpable actions out of which the structural mischief grows.

He knows that there is in many or in all functional disorders, and even in some which have gone on to the production of structural change, a tendency to salutary terminations. In the paroxysm of an intermittent, he can admit that the successive stages seem intended to effect the quiescence in which they terminate. Deep-seated abscesses, for instance in so large and important a viscus as the liver, shew in their progress a tendency to seek or form communications by which the purulent collection may be carried away with safety. Almost all, perhaps all, the irritations of phthisis are the concomitants of an effort, always going on, for the riddance of the lungs from them; and the most deplorable changes in the course of scirrhous affections appear to be but the attempts of nature to break up or to separate from the body a portion so peculiarly diseased that its continued attachment to the system is inconsistent with

the continuance of life. Admitting that these are the best means of relief which the laws of disease allow, and seeing, in too many melancholy examples, the inefficiency of the laws to the salutary end proposed, he cannot but draw the conclusion that *art* was intended to step in and supply what is wanting; and that it may often direct the actions thus originated, and sometimes most beneficially counteract them by others artificially excited. To know when to do this is an essential part of the wisdom of practical medicine, and a knowledge of the means of doing it is another of equal importance.

As a general rule it may be stated, (and the highest authorities might, if necessary, be quoted for it in every age of medicine,*) that wherever it can be safely done, the natural tendency to cure, supposing it to be evident, is to be followed. In very slight disorders no benefit arises from interference. A slight cold, or a slight diarrhœa, for example, will cure itself by the discharge which constitutes one of the first of the effects of the disorder. A slight hemorrhage, or a slight external inflammation, may also be left to itself; but for a more violent or continued hemorrhage, although its object be apparent and salutary, we must substitute means which are capable of giving equal relief, and are at the same time more under our control. A more severe inflammation, also, or even the slightest if seated in a part not exposed to sight, can seldom or never be permitted to proceed uncontrolled; because inflammation seldom terminates without some product which may excite secondary inconvenience,—in other words, seldom terminates simply in what is called resolution, but either, when continuing, or when it attains a certain vehemence, ends, by a necessity arising from the laws of disease, in copious effusion, or in suppuration, or in the thickening or other alteration of parts, or the agglutination of opposite surfaces, or in ulceration, or mortification; the inconvenience or the danger of which effects in the head, the chest, the abdomen, or the articulations and extremities, are such that art must be vigorously employed to arrest the progress of the first functional disorder, and prevent the advance to those new formations or structural changes which, albeit they are natural methods of cure, are methods inconvenient and ineligible, or unsafe.

But it often happens that the functional disorder, the disordered action, is too violent, and will not be altogether suppressed: in these cases our efforts are limited to its moderation, and to conducting it to the least dangerous or least inconvenient termination that circumstances will permit. If effusions or suppuration cannot be prevented, their extent may be limited, or their escape facilitated; and if structural change cannot be altogether prevented, means may be found of saving a considerable portion of the suffering organ, so that its natural function may remain but slightly impaired.

When medical aid is sought for at a period too late to secure these advantages, and morbid actions have passed, unrestrained, into their ordinary effects on structure, medicine yet has its principles and resources. Circumstances have changed, and measures must be adapted to them. If effusion has taken place, as in various forms of dropsy, its absorption or its removal may be effected; if suppuration, its discharge, and sometimes its absorption; if structural change, its gradual repair or its removal. The resources are not always efficacious, but they always deserve a trial. Even when promising to be most successful, the frame is irritated by the presence and persistence of the disease, the strength of the body is reduced, and life is endangered. This irritation must, if possible, be allayed, the debility guarded against or removed, the danger to life averted. Whilst these indications are pursued, some new disease may be excited, or some of the *conversions* of which we have spoken (see Disease) may take place. The supervention of a new disease, for instance of pleuritis or phthisis, always demands prompt attention; the conversion of the original disease into another is occasionally salutary; that is to say, when the new disease is less dangerous than the old, and entirely takes the place of it, as in the case of an affection of the skin supervening on disease of some internal organ. It is a very common object of art to produce this kind of conversion. Even a febrile disorder of the constitution has sometimes been considered capable of producing curative effects: Celsus enumerates among the accidental circumstances which cure the sacer ignis, *a day's fever*; "medicamentum ejus fortuitum est, uno die febris, quæ humorem noxium absumat;"* thus adding the theory of the cure also. The authority of Hippocrates may be quoted to support a similar fact concerning convulsions dispersed by fever; and even epilepsy removed by the supervention of an intermittent; and Bartholinus and Salmuth are quoted by Hoffmann to the same effect. Hoffmann adds that he has often observed the convulsions produced by worms put an end to when a febrile action had destroyed the worms; considering the attendant fever as a salutary process set up to rid the body of the worms, effecting its purpose either by heat or by producing acrid bile.† Even chronic glandular disorders, which are perhaps generally exasperated by any febrile disorder, sometimes have disappeared, and old enlargements of the glands have seemed to be removed by an absorption induced by the fever attendant on measles.‡

In all these instances, if we admit the facts

* Medicinæ leges naturæ legibus debent esse consentaneæ. Felix medicatio cui adjutrix natura succurrit, irrita vero quæ repugnante natura tentatur. *Fernelius*, in præfat. lib. i. See also *Hoffmann*, vol. iii. s. 2.

‡ Dr. Forbes has communicated to us a striking fact of this kind.

without cavil, and in any other instances in which it may be thought salutary to excite any degree of fever, it can only be understood that certain circumstances accompanying the febrile state, certain conditions of the extreme vessels and nerves, are the causes of any benefit that is obtained. It must generally be more desirable to induce the same condition, if practicable, by other means,—by medicines which can affect the capillaries or the ultimate nervous actions without producing a concomitant fever; and this, we shall see, is another principle of practical medicine. By some of the older physicians, as by Van Helmont and Campanella, the disposition to regard fever as always a curative effort led to the mischievous doctrine that by all means the fever should be increased by calefaciants and tonics.* This is one among many instances in which a correct principle has been hurtfully perverted; and the remains of this prejudice only disappeared in the memory of practitioners yet living.

If medicine could be so directed as to reach the first link in the chain of diseased effects, deep-seated and often hardly discernible, in the nervous and vascular systems, and to which the term *proximate cause* has often been applied, the treatment of mere symptoms would become but a small part of our duty. It is to this point that the efforts of enlightened medicine constantly tend. Whilst we try to relieve pain, we carefully seek for the diseased action of which it is a symptom; and, not content to allay the pain by destroying acuteness of sensation, seek to remove the diseased action, that a permanent cure may be effected. If we desire to suppress the immoderate evacuations of diarrhœa, we carefully consider what particular state of the intestinal canal occasions the disorder; and in such a case inconsiderate and empirical practice, never successful except by chance, may even be fatal. To attempt to remove the effusions attendant on chronic pleuritis or peritonitis without regarding the continuance of the inflammatory disease, or to attempt to counteract the prostration of strength in a fever by other means than removing the febrile state, would be so exclusively to attend to mere symptoms, as to follow methods of treatment most inefficient and unsuccessful.

Yet it arises from the defective state of our pathology, combined with our anxiety, and even with our duty to relieve the afflictions of the sick, that we are often glad to treat symptoms only; and sometimes it would appear that when prominent symptoms are removed, the disease is at an end. As we can generally see and act upon the symptoms, although we are oftentimes unable to penetrate to the primary disordered actions, it happily follows that the limitation of our knowledge concerning the causes of disease does not determine the limits of our practical power, or always produce uncertainty or inconvenience. To the philosophical inquirer, however, it will always be unsatisfactory to be unable to account for some of the principal achievements of medicine; as the cure of an intermittent by bark, of syphilis by mercury, and of scabies by sulphur. In each of these cases the curative means are employed with singular confidence, and with general success; in each we see the grounds of hope that there are, even now, undiscovered remedies of equal efficacy in other maladies; yet, in each case, to speak candidly, it would be presumption to attempt an explanation of the mode in which the methods employed produce their marked and salutary effects.

To meet the complications of disease, the principles of treatment must often be equally complicated: two or more simple principles being not only simultaneously acted upon, but respectively modified by the existing circumstances of morbid complication. Chronic inflammation may exist with effusion, and both with debility; and although the principal indication or principle to be followed is in such a case to put an end to the inflammation, respect must be had to the existing debility, and relief from the mere effusion must neither always be postponed until the difficulty of acting on first indications is overcome, nor attempted without regard to the original cause or to the actual strength of the patient. There may be unequal growth, redundancy, or hypertrophy, in one or more portions of the frame, deficiency in others. General plethora may be combined with general debility. In these and numerous other complications, the principles of cure, being two-fold or three-fold, demand more from the practitioner than lectures or books can inculcate; a discriminating wisdom which must partly depend on his organization, and partly on his attention to the instructive examples afforded by daily practice.

Structural change is always preceded by disordered function, and the principles of treatment which are the ordinary guides of practice have reference to the means of restoring functional regularity. Disordered function consists, we have said, (Art. Disease,) of, 1. vascular disturbance or irregularity, producing local or general excess or defect of sanguineous supply; 2. nervous disturbance or irregularity, producing local or general excess or defect of nervous energy; 3. of combinations of these disturbances, producing various affections of nutrition, secretion, absorption, evacuation, muscular motion, or the sensorial offices, or the intelligence and will.

The modes in which we attempt to control these morbid states, and re-establish natural actions, would seem then, very obviously, to be such as tend to equalize the vascular and nervous actions, simply or conjointly, and in every degree of their functional combination; in other words, to excite or depress, to stimulate or to allay, in every case, as each case may require. In the practice of surgery, or rather in the medicinal means employed in external affections, we can generally recognise these simple principles; and when to stimulate and when to lower is acknowledged to be so compendious a surgical principle as nearly to include every other. In the treatment of

* See *Baglivi*, De Praxi Medica, lib. i. cap. xii. sect. 2.

such cases as fall under the physician's care, the principles are, we apprehend, equally applicable, although their simplicity is in some degree hidden by the variety of the phenomena, the frequent obscurity of their origin, and the number of the constitutional and local means employed. If this be so, the Brunonian doctrine erred less in its principle of dividing diseases into two great classes, than in the application of the principle to the actual arrangement of diseases, and in not admitting the simultaneous existence of states compounded of and exemplifying both the divisions.

Admitting the great difficulty of determining in what precise manner medicines produce their least doubtful effects, we plainly observe how both vascular and nervous excitement are sometimes lessened by *evacuants*, general or partial; by general or local bleeding, by purgatives, diuretics, and diaphoretics; and how the evacuant plan is supported by the auxiliary one of diminishing the supplies introduced into the system. It is equally clear that we try to rouse both the vascular and nervous systems by *stimulants*, including various agents exerting a more or less durable tonic power on the contractile forces, or on the digestive function, or directly on the nervous system, or on the vascular extremities on the internal or external surfaces. Several of the agents employed in certain circumstances as general evacuants are local stimulants, which in other circumstances are used simply as such; those, for instance, which excite the bowels, the kidneys, the uterus, or the skin. In some instances even venesection, the most direct evacuant, has the effect of a stimulus, by removing some oppression, as in apoplexy; in other cases, as of nervous excitement connected with vascular disturbance, it is a direct sedative; and in certain states of fever a brisk purgative, by its effects on the intestinal surfaces, acts as a stimulant to the whole system. We are also possessed of means of allaying inordinate actions by medicines which do not act as evacuants, by *sedative* applications. Opium and other medicines of this class are daily employed as auxiliaries to bleeding, and as means of restraining violent muscular actions, or irregular and profuse secretions, or sensations too acute, or mental excitement so great as to be incompatible with repose or with reasonable mental acts. The same substances, in smaller doses, are sometimes used as stimulants; and as irritation is often connected with debility, all stimulants may sometimes be said to act as sedatives. All that belongs to a knowledge of the ordinary properties of medicines of different kinds or in different doses may soon be known; but the great art of medicine (expressed in a well-known and often quoted saying of Boerhaave,) is the application of the proper medicine in the proper dose at the proper time.

Both in cases requiring evacuants or stimulants, and also in cases of long-continued disorder of any function or organ, leading to structural changes and new formations, the employment of evacuants, of stimulants, or of sedatives, may be so regulated as to produce gradual alterations of action, to suspend actions which are morbid, or to restore, or excite, or regulate actions which are only disturbed. When thus employed, the medicinal means are called alterative, and they have already been spoken of under the head of ALTERATIVES.

There can be no doubt that the operation of medicines prescribed with these intentions is contemporaneously exerted both on the nervous and the vascular system, and generally by a primary influence on the functions of digestion and assimilation.

Besides the general effect of medicines as stimulants, evacuants, or sedatives, they commonly possess, as we have seen, a power of acting locally, from which, in many instances, even their general operation is obtained: the various purgatives act with greater or less energy on particular portions of the intestinal canal, some on the duodenum, some on the colon and rectum, and yet all may be employed as evacuants. But there are a few medicinal substances which seem to exert a still more especial influence on particular parts of the body: it may, perhaps, be said that iodine especially stimulates the absorbent and glandular system; there can be no doubt that the secale cornutum singularly stimulates the muscles of the uterus, and that the strychnine exerts the same power over the whole system of voluntary muscles. We are content therefore to employ these agents empirically.

In a great variety of cases, and for a great variety of purposes, external irritants are employed; to aid in checking acute diseases, and to suspend those which are chronic; to relieve local internal plethora; to free internal parts from painful disorder; to disembarrass, as it were, in some cases, the constitution from superfluous or morbid humours, and prevent their specific irritations of glandular or other tissues. In the familiar instance of cynanche tonsillaris it may often be noted how the scarlet colour of the fauces, with the swelling and other appearances of inflammation, disappear as soon as a blister has been applied with effect to the throat; the relief being plainly attributable here to a simple transference of action. The cough and some of the other symptoms of phthisis are generally, although but temporarily, relieved whenever a pustular eruption is produced on the chest by the antimonium tartarizatum applied in the form of ointment; and this suspension of symptoms is the result, perhaps, of a transference of irritation from the bronchial mucous surface to the skin, rather than of any suspension of the disease itself; although it is often sought to suspend the actions of diseases themselves by similar means, or by setons and issues. When the new actions induced by counter-irritation produce relief from pain, the effect may either be ascribed to a transference of irritation, inducing an altered condition of the nerves, or to the discharge of humours from the circulation, which in such cases were productive of nervous irritation, as in others they seem to be of all the disordered actions of the scrofulous constitution.

As the advantage obtained from alterative medicines appears to be derived through their influence on the functions of digestion and assimilation, and by their general operation on the nervous and vascular system; so, on the other hand, it may sometimes be observed that medicines of great power are singularly modified in their effects by the state of the body at the period of their administration. In the latter case all the operation of the medicines seems happily directed to a specific movement or alteration in the part of the system particularly affected, and their usual effects on the system at large are placed in a state of abeyance. Calomel, and opium, and wine, have been given to an enormous extent in tetanus, and sometimes in other affections, without salivation, or mental elevation, or oppression. In certain states of nervous irritation, very young children have taken, with advantage, opiates in doses which would have been destructive to them in a state of health. The same observation has been made in the case of adults affected with calculus; the quantity of opium given in such cases having sometimes been governed solely by the relief afforded, and yet producing no effect on the system in general.* In hydrocephalus the power of sustaining immense quantities of calomel has been ascribed to the peculiarly insensible state of the nervous system; but the same power is occasionally seen in cases of croup, although certainly in the latter affection the debility produced by large quantities of mercury sometimes becomes a serious consideration on the decline of the original malady. To these illustrations may be added that afforded by the tolerance of large bleedings, of calomel, and of opium, in inflammatory disorders in general, and of the tartar-emetic in pneumonia especially.

The best approach to the general principles of practical medicine, and the most convincing illustrations of their authenticity, are to be gained by reflecting on the intentions of all the usual parts of practice in the most common examples of disease.

Taking the example of *fever*, the most general morbid affection of the frame, we may perceive that the intentions acted upon are sometimes to check the first depression by direct stimulants and tonics, which is chiefly if not solely practicable in fevers of an intermittent type. When excitement supervenes on the first depression, we seek to allay it by evacuants, acting either on the mucous and cutaneous surfaces, in the shape of purgatives and diaphoretics, or on the whole system, by venesection. We lessen the quantity and stimulating quality of the food. When inflammatory actions arise, to these means are added local depletion, or local evacuation, and sometimes sedatives, as the application of cold, or the combination of opium with calomel; and very frequently we resort to some of the forms of counter-irritation; all these means being varied according to the seat of the inflammation. After a certain period the febrile actions decline, the different organs are left in a state of weakness; even the inflammatory affections which still linger behind seem connected with debility: and now we resort more freely to tonics and stimulants, medicinal and regiminal. Throughout the whole course of a disease, various in its forms, severe in its symptoms, and uncertain in its results, there are certain plain rules for our guidance, few in number, drawn from the existence of certain states of increased, or diminished, or irregular actions at the time. The principles are not obscure, but it is still their wise and timely application which constitutes a good practitioner. In following, for instance, that apparently plain indication of giving tonics or stimulants in the stage of debility consequent on fevers or other maladies, not only is it necessary to commence their administration with exact attention to the proper time for so doing, but delicately to apportion our attempts to the existing strength; according to the ancient and sage maxim, that *debilibus debilia, valentibus valentiora conducunt*; a rule which was supported by John Hunter, when he maintained the principle of not "increasing the action without giving real strength," and that we should always have regard to "the balance which ought to subsist between the power and action of every part."*

In the course of a fever we find the most remarkable exemplifications of the effect of mental derangement; certain states of the mind seeming to increase or moderate the symptoms of a disease to which they also increase or lessen the predisposition.

There is a very important *sedative* appliance, the effect of which is never so universally observable in fever; although it is not to be overlooked in any affection; namely, *repose* of the affected or disturbed organ. With as much care as the surgeon takes directly to impede the undue use of maimed or diseased extremities or parts of the body, should the physician forbid or obviate the undue exercise of the whole muscular system in a fever; and not only of the muscular system, but of the system of circulation and the nervous system. It is, indeed, in some degree with this view that he inhibits a full or stimulating diet; but he must also prevent, as much as possible, the access of all external circumstances which excite the senses, the mind, the volition, and the locomotive forces. The benefit of this kind of repose in a fever is always in proportion to its extent. In slighter maladies its use needs no illustration.

In the treatment of *inflammations*, not originating in the state of fever, the same principles are followed; active evacuations during their active stage, combined with various sedative means, sometimes opium, sometimes the tartar emetic, which, although an evacuant when employed, after the old method, in small doses, is a sedative when given to the extent common in modern practice, and particularly, as has been mentioned, in pneumonia. The chronic forms of inflammation, like those in

* Parr's London Medical Dictionary, article *Calculus*.

* Treatise on the Blood, &c. Introduction.

the latter period of fevers, are sometimes combated by stimulants, external or internal, and these may be simultaneously employed with some local forms of evacuation, and also with sedative agents; the emptying of distended and disordered vessels, the excitement of the vessels themselves, the strengthening of the body, and the expulsion of morbid humours, all requiring to be attended to.

The importance of local applications, both internal and external, is seen to be very great. Even in acute inflammations they are highly serviceable auxiliaries, and in chronic affections they are often alone equal to effecting a cure. Whilst by general bloodletting and other evacuants we seek to lessen the quantity of circulating fluid, and to lower the energy of the heart, by local means we still endeavour to alter the state of the capillaries; and in cases in which neither general evacuants nor general stimulants are required, local means applied to the internal or external surfaces may perhaps effect all that the case requires. Such is the result of daily experience; and the fact is consistent with the physiological character of the capillaries, the powers of which are to a certain extent independent of the heart; insomuch that they are even exerted for a time after all communication between the capillaries and the heart is cut off. The application of leeches, of blisters, of friction, and of cold and warmth to the body, amply illustrate the action and the utility of local measures in inflammations, in fevers, and in various local affections: and in other cases, diuretics, purgatives, expectorants, emmenagogues, are used with a design of obtaining specific local actions, which are often excited with equal certainty and advantage.

External applications include the various forms of bathing, which may be so ordered as to answer in different cases the purposes of a stimulant, of a sedative, or of transferring vascular and nervous excitement to external from internal parts. (See Bathing.) The use of fomentations is equally applied to all these purposes, to stimulate inactive parts, or to allay pain and inflammation.

When it is the object of our practice to relieve a patient from the inconveniences or threatened dangers of *plethora*, the reduction of the quantity of circulating fluid is in ordinary cases the plain indication or principle which we keep in view; and this we attempt to pursue by direct evacuants, bloodletting, and purgatives which stimulate the capillary extremities in the intestines to the evacuation of fluid; perhaps, also, by diuretics and diaphoretics, which act in a similar manner on the kidneys and skin. These indications may become combined with that of giving tone to the containing vessels; or, more commonly, with that of guarding some particular organ from the effects of determination or congestion; and we fulfil the latter indication by local depletion, by the sedative action of cold, by establishing artificial discharges, and by warning the patient against hurtful exercises or postures. Whilst we try by these means to diminish the quantity of fluid already existing in the body, and to avert its, evil consequences, we are careful to cut off the supplies, by a proper regulation of the quantity and of the quality of aliment; and we debar the patient from solid or fluid stimulants which would counteract our evacuating plan. In some cases of congestion, as of the skin, or of the abdominal viscera, the admission of medicinal or dietetical stimulants, and of external stimulating applications, may constitute a part of the indications.

In all the approaches to *anæmia* and to *atrophy*, our principles of proceeding are totally different. To supply proper food, and by cautious attempts to rouse or stimulate the powers on which the digestion and assimilation of that food depend, not only demands every resource of medicine, but the judicious application of the air as a means of renovation, and the careful avoidance of evacuants which would destroy the feeble remains of vitality.

In combating the *profluviæ*, we have to counteract the increased discharge by stimulants which act on the too much relaxed extremities of the capillaries, or we have to lessen the determination to them by new modes of evacuation, or we have to remove their state of congestion by local depletion instead of permitting the evacuating discharge to proceed uncontrouled; and external means are sometimes employed to assist one of these kinds of indication and sometimes another: the direct removal, also, or allaying of the irritation of the capillaries, whether directly or sympathetically excited, is often had recourse to, and by the use of sedatives.

In the case of *suppressed secretions*, whatever may be the cause of the suppression, our means of relieving and removing the disorder are still either vicarious evacuants, or stimulants, or sedatives. Take the periodical uterine discharge as an example. Its suppression is sometimes cured by bloodletting or by leeches; sometimes by purgatives; sometimes by local, sometimes by specific, sometimes by general stimulants, as tonics, exercise, change of air, and diet; and sometimes by sedatives, which remove irritations of the affected organ incompatible with functional regularity.

In violent *nervous disorders*, where at first sight it might appear that our principles of treatment were more numerous, it is found on examination that they are only more complicated than in common cases. In epilepsy, in hysteria, in mental disorders, whether the cause is in the brain itself, or in its bloodvessels, or in some other organ, the means of cure are but the means of evacuation or of stimulation, or of allaying morbid movements, general or local, immediate or remote, occasional or habitual.

In the case of *morbid formations*, and in that of *scrofula*, we attempt to controul evident disordered actions in the nerves and bloodvessels, actions not easy to be defined, by diminishing or by increasing the supply of blood or of nervous energy sent to them, by allaying irritations, and by setting up new and controllable actions to oppose and suspend the old.

Hereafter, in these instances of morbid for-

mations, as in those of calculi and of poisoning, very material chemical principles may enlarge our views of practice and add to our means. These are at present extremely limited, and chemical medicine, of which Paracelsus may be said to have been the founder, is yet in its infancy; indeed it is yet very doubtful if any instances of the successful application of chemistry to medicine can be cited; the chemical medicines, so called, which are employed in cases of calculus, or of simple gastric acidity, not appearing to act as direct chemical agents, but by their influence on the organs of digestion. Yet the detection of some fluid ingesta in the blood, and in the urine, as well as the direct influence of atmospheric air on the blood, are facts sufficient to defend chemical therapeutics from the imputation of extravagance; and we cannot but be of opinion that the improvement of medicine will, during the next century, proceed much in that direction. More accurate investigation of the fluids in a state of health will lead to a fuller acquaintance with the changes effected in them by disease, and it is not forbidden to us to hope that more direct means may eventually be discovered of checking several diseases than we have yet ventured to suppose the existence of. This probability, however, has been recently disputed; the chemists, on the one hand, being accused of expecting too much from their science, and the physiologists, on the other, reproached with a neglect of chemistry. Dr. Thomas Thomson of Glasgow, a chemist of the first reputation, and a man of great knowledge and great wisdom, expressed himself on this subject in the following terms, in a work published a few years ago:—

"I need not observe to those gentlemen who have paid attention to the subject, that by far the most likely means of improving physiology is a cautious application of chemistry to the investigation of the different constituents of the human body. An accurate knowledge of the chemical composition of every organ, and of the alterations produced on that organ by disease, would probably throw new and unexpected light upon the nature and treatment of many diseases. Physiology hitherto has been handled almost exclusively by the anatomists. These gentlemen have acted with a zeal and industry that cannot be too much admired. * * * * * A new and more subtile species of anatomy remains still to be applied. Where the labours of the anatomist terminate, those of the chemist should begin. This chemical investigation of the animal body may be just said to be commencing at present; for it was not till the atomic theory was brought to considerable simplicity and perfection, that such an investigation was possible. It is easy to see that it must contribute prodigiously to the advancement of physiological knowledge."*

More recently, Dr. Prout has expressed himself in terms more sanguine; and to the controversy which ensued between this distinguished pathologist and Dr. Wilson Philip, a physician who stands peculiarly characterized by the philosophical spirit with which he has cultivated physiology, pathology, and the practice of medicine, the reader might with less hesitation be referred, if the discussion had not provoked more discourtesy than should ever be shewn by great improvers of science, to whom truth alone should be of any real consequence.* All parties and all authorities will, we believe, at least concede that chemistry may and will prove a valuable auxiliary to physiology and to pathology; and that its subsequent application to the treatment of diseases may not unreasonably be expected. No one will be found, we imagine, to contend that chemistry will ever explain every thing in physiology, or that the practice of medicine will ever rest on chemical principles alone.

There is much reason to believe that the advantage derived from medicines in some states of disease arises from the changes they effect in the intimate elaborations carried on within the bloodvessels, and of which the products are the various healthy and morbid secretions. Such would seem to be particularly the case in the instance of specific inflammations; and the same is very probably true as respects several or all of the morbid formations. The disposition of a scrofulous constitution towards the formation of tubercles is probably connected with as definite a change in the character of the blood as that which more palpably, and by general acknowledgment, exists in chlorosis and in scorbutus, in some fevers, and in the Asiatic cholera. In many of these cases, as well in colica pictonum, and in the tremors produced by exposure to mercurial fumes, it cannot at present be decided how far the supposed sanguineous detriment exists, or, if existing, to what extent it is combined with, or even dependent on, injury of the nervous system.

In several disorders which the pathologist unhesitatingly admits to be nervous in their character—in tic douloureux for example—the cure by specific modes of treatment seems to depend on some change wrought in the condition of the nerves or nervous system itself, different from mere sanguineous excitement or congestion, and different from deficient supply of blood. The whole subject of nervous pathology is in great obscurity. It is possible that the minute ramifications of the several nerves may possess various properties as distinct from and to as great a degree independent of those of the larger nervous masses as are some of the functions of the capillaries from those of the heart; and a knowledge of such properties, if existent, must be preliminary to any near approach to correct principles of treatment in nervous disorders.

A few medicinal applications require to be separately alluded to, as being employed on mere mechanical principles;—demulcents in

* An Attempt to establish the First Principles of Chemistry by Experiment. By Thomas Thomson, M.D. Regius Professor of Chemistry in the University of Glasgow, &c. &c. Lond. 1825. Introduction.

* See the Report of Dr. Prout's Gulstonian lectures, and the whole controversy in the Medical Gazette for 1831: also a paper in the same volume by Dr. Stevens, on the Treatment of Malignant Diseases.

irritations of mucous passages; some of the anthelmintics, as the filings of tin; and various emplastra, when the intention is to give support to subjacent or neighbouring parts. None of these require further observation.

The principle of treatment sometimes recommended in chronic and obstinate diseases, and spoken of in the article DISEASE, that, namely, of producing some strong impression or commotion of the system, in the hope that the system may, in such an artificial and general disturbance, rectify or *right* itself, might, in different cases, produce its advantages by acting on the nervous or on the vascular system, or on both. As views of treatment become more and more understood, such treatment, however, will be less and less resorted to; and if sudden and violent measures should be thought desirable in lingering states of disorder, the principles of their application and use will be better comprehended. It may be observed, that much of the success of irregular practitioners seems no less to depend upon this principle than that part of the benefit often ascribed to the use of various mineral waters arises from the general change of diet, regimen, and habits of life, with which a temporary residence at watering places is almost in all cases accompanied. The principle by which these circumstances effect favourable changes in the health seems especially deserving of consideration, both in such cases of chronic disorder as are connected with morbid conditions of the nervous system, including those which especially and in various degrees affect the mind; and in all diseases which depend upon, or which have induced, an altered condition of the blood.

Careful consideration will generally shew, even in chronic, and obstinate, and anomalous maladies, some clear indications to be followed for the relief of the patient; and in the cases in which any expectation of a perfect cure is to be indulged, the means of effecting it can hardly ever be wanting to those who can reasonably entertain the expectation. The very principle on which relief seems sometimes to be obtained by changing the habits of the patient in many particulars, may perhaps be found, if inquired into, to be resolvable into that of removing some unexpected cause of irritation, which removed, digestion and assimilation, and the proper distribution of venous and sanguineous energy are restored, and the balance of health is regained. The *means* of relief will still be found to have been something which has imparted power or stimulus to overcome the morbid obstacle, or something which has directly allayed some morbid irritation; or, lastly, something which has produced a delayed or much required evacuation of some morbid material, or something which has improved the state of the blood. The principle of relieving long-continued ailments by attention to the digestive organs is spoken of by Dr. Heberden in his Commentaries.* It has of late years gained much attention in this country, and still more on the continent, insomuch that practitioners have not been wanting who have ascribed every possible disorder to primary digestive derangement. A direct improvement of the blood is a very probable consequence of such a plan, and various amelioratious of nervous and vascular actions may follow, or may only accompany this change.

The first *principles* of practical medicine, then, are few and simple. In a work every article of which is an illustration of those principles, we need not dwell longer on the principles themselves. It may almost be said, employing the words of Hoffmann, that there is no other method of cure, and that there should be no other intention in the physician, than to reduce to order the actions and excretions when not in a natural state; and that all kinds of medicines do but this, to allay actions which are excessive, and excite or promote and equalize those which are depressed and obstructed.* But the *means* of fulfilling these indications are very various; and if the judgment of the practitioner is exercised in their application, so their increase and diversified combination afford equal scope for his ingenuity and invention. Departing from all rational principles, physiological or pathological, the physicians of the middle ages vainly sought some universal medicine which should accomplish every varied indication at once. Such dreams have long ceased to be indulged in, although some base pretenders yet insult the public sense by professing them; and the only hope of attaining to principles of universal application depends on the gradual improvement of our knowledge of all the actions of the body in health and disease. The principles of medicine, not dependent solely on a doctrine of solidism or of the humours, lead, therefore, to no extreme and exclusive practice; and the influence of the moving powers is admitted without excluding just views of their solid and fluid results. The mutual dependencies of the nervous and vascular energies, and the properties of and changes effected in the blood, being all taken into consideration, we admit nothing but what is known, and wait for further explanations from the constant progress of all the sciences connected with medicine.

From early infancy even to extreme old age, the few principles now enumerated seem at present to be the constant guide of our art in its attempts to rouse, to regulate, or to appease, actions insufficient, or too disorderly, or too energetic, to be consistent with comfort, with freedom from uneasiness and pain, or with the maintenance of health and strength of body or of mind. In all the varieties of their application, the object is to restore healthy actions as soon, and with as little waste of strength, and

* De Ratione Medendi. See also *Baglivi*. In chronicis pauca remedia requiruntur ——————— semper tamen in morborum diuturnitate consulendum est digestionibus. Animadv. Pract. Nov.

* Neque aliam dari medendi viam, vel etiam medentum debere esse intentionem, arbitramur, quam ut motus et excretiones, a naturali statu desciscentes, in ordinem reducant. with as little suffering, as possible: or, as a fashionable physician of ancient Rome was in the habit of professing to do, *cito, tuto, et jucunde*: and where a cure is out of the power of our art, the same principles lead to means of relief by which life is made comfortable for a long period, during which the patient, if left to nature, would be consigned to misery. The time *may* come when, guided by yet undiscovered knowledge, and new and more direct principles, the tendency to tubercular and other morbid formations may be surely checked; chronic inflammations readily cured; and fever suspended in its first movements. But the day of these triumphs is yet distant.

Hoffmann mentions it as the first criterion of a man skilled in medical art to know "*cur et quare* hoc vel illud alimentum ad valetudinem conservandam morbosque sanandos salutare vel minus tale sit dicendum;" and he quotes with deserved praise the eulogium of Thuanus on Hollerius, a famous physician of Paris, who by constant meditation had so improved his judgment that he often cured those ill of such deplorable maladies as the other physicians of the time, "riding rapidly through the streets," (per vicos vaga cursitatione mulos fatigantibus,) knew little or nothing about. We may confidently recommend to the student the diligent perusal of the works of the admirable physician whom we have here and already more than once quoted in this article. His learning and admirable good sense, the liberal spirit in which he viewed all parts of medicine, his discrimination as regards the innumerable controversies existing in his time, his wise direction of the medical practitioner's mind to things concerning which the senses could give information, things useful and about which men could speak reasonably,—"quæ in sensus incurrunt, quæ usum habent, et de quibus evidens ratio constat et dare potest,"—rather than to subtile disquisitions relating to things more obscure;—these and many other merits have not only endeared his name to learned physicians, but to liberal scholars, from the time when his writings appeared to the present day. Notwithstanding the subsequent undoubted advancement of medicine, there are few pages of his voluminous works to which the practical physician may not yet refer with advantage.

The number of writers in whose publications any specific notice of the abstract principles of medicine is to be found is not very great. We do not mention writers professedly on the practice of medicine, whose works are, like the separate articles of this work, *illustrations* of principles. Many valuable observations occur in Baglivi,* and many ingenious ones in Cabanis;† the works of M. Broussais, amidst much false and much doubtful theory, contain views and principles both original and important. In Dr. Heberden's Commentaries will be found a sensible chapter De Ratione Medendi, and another in Dr. Gregory's Conspectus Medicinæ Theoreticæ, with the same title. Dr. Burne made it the subject of an excellent oration delivered to the Medical Society of London a few years ago, and since published. And we may mention, that in the Outlines of Pathology just published by Dr. Alison, the English reader is for the first time presented with so clear, condensed, and comprehensive a view of the whole subject of *disease*, as can hardly fail to lead those who read it with care and reflection to a knowledge of the principles by which their practice should be regulated in all diseases.

At the same time, no reading nor reflection can make a good practitioner. Like an able orator, he must add to all the rules of his art daily habit and practice. His mind must be continually presented even with *numerous* examples and illustrations to guide and assist his judgment, and to correct the errors of reasoning on a practical subject. The symptoms of disease may be well understood and remembered, and the general principles of practice; but the treatment of diseases comprehends a multiplicity of details, essential or indispensable to the cure, and yet which easily, or almost inevitably, escape the memory of him who, although thoroughly grounded in the principles of medicine, is not continually exercised in prescribing for the sick.

The great utility of teaching by examples, selected at the bed-side, or by what is called clinical teaching, so long neglected in this country, and for the introduction of which we owe so large a debt of gratitude to Rutherford and Cullen, begins to be universally acknowledged. The full benefit of this admirable method will be the inheritance of another generation. A long existing defect in this respect has doubtless obscured the principles of practice, and in many instances quite shut them out of the practitioner's view during his whole life.*

But, if so engaged and so prepared,—by the principles already mentioned, and by others hereafter to be discovered, or by additional means of fulfilling the indications of medicine, the practitioner of the medical art has the privilege of feeling assured that he is useful; and the art itself, thus guided, and in every stage of its imperfection even to its final advancement, will continue to be of most singular service to mankind; relieving the sick, to use the expressions of Hippocrates, from the greatest of evils, from diseases, from pains, from sadness of mind, and from death.

By no one circumstance, we would add, will the practitioner find himself more assisted in his practical efforts, more enriched in practical

* Opera Omnia, Lugd. 1733.

† Du Degré de Certitude de la Médecine.

* For an account of Dr. Cullen's clinical teaching in Edinburgh, the reader is referred to Dr. John Thomson's recently published life of Cullen. Every pupil of the great school of Edinburgh must rejoice to see the reputation of one of its greatest founders, and one to whom practical medicine is so immensely indebted, placed in its true light by a man of learning and science, and rescued from the superficial criticism in which it has of late years been too much the habit of a certain class of writers and lecturers to indulge when mentioning Dr. Cullen's practical works.

resources, and better able to command them in all emergencies, than by the cultivation of a sincere and anxious desire to relieve his patients from whatever physical evils oppress them:—in all the varieties of his practice no other feeling will so surely and so happily stimulate his mind.

(J. Conolly.)

MELÆNA.—This name (*μέλαινα νοῦσος*, the *black disease*) was adopted by Sauvages from the writings ascribed to Hippocrates, to designate a genus of disease which he defines, "Alvifluxus materiæ nigricantis, atro-rubræ, dejectione aut vomitione frequenti notatus;" and this is the sense in which it is generally employed by modern nosologists and practical writers. We mean, therefore, by melæna, the occurrence, *as a symptom* in any disease, of very dark-coloured, grumous, pitchy, often highly-fetid evacuations by stool, commonly joined with sanguineous vomiting; or we use the word *as the name of a disease* in which such evacuations, with or without vomiting of blood, constitute the characteristic symptom. In these two senses authors speak of *symptomatic* and *idiopathic* melæna; but even where the latter phrase is with most propriety employed, the hemorrhage may generally be traced to some constitutional disorder or local organic disease as its primary cause. It has been mentioned in the article Hematemesis, that there is so close an affinity between that disease and melæna, that often they are not easily to be discriminated. Hematemesis is properly a hemorrhage from the mucous membrane of the stomach, and is *chiefly* characterised by vomiting of blood: melæna properly consists in hemorrhage from the mucous membrane of the small intestines, and is *chiefly* characterized by the dark evacuations by stool which have just been described. But as these two symptoms very frequently concur in the same case,—as blood poured out by the stomach is often carried downward into the intestines, and blood effused in the duodenum may pass upwards through the pylorus into the stomach; and as, moreover, these two hemorrhages are so much akin to each other in their seats, their causes, pathology, and treatment, a distinction between them is not always easy, and is seldom practically important. There exist, however, sufficient distinctions between them in all these respects to make it proper to treat of them separately in a system or a dictionary of medicine.

Synonymes. Μέλαινα νοῦσος? *(Hippoc. de Morbis,* lib. ii.) Morbus niger; Fluxus splenicus; Melæna splenetica *(Sauvages)*; Secessus niger *(Hoffmann)*.

The description of the *μέλαινα νοῦσος* by the author of the treatise "On Diseases" ascribed to Hippocrates, is rather a matter of literary curiosity than of any practical importance. It is in the following words, translated as literally as the English idiom will permit:—

"The patient vomits black bile (*μέλαιναν*), resembling lees of wine; at other times a matter resembling blood. Sometimes the matter vomited resembles the *second* wine (*οἶνον τὸν δεύτερον*, that obtained by putting the grapes into the wine-press:) sometimes it is like the ink of the cuttle-fish; sometimes it is acid, like vinegar; sometimes it consists of saliva and thin phlegm; sometimes of greenish bile. When the black blood-like matter is vomited, it smells like putrid or sanious blood (*δοκεεῖ οἷον φόνου ὀζεῖν*). The fauces and mouth are scalded by the acrimony of the vomit; it sets the teeth on edge, and effervesces with the earth in which it falls; (this is probably the meaning of *τὴν γῆν αἴρει*.) When the vomiting is over, temporary relief ensues; but the patient cannot bear either emptiness or fulness of the stomach, the first causing flatulence and acid eructations, the latter a sense of weight at the præcordia, and a feeling as if the breast and back were pricked with sharp instruments. There are aching pains of the sides; a slight fever; the sight grows dim; and the patient is unable to stand. His complexion turns dark-coloured, and he becomes emaciated." Such is the description of the disease: the treatment it is unnecessary to give at length, even were it possible to render it faithfully. As far as we can understand it, it consisted in purgatives given frequently, (*φάρμακον πιπίσκειν θαμὰ*,) emeties, (*φαρμακοπόσιας τὰς ἄνω*,) and afterwards venesection, if not forbidden by debility; a diet of whey, milk in the proper season, and whatever is cooling and laxative, excluding sweet, oily, and rancid articles; emollient clysters, if required on account of costiveness; great quietude, and regularity of regimen. "If these things be done," adds our author, "the disease, as age advances, is removed, even if it remains in the habit till old age. But if the skin assumes a dark hue, it (quere the colour or the disease?) will continue till death."*

It is remarkable that the above description contains not a word respecting the black discharges by stool, which, with Sauvages and the moderns, characterize melæna, though this symptom (*ὑποχωρήματα μέλανα, ὀκοῖον αἷμα*) is often mentioned in other parts of the Hippocratic writings.

Hoffmann treats at considerable length of hematemesis and melæna, the latter of which (vomitus cruentus *cum secessu nigro*) he considers by far the more dangerous form of the disease, and identical with the morbus niger of Hippocrates.†

Sauvages introduced the name of melæna to denote this particular disease. He makes it a distinct genus, and assigns to it several species,

* *Hippocrat. περὶ νοῦσων*, lib. ii. ad finem. Opera, p. 486, edit. Foesii, Genevæ, fol. 1567. The writer of this article has had the kind assistance of a friend distinguished by his philological attainments in revising the above translation. The last passage is scarcely intelligible, but seems to indicate that the disease in question is one of a very chronic nature and slow of removal; *ταῦτα ποιεῖν· καὶ ἅμα τῇ ἡλικίῃ ἀποφεύγεται καὶ ἡ νοῦσος, εἰ καὶ καταγήρασκει σὺν τῷ σώματι· ἢν δὲ μελανθῇ συναποθνήσκει*. The two other diseases, called *ἄλλη μέλαινα νοῦσος*, and *σφακελῶδης* (*νοῦσος*) have nothing to do with our present subject.

† Opera Omnia, tom. ii. p. 214.

some of which appear to be founded on observation, if not on correct pathology; others are hypothetical and fanciful.

Although Cullen has omitted melæna in his catalogue of diseases, he gives some account of it in his "First Lines," principally with reference to its pathology.

Morgagni, Haller, Lieutaud, Tissot,* but especially Portal,† have, among continental writers, mainly contributed to advance our knowledge of the history, pathology, and treatment of this disease. The series of cases and dissections recorded by Portal are particularly worthy of diligent perusal.

In the publications of our own country, Dr. Francis Home,‡ Dr. Marcard,§ and more recently Dr. Brooke‖ and Dr. Cheyne¶ of Dublin, Dr. Ayre,** and Dr. Belcombe,†† have recorded instructive cases and dissections of this disease. But there are few subjects in pathology which stand more in need of fuller and more careful investigation.

General history and symptoms.—Melæna, as well as hematemesis, so generally occurs as a symptomatic affection, that a description can hardly be framed which shall embrace all the various symptoms by which it is accompanied, according to the various causes which produce it. A much better notion of these will be gathered from a perusal of the cases above referred to, especially those so admirably detailed by Portal, than from any general description. The following may, however, be taken as a comprehensive view of the usual course of what has been termed idiopathic melæna.

The patient has for a considerable time shown symptoms of progressive constitutional disorder: the functions of the stomach have become debilitated; those of the liver and the bowels are imperfectly and sluggishly performed. The countenance has assumed a sallow, dusky, or "leaden" hue; the adnatæ of the eyes have become dull or greenish; the tongue is furred and clammy, or more or less dry; the breath often tainted. The pulse is habitually frequent, or is periodically accelerated towards evening; in other cases it is intermitting and irregular; and there are palpitations of the heart, or a pulsation at the epigastrium. The symptoms altogether are those of aggravated dyspepsia, to which are often superadded those of visceral congestion. On examination of the abdomen, there is to be felt a circumscribed enlargement or general tension and fulness in one or more of the abdominal regions; sometimes also tenderness to the touch. Upon the occurrence of any exciting cause of hemorrhage, an attack of melæna is induced, which is most commonly, but not always, accompanied by hematemesis, and at any rate with the same or very analogous symptoms. After complaining of much præcordial oppression and anxiety, tensive pain of the hypochondria, or dull pain at the scrobiculus cordis, with nausea, general uneasiness of the abdomen, and more or less tormina,—together with the common hemorrhagic symptoms of giddiness, coldness of the extremities, a tendency to faint, &c.—the patient is suddenly seized with vomiting of dark-coloured blood, together with a discharge, by stool, of blood of the same appearance, or more frequently of a very dark and often extremely fetid semifluid mass, of the consistence and colour of tar. Sometimes this discharge by stool occurs without any vomiting: it is invariably accompanied by great faintness and exhaustion. Occasionally the black matter discharged by stool is mixed with blood of more unequivocal appearance, or with dark-coloured bile, which may be distinguished from the former by dilution with water, which brings out a yellowish or greenish tinge. In some comparatively rare cases, the matter discharged by stool and vomiting is of a sooty blackness, (οἷον πόλυπου θήλου, Hippoc.) has no smell, and assumes neither a bilious nor sanguineous tinge on dilution with water: this appears to be the true *melanosis* of the ancients. For some time after the cessation of the hemorrhage the patient remains in a very weak and precarious state, extremely liable to its recurrence, and requires to be carefully watched. Even after the attack appears to be entirely over, a predisposition to its return remains, and unless this be overcome by medical treatment, or by the resources of the constitution, it will in most cases ultimately prove fatal.

Appearances on dissection.—Although a considerable number of dissections of patients who have died of this disease have been recorded, the subject is one which stands in need of much further investigation with a view to a satisfactory pathology of the several varieties of melæna and hematemesis. It is sufficiently established, by the researches of Portal, Andral, and other morbid anatomists, that no lesion of the mucous membrane of the stomach and intestines, except in some very rare cases, is to be met with in cases of gastric and intestinal hemorrhage. (See Hematemesis.)

In a few cases partial reddening, softening, and oozing of dark-coloured fluid (similar to that discharged during the disease) is stated by Portal to have been observed in the villous membrane of the bowels. Morgagni records a case where the whole tract of the intestines was found "horribly inflamed." But much more frequently no trace of disease is discovered in the stomach and intestines; these organs have on the contrary been found remarkably pale and exanguious,* while marks of congestion appeared in the turgescence of the mesenteric and gastric veins, loaded with dark-coloured blood.† Chronic enlargement or structural disease of the liver and spleen has been found in cases where the symptoms had led to suspect them to exist during

* *Morgagni.* † *Portal.*

life. It is highly desirable that in future investigations not only the state of these viscera be most carefully examined, but also the condition of the circulating system, and especially of the heart and great vessels, morbid alterations in which have only of late begun to attract a proper degree of attention, as causes of venous congestion and of *passive* hemorrhage.

Causes.—The predisposing and exciting causes of gastro-intestinal hemorrhage have been pretty fully considered in the article Hematemesis, and therefore it is not necessary to prolong the present article by recurring at any length to this part of the subject. Organic disease, a cachectic or greatly debilitated state of the constitution, sedentary employment, intense anxiety and close application to business, and a full and stimulating diet, with neglect of air and exercise, are the most usual predisposing causes, to which must be added fretfulness and irascibility of temper. These causes are most apt to induce a predisposition to melæna in males about the age of forty-five or fifty, in females about the time of the cessation of the menstrual periods. The exciting causes are those which occasion hemorrhage in general, as intemperance or any kind of excess, but especially any violent mental emotion or struggle, and none so frequently as a burst of passion. This has often induced not only a first attack of melæna or hematemesis, but the same cause has given rise to its recurrence at several times, when the patient seemed to be going on favourably, and to the final catastrophe by bringing on a last and fatal attack. This is well illustrated in Portal's first case, (that of the botanist Aublet,) and furnishes a most important caution as to the *moral* management of patients who are predisposed to, and especially who have already suffered from this disease. Irritating and drastic purgatives are well known to occasion bloody stools, when injudiciously employed, and sometimes when given with every proper precaution; but they can hardly be supposed to induce a true attack of melæna, unless where a great predisposition exists.

Varieties of melæna.—It is important in melæna, as in hematemesis, to distinguish with as much accuracy as possible the varieties which exist in the disease, or the *species* into which it may be distinguished, according to the nature of its causes, the kind of constitution in which it occurs, and the series of symptoms which precede or accompany it. It is evident that on such discrimination alone, a rational pathology or judicious therapeutical system can be founded. The fullest and most accurate enumeration of these varieties which has yet been made, is that of Portal.* His species are the following: 1. melæna supervening in *acute* (continued) fevers; 2. preceding, accompanying, or following intermittent fevers; 3. supervening on strong mental emotion, cases of which are so common; 4. following suppression of hemorrhoids or other habitual evacuations, and especially supervening on the cessation of the menses; 5. depending on the effect of gout upon those organs in whose substance the vena portæ is ramified; 6. that arising from scurvy, whether from this disease occasioning, as it often does, congestion of the spleen and liver, or from an alteration in the quality of the blood; 7. occurring in dropsy, either from the compression produced by the fluid effused in the abdomen, or from the accompanying organic disease of the liver, spleen, and other viscera. This division is evidently not strictly pathological, but it is much preferable to that of Sauvages, and may be useful to those who have leisure and opportunity for a further investigation of this very important subject. Portal illustrates each of his proposed species by reference to his own cases, and to some instances furnished by other authors. Pinel's division into species, of hematemesis* (under which he comprehends melæna,) may also be consulted with advantage, but not implicitly adopted. Dr. Mason Good's division of melæna into two species, (melæna *cholæa* and melæna *cruenta*,) appears captivating by its simplicity; but he is evidently mistaken when he professes to derive it from Hippocrates; and moreover he starts with a generic definition totally at variance with the usual acceptation of the term melæna, and which seems to rest wholly on the dark hue of the skin, the only circumstance common to melæna, (the melæna *cruenta* of Good,) and the green jaundice described by Dr. Baillie, (his melæna *cholæa*.)

Pathology.—This branch of the subject has been in a great measure anticipated in the article Hematemesis. It may, however, be useful to take a brief review of the opinions which have been adopted respecting the nature of melæna by pathologists. The notion universally entertained before the time of Hoffmann and Morgagni, was that melæna depended on a flow of *black bile*, or of dark venous blood, (for these terms seem to have been almost convertible, *bilis atra*, *melancholicus humor*, *fæx sanguinis*, &c.) from the spleen, which was supposed to be its great reservoir into the stomach and intestines, through the veins called vasa brevia. The latest supporter of this opinion was Van Swieten; but it is not very easy to understand what he means by *atrabilis*.

According to Hoffmann, melæna consists of a true hemorrhage from some of the viscera of the abdomen, most commonly from the small intestines; but in conformity to the notions of his time, he conceived that this could only take place by the *rupture* of a vessel. He therefore supposes that the branches of the meseraic veins ramified on the inner surface of the ileum are ruptured in consequence of impediments to the return of the blood through these veins, in hypochondriacal and hemorrhoidal subjects, in whom this disease, he says, chiefly occurs; from which impediments follow "distentions,

* Op. citat. p. 211.

* Dict. des Sciences Médicales, art. Hématemèse, tom. xx.

spasms, and congestion in those vessels, and finally effusion."* Cullen adopts Hoffmann's view of this disease: he considers it to be a *venous* hemorrhage, from obstructed circulation in the vena portæ and its branches; he thinks that its causes are of the same nature with those which give rise to the hemorrhoidal flux; but does not deny that in some cases there may be a true *atrabilis*, producing the symptoms of melæna.† Portal chiefly differs from Hoffmann and Cullen in referring hematemesis and melæna to *arterial* hemorrhage from the stomach and intestines, occasioned by the afflux of blood by the arterial branches being greater than the corresponding veins can take up; maintaining that this is mostly owing to the compression of the trunk or branches of the vena portæ, occasioned by obstructions not merely of the spleen, as was formerly thought, but also of the liver, pancreas, mesentery, and other viscera of the abdomen. The opinions of Portal, modified by the doctrines of Bichat and his school respecting arterial exhalation from mucous membranes, constitute the now generally adopted pathology of melæna and hematemesis. (See HEMATEMESIS.) The dark colour of the blood, as has been observed by Portal, (and the observation is as old as Aretæus,) does not prove that the blood is derived from the veins, for the fluid and gaseous contents of the alimentary canal will act upon it after it is poured out, and deprive it of its bright colour. Perhaps this explanation of the intense blackness and pitchy appearance of the stools in melæna is not quite satisfactory. Dr. Ayre has ingeniously contended, that as no trace of lesion is generally found in the mucous membrane on dissection, the hemorrhage which constitutes melæna and hematemesis does not take place from the capillary exhalents of the mucous membrane, but from the extreme minute ramifications of the vena portæ in the glandular texture of the liver. He argues that a certain degree of congestion of that important viscus will occasion an excessive and vitiated secretion of bile, constituting the common autumnal cholera, and the various modifications of bilious disorder; but that when this congestion occurs in a still greater degree, the extreme branches of the vena portæ are so distended that they cease to secrete bile, and pour out the dark and highly-carbonized blood which oppresses them, unchanged; that this is taken up by the biliary pores and conveyed by the gall-ducts to the duodenum, whence it either regurgitates into the stomach, or is carried down the course of the intestines. Dr. Ayre conceives, therefore, that melæna and hematemesis scarcely differ, but in degree, as to the pathological condition which occasions their symptoms, from cholera and other bilious disorders: and he accordingly proposes the same treatment for both.‡ These views are certainly ingenious, and, if established, would be highly important. But the arguments adduced by Dr. Ayre in his work are not conclusive; and his theory must still be considered as an hypothesis which may not impossibly afford the true explanation of *some* cases of hematemesis and mælena, where there is evidence of hepatic congestion existing in a great degree.

The pathology of melæna is still an obscure and very interesting object of inquiry. It is highly probable that in certain cases it depends not so much on mechanical obstruction and congestion of the blood in the veins of the abdominal organs, as on a change in the physical and perhaps vital qualities of the blood itself,* which gives it a tendency to escape every where from its vessels. Such a state seems manifestly to exist in certain cases of purpura and of scurvy, in fevers of the typhoid type, and in some malignant varieties of small-pox, in all of which melæna, as an occasional symptom, occurs. Fully to develope this as yet mysterious condition of the blood, its dependence on the state of the nervous system, its connexion with the nature of fevers and other diseases, is a problem of the greatest importance and difficulty in pathological science.

Though we have considered melæna as altogether a hemorrhagic disease, yet it may be proper to notice two cases in which the symptoms may closely resemble those of hemorrhage, yet not be truly such. The first is a discharge from the intestines of very dark and putrescent bile secreted in abundance from some irritation or congestion of the liver; the second, a truly *melanotic* discharge, proceeding (as supposed by Dr. Marcard in the case related by him,) from the breaking down of what he calls an atheromatous encysted tumour, in fact a mass of melanosis, either connected with the liver or alimentary canal, or else perhaps from a secretion of matter of the same kind from the mucous membrane of the stomach and intestines. The production of melanosis is not well understood. Does it consist of blood very little altered? Is the black matter vomited in cases of scirrhous pylorus for a considerable time before death, of the nature of melanosis?

Melanotic matter is distinguished from the sanguineous dejections of melæna by the absence of smell, and by the effect of dilution with water. The latter circumstance distinguishes it also from bile.

Diagnosis.—Except the two cases just mentioned, and that of hematemesis, the discrimination of which from melæna (as they may jointly occur, and at any rate require similar treatment,) is not practically important, melæna cannot require to be distinguished from any other affections, except hemorrhage arising from ulcerations, wounds, and injuries of the intestines, (which are not properly to be referred to melæna,) and the hemorrhoidal discharge. From the latter, where any necessity arises for discrimination, a better diagnosis cannot be laid down than that of Hoffmann, who says that

* *Hoffmann*, op. citat. p. 214.
† First Lines.
‡ Ayre on Marasmus, (First Edit. 1818.)

* *Andral*, Pathol. Anat.

melæna is to be distinguished by the tormina and spasmodic pain by which it is accompanied, and the imminent danger of death in which it places the patient; whereas the hemorrhoidal discharge is free from spasmodic pain of the bowels, and brings relief to any uneasiness which previously existed. Ulceration of the bowels is known by peculiar symptoms, which will be pointed out in treating of that affection.

Prognosis.—Melæna is almost always a symptom portending considerable danger. The only exceptions to this are where it occurs as a truly *critical* hemorrhage in fevers, or where it is attendant on hematemesis in young and plethoric females of unbroken constitution, and with vicarious or suppressed menstruation. The profuse discharge of blood, the debilitated state of the system in which it often occurs, and the organic diseases with which it is apt to be complicated, are the circumstances which constitute the danger by which its degree is to be estimated. The putrescent blood effused into the intestines and stagnating there, acting as a poison upon the nervous system, or re-absorbed into the circulating mass, was thought by Hoffmann to be the chief source of danger in this disease; and hence the great stress which he and others of the continental writers laid on clearing out the bowels by laxative clysters.

Treatment.—In the treatment of melæna, we have to deal with an intractable and too often an incurable disease, and almost always with an enfeebled and exhausted habit. Organic disease is always to be suspected in chronic cases, and where the disease occurs in advanced life, or in persons much exhausted by sedentary labour and anxiety, or weakened by intemperate habits, it is commonly a symptom of what is popularly but expressively termed "a breaking-up of the constitution." There is, therefore, little scope for active, much less for *heroic* remedies. Both during the hemorrhage and in the intervals, or after its cessation, the greatest quiet is to be enjoined; all disturbance of mind or body is to be sedulously avoided. The strength must be supported by the mildest nourishment, in such regulated quantities as not to disturb the stomach. The bowels must be kept open by the gentlest means, as castor-oil and mucilaginous clysters; nervous irritation is to be allayed by camphor and hyoscyamus. Opium and stimulating antispasmodics are to be avoided. Refreshing and antiseptic beverages, as lemonade, whey, &c. may be allowed in moderation; wine only where the debility is such as to require it, and where there is no febrile movement in the pulse; regard being also had to the constitution and previous habits of the patient.

Respecting astringents, we may refer to what has been said in the article on HEMATEMESIS; observing only that they must in the case of melæna be employed with still greater caution. This applies especially to the more powerful remedies of this class. The mineral acids are useful rather as refrigerants and gentle tonics than as astringents. Where more of a styptic effect is required, the diluted sulphuric acid should be preferred; where a tonic or alterative effect is wished, the nitric. Dr. Mason Good recommends in preference the vegetable acids, and particularly the acetic. The remedy which has acquired the highest reputation as a styptic in melæna, is the oil of turpentine. It appears to have been first recommended by Mr. Adair, in the fourth volume of "Medical Facts, &c." Dr. Brooke of Dublin, and Dr. Cheyne have since published cases illustrative of its employment, which have been already referred to, and Dr. Elliotson, in his published lectures, has borne testimony to its usefulness. Dr. Brooke gives three cases, in all of which the hemorrhage was effectually and promptly arrested by the remedy when other treatment had failed. One of his patients died shortly afterwards, but the case was one of long standing, and probably connected with organic disease of the stomach; but this could not be ascertained, as inspection of the body was not allowed. The other two cases were doing well at the date of the paper, but only a short period had elapsed. It is evident that the oleum terebinthinæ, however successful in arresting the hemorrhage, has no influence on the primary cause of the disease, and therefore can be esteemed only a valuable palliative remedy. The formula employed by Dr. Brooke was the following:

℞. Olei terebinthinæ, guttas xxv.
Aquæ cinnamomi, ℥i.
Syrupi aurantii, ℥i. M. fiat haustus ter die sumendus.

In Dr. Cheyne's case the result was less favourable, but the circumstances of it are not the less instructive, especially as it illustrates a caution given by Hoffmann, that astringents given in melæna are, in cachectic habits, likely to produce "a sudden transition to dropsy." A profuse melæna had continued two days. The patient (a tailor, aged twenty-four, and of cachectic habit,) was growing weaker and weaker, when a "small dose" of ol. terebinth. was ordered to be taken every second hour. Dr. Cheyne does not state how many doses were taken; but it stopped the hemorrhage, but at the same time "seemed to lock up the bowels, so that for nearly three days he was without a stool, his abdomen all the while increasing in bulk. On the 16th, (the ol. terebinth. had been prescribed on the 11th,) there was evident fluctuation, and the stools, when at length obtained, consisted of hardened colourless faeces." First, crystals of tartar, then blue pill with squills, were given, which last affected his mouth in two days, and were discontinued. On the 28th, having taken a purgative, the hematemesis and melæna recurred; it continued two days, and the tension of the abdomen diminishing, he grew very weak and faint, and died on the 30th. The dissection is given at length, but need not be inserted here. Dr. Cheyne candidly owns that the treatment in this case was too energetic; that with more of *expectancy* the patient might have lived longer. This is an instructive point of the case: another important one is, the alternate morbid excess of action in the serous and the mucous exhalents,

—a fact often to be noticed in practice, and in the present instance affording a valuable caution against the too free use of astringents in certain hemorrhages.

When the hemorrhage is arrested, without any such unfavourable concomitant events, we must endeavour to support the strength of the patient by moderate restoratives, according to the circumstances of the case, and do what we can to obviate the recurrence of hemorrhage by proper regimen, and medicinal treatment directed to the primary disease. This must necessarily vary according to the nature of the case, and it is unnecessary here to enter into the details of the various treatment which may be required in particular cases. The histories related by Portal may furnish some valuable hints if read with due discrimination, and allowance for national peculiarities of opinion and practice. His favourite remedies appear to have been leeches to the anus, and a course of very gentle alteratives, such as lime-water with infusion of camomile, of taraxacum, and other cichoraceæ, pills composed of soap and bitter extracts, clysters, tepid bathing; and in cases where a more tonic treatment was indicated, he prescribed the waters of Vichi, (a saline chalybeate highly impregnated with carbonic-acid gas,) cinchona, and the moderate use of sound wine. In old and feeble persons especially, he found the best effects to result from the employment of the two last-mentioned articles.

(George Goldie.)

MELANCHOLIA.—See Insanity.

MELANOSIS, from μελας, *black*, and νόσος, *disease*.—Syn. Melanoma; tumeurs mélaniques; dégénérescence noire; cancer noire; cancer mélané.

The term melanosis is employed to designate a morbid product, the distinctive character of which consists in a dark brown or black colour, of various degrees of intensity.

Although there can be no doubt that many of the ancient physicians were aware of the existence of the disease—at least in some of its forms, which we are about to describe—there is no such description of it in their writings as would lead us to believe that they regarded it either as a distinct disease, or in any other point of view than as one of the many local or general morbid states, which they supposed to originate in the predominance of one of the four elements—the *atrabilis*—of their humoral pathology.

The first account of this disease (the discovery of which is claimed by Dupuytren) was given by Laennec, in the Bulletins de la Faculté de Médecine de Paris, in 1806, and it was then named by him mélanose.

This distinguished pathologist describes melanosis as an accidental product, possessing a degree of consistence equal to that of the lymphatic glands, a deep black colour, a homogenous tissue, somewhat humid, opaque, and presenting an appearance similar to that of the tissue of the bronchial glands of the adult. He says that it afterwards becomes soft, when there oozes out from it, on pressure, a yellowish red, thin fluid, mixed with small black particles, which are sometimes firm, at others friable, but still presenting a certain degree of flaccidity to the touch. At a more advanced period of this softening process, the particles, and soon afterwards the remainder of the mass of which they form a part, becomes quite friable, and is converted into a kind of liquid pulp.

The same author regards melanosis as occurring under the four following forms: viz., 1. that of masses enclosed in cysts *(mélanoses enkystées)*; 2. that of masses without cysts *(mélanoses non enkystées)*; 3. that of infiltration in the tissue of organs; 4. that of deposition on the surface of organs.

A *liquid* form of melanosis (which is, in fact, the fourth kind of Laennec) has since been admitted by pathologists. Laennec not only knew of the existence of the disease under this form, but has even described it, although he has not given it a place among what he conceived to be the essential forms of the disease. This circumstance, which some may consider as an oversight on the part of Laennec, is obviously to be referred to a fundamental error in the pathological doctrines which he maintained regarding the mode of formation, development, and termination of accidental or new products; for he believed that all these products possessed at first a greater or less degree of density, to which state he gave the name of *crudity*; and that they afterwards undergo, at some period or other of their existence, by means of some change taking place within themselves, a process of solution, which he describes as the period or state of *softening*. The idea, therefore, of melanosis existing *primarily* in a *fluid* form was repugnant to such doctrines; consequently this form of the disease could not be admitted by him into the class of accidental tissues, to which he conceived melanosis to belong.

The division of melanosis, as to its forms, established by Laennec, has been adopted, with some slight modifications, by almost every author of note who has treated of this subject. The results of more recent researches, however, on melanosis and other morbid states and products which present the same distinctive physical character as the former, seem to us to suggest the necessity of a different arrangement of melanotic formations, and to warrant us in proposing one, which, we think, will comprehend all the forms and conditions under which these formations have been observed to occur.

Melanotic formations may take place in various and different parts of the body; may present considerable variety in the forms which they assume; and may owe their production to the operation of very different agents.

These circumstances do not appear to have been well understood, or their importance sufficiently appreciated, as Laennec has confined his description of melanosis to one kind only of

black deposit; whilst Breschet,* Heusinger,† Noack,‡ Andral,§ and many others, have included under the same general denomination various and very different morbid states and products, because of their presenting, as their most remarkable character, a greater or less degree of blackness. To reject every black discoloration or product which does not agree in all its characters with those assigned to melanosis by Laennec, or to collect them indiscriminately into one entire group under the same appellation, as has been done by others, would obviously render the pathology of melanotic formations equally incomplete and inaccurate.

In order to conciliate these differences, and at the same time to facilitate the study of melanotic formations, we shall consider the latter as susceptible of being grouped under two heads, each presenting a certain number of forms, the distinctive or pathognomonic characters of which are derived from some peculiarity of seat, origin, or nature.

In accordance with this plan, we shall comprehend all anormal black substances, fluid or solid, found in the body, under the general title of *melanotic formations*. When these formations depend (as is the case with several of them) on some change taking place in the economy, or the important function of secretion, independently of at least the direct influence of any external cause; or, in other words, when they constitute what is called an idiopathic disease, we shall consider them as belonging to the first head, and as deserving the name of *true melanosis*.

Other melanotic formations have quite another origin, being the consequence of the accumulation of a black material introduced into the body from without; the action of chemical agents; and the stagnation of the blood. These we propose to include under the title of *spurious melanosis*.

We are perfectly aware that these terms are inaccurate, and that to avoid the ambiguity which the use of them may create, we might have arranged all black products or deposits under the general head of melanotic formations, distinguishing each kind in reference to some peculiarity in its external form, origin, or mode of production. By doing so, however, we should not have drawn a sufficiently marked line of separation between these anormal products, which, as we have already said, differ in their nature, and offer only one common external character by means of which they can be recognized by the practical pathologist.

The following tabular view will show at once the nature of the arrangement which we have adopted.

Classification of melanotic formations.

I. TRUE MELANOSIS.

Origin.	A modification of secretion.
Locality.	1. Tissues, systems, and organs.
	a, in the substance and on the surface of organs.
	b, in the cavities of hollow organs.
	2. New formations.
Form.	1. Punctiform.
	2. Tuberiform.
	3. Stratiform.
	4. Liquiform.
Seat.	1. Molecular structure of organs.
	2. The blood.

II. SPURIOUS MELANOSIS.

Origin.	A. Introduction of carbonaceous matter.
	B. Action of chemical agents.
	C. Stagnation of the blood.
Locality.	Of first kind: the lungs.
	Of second kind: the digestive organs; the surface of serous and mucous membranes; the cavities of hollow organs; new formations.
	Of third kind: the blood.
Form.	Of first kind: uniform.
	Of second kind: 1. punctiform; 2. ramiform; 3. stratiform; 4. liquiform.
	Of third kind: punctiform and ramiform.
Seat.	1. The blood, contained in its proper vessels, or effused.
	2. Pulmonary tissue: cellular and membraneous.

From a very cursory view of the several circumstances included in the above arrangement, it will readily be perceived that melanotic formations must differ very materially from each other both in their composition and conformation.

I.—TRUE MELANOSIS.

Locality of the disease.—The cellular and adipose tissues are much more frequently found to present the true melanotic deposit than any other tissue of the body. Here, also, the quantity of the deposit is infinitely greater than in any other texture, and is always in proportion either to the quantity of this tissue, considered as a simple element, or as a component part of organs; or to the facility with which it admits, from its situation, of mechanical distention. Hence the reason why the largest masses of melanotic deposit have been found in the retro-peritoneal cellular and adipose tissues.

It is also of importance to know that melanosis may occur in either of these tissues separately. Marked examples of it, confined to the *cellular* tissue, are common in various parts of the body; and the most striking example of its circumscribed existence in *adipose* tissue is

* Considérations sur une Altération Organique appelée dégénérescence noire, mélanose, &c., Paris, 1821; Journal de Phys. Expér., vol. i. No. 4.

† Untersuchungen über die anomale Kohlen; und Pigmentbildung. Eisenbach, 1823; Archives Gén. de Médecine, t. v.

‡ Précis d'Anatomie Pathologique, t. i; Dictionnaire de Médecine, t. xviii. art. Mélanose.

§ Comment. de Melan. cum in Homin. tum in equis obveniente, &c. 4to., c. trib. tab. æn. Lips. 1826.

observed in the appendiculæ epiploicæ, or the fatty appendiees of the colon, these bodies being sometimes converted into a homogeneous solid mass of melanotic matter.

Occurring, besides, as a primary affection of these tissues, the melanotie matter frequently extends to those situated in the immediate vicinity of the former, which it penetrates, or in which it forms excavations of various sizes, on account of the compression and subsequent absorption to which they have been subjected during the progressive development of this morbid product.

It is also by means of the eellular tissue that melanotic tumours spread to a great extent along the course of the bloodvessels and nerves, between the folds of the mesentery, and in the eavity of the pelvis, and where, on aecount of the size which they attain, they sometimes give rise to very serious eonsequences, to which we shall more particularly allude hereafter.

Mucous membranes.—The melanotic deposit, notwithstanding what has been said to the contrary, has very rarely been observed in mucous tissue. We ourselves have only met with one example of it in this tissue, and it was even doubtful whether the deposit had its origin in the mucous or submucous tissue, both of them being simultaneously and contiguously affected.

Skin.—An opposite opinion has been entertained regarding the production of melanosis in this tissue, viz. that when found in the skin, it was to be regarded as the extension of that which existed at the same time in the subjacent cellular or adipose tissues. Sueh is frequently the source of melanosis of the skin; but we have found it to exist as a primary affeetion of this tissue, particularly in the horse. In this animal the melanotic matter may be seen occupying the very centre of the *cutis vera* in the form of black points, or varying from the size of a hemp-seed to that of a large pea, whether the subjacent textures eontain any of the blaek deposit or not.

Muscular, arterial, and venous tissues; serous and synovial membranes; aponeurosis, tendon, and cartilage.—These have not, so far as we are aware, been found to contain any trace of the melanotie deposit as a primary disease. All of them may present the dark brown or black colour of melanosis, but this arises from contiguity, the imbibition or infiltration of the black matter when in a state of fluidity, or from other causes of a very opposite kind, to which we shall particularly direct the attention of the reader in a subsequent part of this article.

Bone.—The bones are not often affected with melanosis; the spongy bones, as the sternum, more frequently than others.

Liver.—Of all the *compound tissues* or organs the liver is by far the most frequently affected with melanosis: in this respect it is inferior only to the cellular and adipose tissues. The frequent occurrence of the disease, as well as the extent to which it proceeds in this organ, are no doubt in great measure to be attributed to the predominanee of the cellulo-vascular element which enters into its composition. We shall, however, endeavour to show that the melanotie deposit is not confined to this element, but that it invades, as a primary formation, the molecular structure of this organ.

Lungs.—Notwithstanding the supposed frequency of melanosis in the lungs, it is by no means so often observed in this organ as in the liver; nor, perhaps, does it ever acquire the same extent as in the latter, although we are aware that eases have been recorded of the whole of both lungs being filled with it. This form of the disease will be considered under *spurious melanosis*, to whieh division of our subject we conceive it ought to be referred.

Brain.—Few cases of true melanosis of this organ are recorded by pathologists. We have only met with one ease, the particulars of which will be related when we come to consider the physical and other eharaeters of melanotic formations. Dr. Hooper* has represented a ease of true melanosis of the brain.

Melanosis of the *kidney* has been occasionally met with. It is also found in the *testes* and *ovaries;* and Andral says that it occurs in the *uterus.* It has also been seen in the *breast.*

The *pancreas* and *lymphatic glands* in several parts of the body, and the *thyroid* and *parotid glands*, have presented the disease in various forms.

Melanosis of the *eye* has been frequently observed by surgeons, either alone, or combined with other morbid products.

Examples of melanosis occurring in the eavities of serous and mucous membranes are given by various authors; and Breschet, Cruveilhier, and Andral, have described it as existing within the veins. We have also had occasion to observe it in these eavities; but it is the spurious melanosis whieh has, in general, been observed in these situations, and has been described as examples of the true kind.

Blood.—The presenee of true melanotie matter in the blood is an important fact, and one which, under favourable circumstances, may be easily ascertained.

It has chiefly been in the minute veins of the liver that we have observed melanosis as a primary formation in the blood. The vessels which, in this organ, contain the melanotic matter, appear like blaek lines, striæ, or dots, and sometimes in a pencillated form, all of whieh appearances may be recognized as originating in the ultimate extremities of the veins of the liver, most probably the hepatic.

We are not disposed to believe that the blaek ramiform appearance so frequently seen in the lungs is owing to the presence of true melanotie matter in the extreme branches of the veins. Such may sometimes be the case, although we have not been able to satisfy ourselves that it really is so. The blaek colour of the contents of these vessels we rather attribute to the simple stagnation of the blood, and to the subsequent removal of *that*, the produetion of the red colour. A similar vascular arrangement of black

* The Morbid Anatomy of the Human Brain, pl. xii. fig. 2 and 3.

matter has also been seen in the vessels of the stomach, and described as melanosis by several pathologists. But in this case error is conspicuous. The writer of this article has shown in another publication* that the black colour of the blood, not unfrequently seen in the vessels of the stomach, in the cavity of this organ, and in that of the intestines, is the result of a chemical process, and is always observed when the blood in these parts is either directly or indirectly brought in contact with the acid products which they contain: melanotic formations of this kind naturally take their place among those of spurious melanosis.

The existence of the matter of melanosis in the blood accounts satisfactorily for its being sometimes met with in the cavities of some secreting organs. It is also said to have been found in the saliva and bile, and likewise in the sweat and urine, in which last fluid a dark colouring matter was found by Dr. Marcet, which has received the name of *melanic acid*. The presence of melanotic matter in these secretions does not, however, appear to us to have been proved, except in the serous and mucous. It has, however, been observed in the medulla of bones, and in the humours of the eye.

Melanotic fluid may be found in cavities, either natural or accidental, without its being the product of their secretion. This happens when melanotic tumours perforate the walls of these cavities, and pour their fluid contents into them. This we have observed in the thorax and abdomen; and in one case a melanotic tumour had perforated the right lateral ventricle of the brain, in which was found a considerable quantity of black fluid, which afterwards passed into the third and fourth ventricles, and thence into the theca vertebralis. Such also is, in general, the source of the melanotic fluid found in accidental cavities.

The production of melanosis, scirrhus, carcinoma, and encephaloid formations in the same organ, and even in the same diseased mass, is occasionally met with.

The simultaneous existence of melanosis with these diseases, and the real or supposed analogy which the former presents in regard to its mode of development, progress, and termination, when compared with the latter, have induced some pathologists to consider melanosis as a species of cancer: how far this opinion is founded in truth we shall not at present stop to enquire.

Such is, we believe, a correct, though general statement of the topography of melanosis. We shall now endeavour to describe the various forms which it assumes in the different tissues, systems, and organs of the body.

Of the forms of true melanosis.

1. *Punctiform melanosis.*—Of the four forms under which we have included the true melanotic deposit, the first is that in which the black colouring matter appears in minute points or dots, grouped together in a small space, or scattered irregularly over a considerable extent of surface, and which we have termed *punctiform*. These appearances are most frequently met with in the liver. The cut surface of this organ appears as if it had been dusted over with soot or charcoal powder. When examined by the aid of a lens, the black points sometimes present a stellated or pencillated arrangement, which in some cases can be distinctly seen to originate in the ramiform expansion of a minute vein filled with black matter. At other times the melanotic matter appears to be deposited in the molecular structure of the organ in a manner similar to that of the organizable part of the blood. In such cases it consists of the most minute points disseminated throughout the acini or little lobules of the liver, and which then assume a uniform grey aspect. The various shades of grey and black which the liver presents when thus affected, depend on the greater or less quantity of the black punctiform injection; and we are inclined to believe that the melanotic tumour in this organ has, sometimes, a similar origin. We have always found the two forms, the punctiform and tuberiform, combined in the liver, lungs, and also the kidney. The "*infiltration des organes par la matière des mélanoses*" of Laennec is, in many instances, owing to the punctiform dissemination of the melanotic matter. In others it is obviously produced, as Laennec believed, by the simple diffusion of the liquid black matter throughout the tissues of an organ more or less remote from the part where it was formed. It is likewise to be attributed to general venous capillary congestion, or the effusion of blood, and the subsequent changes which this fluid undergoes, to be mentioned hereafter.

Punctiform melanosis is not observed in the brain, cellular, adipose, serous, and fibrous tissues. It may take place in mucous membranes; but its occurrence must be rare, as we have already said that we have only seen one case of melanosis of this tissue, in which the submucous tissue was affected at the same time.

2. *Tuberiform melanosis.* This is by far the most common of all the forms of melanosis. The bulk of the melanotic tumour varies greatly, and, as we have already said, always acquires its maximum in loose cellular and adipose tissues. Sometimes not larger than a pin's head, at others it equals in bulk the head of a child, or even that of an adult. It is, however, only in the horse that it acquires such an extraordinary size; in man it is seldom larger than an orange.

The great size of melanotic tumours depends on the agglomeration of smaller ones, the number of which varies with the size of the aggregated mass, or with that of the individual tumours of which it is composed.

The melanotic tumour, when single, is always of a spheroidal or ovoid form; and when aggregated, presents a lobulated appearance. In compound tissues or organs it is more frequently found single; in the cellular and adipose tissues, aggregated.

In both of these forms it has been described

* Recherches sur la Dissolution Chimique ou Digestion des parois de l'Estomac après la mort, &c. Journal Hebdomadaire de Médecine, 1830. No. 87, p. 351. No. 91, p. 517.

as encysted and non-encysted. It is said to be encysted when contained in a membraneous capsule, and non-encysted when it lies in immediate contact with the tissue of the organ in which it is seated.

The encysted melanotic tumour does not, so far as our observation extends, occur, unless in a very imperfect state, in any of the compound tissues. It is chiefly found in the cellular and adipose tissues, a circumstance which the nature of the tissues sufficiently explains. The cyst of the tumour consists of cellular membrane—not of new formation—stretched out in the form of a thin transparent covering, from the gradual accumulation of the black melanotic matter contained within it. Hence melanotic tumours of the latter tissues are always provided with an external covering, which, as it not only adheres closely to them, but generally forms a constituent part of their internal arrangement, is separated from the loose surrounding cellular tissue when these tumours are removed, and which are therefore said to be contained in a cyst.

The tuberiform arrangement of the melanotic matter contained within a cyst is not confined to the cellular tissue as a simple element, or to those organs in which this tissue is more or less abundant. We have found it on the surface of the pleura and peritoneum in man,* and also in the horse. In this situation the melanotic tumours frequently assume a pedunculated appearance, being suspended by a slender neck, like some polypi, and are covered by a thin transparent serous membrane. Under such circumstances it is often difficult to determine whether the serous covering of these tumours is a new product, or merely an extension of pleura or peritoneum produced by the gradual accumulation of the melanotic matter in the cellular tissue beneath these membranes; and the difficulty of the case is increased if there exist at the same time, and in the same organ, tumours of a similar nature either in the sub-serous cellular tissue or in the parenchyma which it covers. Instances, however, have occurred which have afforded us the means of determining the seat of these extra-pleural and extra-peritoneal melanotic tumours. Thus we have seen these tumours co-existing with the more simple forms of the melanotic deposit, such as striæ or patches, consisting of a fluid or semi-concrete black matter lying on the free surface of the pleura or peritoneum, and enclosed in a fine, loose, spongy tissue, or serous covering of considerable tenacity, although almost equal in tenuity to a spider's web. The pleura and peritoneum beneath the melanotic deposit were perfectly entire, and therefore the solid material, whether cellular or serous tissue, in which it was enclosed, must be regarded as a new formation. The inference which we would draw from this is, that the melanotic tumour may, in some instances, have a similar origin, viz. in the deposition of melanotic matter on the surface of the serous membranes, and the subsequent or simultaneous formation of a tissue, which afterwards acquires the solidity and characters of a general serous envelope.

Melanotic tumours of the pleura pulmonalis and costalis are found either solitary or aggregated in considerable number, and vary in bulk from the size of a pea or less, to that of a cherry. When they are found in the peritoneum, it is generally where this membrane receives the name of epiploon.

3. *Stratiform melanosis.*—This form of the melanotic deposit occurs only in serous surfaces: it presents two degrees or stages. In the first the black matter is so sparing in quantity that the serous membrane on which it is deposited presents an appearance as if it had been painted with ink, or stained with a deep brown or black colour. In the second the black deposit is more copious, forms a distinct layer on the surface of the serous membrane, above which it is seen to project. The consistence of the matter thus deposited resembles, in general, that of firm jelly, and is enclosed, as we have already said when speaking of the preceding form of melanosis, either in a soft spongy tissue, or fine transparent serous membrane of new formation; so that, when pressed, it feels pulpy, but is not removed by a scalpel being passed over it, unless some force is employed.

This form of melanosis is described by Andral and others as occurring frequently on the peritoneum in chronic peritonitis. Such, however, is not the case. The "*mélanoses déposées sous forme de couches solides à la surface des membranes,*" described by this author, is of a diametrically opposite nature to that which we are now discussing under the appellation of the *stratiform*. It is the result of the chemical action of certain fluids and gases, formed in general in the digestive organs, on the blood contained in the vessels of the pseudo-membranes of the peritoneum, or effused into the substance of the one, or on the surface of the other, as we shall endeavour to demonstrate when we come to treat of this mode of production of melanotic formations.

The stratiform melanosis of serous membranes has not been observed to any extent in man. In the horse it is sometimes considerable in degree and extent, and is chiefly found on the peritoneum, pleuræ, and pericardium.

4. *Liquiform melanosis.*—The appearance of melanosis in a liquid form has in general been confined to natural or accidental cavities, into which it has been supposed to be poured by a process somewhat analogous to that of secretion. This is certainly one of the modes to which its presence in these situations is to be attributed; but it is also owing, as we have already remarked, to the effusion of the same substance during the softening process of melanotic tumours; and it may also be observed that some of these tumours, when encysted, are found to be composed entirely of the black fluid or semi-fluid matter of melanosis. We shall, however, confine our description of the liquid form of melanosis as it occurs in natural or accidental cavities.

* Transactions of the Medico-Chirurgical Society of Edin. vol. i. p. 279, and Edin. Med. and Surg. Journal, vol. xxvii. p. 151.

Among the former, the cavities of the pleura and peritoneum furnish almost the only examples in which liquid melanosis has been observed, and that, too, in very small quantity. We have never seen it in man, and rarely in the horse.

The mucous cavities, particularly of the stomach and intestines, are mentioned by several pathologists as furnishing, not unfrequently, examples of the presence of melanosis under this form. But in this instance, as in those to which we have already more than once alluded, in which other forms of melanosis are supposed to have their seat in the mucous tissue itself, the same mistake has been committed: the blood, either effused into these cavities or contained in the vessels of their proper tissue, and having been submitted to the influence of an external chemical agent, being in general the *material* thus improperly denominated.

As an example of accidental cavities in which fluid melanosis has been found, we may mention the serous cysts which form in the ovaries, and the capsules of the ova which have escaped from these bodies.

Whatever form the melanotic deposit may assume, it is never, so far as we know, confined to one tissue or organ only; on the contrary, it is found to pervade a greater or less number of these simultaneously or successively; being, in some cases, equally extensive every where; in others, small in quantity in one organ, while in another it is so abundant, that hardly any of the natural texture is to be perceived. The tuberiform deposit is the most conspicuous and prevalent of all the forms which this morbid product assumes.

General characters of melanosis.

1. *Physical characters.*—These comprehend chiefly the colour, bulk, and consistence of the several forms of melanosis which we have described.

The *colour* of melanosis, whether in the solid or fluid state, although always tending to black, frequently presents various shades of brown, such as that of bister or China ink, having either the dull aspect of soot, or the glossiness of pitch. The deep black colour and glossy aspect is more frequently met with in inferior animals than in man; and in both, these appearances are most marked when the melanotic deposit exists in the form of a firm tumour. It is hardly necessary to observe that the quantity of cellular tissue intermixed with the melanotic matter, as well as the presence of a certain quantity of blood, give rise to a greater variety in the shade and depth of colour than this substance would otherwise present.

The *bulk* which the melanotic deposit may acquire is sometimes very considerable even in the human species. It may form irregular or lobulated masses in the cellular tissue as large or larger than the fist; and in parenchymatous organs, such as the liver, it acquires the bulk of a hen's egg, or even that of a small orange. In the cellular tissue, the larger masses are almost always produced by the union of smaller ones, although in one instance we found in this situation a single tumour as large as a hen's egg. In the liver, single tumors of a large size are more common than in any other of the compound tissues, or even the cellular tissue, for the reasons which we have already stated. In the horse, the aggregated melanotic tumor has sometimes been found to weigh from twenty to thirty and even forty pounds.

The *consistence* of melanosis, as we have already seen, presents great variety: there are two circumstances which seem to determine the degree of consistence which it is found to present when examined *in situ*: these are the *texture* and the *form* of the part in which the deposit takes place. Thus it is never found solid in large cavities, such as the abdominal and thoracic, for the plain reason that its diffusion is not limited by dense unyielding tissues. Even in tumours attached to the serous covering of these cavities, it is found for the same reason either perfectly fluid or not more dense than animal jelly. In loose cellular tissue too, one, two, or a limited number of cells, more or less distended into the form of small tumours, are occasionally found to contain the black matter in a fluid state. In the dense texture of the cutis, on the contrary, even the smallest tumours may be nearly as hard as cartilage, and are generally as firm as the pancreas. In the lymphatic glands, and in the brain, the melanotic tumour acquires only a medium degree of consistence, although it is generally firmer in the former than in the latter, on account of the capsule of the glands acting as a compressing cause. In the liver and lungs we perceive the same relation between the structure of these organs and the consistence of the melanotic tumours formed in them. In both they are pretty firm; much about the consistence of a lymphatic gland; from the black matter being contained either in the capillaries, molecular structure, or cellular texture of these organs.

It is an important fact that the conditions of texture and form, or of composition and conformation of the tissue or organ in which the melanotic deposit takes place, determine almost exclusively the degree of consistence which this morbid product, and indeed every other, presents when examined *in situ*. That absorption and imbibition exercise a certain influence in modifying, under certain circumstances, the consistence of this matter, cannot be doubted, inasmuch as they are known to give rise to very marked changes in the consistence of some other morbid products. We have, however, already shown that the operation of either of these modifying causes, as regards the consistence of melanosis, must be very limited, since there is always a direct relation between the consistence of this morbid product and the conditions of the tissues which we have named, in which it is received and retained. It is indeed from a knowledge of this pathological fact that we are led to believe that the *primary* condition of melanosis is that of a fluid, formed or collected in the capillaries and minute cellular areolæ, or combined with the solid or fluid elements of the body. If this fact is not admitted to be demonstrated by the

evidence which we have adduced, we should then be compelled to adopt, at least in part, the opinion of Laennec, namely, that melanosis is, *ab origine*, a solid accidental product: as to its being a *tissue*, as it was believed or said to be by the same author, we shall inquire by-and-by, when speaking of its anatomical characters. And to show that this mode of origin is not peculiar to melanosis, we may mention that tubercle, cancer, and every other morbid product can be traced to this their primary and fluid state of formation. In this respect, therefore, there is no difference between morbid and natural products. The law is the same in both: the hardest texture in the latter, namely, bone, being in its primitive state a mere jelly, as scirrhus and accidental bony formations are in the former. Even calculi do not form an exception to this law, the bile, urine, and other fluids, in a morbid state, constituting the primary forms of these bodies, before their respective elements become tangible to our senses by means of chemical agency; and as the last link in this chain of analogy, the blood—the *fons et origo vitæ*—may be regarded as the representative of the primary condition of organization in general.

Like all colouring matters in a fluid state, that of melanosis, when placed in contact with a white surface, communicates to it its peculiar tint, but the stain thus produced is readily removed by ablution. In its natural state, or when mixed with water, exposed to the air it becomes dry, brittle, and pulverisable, and does not emit the odour of putrefaction until after a long period. When burnt, it swells, gives out a great deal of smoke, a marked empyreumatic odour, and is converted into a carbonaceous substance. It is quite opaque, and has no marked odour or taste.

2. *Anatomical characters of melanosis.*—Several of the anatomical characters of melanosis have already been enumerated in the description which we have given of the different forms of this disease. When speaking of what is called the *encysted* melanosis, we explained the reason why this appellation had been employed, namely, that the single or aggregated masses of melanotic matter found in the cellular tissue are enclosed in and united together by a capsule of the same tissue stretched out by the gradual accumulation of this matter. This membranous covering (for it is not a cyst) is generally so thin and transparent that the black colour of the melanotic matter is hardly if at all obscured by it. If the tumour be simple, and a quantity of the black deposit has been washed out of it, a multitude of fine filaments and lamellæ are seen connected with the membranous covering of the tumour, traversing the substance of the latter in every direction, and presenting an appearance resembling cellular tissue when distended with serosity. When a number of tumours are united into one mass, they are included in a common capsule, and separated from one another by their respective coverings and portions of cellular tissue contained in the angular spaces sometimes left between them.

It is in these filamentous and cellular tissues alone, which are obviously not of new formation, that bloodvessels or nerves are to be seen. Minute arteries and veins can be seen ramifying in both, although they are rarely numerous, and we have never seen them pass beyond the limits of these tissues. Large branches and even trunks of arteries, veins, and nerves are sometimes found passing over the surface, or included in the aggregated masses of melanotic tumours.

There is a considerable difference as to the relative quantity of cellular tissue and melanotic deposit which constitute these tumours, when examined in man and in inferior animals. We have never found the melanotic tumour in the horse to contain much cellular tissue: indeed, it is sometimes impossible to detect its presence until after the tumour has been macerated and the black matter squeezed out, when there is found to remain a small quantity of extremely fine, soft, cellular tissue. In man, on the contrary, we have seen it at least equal in quantity to the black matter in tumours nearly as large as a goose's egg, formed in the subcutaneous cellular tissue. An example of this kind of melanotic tumour, which we had an opportunity of examining in the recent state, is now preserved in the Museum of the Royal College of Surgeons of Edinburgh, and a drawing of it is in the possession of Dr. Thomson, the distinguished Professor of Pathology in the university of that city. The cellular tissue was remarkably conspicuous, in some points almost as dense as fibrous tissue, formed bundles which intersected one another in various directions, and thus formed irregular cells of various dimensions, in which the melanotic deposit, of the consistence of fluid pitch, but without tenacity, was contained.

We have stated that the bloodvessels are confined in their distribution to the cellular tissue, which enters into the composition of melanotic tumours, and that they are never seen to penetrate the black deposit. There is, however, one kind of tumour, already alluded to, which is almost entirely formed of bloodvessels and a black or deep brown fluid. We formerly expressed a doubt whether this tumour should be regarded as one of the true melanotic kind, by reason of its anatomical composition being an exception to that observed in all others. This kind of tumour we have only met with once, and so far as we know there is only one other example of a similar kind on record. The subject of our case was an old man, between seventy and eighty years of age, brought to the Hôtel Dieu of Paris in a state of incomplete paralysis, and incapable of giving any account of himself. He lived several days; had little or no fever or excitement of any kind. The paralysis soon became complete and general, and he died in a state of collapse and profound stupor. On examining the body after death, black or deep brown-coloured tumours, two of which were as large as a hen's egg, occupied both hemispheres of the brain. One of them had made its way through the walls of the right lateral ventricle,

poured a quantity of the black fluid with which it was impregnated into this cavity, which had passed from thence into the opposite ventricle, the third and fourth, and along the spinal cord to its inferior extremity. Although these tumours were almost entirely surrounded by the medullary substance, they must have been seated originally on the external surface of the brain between the convolutions; for they were intimately connected with the pia mater, the bloodvessels of which constituted by far the greater part of their bulk. The bloodvessels were crowded together in parallel bundles at their exit from the pia mater, became tortuous in the substance of the tumours, some of them having nearly a line in diameter; were reflected backwards at their extremities in the form of irregular interlaced groups, towards which two or three small arteries coming from the pia mater were seen to distribute themselves. The black colouring matter of these tumours was very abundant, nearly as fluid as ink, and was contained not only in the loose cellular tissue which separated the bloodvessels from one another, but likewise in the vessels themselves. The veins (or large tortuous vessels described above) were completely filled with it, whilst the arteries, minute as they were, were distinctly seen to carry red blood. The medullary substance was slightly reddened and somewhat soft where it was in contact with one of the large tumours only. The cortical substance of the convolutions contained three or four melanotic tumours rather larger than hemp-seed. They were quite unconnected with the pia mater, were not composed of bloodvessels like the others, presented the usual consistence of melanosis, and contained but a minute quantity of cellular tissue.

Besides these black tumours—vascular and non-vascular—there was one of another kind, about the size of a small cherry, situated in the brown substance of the corpus striatum of the right hemisphere. Instead of being black, it was of a reddish grey colour, and was traversed by a great many minute vessels filled with red blood. It was nearly of the same consistence as the others, but, when pressed, discharged a small quantity of a milky or creamy looking fluid. After having been submitted for some time to ablution and gentle pressure, it assumed an appearance somewhat similar to that observed in the black vascular tumours: its tissue was of a spongy reticulated character, of a dull red colour, and vascular. There was no tumour of a similar kind in any other organ of the body; but as it participated in the characters of erectile and carcinomatous formations, we may mention at present that there existed a somewhat analogous disease of the right parotid gland. This body formed a large oblong tumour, composed of a substance partly of a scirrhous and partly of a mammary aspect and consistence, grouped into irregular masses of various sizes, surrounded by a considerable degree of ecchymosis. At its upper extremity and on a level with the ear there was a melanotic tumour of a firm consistence and homogeneous aspect, as large as a Spanish nut. This tumour had perforated the external auditory canal, and projected into its interior.

Black tumours, similar to those of the brain, were also found in the abdominal viscera. The duodenum contained one, the ileum five, and the epiploon one. In the intestines they appeared to be seated in the submucous cellular tissue, and formed the bottoms of black ragged ulcers occupying the mucous membrane. They were of a round or oval shape, flat, the largest of them about an inch in diameter. The one found in the epiploon was nearly as large as a walnut. It was attached to one of the prolongations of this covering, between which and the tumour there existed the same kind of vascular connexion as between the pia mater and some of the tumours in the brain: it presented likewise the same internal structure as the latter. Those which were found in the submucous cellular tissue did not present any peculiarity of structure.

The above description contains the most of the anatomical facts of any importance connected with this interesting case, which occurred under the care of Dr. Menière, while *interne* in the Hôtel Dieu, and to whom we feel much indebted for the opportunity he afforded us of examining and delineating the appearances we have described. When shewn to Baron Dupuytren, he pronounced the case to be one of melanosis, or, in his own language, *cancer noire;* his opinion being obviously founded on the *colour* of the tumours, without any regard to their *structure*.

Dr. Menière, on the contrary, who has had extensive opportunities of examining diseased structures, considered it to be a case of fungus hæmatodes, the vascular organization of the tumours constituting, according to him, the essential character of the disease; whilst the black colour was merely an accidental circumstance of very inferior importance. We ourselves are of opinion that neither of these notions is borne out by the anatomical facts of the case, as above related; and had we not already extended this part of our article beyond the limits usually assigned to descriptive details in a work of a practical nature, we should have furnished collateral evidence sufficient to shew that both opinions are exclusive, incomplete, and inaccurate. We shall, therefore, only make a few remarks with a view to our being justified in placing for the present this case in the division of *true melanosis*. And first, we have two or three melanotic tumours of the ordinary kind in the cortical substance of the brain; one in the parotid, or in a carcinomatous tumour found in that gland; to which we may add those of the intestines: we have here, therefore, as far as regards these tumours, a case of true melanosis. Secondly, there existed a large tumour behind the ear and in the parotid, presenting the most marked characters of scirrhus and cancer. Here, then, we have a case of cancer, but not of fungus hæmatodes. Thirdly, we have the black vascular tumours of the brain. The question is—did they present the anatomical characters of scirrhus, cancer, or fungus hæmatodes?

Certainly not. They were no doubt vascular, but must not on that account be identified with carcinoma or fungus hæmatodes, for the essential character of both of these was wanting, viz. a fluid resembling milk or cream, or a substance of the colour and consistence of brain; and, besides, carcinoma and fungus hæmatodes do not necessarily possess a high degree of vascular organization.

The production of the black vascular tumours of the brain may be accounted for as follows. The original state of these tumours we believe to have been the same as that of the small tumour situated in the corpus striatum, and which, we said, was of a compound nature, from its structure resembling that of erectile tumours, and the fluid it contained being similar to that which is found in carcinomatous tissue. The melanotic fluid, which we found deposited in the usual way, that is to say, in the form of small, dense, homogeneous tumours, in several points of the brain and elsewhere, appears also to have been deposited in these erecto-carcinomatous tumours, after they had acquired considerable bulk. Thus the black fluid which they contained, (which we have no reason for believing differed in any respect from that contained in those that were not vascular,) instead of being deposited in the form of a homogeneous mass, assumed the form and arrangement of the anatomical elements of these tumours, that is to say, was collected in the veins and cellular tissue of which they were composed. From these remarks on the origin and mode of production of the black vascular tumours of the brain, we do not hesitate to say that, in the strict sense of the term, they do not merit the appellation of true melanotic tumours, but that they ought to be considered as examples of melanosis taking place in a tissue of new formation, just as it is found to do in other tissues, whether healthy or diseased.

The other case of vascular melanosis to which we alluded is mentioned by Lobstein.* The patient was an emaciated old woman between eighty-five and ninety years of age. The inspection of the body was made by M. Alex. Lauth, and also delineations of the melanotic tumours. Besides melanosis of the spongy substance of the inferior third of the femur, there were several black tumours on the anterior region of the neck, and a large one in the inferior lobe of the right lung. The former appeared to be encysted; they were of a round form and lobulated; the most of them moveable under the skin, and were formed of a plexus of veins coming from the neighbouring veins, which became dilated as they approached the tumours. All these vessels, not only those which penetrated, but also those which formed the tumours, were filled with a deep brown substance, having, from the presence of an irregular filamentous tissue, an appearance of organization. In some of the veins, the substance which filled them adhered firmly to their internal surface, and seemed continuous with their tissue, although the latter differed from the former, from its being firmer and of a whitish colour.

The matter contained in the tumour in the lung was fluid, and as black as ink; it was infiltrated into the pulmonary parenchyma, which was reduced to a filamentous tissue. However, when minutely examined, this tissue was found to be composed of arteries and veins swimming in the melanotic fluid, and containing a quantity of it in their interior.

Although the author of this observation does not speak of any other morbid product having been found in the body, except a small horny excrescence on the left side of the thorax, we feel satisfied that the vascular tumours which he has described were precisely of the same kind as those of which we have just given a description. The most important circumstance in both cases was the presence of the melanotic matter within the bloodvessels of the tumours. In Lobstein's case it appears to have been contained in the arteries as well as veins, whilst in ours it was observed only in the latter. In either case the presence of melanosis in the blood is clearly demonstrated. Venous absorption might be considered by some sufficient to explain its presence in the veins; but it was also found in the arteries; and besides, we have already shewn that its existence in the veins of the hepatic tissue is prior to, and independent of, its presence in the cellular tissue, or its combination with the molecular structure of this organ.

3. *Chemical composition.*—The melanotic deposit in the fluid and solid state has been submitted to very minute chemical analysis in this country and on the continent; the uniform result of which shews that melanosis bears a strong analogy in its composition to that of the blood. The most complete analyses of melanosis that have been published are those of Lassaigne and Barruel* in France, and of Dr. Henry of Manchester.† We shall not enter into the details of the analysis of the melanotic deposit furnished by each of these able chemists, but shall content ourselves by giving the facts thus elicited, which seem to prove that the composition of this morbid product is very similar to that of the blood; referring the reader for further information to the works mentioned below.

Mons. Lassaigne found the melanotic tumour of the horse composed of—1st. coloured fibrine; 2d. a black colouring matter soluble in weak sulphuric acid, and in a solution of the subcarbonate of soda, each of which becoming at the same time of a red colour; 3d. a small quantity of albumen; 4th. muriate of soda, subcarbonate of soda, phosphate of lime, and oxide of iron. According to Mons. Barruel, melanosis of the human subject is essentially composed of the colouring matter of the

* Traité d'Anatomie Pathologique, tome premier, p. 461.

* Considérations sur une altération organique appelée dégénérescence noire, &c. Par G. Breschet, Chef des travaux anatomiques à la Faculté de Médecine de Paris, &c. &c.

† A case of melanosis, &c. by Thos. Fawdington.

blood, united with fibrine, both of them "*se trouvant dans un état particulier*," and three distinct kinds of fatty matter. The first of these is soluble in alcohol at a moderate temperature, crystallizable; the second soluble in alcohol at a boiling heat only, soft, and not crystallizable; the third fluid at the ordinary temperature of the air, and of a reddish-brown colour. This chemist found also a considerable quantity of the phosphate of lime and iron.

The following is the result of the analysis obtained by Dr. Henry from a portion of a softened melanotic tumour taken from Mr. Fawdington's patient, and after it had been kept some time in spirit:—

1st. By filtering through paper, much of the colouring matter remained on the paper, and the colour of that which passed through was much less intense.

2d. Boiling does not destroy the colour, nor even when a little caustic potash has been added.

3d. It is not changed by acids even when heated, except by nitric acid, which deprives it of its black colour, and turns it yellow.

4th. A stream of chlorine passed through the liquid destroys the colour, and throws down light fawn-coloured flocculi.

5th. A few grains of corrosive sublimate stirred up with the fluid precipitates the whole of the colouring matter, and leaves the supernatant liquid quite clear.

6th and 7th. Nitrate of mercury and muriate of tin produce the same effect, but more slowly. We may also mention that M. Foy* found in the melanotic tumour of the horse,

Albumen	15,00
Fibrine	6,25
A highly carbonized principle, probably altered cruor	31,40
Water	18,75
Oxide of iron	1,75
Sub-phosphate of lime	8,75
Muriate of potash	5,00
Ditto soda	3,75
Carbonate of soda	2,50

From the results of all these analyses it is sufficiently obvious that melanosis is essentially composed of the constituent elements of the blood. The colouring material of its composition appears, also, to bear considerable analogy to that of the blood, and is, according to Foy, a highly carbonized principle. Andral puts it as a query, whether the fatty substances found by Barruel belonged to the melanotic tumours analysed by this chemist, or to the tissues of the organ in which the tumours were formed! That these fatty substances may have become incorporated with the melanotic matter during its deposition is possible; but it must also be admitted that they may have been deposited along with it as constituents of the blood, inasmuch as it has been shewn by Lecanu* and by Dr. B. Babington, that this fluid always contains in the healthy state a certain quantity of fatty crystalline and oily matter.

Seat, nature, and origin of melanosis.—We must refer the reader to the preceding section for proofs that the material of which melanosis is composed is formed in the blood, and afterwards deposited in the various parts in which it is found. It is not only because this material is seen in the blood that we have fixed its *seat* in this fluid, but because our anatomical researches shew that it is there formed. The chemical analysis which we have given of this substance confirms the accuracy of this opinion, by shewing that it is essentially composed of the colouring matter of the blood. The separation of this colouring matter, as well as its deposition, in the form of melanosis, must be regarded as the result of a process similar to that of secretion. Several pathologists in France and Germany regard the carbonaceous material of melanosis as having its origin in a modification of the secretion of the natural pigments of the body, and more especially of that on which the colour of the hair and skin depends. This opinion was first entertained by Gohier,† who states that melanosis probably depends on the increase or diminution of some of the elements which enter into the composition of the body of the white and grey horse, or in some remarkable change in the nature of the secreted fluids. The carbon, says this author, which is found in melanosis, is too easily separated by calcination, to permit us to ascribe the colour of this disease to any other substance. Breschet afterwards pointed out the analogy which exists between the black matter of melanosis and that which colours the choroid, the uvea, the rete mucosum of Malpighi in the negro, and the placenta of certain carnivorous animals. He regarded, also, the colouring matter of several morbid secretions as of a similar nature, such as melæna, the black coating of the tongue in fevers, the fluids rejected by vomiting in yellow fever, &c.—an opinion which we consider to be by no means correct. A similar opinion is, however, entertained by Heusinger in his researches on the accidental production of pigments and carbon in the human body. The following are the deductions which this author gives as the result of his investigations:—1. that all the pigments secreted in the body in the healthy state are rich in carbon; 2. that the accidental pigments resemble the natural; 3. that the anomalous pigments are a modification of the colouring matter of the blood; 4. that their secretion is intimately connected with that of the fat; 5. that they announce the predominance of the venous system, the want of oxidation, and particularly the decarbonization of the blood. Some of these deductions, viz. that the secretion of the colouring matter of melanosis is intimately connected with that of the fat and

† Mémoires et Observations sur la Chirurgie et la Méd. Vétérinaire, Lyon 1813, tom. i.

the predominance of the venous system, do not appear to us to be supported either by the evidence brought forward by the author, or by such facts as have fallen under our own observation; for in the many cases of melanosis which we have seen in man and various kinds of animals, there did not appear to be any visible connexion between this disease, either with regard to its locality, degree, and extent, and the secretion of fat, or any state of the venous system in particular. The much greater frequency of melanosis in the grey and white, than in the bay, brown, or black horse, is a circumstance of some importanee, and which may he regarded as favourable to the theory which ascribes the origin of melanosis to the accumulation in the blood of the carbon which is naturally employed to colour different parts of the body, and more particularly the hair. This theory we are disposed to adopt, not only as regards the formation of the disease under these eircumstances of colour, but also when it occurs in animals of a dark colour, and in man indiscriminately, whatever may be the peculiar tint of the skin or colour of the hair. In the first instance, the colouring matter formed is not deposited in the regular physiological order; in the second it is formed in too great quantity. In both cases its presence and accumulation in the blood is accounted for. Its deposition as an anomalous product in various parts of the body follows, as we have already said, as a consequence of its separation from that fluid by a process of secretion.

Causes.—The above remarks anticipate the necessity of any further notice on what is called the *proximate causes* of melanosis. With regard to the *remote causes* of this disease, particularly the influence of external agents, it does not appear to us that our knowledge amounts to anything more than conjecture. We know that the development of colour in general is favoured by exposure to light, heat, and that combination of physical agents which constitutes the climate of warm countries; and that it is retarded by obseurity, eold, imperfect sourees of nutrition, &c. None of these facts, however, seem capable of affording us any explanation respecting the remote origin of melanosis, still less of its affecting one kind of animal rather than another. We should have observed before, that melanosis occurs most frequently towards the decline of life.

Progress of melanosis.—Under this head it is our intention to describe, 1st, the changes which take place in the melanotic deposit itself; 2nd, the changes induced by this deposit in the tissues and organs in which it is contained, or with which it is more or less immediately connected.

1st. *Changes produced in the melanotic deposit.*—Only two changes are observed to take place in the melanotic matter after its deposition. The first consists in the inspissation or solidification; the second in the softening or liquefaction of the melanotic matter. What we have already said on the various forms, the physical and anatomical characters of melanosis, will in a great measure enable the reader to trace these changes to their respective causes, and to explain the manner in which they are produced. We have, we hope, satisfactorily shewn that the material of which melanosis is composed exists primarily in a fluid form, and that every increase of eonsistence which it afterwards acquires, is owing ehiefly either to its combination with the moleeular structure, or the dense unyielding nature of the tissues or organs in which it is deposited. In the first instance, (examples of which were pointed out in the liver,) its consistence becomes eonsiderable; in the second, it acquires its maximum of density, of which its development in the eutis vera furnished us with the most striking examples. When retained in the vessels in which it is formed, it either remains in its primitive state of fluidity, (see our case of melanosis of the brain;) or it acquires a eertain degree of consistence, (Lobstein's ease of melanosis of the neck, &e. l. c.) We also found that when it is effused on the surfaee of the serous membrane, the degree of consistence which it afterwards acquires depends entirely on the development of an accidental serous or cellular tissue within which it is included. Its various degrees of consistence in eavities, viz. those formed in the cellular tissue by its gradual accumulation, are referahle to the same causes: the mechanical resistance offered to its diffusion by the tissues and organs we have named. These facts regarding the manner in which the solidification of the melanotic matter is effected, as well as the causes to which it is to be referred, appear to us so conclusive, that it would serve no good purpose were we to call in the evidence of analogy furnished us by the mode of development of other products of a similar and dissimilar kind, as farther proof of the accuracy of the opinion which we have just expressed.

From these facts it follows as a consequenee that the process of softening cannot take place until that of solidification has been at least earried to a eertain extent: perhaps it never does take place until it has been carried to its maximum. For the softening of the melanotic deposit is observed only when it has acquired the form of a tumour, or occupies an irregular portion of an organ. Under these eirenmstances, the softening of the hardened melanotic mass is effected in the two following ways: first, by the destruction of the tissues ineluded within it and around it; second, by the effusion of serosity caused by its stimulating power as a foreign body. The liver and lungs furnish the best examples of softening of melanotic tumours, from the destruction of the tissues in which they are formed. When a portion of either of these organs is occupied by the melanotie deposit which has so accumulated as to compress or obliterate the vessels contained within it, that pass through it, or ramify in its immediate vicinity, congestion or death of the parts to which these vessels are distributed, follows as a necessary consequence. Besides this cause of effusion, (congestion,) the stimulus of the melanotic tumour is now more partieularly felt, and the serous part of the blood

is poured out in abundance, which, mixing with the melanotic matter, converts it into a soft pulp, or a thin dark-brown or black liquid.

It were needless to insist farther on these changes, or to combat the opinion which Laennec entertained in regard to the manner in which he imagined the last process was accomplished: that melanosis is not a tissue, but an unorganizable fluid, capable only of a certain degree of solidification, must appear obvious to every impartial pathologist who has had an opportunity of observing it in the different tissues and organs in which it is deposited, and under the various forms which it assumes.

2. *Changes induced by the melanotic deposit in the tissues and organs in which it is contained, or with which it is more or less immediately connected.*—These changes are few in number, viz., *irritation*, *compression*, and *ulceration*.

We have just alluded to irritation as a consequence of the presence of masses of the melanotic deposit, and the subsequent afflux of blood to the surrounding parts. It is seldom carried to the extent of inflammation and ulceration; and when either of these occurs, it is almost always confined to the tissues in immediate contact with the melanotic masses.

Compression, we have also said, may be carried to such a degree by the gradual accumulation of the melanotic deposit, that circulation ceases in the cellular tissue in which this deposit is contained. The same thing also occurs in the cellular covering of melanotic tumours, and more particularly in the skin and mucous membrane of the intestines, when, from the bulk of the tumours, these tissues become more or less stretched. Hollow organs, such as veins, the rectum, and colon, are occasionally much compressed, nearly or entirely obliterated. These effects, however, are only observed when the melanotic tumours have acquired a great bulk, and are, therefore, much more frequently met with in the horse than in man.

Ulceration is not common as a consequence of melanosis, and in the cases in which we have observed it, it was obviously to be referred to the combined operation of the two causes mentioned above; compression, perhaps, having a greater share in its production than irritation. Thus we have only observed it in the skin and mucous membrane when greatly stretched by melanotic tumours situated beneath them. We have a very good example of ulceration of the mucous membrane of the intestines in our case of melanosis of the brain, &c.; and Breschet gives a case of ulceration of the skin of the groin produced by a large melanotic tumour situated immediately beneath it.* Ulceration of the skin, notwithstanding its great thickness, is more frequently seen in the horse. The writer of this article has related a case in which the ulceration was accompanied with suppuration, and which may be regarded as an example of ulceration from irritation rather than from compression and subsequent obliteration of the capillaries.* With regard to the melanotic ulcer, its form is sometimes regular, at other times very irregular; its edges thin, soft, beveled from within outwards, pale, or more or less red, or tinged with black, and a black fluid oozes from its surface. But if chronic inflammation supervenes in the tissues surrounding it, these tissues acquire a considerable degree of thickness from their being infiltrated with serosity and coagulable lymph. They thus become hard, and project around the orifice of the ulcer in the form of a broad everted border, or form on its internal surface a number of irregular projections or excrescences. When cut through, a grating sound is produced, and the cut surface presents a pale grey colour, such as is observed in scirrhus.

Ulceration from melanosis of other tissues and organs of the body has very rarely been met with. Bayle relates two cases of what he conceives to be ulceration of the lungs as a consequence of the softening of melanosis,† and which are considered in the same point of view by Laennec.‡ But we agree with Andral in thinking that they were cases of tubercular excavations or dilatations of the bronchi, the pulmonary tissue around them being the seat of chronic inflammation, and infiltrated with what is called black pulmonary matter.

Symptoms and diagnosis of melanosis.—Among the various modifications of function to which melanosis gives rise, we do not believe that the most careful examination will enable the physician to perceive in any one of them a sign of the existence of this disease in internal organs. It is only when melanosis makes its appearance externally, that he can hazard an opinion that any derangement of function is owing to its presence in one or more internal organs; that oppression and difficulty of the respiration are produced by a similar disease of the lungs, when, by means of auscultation and percussion, he finds that certain portions of the lungs are impervious to the air, without having become so by any other disease with the characters of which he is acquainted; and that ascites and œdema of the inferior extremities are in all probability the consequence of compression of the portal system of the liver, from the presence of melanotic tumours in that organ. The presence of black sputa in the first case may, under certain circumstances, afford him some assistance in establishing his diagnosis; as its quantity, and its appearance at the time that one or more of the supposed tumours in the lung have been observed to soften.

Vomiting and dejections of black matter do not afford any evidence of the existence of melanosis either in the stomach or intestines,

‡ Traité d'auscult. médiate, &c. tom. ii. p. 31.

or any other organ. The same may be said of the state of the pulse, temperature, and nutrition in general. In some cases the pulse and temperature have assumed a febrile character, and the patients become lean, pale, or sallow; changes which may be attributed to the mere mechanical presence of a great quantity of the melanotic deposit in important organs, thus operating on the one hand as a morbid stimulus, and on the other preventing the blood from undergoing various important changes. Melanosis does not appear to give rise to pain except where nerves have been impacted within, or compressed by it in some unyielding cavity. It is for this reason that the eye is generally the seat of pain in melanosis.

Prognosis.—Under whatever circumstances this disease may present itself, it ultimately proceeds to a fatal termination. It is sometimes developed with considerable rapidity, and when it occupies important organs, such as the brain or lungs, the life of the patient is seldom prolonged beyond a few weeks or months. The fatal effects of the disease are also retarded or accelerated by its extent; being greatly accelerated if it occupies the greater part or the whole of an organ, or a great number of organs at the same time, which is frequently the case, and retarded if limited to one organ or tissue. But we must again repeat that, however favourable the circumstances may be under which it first announces its existence, its tendency is to increase and ultimately to prove fatal.

Treatment.—From what we have said of this disease, it is but too obvious that any mode of treatment that can be adopted must be only palliative in its effects. To have pointed out, so minutely as we have done, the physical, anatomical, and chemical characters of melanosis, in order to show that it originates in a modification of secretion of a carbonaceous pigment analogous to the colouring matter of the blood, may, therefore, appear to the reader to be a waste of labour and of time; but we must remind him that there are a host of diseases the treatment of which is founded on no surer grounds, and respecting the history of which we know much less than we do of that of melanosis. In this respect, therefore, the scientific practitioner will at least have the advantage of being able to give a satisfactory reason for the mode of practice which he may think proper to adopt in the treatment of this very remarkable disease.

II.—Spurious melanosis.

A. *From the introduction of carbonaceous matter.*— Although certain forms of black discoloration of the pulmonary tissue were supposed by Laennec to originate in the inhalation of the carbonaceous product of ordinary combustion, an opinion which was previously entertained by Mr. Pearson,* there was no recorded fact that could be regarded as furnishing undeniable evidence of the accuracy of this opinion till lately, when a case of this kind occurred in a patient admitted into the infirmary of Edinburgh. The medical public are indebted to the late Dr. J. C. Gregory, who had charge of the patient, for the history of the case, the description of the post-mortem appearances observed in the body, and particularly in the lungs, together with the results of the chemical examination of the black matter found in this organ.* The following are the morbid appearances which were found in the lungs of this patient after death: "Both lungs presented one uniform black carbonaceous colour, pervading every part of their substance. The right lung was much disorganized, and exhibited in its upper and middle lobes several large irregular cavities, communicating with one another, and traversed by numerous bands of pulmonary substance and vessels. These cavities contained a good deal of fluid, which, as well as the walls of the cavities, partook of the same black colour. A considerable portion of the pulmonary substance surrounding them was dense, hepatized, and friable. The rest of the lung was also somewhat condensed, and very œdematous. The serum, when expressed, was of the same black colour as the substance of the lung. The left lung did not appear to contain any cavities, but was condensed, and loaded with black serum. Some minute hard points could be felt in various parts of both lungs, but they did not differ at all in colour from the surrounding substance; and no distinct tubercular deposition or infiltration could be detected in those portions of the lungs which were most hepatized, even with the aid of the microscope. The texture in these parts appeared quite uniform, and the minute hard points felt in other parts rather conveyed the impression of their being merely the ends of small bronchial branches divided in making the section. The bronchial glands did not appear enlarged, but partook of the same black colour as the substance of the lungs." No other organ of the body presented any trace of this black discoloration. As a minute analysis of the black matter contained in the serum which was expressed from the substance of the lungs was made by Dr. Christison, we shall offer no apology to the reader for giving, in his own words, the results which he obtained.

"1. Concentrated nitric acid boiled on it did not alter the colour.

"2. Immersion in a strong solution of chlorine had also no effect.

"3. A strong solution of caustic potass boiled on it took up some animal matter, and filtrated very slowly. The first part which passed through was opaque and black; but the last portions were of a pale yellowish-brown colour, and transparent; so that none of the black matter was dissolved. The black matter remained in the filter, and this, well washed and dried, burned like charcoal powder, without swelling up, and with scarcely any animal empyreuma, leaving a considerable pale-grey ash.

* Philos. Trans., 1813, part ii.

* Case of peculiar black infiltration of the whole lungs, resembling melanosis, by J. C. Gregory, M.D. &c. Edin. Med. and Surg. Journal, No. 109.

"4. A small portion of black powder, left after the action of boiling nitric acid, was well washed, dried, and introduced into a minute glass ball, with a tube attached, which was subsequently drawn out, by means of the spirit-lamp flame, to a fine bore. On the application of a low red heat to the ball, there was disengaged, at the open end of the tube, a considerable quantity of gas, which had the odour of coal-gas, and on the approach of a light, took fire and burned with a dense white flame. In the tube a dark yellow fluid likewise condensed, which had very exactly the odour of impure coal-tar naphtha, and became a soft mass on cooling, of the consistence of lard. This, when compressed between layers of filtering paper, yielded an oily stain to the paper, and left a white matter, which dissolved in boiling alcohol, and separated again on cooling, in the form of minute obscure crystals."

"In the product of this experiment," says Dr. Christison, "it is scarcely possible not to recognise the ordinary products of the distillation of coal. A gas of the same quality was procured, and likewise a naphthous fluid, holding in solution a crystalline principle, analogous to, if not identified with, naphthaline."

The history of this case, the morbid appearances found in the lungs, and the results of the chemical analysis of the black matter in particular, do not permit of a doubt as to the origin and nature of the black discoloration of the lungs in this interesting case. The profession of the patient, which exposed him to the habitual inhalation of the coal-dust always contained in the atmosphere of a mine, and the black matter found in the lungs consisting essentially of this substance, are circumstances which demonstrate clearly the origin of the black matter, and its identity with the carbonaceous powder inhaled with the air in breathing. Besides these circumstances, the non-existence of any kind of black discoloration in any other organ of the body would furnish a strong reason for our not regarding this case as one of true melanosis. We have, indeed, never seen, nor do we know of, a case of melanosis occupying the greater part of an organ, without other organs being simultaneously affected to a greater or less extent with the same disease. Aware of this fact, we have always entertained doubts regarding the real nature of a case of black discoloration of the lungs which we had an opportunity of examining several years ago, which occurred in a middle-aged man, who was an out-patient of the Old Town Dispensary of Edinburgh. He was attended by Dr. Probart of Bury St. Edmunds, who was then in Edinburgh, along with whom the writer of this article examined the body after death. The morbid appearances observed in the lungs were in almost every respect the same as those that have been detailed in the preceding case. The whole of both lungs was perfectly black; in many parts indurated and œdematous; in others softened and excavated. There were no tubercles, nor was there any similar discoloration in any other part of the body.

Dr. Allen Thomson has informed us that he has likewise seen a similar case of black discoloration of both lungs. No analysis of the black matter in either of these cases was made; and besides, not having been able to ascertain the profession of either of the patients, our opinion with regard to the origin and nature of the black discoloration of the lungs in both cases must be founded entirely on the anatomical facts to which we have alluded, viz. the universal black discoloration of both lungs, and the non-existence of any similar discoloration of any other organ or tissue of the body.

It is surprising that no case of universal black discoloration of the lungs produced by the inhalation of carbonaceous matter is to be found on record previous to that of Dr. Gregory, when we reflect that so many individuals are daily exposed in this country to the cause by which it is produced. We can hardly attribute this silence, on the existence of such a conspicuous morbid state, to the paucity of post-mortem examinations. Is it not more probable that the accumulation of the carbonaceous matter in the lungs is determined by a morbid state of these organs? — that, although carried into the lungs with the air, it is removed by expectoration or absorption, and its accumulation in these viscera thereby prevented? We are, indeed, much disposed to believe that these circumstances must tend to favour or prevent the occurrence of this diseased state of the lungs. In the cases referred to we have not been able to ascertain that there existed any particular morbid state of the lungs which could have prevented or favoured the accumulation of the inspired carbonaceous matter. We, however, consider it a subject worthy the attention of the medical practitioner who has the opportunity of studying the diseases of persons employed in coal-mines, whether the black discoloration of the lungs is observed to occur in those only who have suffered from pulmonary complaints; although it may be often difficult to discriminate between cause and effect, between the original disease, and the changes which must take place in the structure and functions of the lungs from the presence of the inspired carbonaceous substance.

Symptoms.—The symptoms presented by Dr. Gregory's patient as well as our own, were referable to the presence of the inspired carbonaceous matter, acting, 1st, mechanically, and giving rise to atrophy of the pulmonary tissue, compression and obliteration of the air-cells, bronchi, and bloodvessels; and, 2d, as a foreign body, producing a greater or less degree of irritation. To these modifications of the pulmonary organs are to be ascribed the local symptoms, such as the dyspnœa, cough, the mucous and cavernous *râles*, and the increased secretion and expectoration of mucus. The presence of black matter in the expectorated fluids was no doubt to be attributed to the existence of a direct communication between some of the bronchi and the excavations formed in the substance of the lung.

Although there were also softening and excavation of the lungs in the case which we examined, it does not appear from the account which we have received of the history of the case, that the sputa were discoloured by the admixture of black matter; and as it is stated that the mucous *râles* heard in this case were remarkably strong, but not *cavernous*, it may be presumed that the absence of the black matter was owing to there being no communication between the bronchi and the softened or excavated portions of the lung, or that the solidification of this organ was so great from the presence of the carbonaceous matter, that the former did not admit of being sufficiently compressed to expel any of this substance with the mucous secretion of the bronchi.

The general symptoms produced by the accumulation of the carbonaceous matter in the lungs were chiefly the general cachectic condition of the body, and anasarca, both of them depending on the state of the pulmonary circulation. The great diminution in the quantity of the blood admitted into the lungs, which must necessarily have followed the presence of such a quantity of foreign matter in this organ, as well as the imperfect change which must have been effected in that which was allowed to pass through the pulmonary vessels, will sufficiently explain the cachectic state of the patient. The anasarca must also be attributed to the same cause, viz. the presence of the accumulated carbonaceous matter, and its mechanical effects on the pulmonary veins, thereby giving rise to general venous congestion and effusion of serosity into the cellular tissue.

Diagnosis.—Being in possession of such a limited number of facts in regard to this singular, if not rare, affection of the lungs, we should not feel justified were we to assign to it characters by means of which it may be distinguished from certain organic affections to which the same organs are subject. We, indeed, know of no modification of function, local or general, by means of which this form of spurious melanosis is to be distinguished from true melanosis of the lungs. We may, however, suggest that, as the former pervades the whole of both lungs, dyspnœa may be greater than in the latter, which always leaves a portion, and often a considerable extent of lung in the healthy state;—that respiration will be found to be natural, or nearly so, in several portions of the lung affected with true melanosis; whilst in the spurious form of the disease, depending on the universal deposition and accumulation of inhaled carbonaceous matter, the respiratory sound, or at least the respiratory *murmur*, that which takes place in the air-cells, will either be greatly obscured or inaudible, and will be replaced by *bronchial* respiration, the *ronflement* and *sonorous râles* which accompany the solidification or condensation of the pulmonary tissue. We need hardly mention that the presence of black matter in the sputa cannot be regarded as a *pathognomonic* sign, unless its real nature has been determined by chemical analysis.

The only other disease with which this spurious form of melanosis is likely to be confounded, is chronic catarrh. We are, however, disposed to believe that the presence of anasarca, as well as the dull sound of the chest on percussion, will be sufficient to enable us to distinguish the former disease from the latter, in which the sound of the chest is not materially affected, and which is not accompanied with anasarca, unless it be complicated with disease of the heart. The emaciation, diarrhœa, and hectic, which accompany phthisis, will prevent the physician from confounding this disease with spurious melanosis of the lungs, even when the latter has given rise to softening and excavation of the pulmonary tissue.

Treatment.—Imperfect as the description may be which we have given of the changes produced in the structure and functions of the lungs, originating in the inhalation of carbonaceous matter, and in its accumulation in these organs, it is sufficiently obvious that neither the local effects to which the presence of this foreign substance gives rise, nor the general disturbance of nutrition and circulation which follows as a consequence of the former, can be remedied so long as the offending cause remains. How far the removal of this can be accomplished by means of remedies which act chiefly on the absorbent system, is a point which remains to be determined by future observation and experiment.

If the disease has proceeded to such an extent as to produce general atrophy of the pulmonary tissue, softening and excavations in various portions of the lungs, its fatal termination must be inevitable. We cannot, therefore, too strongly impress on the mind of the physician who has the opportunity of doing so, the importance of ascertaining the early signs of this affection, as well as the influence which other diseases may have in favouring its production, as a knowledge of both circumstances will suggest the means to be employed either for its cure or the prevention of its occurrence.

B. *From the action of chemical agents.*—The next kind of melanotic formation which we have to describe is that which is produced by the action of certain chemical agents on the blood.

Our attention was for the first time drawn to this subject nearly three years ago, while making a series of experiments on the chemical dissolution or digestion of the walls of the stomach after death. With regard to the subject of these experiments, it is necessary to observe that the partial or complete dissolution of one or all of the coats of the stomach was found to take place after death, and to be the invariable consequence of the chemical action of an acid fluid contained in the cavity of that organ. A peculiar change in the colour of the blood contained in the veins of the stomach was also observed to accompany the chemical dissolution of the walls of that organ, and which, though less frequent in its occurrence than the latter, was not the less obviously the effect of the same

chemical cause; for, firstly, there was no discoloration of the blood when there was no softening or chemical dissolution of the coats of the stomach: secondly, the discoloration of the blood was observed only in the vessels distributed, or near, to those parts of the stomach which were softened: and thirdly, that both changes were, *cæteris paribus*, nearly in the same ratio as to degree and extent. Although these circumstances might have been regarded by us as affording sufficient evidence that the discoloration of the blood was produced by the direct operation of the same chemical agent by means of which the dissolution of the walls of the stomach was affected, we made several experiments on this interesting and important subject, the results of which leave no doubt as to the accuracy of our former conclusion,—viz. that the discoloration of the blood which accompanies the chemical dissolution of the walls of the stomach is a direct effect of an acid fluid contained in the cavity of that organ, or, as we shall afterwards call it, the gastric acid.* If we kill an animal, a rabbit for example, or open it while alive, and during the process of digestion, the fundus of the stomach is always found to contain a quantity of this acid, mixed with the food in this the depending part of the organ. When the stomach is laid open, a sour smell is immediately perceived to arise from its contents; and if a portion of litmus paper is placed in contact with the latter, it acquires, almost instantaneously, a beautiful red colour. If arterial or venous blood is allowed to flow into the stomach from some of the neighbouring vessels, so soon as it comes in contact with the digested portion of the food, or that in which the gastric acid is most abundant, its natural colour is almost immediately changed to deep brown or black. The rapidity with which this change takes place in the colour of the blood, as well as the degree and extent to which it proceeds, varies with the strength of the gastric acid and the quantity of the blood on which it is made to act. When the digested acid food, or the gastric acid alone, is removed from the stomach in which it was found, and is put into another stomach, or other organ, the vessels of which are conspicuous and filled with blood, this fluid very soon undergoes the same change of colour which we have said takes place when it is poured upon the digested food, and, consequently, when in immediate contact with the chemical agent by which this change is effected.

These facts shew clearly that healthy blood contained in the cavity of the stomach, or in the vessels of that organ, in a dead animal, is changed to a dark brown or black fluid. But the influence of the gastric acid in producing this change in the blood is not limited by the conditions to which we have just alluded. Not only is the blood that has been poured into the cavity of the stomach, or is contained in the vessels of the mucous and submucous tissues, changed from red to brown or black, but likewise that of the sub-peritoneal vessels of the same organ is similarly altered. We have also seen the same black discoloration of the blood in the sub-peritoneal vessels of a neighbouring organ, such as the liver, spleen, intestine, or diaphragm, in contact with that portion of the stomach which contained half-digested food or gastric acid. Hence we can readily conceive that if blood is effused into the cavity of the peritoneum, and in the vicinity of the stomach, it will undergo the same change of colour as that which we have said takes place in this fluid when contained in its proper vessels beneath this membrane. We have produced effusion of blood into the cavity of the peritoneum around the stomach, in several animals, and have thus been able to witness its conversion from red to brown or the deepest black.

The discoloration of the blood in these situations external to the stomach, and depending on the influence of the gastric acid, is an interesting fact, with the nature and origin of which we were entirely ignorant until we observed the effects of this chemical agent on the blood contained in the vessels of the stomach. It is perfectly obvious, from what we have said, that we have, in both cases, the same efficient cause. We have taken a portion of stomach containing gastric juice, placed it on a coagulum of blood, or kept it in close contact with a portion of intestine on which there was a greater or less number of vessels filled with red blood. In both cases the blood assumed a brown or black colour, no doubt from the acid having been carried from the interior of the stomach by imbibition.

There is still another mode in which the black discoloration of the blood may be produced by the gastric acid, viz., when this fluid is effused into the cavity of the peritoneum through an opening which it has made, generally in the fundus of the stomach. It occupies the most depending parts, dissolves the tissues with which it comes in contact, perforates the diaphragm, and passes into the cavity of the thorax. Along with these remarkable effects of the gastric acid, the black discoloration of the blood is no less conspicuous in all the parts on which its chemical influence has been exerted.

Such is a very general sketch of the several modes in which the black discoloration of the blood is produced, when this fluid is exposed to the mediate or immediate influence of the gastric acid. We have already stated that this condition of the blood was not produced till after the death of the animals submitted to our experiments; that these animals were in the enjoyment of the most perfect state of health when killed; and that the gastric juice possessed that property—acidity—by which it is always distinguished during the act of digestion. These facts are the more important when we consider that they establish the formation of a series of changes in the blood after death,

* We employ the term *gastric acid*, because it indicates the seat, and, particularly, the *property* of the chemical agent by means of which the dissolution of the walls of the stomach, and the black discoloration of the blood in that organ, are produced.

which are entirely independent of any morbid condition, local or general, of the animal in which these changes are observed. It is necessary, however, to state that there are two conditions in which the blood may be placed during life, which render it susceptible of being acted upon by the gastric acid: first, when it has ceased, during an uncertain period of time, to circulate; secondly, when it is effused into the cavity of an organ. In both circumstances it is deprived of those properties by means of which it is enabled to resist, to a certain degree, the destructive influence of external agents; and, therefore, undergoes the same changes when submitted to the action of the gastric acid as it does after death.

Locality and order of frequency of the black discoloration of the blood, from the operation of an acid chemical agent.—As the black discoloration of the blood of which we are now treating is produced by the operation of an acid chemical agent, it is consequently met with only in those organs in which this agent exists as a healthy or morbid product, or to which its influence extends in the manner which we have already stated. Hence, as the stomach is the only organ of the body in which an acid fluid is formed, and is at the same time a healthy product, the black discoloration of the blood is no where so frequently observed, so conspicuous, and so extensive as in this organ. The same discoloration of the blood, as to locality and order of frequency, occurs in the intestines, from the anormal formation of a fluid and gaseous acid product. It is owing to the proximity of the peritoneum to these normal and anormal acid products, that blood situated beneath this membrane on its free surface or in its cavity undergoes so often the change of colour in question; and it is to the same circumstance of situation that portions of the liver and spleen are so frequently found to present the same dark colour. The dark discoloration of the blood in the intestines and in the other situations just named, depends, perhaps, more frequently on the presence of sulphuretted hydrogen gas than an acid fluid in the former, owing, no doubt, to this gas possessing the properties of an acid.

Natural and accidental tissues, remote from the stomach and intestines, are also observed to present various kinds of discoloration; but we allude to those which chiefly depend on the presence of various shades of blue, brown, and black. The blue discoloration, which is sometimes very deep, approaching to black, is most frequently observed to occupy the walls of chronic abscesses in various parts of the body. It is not the consequence of putrefaction, but is produced by the presence of a chemical agent, the nature of which we have not been able to ascertain. The brown and black discolorations are observed to accompany the death of parts, preceded or followed by a local accumulation of blood. It is probable that they also sometimes originate in the formation of an acid product, which afterwards acts upon the blood; although they are certainly owing, in general, to changes which take place in the blood itself of the dead part, for which reason we shall refer them to the fourth division of our subject, which contains the description of the black discoloration of the blood from stagnation of this fluid, and the subsequent changes which it undergoes.

Form, situation, and extent of the black discoloration of the blood.

1. *In the vessels of the stomach.*—The blood which undergoes this change of colour derives the peculiarity of the forms which it assumes from its being contained in its proper vessels. The three following forms are the most conspicuous: the punctiform, uniform, and ramiform. All these forms of black discoloration of the blood are met with either separately or combined, and may occupy a portion or the whole surface of the stomach. They are most frequently observed in the fundus of the stomach, for the reasons already assigned; but they may exist in other parts of this organ, as the pyloric portion, small and great curvatures, to which external causes, such as tumours, distention of the colon, enlargement of the spleen, &c. have given a more depending position than that of the fundus, consequently favouring the accumulation of the gastric acid in these parts after death. The situation of these forms of black discoloration of the blood is also modified by the quantity and quality of the contents of the stomach. Thus, if the stomach is nearly empty, the discoloration of the blood is confined to the surface of the rugæ formed by the mucous membrane; and if it is distended by a quantity of gas, the discoloration is limited to the depending part of the organ, and terminates in a defined margin, the course and extent of which are determined by the superposed gas, which has prevented the gastric acid from acting beyond the limits within which it was thus confined. And, lastly, if the stomach is filled with gastric acid, as sometimes happens in stricture of the pylorus, the whole surface of the mucous membrane may present a uniform dark brown or black tint.

With regard to these three forms of the black discoloration of the blood in the vessels of the stomach, it is only further necessary to observe, that although the punctiform and uniform are more frequently produced than the ramiform, on account of the small veins being more often filled with blood than the large ones, the ramiform is most frequently seen; a circumstance which is owing to the mucous membrane and the minute veins within it and beneath it being sooner dissolved by the gastric acid than the large veins. In the punctiform discoloration of the blood, the mucous membrane presents an appearance as if it were dusted over with a quantity of fine charcoal powder; and when the discoloration is uniform, it appears as if painted with bistre or china ink, in the form of patches or streaks of various forms and dimensions. The ramiform discoloration is generally the most conspicuous and striking of the three, because of the black blood being contained in veins of considerable size. They appear as if they had been injected

with chocolate or a mixture of soot and water. The dark blood presents a *curdled* appearance. It does not fill the veins, but is separated and agglomerated into small masses, which become gradually less towards the minute branches, and there appear in the form of black points, having still a ramiform distribution, but are no longer contained within the walls of the veins, the former having been dissolved by the gastric acid. This is the form of the black discoloration of the blood which we have said has been described as examples of melanosis of this fluid,—an opinion which we hope the preceding details have shewn to be erroneous.

2. *Black discoloration of the blood in the vessels of the intestines.* From what we have already said of this change of the blood in the vessels of the stomach, we have only to add that it is less frequently observed in those of the intestines, is seldom so conspicuous, and that it assumes in general the punctiform arrangement. This character of the black discoloration in the intestines is owing to the change of colour taking place in the blood contained in the vessels of the villosities or isolated follicles. The black punctiform discoloration is sometimes observed to occupy the mucous membrane of the greater part of the intestines, both large and small; but we believe it is most frequently seen in the inferior portion of the ileon and in the duodenum.

A similar discoloration of the blood in the vessels of the villosities and isolated follicles is met with in various portions of the intestines in particular, and which is not produced by the action of an acid on the blood. It is the consequence of stagnation, and is not to be distinguished from the former otherwise than by ascertaining the nature of the contents of the intestine in which it is observed.

3. *Black discoloration of the blood effused into the cavity of the stomach and intestines.*—The fact of the black discoloration of the blood effused into the cavity of the stomach and intestines being produced by the chemical action of an acid fluid or gas contained in these situations, does not appear to us to have been even suspected till after the results of our experiments on this subject were made known. If we consult the works that have been published on melæna, (a disease characterized by the presence of black matter in the fluids ejected from the stomach and bowels,) we shall find that the opinions therein expressed, in regard to the black discoloration of the blood in this disease, were founded on mere conjecture.

By some pathologists the black discoloration of the blood was believed to take place in the venous system; by others, that it was not effected till after the blood was effused into the cavity of the stomach or intestines, and that the red colour of the blood was then converted into black by the fluid or gaseous contents of these organs. The latter opinion was, however, entirely conjectural, such conversion of the blood never having been *seen* to take place. Notwithstanding the importance of the subject, it was never submitted to the test of experiment. The matter of black vomit and dejections was *believed* to be blood *altered* in the stomach and intestines, but whether by a chemical or vital agent was quite undetermined. From the results which we have given of our experiments on this particular point at the commencement of this article, it must appear obvious that blood effused into the cavity of the stomach is almost immediately converted into a deep brown or black colour, and, moreover, that this change of colour is owing to the presence of a chemical agent; that this agent is an acid, similar in all its properties to that by means of which the dissolution of the food during digestion is accomplished. We have also stated that, if this acid fluid is not present, as is frequently the case, no such change of the blood introduced into the cavity of the stomach takes place—it preserves its natural colour: and, again, that if the quantity of the blood be so considerable as not to be acted upon uniformly by the acid, only a portion of it is black, whilst the rest is of its natural colour. These circumstances relative to the presence or absence of the gastric acid, and the quantity of blood submitted to its action, appear to us to furnish the most satisfactory explanation of the essential phenomena of melæna. They further shew that there is, properly speaking, no difference between this disease and hematemesis. Both of them originate in the effusion of blood, no matter how produced, whether by exhalation or a solution of continuity. In the latter the blood preserves its natural colour; in the former it is black, because of the reasons just stated—the presence of an acid in the one case, and its absence in the other. On these circumstances alone can the pathologist be justified in making a distinction between hematemesis and melæna.

As this part of our subject is, as we have seen, intimately connected with the latter disease, we shall only further add, that the black discoloration of the blood in the stomach is found to accompany cancer of this organ much more frequently than any other disease. Black vomit almost always accompanies the last stage of this disease,—that is to say, the stage of softening, because of the hemorrhage which then takes place. Next in the order of frequency is follicular ulceration of this organ. In the intestines follicular ulceration is by far the most frequent change which is observed to accompany black dejections. In both organs the ulceration of the follicles is sometimes so extremely limited that it is not perceived until after the mucous membrane has been well washed and exposed to a strong light, when it is seen to occupy the central portion or orifices of the follicles in the form of a red point, with an irregular circumference, probably the ulcerated border of the orifices of these follicles. Next in the order of succession are the numerous diseases of the heart and its orifices, and several of those of the liver and vena portæ, which obstruct mechanically the return of the venous blood, and thus determine its effusion from the digestive mucous membrane. And, lastly, we have met with the same dis-

coloration of the blood in individuals the most feeble and emaciated, in whom this fluid appeared to have almost entirely lost that plastic property on which its coagulation depends, and by means of which its effusion is prevented when accumulated in the capillary system.

The black discoloration of the blood in the vessels of the stomach, produced by the gastric acid after death, is a subject of the greatest importance to the toxicologist, particularly when considered in connexion with the effects which result from the operations of all poisons possessing acid properties on the blood. Although we have directed our attention to this subject, and have been able to ascertain that several of the changes produced in the blood under these opposite circumstances are so characteristic as to afford us the means of determining their nature and origin, we are prevented from making any further allusion to them, because of the minute descriptive details into which we should be obliged to enter, were we to attempt to put the reader in possession of the means whereby he might distinguish post-mortem from pathological black discoloration of the blood in the digestive organs. We must therefore refer him for further information on this subject to the article PSEUDOMORBID APPEARANCES.

4. *Black discoloration of the blood on the surface or in the cavity of the peritoneum.*—As we have already alluded to the manner in which the black discoloration of the blood takes place in these situations, we shall only notice a few circumstances of importance with regard to its seat, and the lesions which it most frequently accompanies.

We have already said that it is met with in the vessels which ramify under the peritoneum; but it is more frequently seen in those which exist in the false membranes of chronic peritonitis. When the blood is effused into the sub-peritoneal tissue, on the surface of the peritoneum, into its cavity, or into false membranes, the black discoloration which it undergoes is remarkably conspicuous, and frequently occupies a great extent of surface. It is only when the discoloured blood is contained within its vessels that it presents, in the situations just named, a ramiform distribution. There is, however, a peculiar modification of this form which requires to be noticed. It occurs in chronic tubercular peritonitis. The tubercles, scattered over a greater or less extent of the peritoneum, are surrounded by a dark ring, or a multitude of minute vessels filled with black blood, having a stellated arrangement. If the tubercles are very minute, they are obscured by these appearances, and the peritoneum seems as if spotted with a deep brown or black pigment, which has been described as melanosis of the peritoneum.

The black discoloration of the blood when effused on the surface of the peritoneum or into false membranes, has still more frequently been taken for melanosis, and described as such. It then assumes the appearance of black patches, striæ, or layers of various extent, occupying either the visceral or abdominal portions of the peritoneum, or both at the same time. If the effused blood has collected in the cavity of the peritoneum, it undergoes the same change of colour which we have seen takes place in the blood effused into the cavity of the stomach and intestines. The external portion of the blood, or that which is in contact with the peritoneal surface of the intestines, is always deepest in colour, being sometimes as black as pitch; whilst that which is more remotely situated is either of its natural colour, or but slightly darkened. From these circumstances, and from what we have already said on the effects of the acid fluid and gaseous contents of the stomach and intestines, there can be no doubt that the black discoloration of the blood contained in the cavity of the peritoneum is owing to the chemical operation of these products. In confirmation of the accuracy of our opinion on this point, we may mention that we have had several opportunities of seeing the blood effused into the cavity of the peritoneum undergo the change in question, in individuals who died from hæmorrhage in consequence of wounds of the abdominal viscera. Although the description which we have given of the forms, situation, and extent of the dark discoloration of the blood in the digestive organs and in those situated in their immediate vicinity, will in general enable the practical pathologist to recognise them in his post-mortem examinations, we would recommend him in all doubtful cases to *test* the contents of the former organs. A sour smell may not be always sufficiently strong to be perceived; and besides, his having determined (by means of litmus paper for example, some of which he should always have in his case of instruments,) chemically, the presence of an acid, every doubt will be removed as to the nature of the black discoloration of the blood in the parts which we have named.

C. *From the stagnation of the blood.*—Black discoloration of the blood has been long known to follow as a consequence of retarded or interrupted circulation. This change in the colour of the blood is never so conspicuous as when it takes place in the extreme venous circulation, or in the capillaries; and it is only when it occurs in the latter situations that it has been described as a form of melanosis. We shall, therefore, confine our remarks to the black discoloration of the blood, which follows in consequence of the stagnation of this fluid in the capillary circulation. It is worthy of remark, that the black discoloration of the blood originating in this cause is much more frequently observed in some organs than in others, and is never so conspicuous or extensive in young as it is in old persons. The circulation of the capillaries being influenced by that of the heart and great bloodvessels, it is also frequently observed to accompany diseases of the latter organs, which impede the circulation of the blood in general, and give rise to a state of venous congestion. Among the local causes of its production, acute and chronic inflammation are the most frequent. This

change in the colour of the blood has not, however, been regarded as a matter of much importance in acute inflammation; whilst in chronic inflammation, on the contrary, it has received much attention, as its presence has been considered as one of the least equivocal characters of this disease. To these causes of the stagnation of the blood and its subsequent black discoloration, we may also add debility, which gives rise to similar states of the blood in depending parts of the body, but more particularly the inferior extremities.

Under the influence of these causes, the blood accumulates in the capillaries, and ultimately ceases to circulate. After a certain length of time it coagulates, and the serum is forced out along with the salts, which are absorbed. That which remains is an almost black substance, of the consistence of firm fibrine, and is probably composed in great part of this animal principle and hematosine. The black colour thus produced appears to us to receive a satisfactory explanation from the circumstance that it follows the stagnation and coagulation of the blood, and consequently the separation and removal of the serous and saline ingredients of this fluid, to the latter of which, as has been clearly demonstrated by Dr. Stevens, its red colour is to be attributed.

The degree and extent of the black discoloration of the blood from stagnation of this fluid will no doubt vary in different individuals, in different organs, and under the influence of different diseases. Thus it is, generally speaking, most frequently observed in persons whose circulation is low; frequently, as we have already said, in the old and infirm, and seldom in the young and healthy; and in those diseases which mechanically or otherwise impede or interrupt the capillary circulation. As we have already extended this article far beyond the limits which we had originally prescribed to it, we shall confine the few remarks which we have yet to make on this part of our subject, to the presence of the black discoloration of the blood in particular organs and diseases, and some of its forms.

There are, strictly speaking, only two organs, the respiratory and digestive, in which this change of the blood bears any resemblance to true melanosis.

1. *Black discoloration of the blood from stagnation in the lungs.*—This change of the blood in the lungs occurs most frequently at an advanced period of life; in phthisis pulmonalis; in chronic catarrh; in emphysema; in dilatation of the bronchi; in induration of the pulmonary tissue; in disease of the heart; in one word, in whatever diseases impede the pulmonary circulation, and render the function of respiration imperfect. The black discoloration of the blood in the lungs is general, if the diseased condition in which it originates has exercised its influence on the venous circulation of these organs in general, as in disease of the heart; and it is confined to a limited extent, although it may occupy a greater or less number of separate points, when produced by local causes, such as tubercles. In the former case, the black discoloration of the blood is seen most conspicuously in the vessels of the inter and intra-lobular tissue. In the former tissue it has a ramiform disposition, in the latter it is capilliform and punctiform; appearances which are best seen on the serous surface of the lung. In the latter case, the vessels containing the black matter occupy the circumference of the tubercles, and have a stellated arrangement. In emphysema, dilatation of the bronchi, induration of the pulmonary tissue around tubercular excavations, the black discoloration is often very extensive, on account of the great obstacle which these morbid states oppose to the return of the venous blood, and the length of time which they have continued to operate.

Chronic inflammation of the pulmonary tissue gives rise to the same form of black discoloration of the blood which we have just said accompanies induration, because of induration being, in general, the consequence of this state of inflammation. Chronic inflammation of the lungs may, however, produce the same change in the blood without being accompanied by induration.

The mucous membrane of the bronchi seldom presents the grey or slate colour so common in the mucous membrane of the digestive organs,—a circumstance that would seem to indicate that these membranes are not exposed to the influence of the same agents to which we ascribe the black discoloration of the blood in question, in the respective organs to which they belong. Be this as it may, the black discoloration of the blood in the mucous membrane of the bronchi is seldom considerable, and is rarely observed, unless in old persons whose lungs are at the same time extensively affected with it. It is also best seen in the bronchi which communicate with tubercular excavations, and in the vicinity of ulcers of the mucous membrane itself.

Black discoloration of the bronchial glands, with regard both to frequency and degree, has appeared to us to occur under the influence of the same causes which give rise to the black discoloration of the blood in the lungs. It is most frequently seen and most marked in the bronchial glands of old persons, and it may occur even in children with tubercular phthisis.

2. *Black discoloration of the blood from stagnation in the digestive organs.*—This change in the colour of the blood is almost exclusively confined to the mucous membrane of the stomach and intestines, and follows as a consequence either of chronic inflammation of that membrane, or of diseases of the heart or liver which impede the return of the venous blood. It is limited to a portion of the mucous membrane when produced by irritation, and if it accompanies chronic ulceration of this membrane or of its follicles, it is often very conspicuous. When produced by an obstacle to the return of the venous blood, particularly if the obstacle is situated in the vena portæ, it may occupy the mucous membrane of the stomach and of the greater part of the intestines. In both cases the mucous membrane presents

a grey, greyish-brown, or slate colour, which is either punctiform or uniform; and which, when examined with a lens, is seen to depend on the presence of a similar coloured fluid contained in the capillaries. The mucous membrane is at the same time thicker than natural, and the follicles and villosities are in some cases hypertrophied.

The appearances produced by the black discoloration of the blood from stagnation in the stomach and intestines, are very similar to those which are the effect of the chemical action of acid fluid and gaseous products contained in these organs. In order, therefore, to distinguish the former kind of discoloration from the latter, it is often necessary to ascertain that no acid chemical agent is present. From the result of our own observations, we are led to believe that the grey slate colour of the mucous membrane is too exclusively received as a physical character of chronic inflammation. That it does take place as a consequence of this pathological state there can be no doubt, inasmuch as we see it produced, for example, in the mucous membrane of the vagina and in the skin from this cause; but, as we have already observed, it is of comparatively rare occurrence in the bronchial mucous membrane, which is perhaps as often the seat of chronic inflammation as the mucous membrane of the digestive organs. It is on account of this circumstance, as well as from actual observation and experiment, that we are led to believe that this character of chronic inflammation of the digestive organs has frequently been mistaken for the discoloration of the blood produced by chemical action of the acid contents of these organs.

(R. Carswell.)

MENINGITIS.—See Brain, Inflammation of.

MENORRHAGIA. This term (derived from μήν, *mensis*, and ῥήγνυμι, *rumpo*) implies morbidly profuse menstruation. Some authors have attempted a distinction between those cases where the menstrual discharge is simply over-abundant, and those where, along with the peculiar menstrual secretion, pure blood is expelled. Dr. Mackintosh of Edinburgh, and Mr. Burns of Glasgow, have restricted the name of menorrhagia to the latter description of cases, calling the former only immoderate flow of the menses. Others, again, have chosen to class those instances where a mixture of pure blood is passed, under the head of uterine hemorrhage. The great object ought to be, not to mislead by too nice and critical refinement in nomenclature. The term uterine hemorrhage is so constantly limited in practice to cases unconnected with menstruation, and occasioned by organic disease, accidental injury, or the consequences of pregnancy or parturition, that it is much more convenient to include under the title at the head of this article all those instances of discharge of real blood from the uterus which occur in connection with the menstrual functions. The cases, indeed, are very rare in which any strikingly profuse menstruation exists, without more or less of real blood escaping at the same time. Dr. Dewees states that, in a very extensive practice of many years' duration, he has scarcely ever known a case of genuine menorrhagia without the admixture of pure blood.*

Menorrhagia is a disease occasionally of great obstinacy, sometimes of alarming severity; and as much of the success of the treatment depends upon a proper discrimination of the different conditions which give rise to it, it becomes necessary to point out somewhat at length in what this difference consists. At the same time it must be acknowledged that it will be impossible to go minutely into every variety of case which may occur in practice.

Menorrhagia not only includes the immoderate quantity of discharge at each monthly period, the time remaining regular; but it is also understood to comprehend the too great frequency of the recurrence of menstruation, even when the quantity lost is not unusually abundant: still the definition of "morbidly profuse menstruation" ought to be remembered, because to constitute the disease the quantity lost must be relative. Many women remain in perfect health who are accustomed to a very considerable discharge regularly, thus menstruating every two or three weeks habitually; and yet, as long as the health continues unimpaired, or nothing more than has always been usual takes place, it would scarcely ever happen that medical advice would be applied for to abate the symptoms. In healthy menstruation the discharge takes place every twenty-eight days, lasts from three to four days, and the quantity lost upon an average is about five or six ounces. But this is merely a general rule: the exceptions are numerous; and it is only when it becomes an exception to the individual's ordinary habits, that disease should be considered to exist. The effect of climate in these cases is very remarkable; and what would be considered a very scanty menstruation in the warmer climates of the east, would be deemed menorrhagia in Lapland. A curious blunder was committed in this respect by Dr. Freind, who stated that the quantity of menstrual discharge in this country averaged about twenty ounces—a menorrhagic excess by no means common; the mistake arising from his having quoted Hippocrates without reflecting that the δύο κότυλαι Ἀττικαὶ applied only to the females of Greece.

Menorrhagia may occur in very opposite states of the system, and has therefore been divided into active and passive; the former arising from too great activity in the vessels of the uterus, the latter from a want of tone in their secreting orifices. Either of these states may exist in a plethoric habit of body, or in one of great debility; but in general the local condition is of the same character with the constitutional in the same individual. After a long continuance of the disorder, the strongest and most plethoric frames are brought down to the state of weakness, and the active menorrhagia may thus become passive. In

* System of Midwifery, p. 147.

active menorrhagia, for a short time, sometimes for two or three days before the expected period, there is a sensation of unusual fulness about the pelvis, with throbbing referred to the situation of the uterus itself, along with sense of heat and weight; the external parts of generation are often slightly swollen, and the mammæ become hot, tumid, and painful. The circulation is quickened, the mouth hot, the tongue dry with thirst, and there is a general feeling of oppression, with headach and giddiness. After these symptoms have lasted for a certain time, the function of menstruation begins; but the discharge comes on with violence, in gushes, and usually accompanied with pure blood, as proved by the presence of coagula. The progress is then variable; sometimes after the first few hours the patient feels relieved, lighter, and cooler, and the rest of the period passes over more quietly and naturally; but in more aggravated cases the flow still proceeds in equal or increased quantity, and lasts for several days, occasionally subdued, but again breaking forth upon the slightest exertion, till at the end of the period the patient is left weak and languid, with a feeble pulse and a pale countenance. By the time of the recurrence of the monthly period the individual is perhaps restored to the previous state of health; but the same train of circumstances is again renewed with perhaps increased severity; and the complaint rarely lasts long without the number of days intervening between the periods being rapidly diminished, till at last scarcely one period is over before the next approaches. The condition then quickly becomes one of passive menorrhagia, both local and general, the symptoms of which are more formidable, and the treatment more difficult.

The patient in passive menorrhagia is habitually languid and with feeble powers, or may have become so from previous long-continued loss of blood in the more active form of the disease. She is subject, perhaps, to palpitations of the heart, and violent headachs with throbbing and beating in the temples, singing in the ears, and giddiness—all arising, not from plethora or absolute determination of blood to the head, but from exhaustion and relative determination. This is a very important distinction, and one which has been too frequently and often fatally overlooked. For a further investigation of this interesting subject the reader is referred to the experiments of Dr. Kellie of Leith, and the practical observations of Dr. Marshall Hall; and also to the article Bloodletting in the present work. For the difference in the pathology of active and passive menorrhagia, we may also refer to the able article Hemorrhage, in which is comprehended much that will apply to the morbidly profuse menstruation, the circumstances being but very slightly modified by the periodical nature of the discharge, and the fact of its being merely an excess of a natural one.

In passive menorrhagia there are rarely any precursory symptoms; if the periods are still regular as to time, they are irregular and unnatural as to duration and the quantity lost. In general the return is also much too frequent, so that at last one period is followed nearly immediately by another, or there will be one continued discharge, varying from time to time in profuseness, from a mere oozing of a thin, half serous discharge, to the full gushes of coagulating blood. When apparently the discharge is safely over, the least excitement of body or mind, the slightest exertion or disturbance, will reproduce it, and the difficulties are again as great as ever. The usual effects of morbid loss of blood gradually or rapidly present themselves. When the complaint has been of long standing, but not very suddenly violent, the complexion becomes sallow and cadaverous; the countenance either pinched and emaciated, or bloated and anasarcous; the pulse rapid and feeble; the legs and feet, and often the whole of the cellular membrane distended with fluid; the respiration short and difficult; and, in fact, all the symptoms of confirmed and extreme cachexia are observed. But the most dangerous character of the complaint is manifested in the sometimes suddenly profuse menorrhagic discharge, the absolute danger being much influenced by the previous resisting power of the individual. In these instances alarming syncope has occasionally been brought on, and the most active measures become imperatively necessary, to rescue the patient and prevent a fatal termination. Instances of death would no doubt be much more frequent, did we not possess very efficient means in general to arrest the discharge. Besides the exhaustion from the menorrhagia itself, it is nearly always the case that patients are afflicted in the intervals with profuse leucorrhœa; and if they are exposed to become pregnant, abortion will be very apt to follow. We have also frequently remarked that those who have suffered much from menorrhagia, are peculiarly liable to uterine hemorrhage after abortion or parturition at the full time.

There is one species of menorrhagia which is not uncommonly met with in practice, and yet has not, we believe, been noticed in books,—where, instead of the periods being regular to the month, or much more frequent than ordinary, the interval is protracted considerably, even to six, seven, or eight weeks. In these instances, whenever the menstruation is regular to the usual time, the discharge is not excessive; but upon any disturbance to the general health, there is more or less of delay, and the discharge is then morbidly profuse. This is common both with married and unmarried women; but when it takes place with the former, it is very frequently mistaken for abortion, being often accompanied by pain and the expulsion of solid masses of coagulated blood with flakes of albumen, not very unlike an early ovum. These women are said in common language to become *obstructed*, but it is under very different circumstances from amenorrhœa, as the protracted period is always followed by profuse hemorrhage. The patients complain for several days, even for two or three weeks, previous to the appearance of the discharge, of the symptoms mentioned as usually preceding active

menorrhagia, and particularly of a more than ordinary sensation of pulse or throbbing in the situation of the uterus.

The causes of menorrhagia may be divided into the constitutional and the accidental; but it often seems to require a combination of both to excite the disease. The active menorrhagia is found to occur in plethoric habits, often apparently as a natural relief to the overloaded system, but aggravated or excited by luxurious living, a sedentary and indolent life, hot rooms, and also by very violent exercise or any other fatiguing exertion. The passive menorrhagia, on the other hand, is caused by all those circumstances which lower the bodily powers, and weaken the action of the heart and arteries. But in both of these cases there are local causes which peculiarly tend to direct the mischief to the uterus, and increase the circulation in the vessels of that organ, leading to the increased discharge, whether that be the immediate effect of excess of activity, or diminished power of retention: such are blows and falls, or any other local violence; frequent and recent abortions, leucorrhœa, over-indulgence in sexual intercourse, irritation in the bladder, diarrhœa, tenesmus, piles, ascarides or scybala in the rectum, or even habitual or accidental costiveness.

In all severe or protracted cases, resisting the usual means of relief, it would be right to make an examination as to the actual state of the uterus itself, as symptoms closely resembling menorrhagia may be owing to organic mischief, particularly ulceration, polypus, and inversion of the womb. These causes are not immediately connected with the present article, and therefore can only be alluded to.

There is a frequent cause of menorrhagia not much attended to, and not mentioned in systematic works on the subject, but the knowledge of which is highly necessary. It has often been observed that the most obstinate forms of chronic menorrhagia occur in those persons who have an impeded or disordered circulation through the abdominal veins, particularly where there is organic or functional disorder of liver. The same cause will very frequently produce hemorrhoidal disturbances; and it is very easy to understand that the uterus in such cases will be a ready outlet for the relief of the over-distended blood-vessels of the lower part of the trunk. We have no doubt that this is not at all an uncommon cause of obstinate menorrhagia, and we are still more convinced of the truth of the opinion by the success which has often attended the adoption of a peculiar plan of treatment presently to be noticed, and which is only adapted to that condition.

Treatment.—In the treatment of menorrhagia it is especially important that we should inform ourselves as much and as accurately as possible of the actual state of the disease, and of the peculiar cause or combination of causes to which its origin may be attributed. It is too often the case that medical men in such instances, as a matter of course, order medicines containing infusion of roses and the mineral acids, and such-like. This is the every-day routine; and in more obstinate cases the astringent gums or metallic salts are added. But however proper such medicines may be in many, they are by no means applicable to all the cases, and much valuable time is lost by this careless mode of prescription.

In discussing the management of menorrhagia, we must bear in mind that sometimes we are called upon to arrest the violence of the discharge from the uterus at the moment, and which is occasionally so excessive as to hazard the life of the patient, unless readily restrained. We shall therefore, in the first instance, treat of this highly necessary part of the subject, and afterwards of the mode of restoring the patient's health in the more chronic forms of the disease, and in the intervals of the discharge. In a patient who has been till recently in a robust and plethoric condition of body, and in whom the menorrhagia has been of recent origin, or has arisen from temporary and accidental causes, it will be often advisable, during the actual profuseness of the discharge, to diminish the action of the heart and arteries by abstraction of blood from the arm, exactly on the same principle on which we should be led to similar practice in hemorrhage from the lungs. It is only in recent cases, however, or in very plethoric subjects, with a strong full pulse, that we may safely venture upon this plan; and then the quantity of blood abstracted must entirely depend upon the circumstances of the case, the powers of the patient being a much better guide than the severity of the symptoms. When the discharge is excessive, that alone will reduce the powers of life to so low an ebb that much additional loss of blood would be dangerous. After having abstracted blood from the arm, when the case requires this evacuation, we may proceed to the other measures, which are proper to all cases of urgent and immediate danger from menorrhagia. The free application of cold to the abdomen, pelvis, loins, and back, is one of the most powerful means we possess of restraining menorrhagia: the cold hip-bath, dashing cold water or vinegar and water on the person, injecting cold water into the vagina, and applying ice, both externally, and internally to the os uteri, may be had recourse to with much and often decisive advantage. It is necessary that in these cases the application of cold should not be entrusted to the nurse or attendants without the superintendence of the practitioner, as they are rarely aware of the mode in which alone the applications can be effectual. After placing cloths dipped in cold vinegar and water to the pubes, they often cover up the patient with the bed-clothes, *warm* and *comfortable*, soon converting the wet linen into a hot and reeking fomentation. Besides which, by the want of judgment, the application of cold, when properly applied in the first instance, will often become prejudicial from being continued too long. Cold is a most powerful sedative, and when the powers of life are reduced to an extreme state of exhaustion from loss of blood, it often becomes necessary for a time to reverse our treatment, and, when the hemorrhage has

ceased, to rouse up the sinking pulse and failing powers by the cautious application of stimuli and artificial warmth. We may do this more safely when we have made the state of the patient more secure by another very effectual plan for restraining the hemorrhage—*plugging the vagina*. In the uterine hemorrhage which occurs shortly after parturition, this expedient is not safe; because, when the blood, by the plug in the vagina, is prevented from flowing externally, the uterus itself may again expand to a very considerable extent from the blood being poured into its cavity; and in this way death may take place, although there is no external flooding. This can only happen, however, where the uterus is in a condition to undergo the expansion, and in menorrhagia this is not the case. A dossil of lint, or a fine cambric handkerchief, may be gradually introduced into the vagina up to the os uteri, so as to fill the vagina firmly throughout its whole extent, and be allowed to remain there. Many prefer soaking the material previously in some strong astringent liquid, and this is perhaps still more efficacious. If the plug produce pain, it must be withdrawn; and at all events it should not be allowed to remain more than twenty-four hours, because it is apt to become very offensive and irritating from the putrefaction of the discharge. On withdrawing it, unless it be done very gently and gradually, a fresh discharge of blood is apt to be occasioned; but it can easily be restrained by another plug, or some of the other remedies.

Strong astringent injections into the vagina, consisting of solutions of alum or sulphate of zinc in infusion of galls or decoction of oak-bark, are often of service. They certainly possess great power, and act partly by coagulating the blood at the orifice of the uterus, which acts as a compress upon the mouths of the bleeding vessels. There is a remedy which is perhaps the most certain of any in restraining the discharge; but as it is not always safe, it should, in the writer's opinion, only be employed in cases where other plans less dangerous have failed—it is that of injecting the uterus itself with an astringent injection. A gum elastic male catheter is carefully inserted within the os uteri, and, by means of a syringe, a very small quantity of a solution of alum or of the acetate of lead is to be gently introduced into the cavity of that organ. Two instances have occurred, within the last four or five years, where violent vomiting was the consequence, followed by uterine inflammation and death; and although certainly such unfortunate results of the practice are exceedingly rare, the knowledge of them must render any one cautious in applying it. Of course, where it is possible to ascertain the immediate cause of the hemorrhage, and that cause can be removed, our remedies will have but a poor chance if such a precaution be neglected. A loaded state of the rectum has been often overlooked in cases of menorrhagia, and even when recognized, many have been unwilling to produce any action of the bowels, from fear that the exertion or the disturbance might reproduce or increase the discharge. Accumulations of hard fæces in the rectum should always be removed as speedily as possible, and this may be safely and effectually accomplished by a lavement of cold water. This remedy alone, indeed, has often stopped an obstinate case of menorrhagia.

Of the internal medicines for restraining the discharge in the violent degree we have mentioned, opium and the acetate of lead are the most to be depended upon. Where the patient is much exhausted, opium may be given in large doses. Mr. Burns advises at least as much as two grains at once; and where it cannot be given by the mouth, it is to be introduced into the rectum as an injection or a suppositary. Many practitioners exhibit the acetate of lead in insufficient doses, dreading the deleterious effects which lead is known sometimes to produce in the animal economy.* When combined with opium, these effects are considered as less likely to be occasioned, and the usual practice has been to give one, two, and even three grains of the acetate of lead, with from half a grain to a grain of opium, every one, two, three, or four hours, according to the urgency of the symptoms. Dr. Mackintosh of Edinburgh has related a case† where the effects of the acetate of lead with opium were very strikingly displayed, in doses of five grains every three hours, for several successive times, without any of the signs of the poison of lead ever appearing. As opium will not always agree, and as the harmless effect of lead has been attributed to the opium being combined with it, it is very satisfactory that Dr. A. T. Thomson has lately proved that the addition of acetic acid to the acetate of lead, so as to make an excess of acid, entirely prevents the deleterious property. Other remedies have been given in the acute form of menorrhagia with success, and though not so much to be depended upon as those already mentioned, must not be lost sight of. Emetics have now and then been serviceable, but would only be safe where we wanted rather to depress the activity of the circulation. The same precaution is necessary with respect to digitalis, which has been much praised by several authors. Large doses of the nitrate of potash or of the oil of turpentine have been also highly spoken of. The most common remedies are the astringent ones, viz. kino and catechu in large doses, alum, sulphuric acid, rhatany root. Alum whey may be given as drink, or a very weak solution of sulphuric acid, made palatable with sugar. In all these cases the most perfect quiet and the horizontal posture are indispensable.

In the more chronic form of the disease the above plans are more or less applicable, but much will depend upon the character of the individual case. When the individual is ple-

* Mr. Dewees states, in his "System of Midwifery," page 149, that sugar of lead has been declared a dangerous remedy, but "upon what ground we are at a loss to determine, having used it most freely for more than twenty years, without the slightest inconvenience from it." He relates a case where he gave it, as an injection into the rectum, in scruple doses.

† Elements of Pathology, vol. ii. p. 363.

thoric, bloodletting may be required; and in many cases Dr. Mackintosh has found advantage from the application of a leech or two to the os uteri itself. Cooling saline medicines may be taken, and the bowels kept open by saline purgatives, avoiding, however, any irritation of the canal. The infusion of roses with Epsom salts will be found one of the most useful forms of purgative, and if it irritates the bowels, henbane may be added. Cold hip-bathing, and also cold astringent injections, will be found useful. This plan, with great quiet, will be found to moderate the attack, and may be continued in the intervals; and it is worthy of remark that the next return of the menstruation may often be rendered comparatively trifling by the use of a full purgative about twenty-four hours before the period, where that can be ascertained, avoiding any medicine of a drastic or stimulating quality. In these instances the diet should be very bland and spare: wine must be left off, although the common remedy in families for every sort of menorrhagia is to drink rather freely of port wine.

In the more feeble constitutions, already, perhaps, reduced by a long continuance of so debilitating a malady, besides the remedies above mentioned to abate the immediate violence of the discharge, we must endeavour in the intervals to strengthen the general frame, and restore tone to the uterus itself. But in these instances we often find it extremely difficult to restrain the discharge itself, however trifling it may be in amount. The least exertion or excitement will reproduce it, and in spite of all our remedies it continues day after day, exhausting the strength. Dr. Mason Good* is of opinion that in these cases there exists a relaxed state of the solids and an attenuated state of the fluids; and certainly the discharge in nearly every such instance appears very thin, and to contain an unusual proportion of serum. Small and repeated doses of the acetate of lead are more serviceable, perhaps, than any other internal medicine, and it may be combined with opium or an additional quantity of acetic acid. The other astringents mentioned before are preferred by some authors, given in more moderate but more frequent doses. The ergot of rye, with the idea of its promoting contraction of the uterus, has been tried in menorrhagia in small and often repeated doses, and by some, it is said, with success; but others have had no reason to speak favourably of it.

In the intervals, every remedy which can give general and local power must be employed. Cold bathing, cold hip-bathing especially, will be found of great use; and the efficacy of the water may be increased by the addition of salt or vinegar. This should be used from two to five minutes every night and morning, and a cold astringent injection should also be thrown up to the uterus. All violent exertions should be avoided, and especially shaking in an uneasy carriage, or horse-exercise. The free use of the flesh-brush will give steadiness to the circulation, and answer nearly all the salutary purposes of exercise, without the risk of mischief from too much fatigue or exertion. The diet should be nourishing, but not stimulating: fluids and the watery vegetables should be taken but sparingly, and only a small quantity of wine, of which claret or port is perhaps the best. Of medicines, the vegetable tonics are scarcely so serviceable as the mineral; but they may often be combined with advantage. The salts of iron require to be carefully administered; but in spite of their well known effects of increasing or producing the menstrual discharge when deficient, their general tonic and astringent effect upon the bloodvessels is often exerted with marked benefit in cases of menorrhagia of the atonic character. The sulphate of zinc may be more easily managed than steel medicines, and in many instances has been more useful; from one to two grains being taken in the form of pill three times a day.

In a case of complication of obstinate skin-affection with menorrhagia, arsenic was found serviceable to the eruption, and during the exhibition of this remedy the menorrhagia ceased. This was quite accidental; but the writer was afterwards induced to try its effect in menorrhagia of the atonic character, where that was the only complaint; and the success of it has occasionally been very considerable. It has been given in doses of five to ten drops of the liquor arsenicalis, gradually increased to twenty-five or thirty, three times a day, carefully watching the effect of the medicine, and diminishing the dose, or discontinuing it altogether, when the peculiar deleterious qualities have been evinced.

Perhaps no artificial medicines are so powerful in their action in chronic cases of menorrhagia as the natural medicinal springs, which contain minute portions of iron in solution; though some of the benefit may be fairly attributed to the change of scene and the purity of atmosphere.

In that congested form of menorrhagia which has been mentioned, accompanied by protracted intervals between the menstrual periods, much advantage is derived by abstracting blood from the uterus or from the neighbouring parts, whenever the proper day has passed over without the appearance of any discharge, and directly the sense of fulness and throbbing in the pulse is perceptible. The bowels also should be freely purged, and the feet put into hot water: in short, the treatment should be partly made up of that appropriate to cases of amenorrhœa, modified by circumstances; whilst in the intervals horse-exercise and active exertion will be not at all improper, but highly salutary. At the time of the actual existence of the profuse discharge, the most perfect quiet is essential, and those remedies which have been directed to alleviate the immediate symptoms.

In obstinate cases of menorrhagia where we have reason to suspect the existence of

* Study of Medicine, vol. v. p. 66.

a congested state of the liver, or an obstructed or rather a retarded circulation through the abdominal veins, before mentioned as a very common though seldom noticed cause of this disease, nearly all the usual remedies for menorrhagia will fail, and the great number of them will do absolute mischief. Although during the immediate flow of the discharge, if violent, the remedies for checking it formerly mentioned become necessary, yet in the intervals we must direct our attention chiefly to the condition of the abdominal viscera. Small doses of alterative mercurial medicines, particularly the Plummer's pill, will be found very useful, and the decoction or extract of dandelion should be given in full doses. A pill of rhubarb, soap, and ipecacuanha, is a very advantageous combination to keep the bowels open, and this may be assisted, if necessary, by domestic enemata; it being of great consequence especially to prevent the collection of any hard or lumpy faeces in the large intestines. In addition to all this, the writer particularly recommends in such cases the frequent application of a few leeches to the anus. Even in very debilitated and exhausted constitutions, this remedy, when carefully watched, may be safely administered, and relief will often be very rapidly manifested.

(C. Locock.)

MENSTRUATION, PATHOLOGY OF. —It is not intended in the present article to discuss the various theories of this important function of the human uterus, which have at various times prevailed. It will be sufficient to state generally that we consider the menstrual discharge to be the consequence of a peculiar periodical condition of the blood-vessels of the uterus, fitting it for impregnation, which condition is analogous to that of "heat" in the inferior animals. In Dr. Hooper's work "On the Morbid Anatomy of the Human Uterus," there is an exact representation of the uterus of a woman who was instantaneously killed by an accident during menstruation; and every one must be struck with the resemblance which it bears to the description given by Mr. Cruikshank in the Philosophical Transactions (1797), of the appearances observed by him in rabbits killed during the state of genital excitement usually called the time of heat. The actual presence of the discharge is the *resolution*, if we may so term it, of the previous condition of the vessels which separate it; for the uterus is fitted for the purposes of impregnation before the menses begin to flow. An instance in proof of this may be given from the Philosophical Transactions (1817), of a young woman who bore two children successively without any previous menstruation; which function, in fact, did not shew itself externally till after the third pregnancy, which ended in a miscarriage.

The function of menstruation lasts, upon the average, for about thirty years of the life of woman, beginning at puberty, and ending somewhere between forty and fifty years of age, unless interrupted by disease, by pregnancy, or by suckling. During this large proportion of female life, there is a great liability to derangements, of one form or another, in the menstrual process; and to which much importance is attributed, though from some remains of the old doctrine that the menses were the outlets of "peccant humours," more anxiety is generally expressed in cases of diminished or suspended discharge than in those where it is unnaturally profuse. Women have also been always in the habit of considering the time of the first appearance of the catamenia, and of their final cessation, as requiring particular caution and management, and as tending to the development of a healthy or diseased condition for a long period of life. The actual flow of the menstrual discharge itself is also looked upon as a time of great delicacy, and as demanding peculiar attention; so that very few diseases can exist, and very few plans of treatment be recommended, without the presence of the menses in some way influencing the nature of the symptoms or the remedies to be applied. It is in this especially that the character of the female constitution in disease is manifested; for before puberty, and after the cessation of menstruation, the female differs but little from the male in the character of disease, unless in those points which may be considered as accidental, such as organic diseases of the sexual organs.

In the present article we propose to consider the medical management of the female at the first appearance of the menstrual discharge, during the continuance of it, and at the final cessation.

Instances of precocious menstruation are by no means uncommon;* but occasional discharges of blood from the vagina of young children cannot be considered in this light, unless accompanied by the usual signs of puberty. Precocity must always be considered relatively as to climate, for the difference in hot and cold countries is very great. Dr. Denman has quoted an opinion of Hume (the historian), which is scarcely borne out by facts; the difference in the time of life when the menses appear being assigned as the reason why women in hot climates are almost universally treated as slaves, and why their influence is so powerful and extensive in cold countries, where personal beauty is in less estimation. "In hot climates women are in the prime of their beauty when they are children in understanding; and when this is matured, they are no longer objects of love. In temperate climates their persons and their minds acquire perfection at or nearly at the same time, and the united power of their beauty and faculties is supposed to be irresistible."† The influence of civilization seems to have been entirely overlooked in this theory; as otherwise the

* We refer in particular to a case by Dr. Wall of Oxford, in the second volume of Medical and Chirurgical Transactions.

† Introduction to the Practice of Midwifery, p. 83.

most chivalrous devotion to the fair sex would be found in the savage inhabitants of the countries of perpetual snow. Precocious menstruation can scarcely be considered as a disease, but it certainly is not desirable, for many obvious reasons; and as artificial circumstances may hasten it, avoiding such causes or counteracting them may not only prevent, but may even supersede it. For example, cases have been related in which girls have menstruated, with all the signs of puberty, at nine or ten years of age, in the East Indies; and having been removed to Europe, the function has ceased, without disorder of the health, and has not appeared again till the age of fourteen or fifteen, at which it usually comes on in this country. Hot and crowded rooms, luxurious habits, early excited passions, and improper indulgences, are well known to promote an early development of sexual power, and should be carefully counteracted in those cases which seem to call for interference. An opposite condition to precocity is also very commonly met with; but however late the period may be at which menstruation first comes on, it is not a disease in itself, so long as the symptoms of puberty are not manifested. The parents of a young woman are often anxious upon this point, and request medical aid to bring on the menstruation; but, unless by attending to the general health, the practitioner is not justified in interfering. In some unfortunate instances the signs of puberty never come on, from some organic deficiency in the genital organs, particularly the ovaria; and all attempts to excite a menstrual discharge would be pernicious.

For a very considerable period before puberty, often two or three years, symptoms of the approaching important change in the system may be detected. It is not at all uncommon to meet at this age with very obstinate disorders, such as headachs, epileptic fits, or cutaneous affections; and upon finding the usual plans of treatment fail, medical men are in the habit of prophesying a cure when menstruation is established: this arises from long experience of the frequent truth of such a result. As the time draws near, the system becomes more irritable; there is a general uneasiness and an alteration of the moral character; there is also very commonly much languor, flushing, sensation of fulness, headach, livid marks round the eyes, disordered appetite, impaired digestion, and disturbed or unnaturally heavy sleep. These symptoms continue for a longer or shorter period; and immediately preceding the first appearance of the discharge, there is much pain and weight, with fulness in the head and pelvis, and throbbings and swelling of the mammæ. Although the actual discharge is rarely quite regular to the month for the first half year or so, passing over a month or two, yet the usual constitutional symptoms just enumerated as directly preceding the discharge are found to observe the lunar intervals, and to be aggravated monthly, even for some time before the flow of the menstrual evacuation itself. With many, the symptoms above mentioned are either so slight or so temporary, that no great attention is paid to them. Where medical aid is required, the plan of treatment must depend a great deal upon circumstances: as a general rule it is best to temporise, knowing that a little patience will carry the patient to the termination of the discomfort. Should there be any very great disturbance, with a full pulse and much headach, the abstraction of a small quantity of blood will be prudent. The diet should be carefully regulated, and abstinence from meat or wine strictly enjoined. The bowels should be kept rather more open than usual, but not with any of the more irritating and drastic purgatives, under the idea of exciting the uterus to action, as is too commonly recommended; the object being to lead the patient through the struggle without any force or disturbance. We should watch excess of action of every description, and restrain it, but not attempt to stimulate any apparent deficiency, unless actual disorder of health be manifested. Circumstances may arise, however, to call for more decisive measures; and the menstruation may be so protracted as to constitute one of the forms of *amenorrhœa*, the nature and treatment of which have been detailed elsewhere. (See Amenorrhœa.)

During the menstrual period, when quite regularly and properly performed, no medical treatment is required; but it should never be lost sight of either by the patient herself or by her medical attendant, in case of any accidental illness, or any general plan of management of the health. Women expect this carefulness, from the great importance they habitually attach to the proper performance of the function; and therefore, in prescribing for females, it is always right to enquire as to the expected time, as well as the regularity of the periods, to guide us as to the propriety of continuing or remitting any part of the remedial measures. There are many things to be guarded against on these occasions, which might be safely followed at any other time; and while much depends on the patient's own prudence, yet the physician is constantly blamed if he lose sight of the necessary precautions. It is necessary to avoid any very active purgative medicines during menstruation, particularly those which irritate the lower part of the rectum, as they are apt to produce a morbid increase of the discharge. Medicines containing the preparations of iron, strong diuretics, emetics, myrrh, or mercury, are usually ordered to be suspended during the periods, although it is very doubtful whether the milder mercurial medicines in gentle doses can be productive of mischief. Cold bathing ought also to be discontinued, particularly the hip and foot baths; and yet it is a well-known fact that the dippers attached to the bathing-machines at the sea-side are in the habit of being for several hours in and out of the sea during the catamenial flow without detriment. Wetting the feet or exposure to

rain under these circumstances has now and then suddenly suppressed the menstruation, and brought on illness of an alarming nature. Dr. Dewees states that in America it is not at all uncommon for young girls, bent upon a party of pleasure, to put the feet in cold water to stop the discharge. It need scarcely be stated that all vaginal injections to restrain leucorrhœa must be left off at these times. Any very violent exercise is to be carefully avoided during menstruation; partly because it is very apt to produce too profuse a discharge, and partly because, on account of the increased weight of the uterus and relaxation of the vagina, a serious degree of prolapsus uteri has been often occasioned by it. Some aggravated instances of this distressing complaint, even in unmarried women, have occurred in the writer's own practice, which have been brought on by dancing, by horse-exercise, and by over-fatigue in walking, during the menstrual period.

The Jews, and even more modern nations, believed that there was something deleterious and contaminating in the menstrual discharge itself; and hence various directions and regulations as to seclusion and cleanliness of person. It is not necessary now to controvert these doctrines; but it were well, perhaps, if more strict attention were to be paid to some part of the regulations even in the present times. Either by accident or by criminal impatience, sexual intercourse has sometimes been permitted during the period of menstruation; and, although not constantly, yet such conduct has been frequently followed by the most serious effects—generally by profuse hemorrhage; at other times by a sudden suppression of the discharge; to which have succeeded fever, delirium, obstinate hysteria, confirmed mania, and even catalepsy. (See Amenorrhœa.)

When the function of menstruation has been once fairly established, it may become disordered in several ways, each forming distinct classes of diseases. Menstruation may be faulty in respect to the quantity of the discharge, the quality of the discharge, the regularity of its appearance, the time of its duration, and the degree of pain with which the process is accompanied. When the discharge has been in any way suppressed in a peculiar condition of health, what has been called *vicarious menstruation* has sometimes periodically occurred from other parts of the body, the stomach, the lungs, the bowels, &c. although Dr. Dewees evidently doubts the existence of such anomalies. For a minute account of these several forms of disordered menstruation, the reader is referred to the articles Amenorrhœa, Dysmenorrhœa, and Menorrhagia.

During pregnancy and suckling, menstruation ceases. This is undeniably the general rule. Under the head of Lactation, the exceptions to this law of nature, as regards *suckling*, have been noticed, and no one perhaps will deny their occasional occurrence. But many practitioners of extensive experience in midwifery have denied the possibility of menstruation going on during pregnancy, and declare the supposed cases to be either false altogether, or that the discharges which do sometimes occur during pregnancy are not menstrual, but are irregular in time, sparing in quantity, and sanguineous in character. They rest their arguments upon the fact, that at a very early period of pregnancy the os uteri is closed by the thick glutinous secretion which is poured out by the glands at the cervix; and also, that from the interior of the uterus being coated with the decidua vera, there is no surface from which the menstrual fluid could be secreted. Many experienced medical men, and women themselves in general, believe not only in the possibility, but in the comparative frequency of menstruation during the first three or four months of pregnancy; and Dr. Dewees mentions a case in which he was firmly convinced that it went on regularly to the *seventh* month, lasting three or four days, exactly as usual, not sanguineous, at least not containing perceptible coagula, and only differing from common periods in being less and less abundant as the pregnancy proceeded, after the fourth period. The first argument, as to the impossibility, is scarcely tenable, when we recollect how readily slight hemorrhages find their way through the os uteri in spite of its closure, from some accidental disturbances of the ovum at any period of pregnancy, without being followed by miscarriage; and if such discharges can escape, why not the menstrual? In reply to the second, Dr. Dewees asserts, that as menstruation occurs from the cervix uteri in the unimpregnated uterus, as well as from the body and fundus, there is sufficient space for some menstrual fluid to be secreted in that part of the cervix which remains uncovered by the deciduous membrane, and, as is well known, is not taken up into the body of the uterus till an advanced period of pregnancy. He states that a very small space will be sufficient for the purpose, as was proved by discovering in a post-mortem examination that the uterus of a young woman who had menstruated quite regularly and properly to the time of her death, retained only a surface healthy enough to perform the menstrual function, of the size of the finger nail, all the rest of the interior being in a state of disease. In stating the opinions on both sides it will be scarcely necessary to advert to our own; but, although firmly convinced that a perfectly regular discharge as to period is not uncommonly found to continue for the first two, three, or four months of actual pregnancy, yet we do not therefore conclude that such discharge necessarily comes from the uterus, or is exactly menstrual. In what the difference consists between the menstrual fluid and blood is not accurately known; that it does not coagulate is not saying much, as the blood of persons affected with scurvy, or of those killed by lightning or by some of the powerful narcotic poisons, does not coagulate; and menstruation is rarely very profuse without coagula being also expelled, no other secretion ever contain-

ing pure blood mixed with it, unless from organic lesion.

From habit, there is a tendency of the circulation towards the uterus every month, even during pregnancy; and few women are found who do not experience the symptoms occasioned by it, for the first month or two: hence it is that miscarriages are so apt to occur at those periods at which menstruation would have appeared, had not the process been interrupted by pregnancy; and hence, also, a periodical relief resembling menstruation may occur for the first few months, the bloodvessels at the cervix uteri, or the upper part of the vagina, giving way for the purpose. When this occurs, as it is unnatural, and might lead to abortion, great care is required; and when patients have shewn a tendency to it, they should be kept in the horizontal posture for a few days, and a few ounces of blood be abstracted from the arm, or, by means of leeches or cupping, from the neighbourhood of the uterus. Although it is not pretended that these cases are common, and they can only be regarded as exceptions to a general rule, yet it is important that no one should blindly deny their possibility, since it might lead to a neglect of those precautions which pregnancy requires.

The important period of the cessation of the menses is liable to the same varieties as that occasionally observed on the first appearance, and is also accompanied with many very striking changes in the animal economy. It is an age which is always looked upon by the female sex with a certain degree of apprehension, as one in which the foundation is often laid of many a painful and dangerous malady; and yet those who previously are suffering from long-continued general illness or any obstinate chronic disease, are accustomed to look forward to the time when the constitution shall become *settled*, as it is termed, for a relief to their sufferings and a restoration to more perfect health. When the uterus is no longer in a condition to perform the function of menstruation, the power of conception also ceases; and it has been considered by some authors that this was a wise ordination to prevent women from becoming mothers at so advanced an age that they would be incapable of properly attending to their offspring while still too tender to provide for themselves. As it has been generally acknowledged that the uterus is most fitted for impregnation directly before or after each menstrual period; so it also happens, that for a short time before that process ceases for ever, there appears to be an unusual degree of stimulus in the generative faculty; and many women who have ceased to bear children for years, or who have been hitherto barren through the whole of their married existence, at this time, to the surprise of their friends and of themselves, become pregnant. Still more commonly, however, does it happen that women mistake their condition under these circumstances, and so obstinately believe themselves pregnant, that it becomes exceedingly difficult to convince them of their error. It is easy to suppose that at this particular age such mistakes are likely to arise, for the symptoms that naturally accompany the cessation of the function much resemble those of pregnancy. Women are unwilling to be thought beyond the age of bearing children, and are perhaps on that account misled by their wishes; but they not unreasonably are struck with the first sign which generally occurs, —namely, the passing over of the menstrual period; and their attention is ready to seize hold of every flattering explanation of the circumstance. Other symptoms are soon manifested; the size increases, the breasts even become swollen and painful, the stomach disordered, and the appetite capricious, so that a pregnancy sickness is not uncommon; flatulence collects in the intestines, and whilst on this account the size still increases, the sudden motions and rolling about of the confined air are mistaken, even by women who have previously borne many children, for the plunging of a fœtus. It is only by time, or by an examination per vaginam, that the mistake is detected, much to the annoyance of the patient and her friends; but the symptoms are easily removed by the free exhibition of carminatives and purgatives, the use of active exercise, and bandaging the distended abdomen, which has probably been allowed more room to expand than formerly, from a fear of tight lacing in pregnancy.

In this country the average age at which women cease to menstruate, or "*the time of life*," as it has been called, is forty-five. Where they have begun early, it generally ceases early; and, on the other hand, where they have begun late in life, it often lasts much later than common. Some women have ceased entirely before the age of thirty; others have gone on to nearly sixty, or even beyond this period. Many of the cases, however, which have been related of women who have continued to menstruate till seventy, eighty, or upwards, or who have begun again ten or fifteen years after having apparently left off for ever, were not genuine cases of menstruation, but sanguineous discharges, generally irregular, and arising from some disease of the uterus.

Menstruation ceases sometimes at once, when the female has arrived at the usual age; but this rarely happens, unless accidentally as it may be termed. For instance, something or other takes place to check the expected discharge, which would have had the same effect at a much earlier age, such as cold, fright, some acute illness, or any other fortuitous occurrence. At any earlier period the menstruation would return on the cessation of the illness; but now it seems to take the opportunity of departing without further trouble, and never again appears. Much more frequently the change is gradual, and accompanied with such irregularities that it has not inaptly been called "*the dodging time of life.*" The quantity varies much as well as the regularity of the return; sometimes for two or three successive periods it is extremely scanty, and then suddenly is so profuse as to partake of the character of uterine hemorrhage, and even

to create alarm as to the immediate result. The discharge sometimes returns every two or three weeks, and then ceases for several weeks or even months, and afterwards perhaps for a time recurs as regularly as usual. In females in whom it has been always previously the most regular, and when the person has been uniformly healthy and of temperate habits, the cessation of the function goes off the most quietly, and with the least subsequent derangement of the system. Many, however, who have not been so fortunate in their state of health, by being carefully conducted through this critical period, have apparently renewed their existence, have lost their previous delicacy of constitution, and become more healthy than ever; so that it has been remarked that their lives are likely to be prolonged to a more advanced age than men of equal standing and at the time of equal health.

But this is the most favourable termination of the period; for with many it is only the beginning of a train of great suffering and of constant illness, ending in an early death.

Whenever there is any tendency to organic disease, or any weak point in the frame, this is the time when the mischief becomes manifest, and the symptoms are first detected. It is not, as Dr. Dewees has very properly remarked, that the particular diseases are caused by cessation of the menses, but the seeds of such affections already existing are roused into activity by the changes which take place in the system at that period. For perhaps thirty years of the woman's life there may have been an habitual monthly discharge of from four to six ounces, more or less, of a secretion which is nearly allied to pure blood, from the uterus; and it is not surprising that, on this being stopped, the long habit should produce a tendency to the same relief every month; which not taking place, the excess is thrown back upon the circulation, and local congestions are the consequence. Even under the most favourable circumstances there are symptoms of congestion, shewn by headach, shortness of breathing, oppression at the præcordia, and a tendency to corpulency. But whenever any organ is in a state of disease, however latent hitherto, the redundancy is thrown especially to that quarter, and the disease is rapidly called into activity.

It is not surprising, from the great alteration which takes place in the organs connected with the function itself, or those which have been particularly affected by it, that they should be the parts most liable to become diseased at this time; and certainly most organic diseases of the uterus and mammæ date their perceptible origin from this period. Besides cancerous tumours, medullary sarcoma, hæmatoma or fungus hæmatodes, attacking the uterus and breast, many serious diseases of other parts often arise. Apoplexy is not an uncommon occurrence, but is not so often fatal at this age as at one more advanced. Organic disease of the liver or of the other abdominal viscera is much more common than of the lungs, the abdominal circulation being perhaps more closely influenced by the want of the uterine secretion. Very obstinate disorders of the skin frequently make their appearance at this age for the first time, producing great distress and disorder of the health. There is sometimes an apparent effort of nature to substitute some other discharge as a compensation for the one which has been suspended; and it is right always to respect these contingencies, as, however disagreeable they may be, the removal or cure of them may be dangerous. Leucorrhœa is a very common instance of this natural relief; and discharges of blood from the hemorrhoidal veins is another, which now and then becomes periodical. Ulcers sometimes form and discharge copiously, on the legs or behind the ears, and should not be carelessly healed, unless other measures are taken to prevent mischief.

The medical management of the important period of cessation of the menses may be easily collected from what has been already remarked. Recollecting the condition of the system, particularly of the circulation, it will be necessary to keep it free from disturbance as much as possible, to relieve any organ or part of the body which may appear oppressed or in a state of congestion, and to watch carefully the first threatenings of any local disease. Should the pulse be full and hard, and should there be any general plethora, frequent small bloodlettings will be advisable. Every local pain, heat, or sensation of fulness, should be relieved by leeches or cupping. The bowels should be kept carefully and freely open by purgatives which do not irritate, but which produce watery motions, such as the neutral salts or castor oil. If the pulse is habitually quick and hard, small but repeated doses of mercurial medicines may often be of service, and remove any obscure inflammatory action which may insidiously be going on. The diet should be mild, and moderate as to quantity, meat and wine either omitted or but sparingly allowed. Exercise must be regulated by the circumstances of the case; it is very desirable where no local mischief appears to exist, as it promotes regularity of action and general health; but otherwise great quietude should be observed. The production of artificial discharges by means of issues, setons, or perpetual blisters, so much in vogue formerly, is now no longer fashionable, from the dislike patients have to such remedies; but viewing what is often effected naturally, we cannot doubt but that their more frequent employment would be highly advantageous.

In some peculiar constitutions most of the disturbance consequent upon cessation of the uterine functions seems to attack the nervous system, and hysteria, epilepsy, or mania sometimes take place. The management of such cases requires some modification in the treatment above recommended: conium has been found of great service by some; and now and then even mild tonics are required to steady the irritable condition of the frame. When such diseases arise for the first time at this period of life, they generally prove obstinate,

and often incurable. Some have proposed to attempt to reproduce the menstruation, as a means of relief when any of the formidable disorders above mentioned come on, by the employment of violent remedies of the emmenagogue class; but this practice might be highly dangerous, and probably excite uterine diseases of the most fatal description.

(C. Locock.)

MESENTERIC DISEASE.—See Tabes Mesenterica.

MILIARIA.—This term, derived from *milium*, a millet seed, is applied to a minute vesicular eruption which occasionally appears in the progress of various acute disorders, the vesicles resembling in size and colour the seeds of the millet plant.

It has been regarded by some authors as an idiopathic eruptive fever, to which the name *miliary fever* has been given: by many of the older writers it has been confounded with scarlatina and rubeola; and from its having been occasionally observed to co-exist with purpura, the idea probably first originated that it was only a modification of this eruption. We have also on record several accounts of an epidemic miliary fever,* which has at various times prevailed, though it is evident that the eruption was only an accidental or symptomatic affection, and as little entitled to characterize an epidemic as the petechiæ that appear in some epidemic fevers, and from which the disease has been termed *petechial* or *spotted fever*.

The miliary eruption appears in the form of small round vesicles about the size of a millet-seed, surrounded by slight inflammation. It is most abundant on the neck, breast, and back, but is less copious on the face and extremities, and sometimes comes out in irregular patches, frequently appearing and again disappearing without evident cause. The vesicles are at first so exceedingly small that they can hardly be distinguished except by their roughness: when examined through a lens, the round vesicular form of the eruption, each vesicle containing transparent lymph, is distinctly visible, though from the red colour of their under-surface being transmitted through the transparent pellicle, they are of a red colour; the lymph, however, becomes in the course of twenty-four or thirty hours opaque, and thus gives a pearly white appearance to the eruption. From this evidently originated the two varieties mentioned by the older writers; the *red* and the *white* miliaria, *(rothen friesel* and *weisse friesel* of the Germans,)—a distinction not only unnecessary but unfounded, as it is apparent that both these supposed varieties are only different stages of the same eruption.

Miliaria is sometimes rapid in its progress, and the eruption copious and generally diffused: in other instances it is partial and slow, and though the vesicles are usually distinct, they sometimes cohere and become confluent, and thus assume the form of phlyctenæ or small bullæ.

Its duration is various: it sometimes passes off in a day or two; the vesicles either breaking, or the lymph being absorbed, slight desquamation of the cuticle terminates the disorder. According to Bateman, it frequently lasts from seven to ten days, and sometimes much longer: indeed, under the treatment formerly pursued, when the sick, according to the expression of Blackmore, lay "drowning in sweats," it was not uncommon for crops of vesicles to be renewed a second, third, or even a fourth time, and the whole disease to be protracted to nearly fifty days.

The only disease with which miliaria can possibly be confounded is *eczema*. From this it may be distinguished by its being invariably symptomatic of some acute febrile disorder, and by its rapid progress and short duration. Besides, in *eczema* the vesicles are usually confluent, and confined to a circumscribed or limited space, whilst in *miliaria* they are generally distinct, and much more numerous.

With regard to the diseases in the progress of which miliaria occasionally appears, we may observe that since the introduction of the cooling regimen which now forms an essential part of the treatment of every variety of febrile disorder, it is comparatively rarely met with. In common continued fever, even in the worst forms of it, when judiciously managed, its appearance is almost unknown. We cannot bring to our recollection a single instance out of the numerous cases which we have had under our care in the Fever Hospital, though we have had repeated occasion to observe it in the crowded ill-ventilated apartments of the lower orders, when ventilation has been unattended to, and a stimulating regimen adopted.

Miliaria is more apt to appear among women after delivery than in any other circumstances; so frequent, indeed, was its occurrence half a century ago, that it was described by some writers as an epidemic among lying-in women. From the accounts given of the management after delivery, by those who witnessed it at the period referred to, there can be no question that the eruption was induced by the injudicious mode of treatment adopted. In later times, since the adoption of a more cooling plan of management after delivery, not only are febrile disorders less frequent and violent, but the miliary eruption is seldom observed; and when it does occasionally appear, its origin may be always traced to an over-heated atmosphere, over-loading the patient with bed-clothes, and the stimulating regimen adopted by the poorer classes, under the mistaken notion that the parturient female may be thus prevented from *catching cold*. Miliaria is also a frequent accompaniment of the milk-fever, and of ephemera or weed, when the perspiration is injudiciously encouraged. Dr. Burns thinks that this is by far the most frequent form under which the miliary rash appears, but he states that it is sometimes observed in women who

* *Pujol*, Mém. sur la fièvre miliare qui régna en Languedoc et dans les provinces limitrophes, durant le printemps de 1782. *Rayer*, Histoire de l'épidemic de suette miliare qui a régné, en 1821, dans le département de l'Oise.

have been much reduced, but who are free from fever.

With other fevers, Bateman remarks, in which a similar method of treatment was pursued, though in a less degree, and the patient was confined to bed, the miliary eruption, with its attendant languor and exhaustion, was frequently conjoined, especially with catarrhal and rheumatic, and also with typhoid, remittent, and intermittent fevers. Whence the writers who have described the miliary fever, speak of it as being disguised under, or counterfeiting the character of these fevers respectively. In the summer, indeed, when ventilation and coolness are not sufficiently attained or attended to, a slight miliary eruption is even now occasionally seen: a miliaria *clinica*, in fact, may be thus induced by any circumstance that confines a person to bed; as an accident, or a surgical operation, an attack of hysteria, a state of asthenia, &c. From the increase of cutaneous heat, connected with the exanthematous fevers of the nosologists, some degree of miliaria is liable to occur in them all, but more especially in scarlatina; and a few larger pearl-coloured vesicles also occasionally appear.*

The miliary eruption does not afford any relief to the symptoms of the disease on which it supervenes: it is generally preceded by an increase of the fever, and a sensation of heat, pricking, or tingling of the skin. A peculiar acid smell of the perspiration is also perceptible, though we apprehend, from this fetor of the perspiration being frequently noticed in various forms of fever in which there is no cutaneous efflorescence, its connexion with the eruption is not satisfactorily established.

Though there be no proof of miliaria being contagious, several attempts to induce the disease by inoculation having failed, it is affirmed by Frank † and other writers to be often epidemic, and in some localities endemic. Rayer has given an excellent description of an epidemic miliaria, attended with symptoms of a malignant character, which proved in many instances rapidly fatal. From the account given by this writer, it seems to have prevailed epidemically, chiefly in Picardy, Languedoc, and Normandy; but it is so little known at Paris, that many physicians have expressed their doubts of the reality of such a disease. From observations made during epidemic visitations, it appears that no age is exempt from it, though the greater proportion of cases occur in adults, and that females are more frequently the subjects of it than males.

In the epidemic which prevailed in the autumn of 1821, in the departments of the Seine and Oise in France, and which was very fatal, we are told by Rayer that the eruption was preceded by feverish indisposition accompanied by copious perspiration, which continued throughout the progress of the disease.

The eruption appeared generally about three or four days afterwards, first on the neck or around the ears, and spread to the chest and back, and thence over the abdomen to the inferior extremities. The rash was sometimes generally diffused; in other cases it was only partial; the vesicles being distinct, small, and diaphanous, though sometimes large and confluent, so that on some parts of the body large bullæ appeared. The odour of the perspiration was often extremely fetid, which continued in general during the progress of the disease.

The disorder was in many instances mild, but in the more severe cases inflammation of the mucous membrane of the intestines, or of the lungs, or of the brain or its membranes supervened, and rendered the disease more dangerous.

Its duration was various. The more severe cases often terminated fatally within twenty-four or forty-eight hours. In the milder cases, it sometimes disappeared in eight days; more generally, however, it was protracted to the end of the second week, and sometimes lasted three weeks.

Treatment.—From what has been stated of the nature of miliaria, it is evident that it is to be regarded only as a symptomatic affection. Free ventilation and a cooling regimen constitute not only the best means of preventing, but of removing the rash; therefore when it supervenes on acute diseases the cooling antiphlogistic treatment is to be pursued. For this purpose the chamber is to be duly ventilated; the linen of the patient changed as often as circumstances permit; the thirst abated by cooling subacid drinks; the bowels regulated; and the diet should be of the mildest kind. Tonics have been often found beneficial, and none are better than the mineral acids—as the diluted sulphuric or oxymuriatic, which may be taken at intervals. When miliaria occurs as an epidemic, the same treatment has been successfully pursued; and when complications arise in the progress of the disorder, the particular local affection must be treated on the principles already fully detailed in the article Fever.

(A. Tweedie.)

MINERAL WATERS.—See Waters, Mineral.

MORTIFICATION.—The term mortification is generally employed in this country to express that state which has been induced in a part of the body by the complete and permanent extinction of its vital properties. On the continent, however, the term *gangrene* is employed to signify the same state; whilst in England it is more commonly used to denote the incipient stage of mortification; a state of a part in which there is a diminution, but not a total extinction of the vital properties; in which the blood is still supposed to circulate in the larger blood-vessels, and the nerves to retain a part of their sensibility: the complete cessation of

* Practical Synopsis of Cutaneous diseases, p. 245.

† De Cur. Hom. Morb. Epit. tom. iii. Sect. 322.

circulation and an entire want of sensibility characterize the second or last stage of mortification, which is called *sphacelus*, whether the dead part has or has not become putrid, whether it has been separated or not from the living parts. Again, some pathologists confine the term gangrene to the death of the *superficial* textures of parts, and particularly of the soft parts; and sphacelus, to the death of the *whole substance* of an organ, as of the soft parts and bones at the same time.

Other denominations have been given to this pathological state, founded on particular conditions of the affected part, which have been observed to precede or accompany mortification. Thus, we have what is called *hot gangrene*, or that which is preceded or accompanied by inflammation; and *cold gangrene*, or gangrene without inflammation. We have also *humid gangrene*, from the affected part containing a greater or less quantity of decomposed or other fluids; and *dry gangrene*, when these fluids are not present, or only in very small quantity, and which being frequently the case in gangrene affecting the external parts of old people, has, on that account, also been named *gangræna senilis*.

Although some of these distinctions are, no doubt, of considerable importance, some of them are extremely vague and improper, and much less deserving of our attention than the conditions of the part affected with mortification, and the causes by which this state is induced.

Before entering upon the general considerations which present themselves on the several kinds of mortification which occur, it may be well to remark that we shall employ the terms *gangrene* and *sphacelus* as they are generally employed in this country; that of *mortification* constituting the generic sign of the disease of which they indicate particular stages. Although, however, the adoption of these two terms is founded on the differences which exist between the morbid conditions to which they are applied, and their use is necessary to distinguish a state of a part yet susceptible of recovery from one that is not, we shall find that it is by no means easy to determine—even when external parts are the seat of mortification, and, consequently, when many of the phenomena of this disease are capable of being submitted to actual observation—whether the vitality of the affected part be partially or wholly destroyed. It is, perhaps, on this account, and as expressing also a favourable doubt, that the term gangrene is much more frequently employed than that of mortification or sphacelus.

As the descriptive characters of mortification were originally drawn from the appearances which this disease presents when it attacks the external parts of the body, they have ever since been employed by the pathologist as the means of enabling him to detect it in internal organs after death. It may, however, be fairly questioned whether the application of the term mortification has not been too restricted; and whether parts deprived of their vitality and separated from the living tissues should not be designated by the same appellation as those which, similarly situated, differ from them only in point of colour, and perhaps smell. Softening of the cerebral substance, of the mucous and frequently of the serous membranes, constitutes a state of positive death; but the softened substance, in these instances, presenting neither the peculiar colour nor odour of external parts when mortified, it has been considered necessary to distinguish softening from mortification, by a term expressive of its principal character—that of softness. We shall, therefore, treat in this article only of those states which are usually comprehended under the term mortification.

Considered in a general point of view, and in relation to the causes by which it is produced, or the morbid conditions of the part in which it occurs, we find that mortification takes place in a variety of ways, and under very different circumstances. A knowledge of these facts suggests the propriety of arranging the several kinds of mortification under the three following heads:—

1. Mortification from cessation of the circulation.
2. Mortification from the violent operation of mechanical, chemical, and physical agents.
3. Mortification from the deleterious influence of certain poisons.

Cessation of the circulation in a part of the body may be produced in the three following ways:—by inflammation; by mechanical causes which obstruct the passage of the blood; by local or general debility.

I. Mortification from inflammation.

There is no tissue or organ of the body which may not become affected with mortification as the immediate or mediate effect of inflammation. Mortification is, however, much more frequently observed in those organs in which the vascular system predominates, or in which an inordinate accumulation of blood is readily produced, on account of their great sensibility and their direct exposure to the influence of those causes which give rise to inflammation. Hence the reason why gangrene and sphacelus occur more frequently in the skin and cellular tissue, mucous membranes and lungs, than in the other tissues and organs of the body, as immediate effects of inflammation; and why they are so rarely observed in serous and fibrous tissues, which contain few or no bloodvessels.

Not only is mortification rarely observed in these latter tissues, but it may also be said never to occur in them as an immediate effect of inflammation, for they are never found in a state of gangrene or sphacelus, unless the cellular membrane with which they are in contact, and from whose vascular system their nutrition is derived, has previously been diseased. Such also is the case in caries, (death of bone,) as a consequence of inflammation of the periosteum and medullary membrane.

These circumstances enable us to explain why, in certain cases, mortification takes place in one tissue and not in another, although the inflammation by which it is preceded is the

same in kind, degree, and duration. There are, however, many other circumstances of perhaps still greater importance, the single or conjoint operation of which favours in a most remarkable manner the termination of inflammation in gangrene and sphacelus.

1. Certain diseased states of an organ or tissue—of the solids in general, or of the blood in particular—are circumstances which, while they predispose to inflammation, give at the same time to this pathological state a peculiar tendency to terminate in gangrene or sphacelus of the parts which it affects. Thus, chronic inflammation of a portion of an organ, particularly when accompanied by induration and obstructed circulation of the affected part, is not unfrequently followed by gangrene and sphacelus; and still more frequently is this the consequence of an acute attack of the same disease, either in that portion of the organ previously modified, or in a contiguous portion of it, through the medium of which the nutrition of the former was derived.

2. In like manner, when inflammation occurs in an organ in a state of congestion, depending on the presence of an obstacle to the return of the venous blood, the danger of its terminating in mortification is increased in proportion to the extent of the obstacle or the degree of congestion to which that obstacle has given rise.

3. The state of general debility which prevails at the termination of protracted fevers, or during the first period of convalescence, is well known not only to favour the development of inflammation, but to give to this disease a great tendency to terminate in mortification.

4. The influence which a diseased state of the blood exercises in the production of mortification is well exemplified in scorbutus; local inflammation in this disease, even when it has only arrived at the congestive stage, frequently terminating with great rapidity in gangrene and sphacelus.

The termination of inflammation in either of these states is likewise regarded by many to depend much on the nature of the cause by which the inflammation has been induced. It would, however, be more correct to say that the termination of inflammation in gangrene or sphacelus depends on the nature of the change which follows the immediate operation of such a cause on the organ in which inflammation afterwards takes place.

It is true that, independently of any peculiarity of constitution, a mechanical stimulus will produce inflammation very different in its external characters, intensity, extent, duration, and mode of termination, from that which follows the operation of a chemical agent or certain poisons. But, were we to attribute these differences solely to something peculiar in the nature of the exciting cause, we should find it impossible to account for the various phenomena by which they are accompanied. For, in one case, the inflammation may be intense, and the gangrene by which it is followed comparatively slight in degree and limited in extent; in another, it may be mild or imperfectly developed, and yet gangrene and sphacelus succeed each other to a great extent; and in a third, whether severe or mild, its termination in mortification may take place slowly, or proceed with frightful rapidity. All these varieties, also, are observed, without a corresponding change in the causes by which they are produced; the same cause producing at one time only inflammation, at another gangrene or sphacelus.

Instead, therefore, of seeking in the nature of the exciting cause itself an explanation of these remarkable differences, we must have recourse either to the peculiar change which it has induced in the part which afterwards becomes the seat of inflammation, or to some previous modification of the kind to which we have already alluded; such as a morbid state of an organ, of the body in general, or of the blood in particular.

The above are some of the more remarkable of the circumstances which favour the development of gangrene or sphacelus as a consequence of inflammation: the following are some of those which exercise an opposite influence.

1. The first of these in importance is a perfect state of health, whereby inflammation, instead of terminating in gangrene or sphacelus, as it would have done in an individual less favourably circumstanced, is limited to one or other of its more simple forms,—as the adhesive, suppurative, or ulcerative.

2. The structure and situation of an organ, whereby the increase in quantity of the fluids of nutrition and secretion, which takes place during inflammation, is either entirely prevented, or very limited in degree and extent. All secreting organs or surfaces which possess a free exit to their superabundant fluids, natural or morbid, furnish examples of this kind; as the serous and mucous membranes, which, compared with the testes or breasts, in which the circulating and effused fluids are retained, are rarely the seat of gangrene or sphacelus as the direct consequences of inflammation.

3. The importance of an organ, whereby death supervenes before mortification can take place as a consequence of inflammation. Mortification of the brain and heart seldom or never occurs, unless when it follows inflammation produced by the direct operation of mechanical causes. When it occurs as an idiopathic affection in the brain and heart, the derangement of function by which it is accompanied becomes so great not only in these organs themselves but throughout the whole body, that general death supervenes, before the inflammation has acquired that degree of severity which gives rise to local death or mortification.

General phenomena of gangrene and sphacelus.—As the more remarkable changes which take place in the circulation, innervation, temperature, colour, and consistence of a part affected with gangrene or sphacelus, as a consequence of inflammation, are seldom ob-

served unless on the external surface of the body, we shall describe them as they occur in the skin and subjacent parts.

When inflammation is about to terminate in gangrene, the inflammatory redness assumes a darker tint; it becomes deep purple, livid, or almost black; the temperature of the part diminishes, but not always its consistence, which, on the contrary, may be increased, from the presence of accumulated fluids; small vesicles appear on its surface, formed by the effusion of serosity, or serosity and blood, under the epidermis; the sensibility of the part, which, as well as the temperature, was previously increased, is now much diminished, and the seat of the pain which accompanies the inflammation is transferred to the deeper-seated tissues in contact with those which have now passed into the state of gangrene.

When these modifications of colour, consistence, temperature, and sensibility, continue to increase, and terminate in sphacelus, the part thus affected assumes a still deeper tint; it becomes of a dirty brown or black colour, sometimes grey, greyish yellow, or greenish. The vesicles or phlyctenæ become more numerous and larger, or the whole of the epidermis covering the sphacelated part may be completely separated and distended with bloody serum, or ruptured from the same cause, and lying in wrinkles in the denuded and discoloured cutis. The skin and cellular tissue beneath the epidermis are swollen and puffy, and crepitate when pressed; or they are soft, and flaccid, and cold, and may be cut, pinched, or otherwise stimulated, without pain or feeling of any kind being induced: and, lastly, the sphacelated surface emits a strong cadaverous odour.

When these latter appearances present themselves, but more particularly when the peculiar odour of gangrene is perceived, they may be regarded as certain signs not only of complete death of the affected part to a certain depth, but also that putrefaction has already taken place. The local emphysema and fetor of putrefaction produced during life, constitute, therefore, signs of great value in mortification. Their absence, however, furnishes no proof that local death may not already have taken place; for putrefaction or chemical decomposition of an organ may not follow as a consequence of the cessation of those powers by means of which it was enabled to resist the injurious influence of external agents, until some time has elapsed, the length of which will depend on various circumstances, but more particularly on the quantity of fluids contained in the affected organ, and the degree of temperature to which it is exposed.

So long as gangrene continues to spread, the dark-red colour by which it is characterised is diffuse, and loses itself insensibly in the surrounding skin. But when it is about to terminate favourably, the dark-red colour becomes more circumscribed, gradually disappears, and is replaced by a brighter red, which extends over the affected surface, accompanied by a diminution of the swelling and pain. By-and-bye the natural temperature returns, and the healthy characters and functions of the part are restored, without any solution of continuity having taken place.

A similar change of colour is observed to precede the cessation of sphacelus. It appears on the limits of the dead parts in the form of a narrow circle, and announces that adhesive inflammation, the means which nature employs to arrest its progress, has commenced. Ulceration then takes place along the internal border of the inflamed skin, and a separation is thus effected between the living and dead parts, the latter falling off in the form of what is called *a slough*. The loss of substance which is thus occasioned is either partially or wholly repaired by means of the coagulable lymph which is thrown out on the denuded surface, and which, becoming organized, assumes a membraneous or granular form, according to the nature of the tissue to be repaired, and constituting ultimately what is called a *cicatrix*.

Such are the general characters of mortification produced by inflammation of the skin and subjacent textures. We say subjacent textures, because inflammation of the former, when such as to produce gangrene and sphacelus, is always complicated with inflammation of the latter.

In other tissues and organs these phenomena are, as we have already observed, more or less modified: the differences which they present depending principally on the degree of vascularity and sensibility of the affected organ. Hence the variety observed in the quantity of blood, and the kind and extent of the effusion by which it is followed in inflammatory gangrene and sphacelus; the change of bulk which organs undergo in either of these stages of mortification; the extent to which their temperature and sensibility may be reduced before they become actually dead; and the length of time that elapses from the commencement to this the ultimate effect of the disease. Examples of these varieties will be found in the following details on mortification of particular tissues and organs.

Mortification of particular tissues from inflammation.

1. *Mortification of the cellular tissue.*—The cellular tissue is not only more frequently the seat of mortification, but is also more extensively and more rapidly destroyed by it, than any other tissue of the body. It presents, likewise, considerable variety in these respects, in different parts of the body; gangrene and sphacelus occurring more frequently in the subcutaneous than in the submucous cellular tissue; in the fingers more frequently than in the toes; in the thigh and arm than in the leg and fore-arm, owing to the one being more exposed than the other to external injury, or other exciting causes of inflammation.

A greater quantity of cellular tissue in one part than in another, whereby the diffusion of the effused fluids is facilitated, and the pre-

sence of fibrous envelopes which afterwards prevent their escape to the external surface, contribute likewise to the greater frequency of the disease, and favour its extension and the rapidity of its progress. The most remarkable example of the influence which these circumstances exercise in the production of gangrene and sphacelus of the cellular tissue, is met with in *erysipelas phlegmonodes*.

a. Subcutaneous cellular tissue.—When erysipelas attacks the subcutaneous cellular tissue of the extremities, and although it may at first be limited to a very small space of the forearm, for example, it sometimes spreads with great rapidity over the whole of that part of the limb, extends upwards to the shoulder and neck, and descends along the back, breast, and side. Throughout the whole of this course the muscles, bloodvessels, nerves, and tendons are laid bare, and float in the putrid cellular tissue, and in the serosity, pus, and blood, that are effused during the violence of the inflammation.

Such is the state of the cellular tissue not only in erysipelas phlegmonodes when it occurs as an idiopathic disease, but also when it succeeds to slight wounds or punctures of the arm in bloodletting, and the fingers in dissection. In such cases the cellular tissue appears to be the primary seat of the inflammation, which may either extend in the manner we have described, or be confined to the cellular sheath of the bloodvessels. In the latter case we have frequently what is called phlebitis; the venous circulation is interrupted; the blood ceases to circulate, coagulates, and nutrition not being maintained by the formation of a collateral circulation, gangrene of the extremity follows as an inevitable consequence.

Besides the *diffuse form* of gangrene and sphacelus of the subcutaneous cellular tissue, there is also a *circumscribed form* which is observed in furunculus, common carbuncle, or anthrax. The great accumulation of blood, and the still greater and rapid effusion of serosity which takes place in these circumscribed acute inflammatory affections, produces a state of extreme induration and compression of the cellular tissue, a greater or less portion of which being thus as if strangulated, dies from want of nutrition, becomes separated from the living parts, and is expelled, in the form of a grey or straw-coloured spongy or pulpy mass, through an opening made in the skin by a similar process, by ulceration, or a surgical operation.

In cynanche parotidea, or mumps, the cellular tissue of the salivary glands is very similarly situated as in carbuncle or anthrax. It is this tissue that is the seat of the inflammation, congestion, and effusion; and being prevented by the unyielding nature of the glandular tissue of the organ from accommodating itself to the increased quantity of the fluids thus poured into it, it soon sloughs, even sometimes before the glandular tissue has undergone any remarkable change of colour or consistence, and before suppuration has commenced.

It may be remarked here that mortification of the adipose tissue always follows that of the skin and cellular tissue, and in fat persons occasions sometimes the most frightful loss of substance.

b. Submucous cellular tissue.—When *diffuse* or *circumscribed* inflammation of the cellular tissue, terminating in gangrene or sphacelus, occurs in internal organs, it presents the same general characters as those we have just now described. In these, however, it never proceeds to the same extent as when it affects the external parts of the body, either on account of the progress of the disease being checked by one or other of the circumstances to which we formerly alluded, or from death taking place at a very early period.

The *diffuse form* of the disease in internal organs is seldom observed except in the pharynx and larynx, either as a primary affection, or in connexion with erysipelas phlegmonodes of the limbs, face, or neck.

In these situations the sloughing of the submucous cellular tissue is very limited, and always accompanied by a corresponding state of the mucous membrane which covers it. The effusions of albuminous and puriform fluids which take place at the same time, occasion a great increase of bulk, and produce dysphagia, great difficulty of breathing, or complete asphyxia. Hence the frequently fatal termination of the disease before it has passed into gangrene or sphacelus, and which has sometimes been described under the name of serous, albuminous, and purulent œdema of these parts.

Circumscribed inflammation of the submucous cellular tissue terminating in gangrene and sphacelus, seldom occurs as a primary affection. It follows, in general, inflammation of the mucous membrane, but may afterwards proceed to a considerable extent, and occasion sloughing of all the other tunics of the organ in which it occurs, but more particularly those of the intestinal tube: such is a frequent cause of intestinal perforation, and the fatal peritonitis by which it is followed.

c. Sub-serous cellular tissue.—Gangrene of this tissue as a consequence of inflammation is more frequently observed than sphacelus. Neither of them occurs to any great extent, even where this cellular tissue is most abundant, and where it might be called *retro*-serous rather than *sub*-serous, as in the mediastinum, iliac and lumbar regions.

Inflammation assumes a gangrenous termination more frequently in the sub-peritoneal than in the sub-pleural cellular tissue. In some forms of peritonitis, for example, this state is very marked, although not to be detected by ocular inspection. It is only after the peritoneal covering of the intestine has been divided circularly, and the intestine itself is stretched or pulled out, that the diseased state of this tissue becomes visible. When thus treated, the intestine may as it were be *unsheathed*, that is to say, drawn out of its peritoneal covering, the muscular coat now constituting its external surface.

The great facility with which the sub-serous cellular tissue is thus torn in some cases of

acute peritonitis, its pulpy softness in some points, and occasionally a certain degree of fœtor, disposes us to believe that these morbid appearances indicate a near approach to, if not an actual state of gangrene.

In the cavity of the pelvis, and in the iliac and lumbar regions, these appearances are more marked and more easily detected. Not only gangrene but sphacelus of the cellular tissue is occasionally found in these regions; the inflammation which precedes it being sometimes confined to the cellular tissue, at others extending to the peritoneum.

Gangrene and sphacelus of the sub-peritoneal cellular tissue occurs more frequently in the cavity of the pelvis than in any of the other regions which we have named, on account of the number and importance of the organs which it contains.

Chronic and acute diseases of the uterus and rectum, as cancer and phlebitis, extend their ravages to this tissue, and excite gangrenous inflammation.

External violence, also, is not an uncommon cause of a similar state of disease in this situation; and we have known more than one case in which a blow or fall has occasioned, from the supervention of inflammation in the cellular tissue, extensive destruction of the contents of the pelvis, such as denudation and necrosis of a part of the sacrum, gangrene and sphacelus of the neck of the uterus, and perforation of the vagina.

d. Lamellated cellular tissue, or that which separates the larger subdivisions of organs. Gangrenous inflammation of the cellular tissue of muscular, glandular, and other organs, is less frequently observed than the former as a primary disease. It is only in certain of these organs, particularly the muscles of voluntary motion and the lungs, that we can detect with certainty its existence as a primary affection. We shall notice its occurrence in the latter only, on account of the peculiar character of the lesion to which it gives rise in this organ. A distinct layer of cellular tissue separates, one from the other, the numerous lobules of which the lung is composed. Either of these—the interlobular cellular tissue, or the lobules themselves—may become the special seat of gangrenous inflammation.

When a portion of lung is examined, in which the interlobular cellular tissue is alone or principally affected, it presents a number of lines of considerable breadth, of a straw-colour, having the peculiar distribution of the lobules, and formed by the effusion of pus into the cellular tissue by which they are separated. In this stage of the inflammation, the cellular tissue is either very soft or easily ruptured, and when sphacelus takes place, is converted into a grey pulp, in which one or several lobules float, attached only by a narrow pedunele composed of their respective bloodvessels and bronchi obliterated.

2. *Mortification of mucous membranes.*—Although inflammation of the mucous membranes is not unfrequently observed to terminate in gangrene and sphacelus, such is by no means so frequently the case as was imagined by the older pathologists. Great congestion, some forms of melanosis, and several other kinds of discoloration of this tissue, produced not only during life but after death, were frequently confounded by them with mortification. The mucous membrane of the throat and intestines is more frequently the seat of this disease than that of any other organ.

In the former it is occasionally met with to a limited extent in cynanche tonsillaris and pharyngea, and constitutes the distinctive anatomical character of cynanche maligna or angina gangrenosa, whether it occurs alone or in connexion with scarlatina.

In the latter it follows as a consequence of certain forms of acute enteritis, either when the inflammation affects the mucous tissue itself, or its follicular structure at the same time.

In either of these situations the mucous and follicular textures are primarily affected, and may be converted into sloughs of considerable extent, without the submucous cellular tissue being destroyed.

Thus deprived of their vitality, the mucous and follicular textures are, at first, of an ash-grey or straw-colour, and may afterwards become brown or black. They are, however, frequently of the colour of the matter with which they are in contact: the fluid part of which is readily imbibed by the soft, spongy tissue of the slough.

The mucous membrane which surrounds the slough is generally gorged with blood, indicating either a state of great congestion, or gangrene. Its colour, particularly in the throat, is livid or deep purple. When, however, the gangrenous inflammation is confined to the follicles, as those of Peyer (glandulæ agminatæ), and when the greater part or the whole of the follicle has sloughed, little congestion or inflammatory redness may remain. And, besides, if these glands have previously been the seat of disease, as in tubercular phthisis or chronic enteritis, a slight attack of acute inflammation may be sufficient to destroy their vitality, without any remarkable increase of vascularity or redness being found in them to indicate the nature of the destructive cause.

In this, as well as in many other cases of the same disease in other parts of the body, the state of sphacelus must be determined by the colour, consistence, and smell of the part, taken in connexion with the other collateral negative evidence, afforded by the absence of any other cause capable of producing such a state.

On the inside of the cheeks, the surface of the velum and amygdala and pharynx, the presence of circumscribed portions of inspissated mucus, or small patches of coagulated albumen or lymph, formed on the surface of the mucous membrane or epithelium, may likewise be confounded with sphacelus. Detached portions of the epithelium may also assume the appearance of sloughs of the mucous membrane.

Gangrenous inflammation of the mucous membrane of the air-passages is by no means common, unless it be accompanied by a similar disease of the pulmonary tissue, in which case

it is generally confined to the smaller bronchi. We have, however, seen it follow perforation of the trachea from malignant disease of the œsophagus, and necrosis of the thyroid cartilage, to which we shall refer more particularly afterwards.

The mucous membrane of the genital and urinary organs is seldom affected with mortification, unless it has been previously injured by mechanical causes, as in some cases of stone of the bladder and kidneys, in lithotomy, stricture of the urethra, and difficult labour, by the improper use of instruments, and also the pressure of the head of the child, to which we shall afterwards refer more particularly, as belonging to another division of our subject.

Of these two systems of organs, the uterus presents the most marked examples of mortification as an immediate consequence of acute inflammation. It attacks the internal surface of this organ either immediately or shortly after delivery; is confined to a small portion of it, particularly to that which gave attachment to the placenta; or occupies its whole extent. The colour of the part affected is of a dirty yellowish grey, brown, black, sometimes greenish or bluish; it feels soft or spongy, is easily torn, and is generally covered with putrilaginous fluid substance of a strong gangrenous odour. When this substance has been removed, the surface is generally found to be rough and irregular, from the presence of the remains of the placenta, and more frequently from an exudation of fibrinous matter, which we have sometimes found to cover the whole surface from the fundus to the os tincæ.

The substance of the uterus is sometimes affected in this manner to a considerable depth, but is more frequently only softened, without having undergone any remarkable change of colour. The presence of pus in the fibrous structure of the uterus is seldom observed beyond the gangrened or sphacelated surface, but is frequently met with in the veins and lymphatics. The appearances which we have described as occurring in gangrenous inflammation of the internal surface of the uterus present considerable variety, owing, apparently, to differences in the seat and extent of the inflammation, and the period at which it proves fatal. But as the investigation of these and other circumstances connected with the pathology of this important subject does not come within the scope of this article, we must refer the reader for further information to the articles Puerperal Fever and Uterine Phlebitis.

3. *Mortification of serous membranes.*—The few general remarks which we have made on gangrene and sphacelus of the sub-serous and retro-serous cellular tissue, shew that the same morbid states must occur in the serous membrane itself. For as the bloodvessels of this membrane are principally, if not entirely, derived from those of the cellular tissue with which it is in immediate contact, any disease capable of arresting the circulation in the vessels of the latter, must be followed by a similar result in those of the former, the portion of which so circumstanced being soon deprived of its vitality. This is, in fact, the mode in which serous membranes become affected with gangrene or sphacelus. It is not from their being loaded with blood, under the stimulus of inflammation, that they die and are separated, but from the supply of their nutritive fluid having been cut off, on account of the morbid condition of the circulation in the cellular tissue to which we have just alluded, or from this tissue having been destroyed by suppuration, ulceration, or sphacelus. Sloughing of the serous membrane occurs from one or all of these morbid states, the immediate or subsequent effects of inflammation, and is often followed by a solution of continuity which establishes a communication between the serous cavity and that of a neighbouring organ; such as between the cavity of the peritoneum and that of the stomach, intestines, uterus, kidneys, and gall-bladder, or between the cavity of the pleura and bronchi. The contents of these organs are effused into the serous cavities, and excite a degree of inflammation which is seldom equalled either in the rapidity of its progress or the certainty with which it destroys life. The inferior portion of the small intestine is the seat and source of these fatal changes of structure much more frequently than any other portion of the digestive tube, or any other organ of the body. And, besides, sloughing of the peritoneum perhaps never occurs under the circumstances we have already mentioned, except in the situation of the glands of Peyer, or occasionally in those of Brunner. Inflammation of these glands is extremely common in various diseases of the digestive organs, and whether acute or chronic, may give rise to the same fatal result, viz. perforation of the intestine and peritonitis. (See Perforation of Organs.)

The colour of the sphacelated serous membrane is generally of an ash-grey, sometimes ochrey from the presence of bile or blood. It is soft and spongy, and frequently does not present any peculiar smell. Before it separates, the subserous cellular tissue around it is frequently seen injected with fine red capillaries; occasionally, also, all the tunics of the intestine are pale, and the accidental opening appears as if it had been made by excision. But the external border of the opening is always smooth, although irregular, whilst on the internal surface of the intestine it is rough or ragged, or presents other marks of being ulcerated.

A dark brown, dark blue, or black colour of the peritoneum, extending over a considerable portion of its surface, has frequently been described by older authors as indicating the presence of mortification of this membrane. These discolorations, however, depend on causes very different from those which give rise to mortification, and the nature of which is particularly noticed in the article Melanosis.

Gangrene and sphacelus of the pleura take place under circumstances very similar to those which produce them in the peritoneum. Sloughing of the pleura is, however, by no means so frequent as that of the peritoneum, as a consequence of inflammation of the sub-serous or pulmonary tissue. This is owing, in the first

place, to the pleura pulmonalis receiving a superior supply of nutritive material from the highly vascular tissue of the lungs, as well as from the interlobular cellular tissue with which it is continuous; and in the second place, from its not being so exposed as the peritoneum, when laid bare, to the operation of highly stimulating fluids.

Gangrenous inflammation of the pulmonary tissue is, next to the presence of tubercle, the most frequent cause of perforation of the pleura pulmonalis from sloughing.

The presence of air and other fluids in pnuemothorax and empyema have been known, either from their stimulating qualities or the mechanical distention which they occasion, to produce gangrene and sphacelus to a considerable extent, of both pleuræ; and the violent inflammation which follows some mechanical injuries is well known to produce a similar effect.

Sloughing of the serous membranes of the brain we have never seen as an immediate consequence of their inflammation; nor do we believe that it ever occurs to any extent, unless it is induced by a mechanical cause, such as wounds and blows on the external surface of the head, or the presence of foreign substances in the brain itself. The same may be said of synovial membranes.

IV. *Mortification of fibrous membranes.*—We have already stated that these membranes become deprived of their vitality, slough, and are separated, only when the cellular tissue with which they are in contact has previously been destroyed. The death of cartilage and bone, as fibrous tissues, takes place in a similar manner,—that is to say, from previous disease of the perichondrium or other contiguous tissue, and of the periosteum. It is, however, worthy of remark that the vascular system of the medullary membrane, particularly of long bones, may be the primary and chief seat of the disease, which afterwards gives rise to necrosis and sphacelus of the periosteum. We allude here to phlebitis of the medullary membrane, which succeeds to amputation and some external injuries; and, although belonging in this case to the province of surgery, it is more immediately connected with medicine and the duties of the physician than might at first sight be believed. For it is of importance, not only in a surgical point of view, to know that such is the nature of the inflammation which often follows amputation and some diseases of bone, but also as regards the diagnosis and treatment of the diseased states to which it so frequently gives rise in internal organs. Thus, we have not only purulent infiltration in the lungs, liver, brain, &c., but, in some cases, also gangrene and sphacelus, particularly in the two former of these organs, as consequences of phlebitis of the medullary membrane of bone.

5. *Mortification of muscular tissue.*—Inflammation of muscular tissue seldom terminates in mortification, unless produced by an injury which affects at the same time other neighbouring tissues. Gangrene and sphacelus of the muscular tissue of the organs of deglutition and digestion, and perhaps of the heart, sometimes accompanies similar states, or severe inflammation of the other tissues with which it is in contact, but particularly of the cellular tissue. The loss of substance, thus occasioned, of the muscular tissue in a hollow organ such as intestine, becomes afterwards a serious, and, perhaps, irremediable evil; for muscular tissue not being reproduced, a cicatrix, equal in extent to the loss of substance sustained, is formed, which, possessing a contractile property, gradually diminishes in bulk, and ultimately constricts, even to complete obliteration, the cavity of the tube in which it exists. Such instances are not rare in the small intestines after fever, and the writer possesses a delineation of a case in which there were three strictures of the small intestine, through which only a small probe or writing-quill could be passed.

We have not seen a case of gangrene of the heart, unless some forms of softening to which this organ is liable are to be regarded as of this nature. (See Softening of Organs.)

Gangrene and sphacelus of arterial and venous tissues may be noticed here, from the functional connexion which exists between them and the heart. They are observed more frequently in the latter than in the former tissue, but do not occur in either until after the cellular sheath of the vessels has been destroyed.

When gangrene or sphacelus of the *spleen* is observed, it is found to follow external injury followed by peritonitis, or, as it is believed by some, a morbid state of the blood, with which it is in general greatly distended, as in severe cases of some intermittent and remittent fevers of marshy countries. The appearances, however, which this organ presents in these fevers is perhaps in a great measure owing to putrefaction.

Mortification of particular organs from inflammation.

Having pointed out what appears to be the most important of the circumstances observed in mortification of the elementary tissues of the body, we shall now proceed to describe those which present themselves when this disease takes place in organs. In doing so we shall confine ourselves to the consideration of mortification of what is called the *parenchyma* of organs, or what in more precise language may be called the *compound tissue* of organs,—the result of a peculiar combination of the simple or elementary tissues.

We have already remarked that the frequency of mortification, the extent to which it proceeds, and consequently its severity, are, *cæteris paribus*, in proportion to the quantity of the cellular and vascular elements which enter into the composition of an organ. In this point of view no organ of the body is so conspicuous as the lungs, and in none does mortification occur so frequently or proceed to such an extent. Being exposed, too, to the direct influence of a great number of those agents which excite inflammation, as well as to the injurious operation of those causes which produce, mechanically or otherwise, great derangement of the circulation in general, the fre-

quency of the occurrence of mortification in this organ is very considerably increased. For these reasons, and because of the characters of the disease being particularly well marked, we shall commence with the description of mortification of the pulmonary tissue.

1. *Mortification of the pulmonary tissue.*—Although inflammation of the pulmonary tissue is extremely common, it does not frequently terminate in mortification. It is, however, highly probable that inflammation of this tissue proceeds frequently the length of the first stage of mortification or gangrene, without our being able to take cognizance of it during life, or, in a great many cases, to detect it after death.

At one period of the history of pathological anatomy, mortification of the lungs was recorded as a common occurrence. The fallacy of this statement was pointed out by Laennec, who considered *gangrene* (used by him in the sense in which we have employed mortification) as rather a rare disease; but it is by no means so rare as this distinguished author was disposed to believe. He states, in his work on "Mediate Auscultation," that he had only met with two examples of it in the course of twenty-four years, and that he knew of only five or six cases of it that had occurred in the Parisian hospitals during the same space of time: we ourselves have seen twice the number of cases in the same hospitals, during a period of not more than three or four years.

When, as a consequence of inflammation, the pulmonary tissue is affected with gangrene, its colour becomes of a deep red, approaching almost to black, whilst its consistence equals that of hepatized lung or liver. When pressed, it breaks down between the fingers like a portion of hepatized lung when similarly treated, but instead of pus, there oozes out from it blood and a dirty white or greenish fluid of the consistence of milk or treacle, having a very disagreeable odour.

When decomposition has taken place throughout the whole of the affected part, or in other words, when the state of sphacelus is produced, the pulmonary tissue seen under the pleura appears sunk beneath the surrounding surface, presents a dirty white, yellowish grey, brown, or greenish black colour, and frequently, when extensive, a mottled aspect, in which all these tints are perceived; it feels flaccid and pulpy, and, when cut into, appears as if converted into a putrid sanies, in which shreds of pulmonary tissue and bloodvessel float or lie detached, and which diffuses around the most insupportable odour of sphacelus.

Complete death of the pulmonary tissue may take place in several points of the same lung at the same time, but in such cases it is limited in extent, and is much more frequently the result of a septic agent than of inflammation. It is when it is confined to one point that it has been found to extend so as to occupy the fourth, the half, or even the whole of a lobe.

In both cases the sphacelated substance may be limited all round by the adhesive inflammation, or it may be confounded with a gangrenous state of the neighbouring tissue. In the first case we have what is called uncircumscribed, in the second circumscribed mortification. The more extensive, however, the state of sphacelus, the more rarely do we find adhesive inflammation to have taken place.

In the circumscribed and multilocular form of sphacelus, we have sometimes found it confined to one, two, or a very limited number of lobules, the line of separation between the healthy and diseased parts being distinctly marked by the interlobular cellular tissue. In this form of the disease, therefore, we are disposed to believe that the gangrenous inflammation commences in, and is confined to, the pulmonary tissue; whereas in the uncircumscribed and diffuse form it attacks both the pulmonary and interlobular at the same time.

The circumscribed and multilocular form of sphacelus just described may have its seat deep in the substance of the lung, or immediately under the pleura. In the first case one or more of the bronchial tubes are perforated, and thus afford an exit to the dead pulmonary tissue, which is gradually discharged by expectoration. In the second case, besides this salutary mode of evacuation of the sphacelated part by perforation of the bronchi, there is another which frequently takes place, and becomes the immediate cause of death, viz., perforation of the pleura. We have already said that sphacelus of the pleura pulmonalis, when a consequence of inflammation, depends on the previous destruction of its sub-cellular and pulmonary tissue, on account of its nutrition being derived from the vessels of these tissues. Sphacelus of either, therefore, is followed by sphacelus of the pleura, which then presents an appearance similar to a portion of skin destroyed by the cautery or caustic potass. When the slough thus formed is separated, or merely ruptured by the pressure of the fluids or air beneath it, a communication is established between the cavity of the pleura and that produced by the destruction of the pulmonary tissue: one of two consequences then follow; viz., acute pleurisy alone, or pleurisy combined with pneumothorax. In the first case the gangrenous excavation communicates only with the cavity of the chest; in the second with this cavity and the bronchi at the same time. It is this latter condition of parts which enables us to explain the formation of pneumothorax in this disease, although in some rare cases a gaseous product has been found without perforation of the bronchi, and which appeared to have been the product of decomposition.

When circumscribed sphacelus is not immediately followed by a fatal termination, the lung is found some time after to contain a certain number of excavations of an ulcerous character, the nature and origin of which were either imperfectly or not at all understood, until investigated by Laennec.*

2. *Mortification of the liver.*—Mortification of the substance of the liver is an extremely rare occurrence as a consequence of

* See Traité de l'Auscultation Médiate, &c. vol. i. p. 445; and the article ULCERATION in this work.

inflammation; so rare is it indeed, that we have not met with a single well-marked case of it in the course of twelve years, during which period the writer has been in the almost daily habit of inspecting the bodies of the dead, and of examining with care every organ of the body. Nor does it appear that it is a more frequent occurrence even in warm climates, where the liver is so often the seat of acute inflammation. "Gangrene," says Annesley, "has been remarked by many writers and teachers as one of the terminations of acute inflammation of the liver; but although we have observed this disease, and made *post-mortem* examinations of it, the number of which has not been exceeded by any other intertropical practitioner, we have never seen a single case of gangrene of this viscus. We are inclined to believe that the appearances which have been taken for gangrene have been merely that black, congested, and softened state of the organ which is sometimes observed in the more acute attacks of the disease supervening to congestion, or, at least, this state of the viscus having speedily run into gangrene after the death of the patient; and therefore, if gangrene had actually existed at the time of dissection, it is to be considered as a consequence of death rather than as a termination of the disease."*

3. *Mortification of the kidneys.*—Gangrene and sphacelus of the substance of these organs is very rarely met with, unless the exciting cause has been of a mechanical or chemical nature: we shall therefore defer what we have to say on mortification of the kidneys until we come to consider the influence of these agents in the production of this disease.

The *testes* and *mammæ* are occasionally affected with gangrene and sphacelus as the consequences of inflammation or mechanical violence, and both organs are sometimes so extensively destroyed as to be rendered unfit for the accomplishment of their important functions: but as the treatment of mortification of these organs requires the skill of the surgeon, we shall not enter into the description of its pathological characters as it occurs in them.

There now remains to be described, mortification of the *lymphatic* and *salivary glands*, and of the *brain* and *nerves*. In neither of these compound tissues, however, is this disease observed (unless in some very rare instances, and then limited in extent,) as a consequence of common inflammation. The former are not unfrequently affected with this disease, where they are superficially seated, and where they are exposed to the influence of certain putrid and septic substances carried into them by absorption, and to which we shall refer in another place. The latter have seldom presented any traces of gangrene or sphacelus except in cases of external injury, pressure, or ligature.

To render the enumeration of the tissues subject to death from inflammation complete, we may also mention the *teeth*, *hair*, and *nails*. Inflammation of the capsule, bulb, or roots of these bodies, is frequently followed by their decay and entire separation.

State of the vascular system in mortification.—Were we to confine our observations to the changes which take place on the external surface of organs affected with inflammation terminating in mortification, as we have done in the preceding pages, we should form a very imperfect idea of the real nature of this disease. In this as well as in every other morbid state, we must look into the interior of the affected organ, examine the several elements of which it is composed; determine the changes that have taken place in each, the order of their succession, and, as far as it may be possible, the influence which they exercise in the production of the various phenomena of the disease. The interesting experiments and anatomical and microscopical investigations which have been made by several distinguished pathologists on this part of our subject, will enable us to give satisfactory information on several of these important points.

When the transparent part of an animal, such as the web of the frog's foot or mesentery of the rabbit, is placed under the microscope, and submitted to the stimulating influence of a mechanical or chemical agent, the capillary vessels of the part, as well as the blood which under these circumstances flows into them, are seen to undergo a regular series of changes, referable to the hydraulic and dynamic conditions of both, and which constitute the pathological state of a part, called *inflammation*.

Without entering into the details connected with this interesting subject, it will be sufficient for our present purpose to state that when inflammation has arrived at what Kaltenbruenner calls its *perfect state*, that is to say, when the capillaries are distended with blood which has ceased to circulate, the part from a deep red soon changes to a dark brown or black colour.

Cessation of the circulation, coagulation, and discoloration of the blood, are the successive changes which announce that the functions of the inflamed part are about to cease. The change of colour which takes place is found to depend chiefly on a corresponding and similar change induced in the blood contained in the vessels of the affected part, or that has been effused during the inflammatory excitement. Soon after the stagnation of the blood, the globules of this fluid are seen to unite, adhere to the internal surface of the vessels, and form a solid dark-coloured mass occupying their whole caliber. The sensibility of the part rapidly diminishes after the coagu-

* Annesley on the Diseases of India, &c., vol. i., p. 434. The explanation given by the author of the appearances to which he refers may be correct, that is to say, that they may have been produced after death; but that any disease can "run into *gangrene* after death" is what we cannot admit without confounding together opposite phenomena, and the limits which language has established between them. *Gangrene* being the decomposition of a living tissue, can only take place in a body that is not dead. *Putrefaction* is the term which the author should have employed, and is used in contradistinction to that of gangrene, to denote the decomposition which takes place in dead animal matter.

lation of the blood, although the nerves themselves are not observed to undergo any perceptible change. The coagulation of the blood is also followed by the cessation of absorption, for the most active poisons introduced into a part, the vessels of which are thus obliterated, either produce none of the effects which are peculiar to them, or do so very tardily and ineffectually, in which latter case they may have found their way beyond the obliterated vessels by imbibition. Under these modifications of function, after a certain length of time nutrition ceases in the affected part, the temperature of which sinks to that of external objects. Its consistence diminishes so soon as decomposition commences, and the colour which it assumes varies with the quantity and quality of the fluids it contains, and the chemical changes which these undergo from the action of the gaseous products of decomposition. Death or mortification of a portion of the body succeeding to inflammation, we therefore regard as an immediate consequence of cessation of the circulation, of which we have examples on a large scale, in ligature and spontaneous obliteration of the principal artery of a limb, unaccompanied by the establishment of a collateral circulation.

The state of the vessels and of the blood which precede the physical signs of mortification may be regarded as representing that state of a part which we call gangrene. The blood has ceased to circulate, it is even coagulated; the application of artificial stimuli to the neighbouring tissues furnishes no evidence of their possessing sensibility or contractility. Yet, as under these circumstances we know that actual death may not have taken place, that the blood may resume its fluidity and circulate anew, and sensibility and contractility again return, the state to which we have alluded may properly be regarded as furnishing us with what may be called the anatomical and physiological characters of gangrene,—a state in which the functions of a part are suspended, analogous to that of the whole body in asphyxia, but not destroyed, whether we regard it as susceptible of recovery, or as an intermediate state which separates inflammation from mortification.

When the recovery of a part from the state of gangrene is about to commence, circulation becomes more active all round the circumference of the diseased part; the coagulated blood gradually disappears by the separation of its globules, and their transmission into the neighbouring currents; absorption is manifested by the more or less rapid removal of the effused fluids, sensation and motion return, and the part is restored to the healthy state.

We have already enumerated the changes which mark the transition from gangrene to mortification. The separation of the dead part takes place within limits fixed by the state of the vascular system. Thus, the line of demarcation between the dead and the living parts does not extend beyond the obliterated vessels; for before adhesive inflammation has taken place, they are found obliterated to a greater or less distance beyond the mortified part. Their obliteration is not necessarily the consequence of the effusion of coagulable lymph. It depends on the plastic property of the blood contained within the vessels, which unites with their living membrane, becomes organized, and thus secures their permanent obliteration.

Obliteration of the bloodvessels, as the cause of mortification of the kind of which we are now treating, is a subject deserving of the most serious consideration both of the surgeon and physician. For it is to this state alone of the bloodvessels in the vicinity of the dead part that immunity from one of the most dangerous consequences of the disease, viz., hemorrhage, is to be ascribed. The presence of coagulable lymph, its organization and union with the parts into which it has been effused, constituting what is called adhesive inflammation, contributes no doubt to prevent hemorrhage during the process of separation of the dead part, or of sloughing. But we are disposed to believe that it is the prevention of hemorrhage from the smaller vessels only that is secured by the adhesive inflammation, while that from the larger ones is prevented by the previous coagulation of the blood contained within them. That it is to the coagulation of the blood in the large vessels of a limb that we must attribute the non-occurrence of hemorrhage after sloughing, is rendered still more obvious from what occurs in some cases of extensive and spreading gangrene, of the inferior extremity for example, and to arrest which it is found necessary to have recourse to amputation. The limb is removed, but the large bloodvessels yield little or no blood; they are, in fact, obliterated by firm coagula. There is no adhesive inflammation present in such cases, and gangrene and sphacelus succeed to the operation, because of the vessels not having been divided above the point at which they were obliterated.

Such is the state of the large bloodvessels which we have found to accompany sphacelus without hemorrhage. When, on the contrary, hemorrhage occurs in this stage of mortification, these vessels are found pervious and filled with fluid or imperfectly coagulated blood; and the cellular and other tissues are more or less infiltrated with serosity, sero-sanguinolent and puriform fluids.

Terminations of mortification.—We have already enumerated the most important and conspicuous local effects of mortification of tissues and organs, such as changes in colour, consistence, sensation, motion, temperature, and bulk, to which we might add those of form, in consequence of loss of substance of various extent.

The solution of continuity which follows the separation of the dead part may, if formed in the substance of a solid organ, be followed by ulceration, instead of being repaired by granulation or the organization of coagulable lymph; or it may be followed by perforation, if the solution of continuity takes place in the walls of a hollow organ, as the intestine, or on the surface of a solid organ, as the lungs,—a termination of sphacelus to which we formerly alluded.

When the dead part is separated, and the affected organ is seated internally, it may either be retained for an indefinite period, or it may be almost immediately expelled through the natural passages, such as the bronchi, trachea, intestines, &c. The dead substance is thus sometimes evacuated entire, as in the case of sloughing of a portion of intus-suscepted intestine, and in some rare cases of partial gangrene of the lungs. In parenchymatous organs, however, the dead portion is much more frequently broken down into shreds by a species of maceration in the surrounding fluids before it is ejected, and is then accompanied by a greater or less quantity of these fluids at the same time.

Signs and symptoms of mortification.—To determine the existence of mortification of an internal organ is, in the great majority of cases, beyond the power of the physician. The evidence which he is enabled to collect from the modifications which take place in the functions of the affected organ, from the state of some particular system or of the economy in general, is frequently far from being sufficient to warrant him in giving a decided opinion on the existence of this disease. Besides, the derangements of function to which it gives rise are, in some cases, either so slight as not to be recognized, or of such a kind as not to be distinguished from others produced by very different morbid states. Nor can we fix any determinate relation between the extent of the disease and the severity of its effects, such, at least, as are made manifest to us through the medium of functional derangement. These remarks apply equally to both stages of mortification, and to the kind and degree of inflammation by which they are preceded. With regard to the latter, it is well known that mortification, and that too of the lungs, may succeed to inflammation so slight as not to have induced a degree of indisposition sufficient to excite the attention of the patient, far less to induce him to apply for medical advice. In such cases it is sometimes not until sphacelus has taken place, when the presence of a cavity can be detected by means of the stethoscope, and the contaminating influence of the putrid fluids has already commenced, that the unfortunate patient sends for assistance, or finds his way to an hospital.

There are certainly no general symptoms which can be considered as the exclusive effects of either state of mortification. The violence and extent of the inflammation by which mortification may be preceded, may lead us to *fear* such a termination, but cannot enable us to *detect* it when it has occurred, even when those symptoms—sudden prostration and sinking of the powers of life—and to which so much importance has been attached, are present. Inflammation alone gives rise to these fatal symptoms in persons naturally feeble, and in those in whom innervation and nutrition in general are so modified by previous excess or privation, as to give to diseases, the most insignificant in themselves, that peculiar assemblage of character generally known under the appellation of adynamia.

We have already enumerated, at the commencement of this article, the more common and obvious conditions of organs which, independently of the general conditions which we have just named, favour the production of mortification, when these organs are attacked with inflammation. We refer the reader to what we have said on this part of our subject, as furnishing additional evidence in favour of the opinion we have given regarding the difficulty of determining the existence of mortification by the manifestation of any peculiar modification of function of the organ in which it has taken place.

Although we reject, as a *sign* of mortification, the sudden occurrence of prostration and sinking of the powers of life in general, succeeding to inflammation, we must nevertheless regard these phenomena as of great and serious import in such cases, inasmuch as they indicate that the progress of the disease is not arrested, and that by means of absorption the system in general has been brought under the poisonous influence of the decomposed and putrid fluids of dead animal matter. These symptoms, which we attribute to the absorption of dead animal matter, are of course common to mortification from inflammation as well as from other causes.

The state of the pulse in persons affected with mortification of an internal organ is very various. If the previous inflammation has been slight, it may not have been much increased in strength or quickness, and may retain this state after the occurrence of sphacelus, and till near the period of dissolution, when it rapidly sinks, and becomes remarkably slow, feeble, and sometimes intermittent. If the inflammatory excitement accompanies the state of sphacelus, the pulse may continue quick, but it is feeble and easily compressed, and always sinks before death. The temperature of the skin is generally morbidly increased at the commencement, but becomes less than natural towards the termination of the disease, when the surface is often cold and covered with a clammy sweat. At the same time the tongue and teeth become covered with sordes, the breath frequently exhales a fetid odour, and there is occasionally singultus, low delirium, and picking of the bed-clothes, or a state of stupor terminating in coma; the countenance assumes a cadaverous aspect, and the whole body as well as the evacuations, which are sometimes involuntary, give out the most offensive fumes, impregnated with the stench of dead and putrid animal matter. In this state the patient dies unconscious, and generally without a struggle. These, the general effects of the absorption of the putrid fluids of sphacelated tissues, are not always so conspicuous; nor do they proceed in all cases to a fatal termination with the same degree of rapidity. When they assume the aggravated form just described, life is seldom prolonged beyond the third, fifth, or seventh day. But when they are marked chiefly by a state of

prostration, a quick, feverish, and feeble pulse, a hot skin, and an offensive smell of the secretions, the course of the disease may be prolonged to the second or third week, when it terminates as before described: it is only in this form of the disease that recovery has been known to take place.

The odour of gangrene, as it is commonly called, is perhaps the only pathognomonic sign of the existence of mortification. We have alluded several times to the presence of this odour in the breath of the patient and in the secreted and excreted fluids, as an almost constant sign of the contaminated state of the blood in the last stage of mortification. But the gangrenous odour to which we at present allude is that derived immediately from the affected organ, and which may, with few exceptions, be regarded as the only sign of the local existence of sphacelus to which we can attach a positive value. We need hardly remind the reader that it is not, however, present in every case of sphacelus;—that it is only either in those cases in which a communication exists naturally between the external surface of the body and the sphacelated tissue, or in those in which a preternatural communication has been established in consequence of the disease itself, and through which the putrid effluvia are discharged into natural canals, as in perforation of the bronchi and intestines from without inwards; or on the surface of the body, in perforation of the walls of the chest and abdomen in the opposite direction.

We have seldom an opportunity of detecting the putrid odour of sphacelus, unless when this disease occurs in the lungs, the digestive organs, the urinary organs in the male and female, and in the organs of generation in the latter. When present in the breath, it is necessary to discover its source, as it may have its origin in the mouth, pharynx, œsophagus, or stomach, or in the larynx, trachea, or lungs; this may be easily accomplished by submitting each of these portions of the digestive and respirating apparatus to a separate examination. It may not be unimportant to observe that extensive sphacelus of the stomach, or rather of accidental tissues formed in this organ, may occur, without the eructations with which it is often accompanied, or even the fluids then ejected by vomiting having any the slightest degree of putrid odour: a circumstance which we attribute to the property which the gastric acid possesses of removing the tainted smell of animal substances.

Much importance is not to be attached to this character of sphacelus when perceived in the alvine evacuations. We have already stated that the excreted fluids acquire this particular odour in consequence of the absorption and the subsequent separation from the blood of the putrid animal matter; consequently the presence of this odour in the dejections may be entirely owing to the elimination of these fluids by the mucous membrane of the intestines from the blood. It may indeed be laid down as a rule, that unless this odour in the alvine evacuations be accompanied by the presence of portions of the intestine, or rather of the mucous membrane of the intestine, it cannot be regarded as a sign of sphacelus of this organ. It is chiefly in some forms of chronic dysentery that the odour of putrefaction and the presence of sphacelated portions of the thickened mucous membrane are observed at the same time in the discharges which accompany that disease. An entire portion of intestine is never discharged unless in intussusception followed by sphacelus. We shall have occasion to notice this morbid condition afterwards, under the subdivision of the present subject which treats of mortification in consequence of a mechanical obstacle to the return of the venous blood.

With regard to the putrid odour of sphacelus in the fluids discharged from the urinary organs and vagina, it is only necessary to observe that, in the former, it always accompanies a turbid, bloody, or puriform state of the urine; and that, in the latter, there is present at the same time a sanious discharge, sometimes containing blood, and sloughs of the mucous and submucous tissues.

The putrid odour is never so conspicuous as in sphacelus of the pulmonary tissue, and when a communication exists between the sphacelated substance and the bronchi. It is conveyed by the expectorated fluids, composed of those coming from the seat of the disease, as well as from the mucous membranes in general. These fluids are sometimes of a dirty grey, brown, or green colour; puriform or sanious; contain sometimes shreds or small portions of the sphacelated lung; and are occasionally streaked with blood. If hemorrhage has taken place, blood alone may be expectorated in greater or less quantity. In sphacelus of this organ, too, there are various physical signs which, with those already mentioned, and particularly the latter, enable us to detect not only the existence of this state, but also its situation and extent, the state of the surrounding pulmonary tissue, and the mode in which the disease has terminated,—circumstances of greater or less importance as regards the prognosis and treatment.

The most important of these physical signs are the following; but we must observe that they are confined to the second stage of mortification, or sphacelus, and that those of the first stage, or gangrene, are in no respect different from those of pneumonia:—so soon as sphacelus has taken place, a loud crepitous rattle is produced, which gradually assumes a gurgling sound, as the quantity of fluids increase, and the sphacelated tissues become separated from the surrounding pulmonary substance, or broken down. The cavernous rattle continues for an indefinite time, and is replaced by pectoriloquism when the contents of the excavation are partially or wholly removed. The resonance of the voice is remarkably distinct and strong in excavations of this kind, particularly when large, and may, according to Laennec, be distinguished from that

which accompanies abscess of the lung, from its having nothing of that *floating* kind of sound of the latter, and is rarely accompanied by the *veiled puff*, so common in the abscess.

When the sphacelus extends to the pleura, and the dead portion is separated, thus establishing a communication between the cavity of the chest and that formed in the substance of the lung, we have, besides the signs already enumerated, those of pleurisy and pneumothorax combined with liquid effusion. If at the same time a communication exists between the bronchi and the excavation, there is heard either the *metallic tinkling* or the *utricular resonance*. The crepitating rattle of pneumonia, which is sometimes heard previous to the occurrence of sphacelus, may continue after the occurrence of it, and may, in some measure, serve to indicate the progress of the disease towards a fatal termination. We have never but once had an opportunity of hearing the crepitating rattle where it indicated the return of the pulmonary tissue to the healthy state. The excavation occupied two-thirds of the inferior lobe of the left lung, and the resolution of the disease was indicated, not only by the state of the pulmonary tissue around the excavation, which was crepitant, and did not contain more blood than usual, but likewise by the presence of an organized false membrane, which lined the internal surface of the excavation, a means which, as noticed first by Laennec, seems sometimes to be employed by nature to limit the progress of mortification.

We must again repeat, that with all these signs our diagnosis can never acquire a positive degree of certitude, unless they are accompanied by the putrid odour of sphacelus.

We have already said that the progress of mortification, although in general more or less rapid, is sometimes slow. Laennec speaks of it as existing in a chronic form in the lungs. It is then accompanied with hectic fever, sometimes considerable, but generally less intense than in most cases of phthisis; the skin feels hot, sometimes even disagreeably so, to the hand; and the expectoration and breath are fetid. This state is accompanied by rapid emaciation, and the disease may be readily mistaken for phthisis; more commonly, however, death supervenes before emaciation has made much progress, the disease appearing to have a greater tendency to produce cachexia than marasmus.

We regard the cure of mortification of the lungs as an exception to the rule, and we have certainly not witnessed this fortunate termination of the disease, except in two or three instances, in which it was not very extensive. In these cases too, the progress of the disease was limited at an early period, no doubt by the obliteration of the bloodvessels and adhesive inflammation. That such was the state of the pulmonary tissue around the excavations which were found to exist in these cases, we feel convinced, not only from the disease being stationary from the commencement, but from the general secondary symptoms of mortification, viz. those produced by the absorption of the putrid fluids, not having manifested themselves during the course of the disease. It is, however, stated by Laennec, that he has known several patients recover, who, judging from the extent of the pectoriloquism, had gangrenous excavations of great size. In one of those patients there was sloughing of the pleura as well as of the pulmonary tissue, giving rise to a pleurisy, which was not cured till after a period of fifteen months.

Prognosis of mortification.—The prognosis of this disease, in the last stage, is always unfavourable, because, on the one hand, of its being accompanied by a loss of substance, and on the other because of the affected organ or the constitution in general being frequently in a situation which the resources of our art can neither remedy nor relieve. Our prognosis will, of course, be greatly modified by the circumstances of each case; the extent of the disease, its seat, the state of the affected organ previous to its occurrence, the age and constitution of the patient, and the situation in which he was placed previous to the attack. In all cases in which we can determine that the progress of the disease has been arrested, will our prognosis be the more favourable; but in those in which the secondary symptoms which we have several times brought under the notice of the reader, are present, the death of the patient may be regarded as inevitable.

Treatment of mortification.—The treatment of mortification from inflammation must be conducted in reference, 1st, to the cause of the disease; 2d, to the disease itself; and, 3d, to its effects, mediate or immediate. With regard to the first head, the efficacy of the means employed will depend much on the extent and degree of the inflammation which accompanies the stage of gangrene or sphacelus, the nature of the affected organ, and the general condition and age of the patient. The progress of the inflammation may be arrested or its violence moderated by the prompt and well regulated use of antiphlogistic remedies, such as general and local bloodletting, saline purgatives, rest, quiet, and total abstinence from food. In those cases in which the inflammatory symptoms have been slight, even from the commencement of the disease, the antiphlogistic treatment has been found to be injurious rather than beneficial, both on account of the debility which is present, and because of its having appeared to retard or prevent the accomplishment of that salutary process by means of which the progress of the disease is arrested. There are other cases in which the use of antiphlogistic remedies is forbidden, by the nature both of the general and local symptoms. There is a total absence of pain, no sign of inflammation in the affected organ, and a state of general debility or prostration. The early occurrence of these symptoms, as well as their presence in the last stage of almost every case of mortification, have rendered many physicians

very cautious in the use of debilitating remedies, and have induced them to place more reliance on the judicious employment of tonics and stimuli, and other means calculated to support the strength of the patient, and assist nature in carrying on the process of elimination and reparation. It is only by a knowledge of the circumstances of each case that we can at all judge of the applicability of either mode of treatment, or when the one should be employed in preference to the other. It is on the same principles that we can reasonably hope to exercise a salutary influence over the disease itself, that is, as regards the removal of the dead portion, and preventing the effects to which it gives rise. The most dangerous of all the effects of mortification are those which follow the absorption of the putrid fluids of the sphacelated tissues, to remove or even mitigate which no means have yet been devised on which any reliance can be placed. It has been proposed to employ solutions of the chlorides of lime and soda, as washes, to destroy the putrid effluvia which accompany sphacelus. We are not certain how far they have been found to accomplish the end in view. Besides, these solutions can be had recourse to only in a very limited number of cases of this disease, and when confined to the organs of generation and the urinary bladder.

II. Mortification from a mechanical obstacle to the circulation of the blood. —The blood may be prevented from arriving at, or returning from, a part of the body by mere mechanical causes. In both cases mortification is the consequence of the cessation of the function of nutrition, either from a deficiency of the arterial or the stagnation of the venous blood. A deficiency of the arterial blood may be occasioned by ligature of the principal artery of a limb, a collateral circulation sufficient for the nutrition of the limb not having been formed; or it may follow in consequence of coagulated blood, or fibrine, organized or unorganized, occupying the entire caliber of such an artery or its principal branches, from ossification of the walls of these vessels, or their conversion into a solid fibrous or ligamentous tissue.

Stagnation of the venous blood may depend on obliteration of the veins caused by the pressure of tumours situated in their immediate vicinity; accidental products formed in their cellular sheath; or the presence of fibrine or other solid substances derived therefrom, formed within the veins, and either simply lodged within them, or more or less intimately connected with their lining membrane; and, lastly, diseases of the heart, which greatly obstruct or prevent the return of the venous blood to this organ. Mortification may also occur in consequence of the arteries, veins, and nerves having all at the same time been submitted to severe pressure, as in the case of ligature and tumours.

Mortification from a mechanical obstacle to the circulation of the blood is by no means equally frequent, either as regards the causes we have just named, or the part of the body in which it occurs. Mortification in consequence of the stagnation of the venous blood is much more often seen than that which follows an obstacle to the arterial circulation, owing obviously to a difference in the organization and relations of the arterial and venous systems, whereby the latter is more frequently and more easily subjected to the influence of mechanical agents, capable of modifying, in the manner alluded to, the circulation of the blood. Mechanical causes which compress or obliterate the veins are often incapable of producing the same effects on the arteries, from the circulation in the former tending to favour rather than oppose their operation, and which in the latter has a powerful influence in resisting every external force which tends to diminish their capacity. And besides, stagnation of the blood in the venous system, by whatever cause produced, may, correctly speaking, be said to depend on the relation which exists between it and the arterial system; that is to say, the mechanical cause is but an obstacle to the passage of the venous blood, while the quantity of this fluid and the extent of the stagnation that follows is determined by the arterial system.

The situation of parts and the mode in which their circulation is affected, are circumstances which modify in a remarkable manner the frequency of mortification. Mortification from mechanical causes which obstruct the circulation of the blood, occurs in the great majority of cases in the extremities, and far more frequently in the inferior than in the superior, partly from their being isolated from other organs which might facilitate the formation of a collateral circulation, and partly from their situation and position, both of which are unfavourable to the circulation of the blood. Mechanical causes, which produce general death when situated in organs on the integrity of whose functions life in general more or less immediately depends, give rise in them only to local death or mortification. In the former the operation of these causes is necessarily of short duration, and is always confined within narrow limits when it is carried to a degree to produce *sphacelus*. Should their influence extend to the circulation of the whole of an organ, such as the lungs or liver, the obstacle to the return of the blood from either being situated in the heart, a state of general congestion is produced, but which never amounts to what is properly called gangrene.

In the latter, on the contrary, mechanical causes which impede or interrupt the circulation of the arterial and venous blood, may continue to operate for a considerable length of time, producing all the regular stages of mortification, as various degrees of congestion, gangrene, and sphacelus. Mortification, however, does occur in the extremities without being preceded by these changes, the reason of which we shall endeavour to assign presently.

With regard to the relative frequency of mortification of the kind of which we are now

treating, it is also of importance to know that this disease is more frequently produced by disease of the heart than of the bloodvessels, and that in this case it is never observed in any other part of the body than the inferior extremities. There are, however, several circumstances, to which we shall particularly allude hereafter, which hasten the termination of congestion of these parts from disease of the heart, in gangrene and sphacelus, and without which such a termination would not unfrequently not take place.

From these general remarks on the influence of mechanical causes, operating through the medium of the circulation, in the production of mortification, and the comparative frequency of this disease in different parts of the body, it is obvious that the descriptive characters of this disease so produced must be founded on the phenomena which it presents when it affects external organs. We shall therefore commence with the description of that form of the disease which occurs most frequently, and which affects the inferior extremities in consequence of an obstacle to the return of the venous blood from these parts, produced by disease of the heart.

1. *Mortification of the inferior extremities from disease of the heart.*—The first local sign that an obstacle exists to the return of the venous blood from the inferior extremities is manifested by the appearance of slight œdema around the ankles. The serosity gradually accumulates in those parts, spreads from thence throughout the cellular tissue beneath the skin and between the muscles; the feet, and afterwards the legs, thighs, and scrotum in the male, and labia pudendi in the female, become swollen; the skin assumes a smooth and glossy aspect, feels tense, and sinks into the cellular tissue when pressed, and does not resume its former shape and situation till raised by the return of the serosity beneath it. The colour of the skin, at first natural, becomes pale and waxy, and may continue in this state during the greater part of the course of the disease. When discolouration of the skin is about to take place, it is seen to depend on the presence of a few subcutaneous veins, which gradually increase in bulk and number, coalesce in several points, and communicate a slightly mottled aspect to the skin, of a dull red or purple colour. On one or more of these points where the congestion is greatest, and where the skin is less yielding, as over the tibia and above the malleoli, phlyctenæ or large bullæ are formed by the effusion of serosity, either alone or mixed with blood, under the cuticle. When these burst, the cutis beneath presents a dark red or brown colour, and very soon is converted into a dirty yellow or ash-grey slough. The separation of the slough is sometimes preceded by an increase of redness in the surrounding cutis, which, from its anatomical characters and the increased temperature and pain by which it is accompanied, is obviously of an inflammatory nature. At other times the redness which precedes or accompanies the separation of the dead part is very slight, and is evidently owing to mere venous congestion, occasioned not only by the disease of the heart, but also by the serosity accumulated in the cellular tissue of the limb, which, from the pressure it occasions, further retards the return of the venous blood, and aggravates all the symptoms produced by the primary cause of the disease.

Although, after the separation of the slough, a loss of substance of considerable extent in depth may appear to have been produced, it perhaps never proceeds beyond the cellular tissue; and it is because of this tissue being greatly distended with serosity, that the loss of substance which follows sloughing appears to have penetrated deeply into the substance of the limb.

Congestion, gangrene, and sphacelus may take place on several parts of the leg, but they are in general limited to the parts we have enumerated, and rarely occur on the feet or toes.

We have already remarked that the temperature of the extremities is always below the natural standard during the first periods of the disease, and that it does not acquire a morbid increase till the distention of the cutis is great, and this tissue becomes discoloured from the congested state of the capillaries. An increase of the sensibility takes place at the same time, and is always greatest where the cutis is most distended, and sometimes amounts to a degree of pain of a darting, pungent, or burning character, which greatly increases the sufferings of the patient. Although the temperature and sensibility of the limb are sometimes very great while the cutis is still entire, but tense, congested, or inflamed, they are never so considerable as when sloughing has taken place, accompanied by inflammation of this tissue. It is also in such cases that the pulse becomes quick and the skin in general hot;—in one word, that febrile symptoms make their appearance. Under these circumstances life is seldom prolonged beyond a few days, otherwise the death of the whole limb would follow as the inevitable consequence of the increased disturbance of the circulation, occasioned by the febrile excitement;—a termination which the author of this paper has witnessed in two cases, in one of which the sphacelus extended even to the walls of the abdomen.

The progress of this kind of mortification, although generally slow, is occasionally very rapid. This difference depends chiefly on the two following circumstances,—a naturally unyielding state of the skin, and the effect produced on the venous circulation of the limb by the effused serosity. It is principally to the latter circumstance that we wish to direct attention, as it may suggest some means to prevent its occurrence and the evils by which it is followed. As soon as the blood has accumulated to a certain extent in the venous system of the inferior extremities, serosity is effused in greater or less quantity, and compresses the veins. A second obstacle is thus created to the return of the venous blood, and consequently the progress and termination

of the disease are greatly accelerated. These effects of compression from the effused serosity are first manifested by the sudden appearance of congestion of the skin, which generally occupies the greater part of the leg. The skin retains its glossy aspect, but becomes all over mottled with various shades of red and purple; is seen traversed in every direction by minute veins and capillaries distended with blood, and the whole limb acquires a degree of hardness peculiar to this state of the circulation. The sloughing which follows may take place without the supervention of inflammation,—at least without this state being marked by uniform redness of the skin,—is more extensive than in the previous form of mortification, but does not extend beyond the skin and cellular tissue.

The separation of the sloughs in mortification from disease of the heart is seldom followed by hemorrhage; and when it does occur, it consists merely in a slight oozing of blood from one or more points of the denuded surface. This circumstance, as well as the state of the blood generally found in the veins after death, is readily accounted for. The blood in the veins in the immediate vicinity of the sphacelated part of the limb, is found coagulated, or these vessels are filled with fibrine. More remote from this part, and sometimes in the greater part of the limb, the blood with which they are distended is also more or less coagulated, but becomes more fluid as we examine it further from the seat of the sphacelus.

Prognosis.—In no disease can our prognosis be more certainly fatal than in mortification in consequence of disease of the heart. Its very occurrence is a sure evidence that the disease on which it depends would soon terminate fatally without the aggravation of suffering which this, perhaps the worst of its effects, never fails to produce. The only favourable circumstance—if such it can be called—relates to the duration of the disease. If the mortification is the consequence of the stagnation of the blood occasioned by the disease of the heart alone, we may venture to predict that its progress towards a fatal termination will be slower than when to this, the primary cause, is added the obstructing influence of the effused serosity.

Treatment.—The treatment of mortification from disease of the heart is not only extremely restricted but entirely palliative. The general treatment which has been or is still employed against the primary disease, and which has been found ineffectual in arresting its progress, is also that which, if no such disease existed, would be adopted for the cure of the mortification. Under such circumstances experience has shown that little more can be done for the patient than to mitigate his sufferings by the frequent administration of anodynes; the application of cold lotions, warm fomentations or poultices to the affected limb; using one or other of these as the feelings of the patient or the stage of the disease may suggest. Both on account of the patient and the assistants, a solution of the chlorides should be used so soon as sloughing has taken place. The limb should also be kept in an elevated position by means of pillows; and as the foot is often cold while the leg is painfully hot, some relief is obtained by covering the former with warm flannel, and the latter with compresses that have been dipped in cold water or the saturnine lotion. It is probable that the occurrence of mortification from disease of the heart might in some cases be prevented by the early confinement of the patient to the horizontal position, by the occasional use of friction with a view to facilitate the venous circulation of the extremities, and the application of a well adjusted bandage from the toes upwards, which would not only prevent the occurrence of great congestion by equalizing the circulation throughout the limb, but also the œdema which follows, and so greatly aggravates the disease.

2. *Mortification of internal organs from a mechanical obstacle to the return of the venous blood.*—We do not believe that there is a single example of mortification of an entire internal organ from an obstacle to the return of the venous blood, and produced by a mechanical cause. We have already stated the reason of this exception, namely, the facilities afforded for the formation of a collateral venous circulation; and the duration of the mechanical cause capable of producing local death being limited by the greater importance of these organs. Mortification of portions of internal organs is, however, occasionally met with, and which can easily be traced to cessation of the circulation from compression of the veins: the lungs, liver, and intestines are the organs in which this form of mortification is most conspicuous. It occurs in the lungs when the cellular structure of these organs has become consolidated by the deposition of coagulable lymph, and produces that state of the pulmonary tissue termed *hepatization*. We allude here to the *grey* hepatization most frequently observed around tubercular excavations, and which is regarded as the consequence of chronic pneumonia. The colour of the indurated pulmonary substance may be grey, purple, livid, or nearly black, and its consistence sometimes such as to equal that of cartilage. In this state it is highly probable that it never regains its natural structure and consistence. When carefully dissected, not only are the veins contained within it found compressed or obliterated, but also the arteries are much diminished in bulk. In fact, all the elementary tissues of the indurated portion of lung are atrophiated; and if the accidental deposit by which these changes are produced is not removed by absorption, the former are soon deprived of their vitality, and both are converted into a soft substance, the colour of which will depend on that of the part previous to this change, as well as the degree of putrefaction which it may have undergone before it can be examined.

Sphacelus of the walls of tubercular excavations is sometimes produced in a similar manner. The veins and arteries which traverse the septa, or ramify in the walls of these excavations, become obliterated by the conversion of

the blood which they contain into masses of firm fibrine. This change may take place previously or subsequently to the formation of the excavations. In the former case the expectoration is copious, sometimes contains pretty large portions of tuberculous matter and softened cellular substance, the odour of which is extremely offensive. In the latter case the only change observed in the expectoration is a tinge of brown, dirty grey, or green, with perhaps a more marked odour of sphacelus.

Induration of the pulmonary tissue and compression of the veins may likewise be produced by the tuberculous matter, when deposited in such quantity as to occupy a large portion or the whole of the lobe of the lung. The author of this article has represented a striking example of induration from infiltration, as it is called, of tuberculous matter terminating in sphacelus, in the first Fasciculus of his work on the "Elementary Forms of Disease." The whole of the upper lobe of the right lung was converted into a solid mass as firm as a piece of boiled cow's-udder, of a pale straw colour, of a homogeneous aspect, and presenting here and there only a few faint traces of the interlobular sections. The upper portion of this lobe contrasted strongly with that we have just described. It was converted into a mass of dirty yellowish grey substance as large as an orange, some parts of it soft and spongy, others quite pulpy or consisting of a dirty grey sanies, in which the bloodvessels, veins, and arteries, were lying denuded and obliterated by firm coagula. There was no increase of vascularity, indicative of previous inflammation, in the infiltrated pulmonary substance, around this the sphacelated portion; and therefore we regard this case as strikingly illustrative of the manner in which local death is not unfrequently produced by the accumulation of accidental products in the parenchyma of organs.

When speaking of mortification of the lungs from inflammation, we alluded to the occasional occurrence of this disease without it, being preceded by the usual phenomena of pneumonia. Although we are not prepared to demonstrate that such cases should be considered as of the same nature as those we have included under the present head, we are satisfied that we have seen one or two instances of sphacelus of the pulmonary tissue depending on induration as a consequence of chronic pneumonia. This opinion is founded not only on the sudden occurrence of the state of sphacelus without the signs or symptoms of previous inflammation, but on the presence of grey indurated pulmonary tissue, which we found forming part of the boundary of that which was sphacelated: such a degree of induration could not have been produced by adhesive inflammation, subsequent to the sphacelus, as death took place within too short a space of time to allow of such being accomplished.

Sphacelus of portions of the liver is not very rare in those cases in which it is nearly filled with cancerous tumours. These tumours produce, mechanically, extensive obliteration of the veins; and when a portion of the liver becomes incarcerated by them, it is converted into a dark brown slough, generally soaked with blood, and sometimes mixed with softened and detached portions of the neighbouring tumours.

An obstacle to the venous circulation gives rise more frequently to sphacelus in the digestive organs than in the liver. It is chiefly in the intestines that cessation of the circulation from a mechanical cause is seen to terminate in sphacelus: we shall adduce one example only of sphacelus, namely, that which occurs in the intestines in the case of intus-susception.

We shall allude shortly to the mechanism of this morbid condition of the intestine, in order that the cause of the sphacelus, in which it sometimes terminates, may be clearly understood. When the superior portion of intestine passes into the inferior, or becomes invaginated, it carries along with it that part of the mesentery to which it is attached. If it does not suffer much compression, the invaginating process may go on to a great extent; but if it is compressed to such a degree that the return of the venous blood is obstructed, this stage of the disease is arrested, on account of the congestion which follows of all the coats of the invaginated portion. The congestion is not the consequence of inflammation; it is produced by pressure, and in the following manner: when the mesentery is put on the stretch by the descent of the superior into the inferior portion of the intestine, the veins belonging to it are compressed between the walls of both portions, just at the point where the invagination terminates superiorly. If adhesive inflammation takes place at this point, the peritoneal surfaces of both portions become united, and the veins obliterated. As the arteries are much less affected by pressure than the veins, they continue to pour their blood into the invaginated portion; this fluid gradually accumulates, and produces an extreme degree of congestion of the mucous and submucous coats, giving to them a deep red or almost black colour. In this state, however, the intestine is not deprived of its vitality. It is in a state of gangrene, but not of sphacelus; for its structure is still entire, and when it has been separated and evacuated, presents, after having been macerated for some time, so as to deprive it of the blood which it contains, the most perfect state of integrity of all its tunics. Occasionally, however, a portion or the whole of the invaginated intestine is found in a state of complete sphacelus, and is passed in the form of irregular spongy masses or shreds of a dirty ash grey, brown, or black colour.

It is not unimportant to know that the invaginated intestine may be detached in separate portions, and passed at different intervals of time. In such a case the physician might be led to suppose that there were several distinct portions of intestine invaginated, whereas there is only one portion. If the invaginated portion of intestine be considerable, it is, perhaps, never separated all at once; on the contrary, it is detached, as we have said, in several distinct portions, two, three, five, or even eight; dif-

ferences which depend on the manner in which the invaginated intestine is disposed of. For if considerable, it does not present a cylindrical form; it is drawn up into the form of abrupt, flattened, or angular coils, determined by the attachment of the vessels and mesentery, so that stagnation of the blood takes place successively in different points, and from below upwards, being always greatest at the inferior extremity of the invaginated portion.

The symptoms of intus-susception derive no peculiarity from the existence of gangrene or sphacelus, unless when a part or the whole of the invaginated portion is passed by stool. We may, however, observe that this disease may, in the great majority of cases, be distinguished from stricture of the intestines occurring after ulceration, by a careful examination of the previous history of the patient. Disorder of the functions of the digestive organs, referable to chronic disease of the intestinal canal, will be found to have existed for a greater or less length of time before the occurrence of those symptoms which indicate an obstacle to the passage of the food or fæces from stricture: these symptoms are but slight at first, repeated at irregular intervals of time, and become more aggravated at every succeeding attack; whereas in intus-susception the presence of a mechanical obstacle is announced suddenly without being necessarily preceded by any marked derangement of the functions of the intestine; the symptoms to which it gives rise are rapid in their course, steady in the increase of their severity, and are aggravated by all the internal remedies calculated to relieve or remove the former.

There are no means of distinguishing this disease from internal strangulation of the intestine until the sphacelated portion is passed by stool. The existence of the former disease may, perhaps, be suspected previous to this period by the oozing of blood from the congested mucous membrane of the invaginated intestine.

The natural cure of intus-susception furnishes us with the most interesting examples of the efficient good which can be accomplished by adhesive inflammation. The serous membranes being endowed with a property which enables them to supply a quantity of coagulable lymph sufficient for the full accomplishment of this process, by the lowest possible degree of inflammation, the solution of continuity which follows the separation of the dead portion of the intestine is often repaired without any appreciable disturbance of the economy. The union of the intestine, let it be remarked, is effected, not between a mucous and serous surface, but between the *two serous surfaces* of the invaginated and invaginating portions of the intestine, and just at the point where the invagination commences: there the separation takes place, and there also the union is effected previous to the separation, which is to maintain the continuity of the intestine, and secure the life of the patient. Under these circumstances the diameter of the intestine may not undergo any perceptible change, and the passage of the food or fæces is accomplished with the same facility as before the occurrence of the disease.

It is consolatory to know that patients may survive the loss of a considerable extent of intestine from intus-susception, and that, too, without their general health having suffered any perceptible alteration. By far the most remarkable instance of this kind that has come to the knowledge of the writer of the present article occurred in the practice of his excellent and distinguished friend, Dr. Forbes of Chichester, with whom he had the opportunity of examining several of the portions of intestine passed by the patient. There were no less than *eight* portions of intestine passed by stool, varying from eleven to thirty-two inches in length, the length of the whole amounting to *twelve feet of entire intestine!* Each portion was complete in itself, presenting in fact the appearance of healthy intestine, that has been allowed to remain for a certain length of time in alcohol. They consisted of the jejunum and ileum, some of them having their serous, others their mucous surface outwards (which is always the case when the intus-suscepted intestine separates in distinct portions), on the former of which the bloodvessels, on the latter the glandulæ agminatæ, were most conspicuously visible. The most interesting feature of this case was the complete recovery of the patient, at least from the immediate consequences of this disease. The subject of this remarkable case was a poor woman of the name of Ann Newland, resident at Emsworth, in Hampshire, and was a patient of Mr. Lyne, surgeon at that place. She had been confined to bed by an anomalous chronic affection for many years previously to the intus-susception. The first portion of intestine came away in the year 1826, the last in 1829. She died in March, 1831, aged thirty-seven years. The greater part of the intestine passed is preserved in the museum of the Chichester Infirmary.

This case also acquires great additional value from the circumstance that the form and dimensions of the intestine at the point where the solution of continuity had taken place, were found, after the death of the patient, to have undergone very little alteration. A slight contraction of the small intestine, and the presence of a thin, pearly-coloured false membrane, little more than half an inch in breadth, and surrounding it in the form of a zone, were the only external appearances which indicated the original seat of the disease. On the corresponding and internal surface of the intestine there was also seen a narrow, slightly elevated, smooth ridge, covered by mucous tissue, and traversing the whole circumference of the intestine, the walls of which, opposite, were considerably thickened.

If any doubt could remain that these appearances were to be admitted as positive evidence of the union and cicatrization of the original solution of continuity of the intestine, that doubt would be entirely removed by the fact that the solution of continuity had taken place in the situation of one of the glands of Peyer, and in such a manner that this gland was divided into two nearly equal portions, one of them terminating in the cicatrix, and the other being

situated at the extremity of one of the detached portions of intestine.

With regard to the treatment of mortification from intus-susception, there are two points which deserve the chief consideration of the physician; the reduction of the invagination, and the separation of the dead portion of intestine. The reduction of the invagination is not to be effected by the *direct* operation of any means which we have in our power to employ. If this is at all to be accomplished, it must be by preventing the accumulation, or diminishing as much as possible the quantity of the fluid contents of the intestine,—that is to say, by confining the patient to a state of absolute rest, by depriving him of food and drink as long as possible, by general bloodletting, and the use of emetics so employed as not to act upon the intestine. Purgatives must be avoided, as having the direct effect of increasing the disease. If this treatment fails to give relief, the physician should act as if there were a certainty that the reduction of the invagination is rendered impossible by the adhesive inflammation, and that a cure may be expected to follow the separation of the dead part of the intestine. Under these circumstances he must wait patiently, and endeavour to remove every cause which can tend to retard or prevent the accomplishment of this salutary result. At this period of the disease he cannot do better than enjoin rest and quiet, and support the strength of the patient by the frequent administration of small quantities of nutritious fluids, or enemata of a similar kind.

Numerous examples of mortification from an obstacle to the venous circulation are met with in those adventitious formations known under the denominations of scirrhus, cancer, medullary sarcoma, fungus hematodes, fibrous tumours, &c. We do not, however, think it necessary to do more than indicate the occurrence of the disease in such cases, as we have already alluded to it when speaking of mortification of the lungs and liver produced by a mechanical obstacle to the return of the venous blood. Such adventitious products, from their situation, connexion, and mode of development, are often destroyed in part, and sometimes entirely, solely on account of the veins in their immediate neighbourhood, or contained within them, being so compressed as to prevent the passage of the blood through them. These substances become gorged with blood, particularly at their circumference, where sloughing commences, which proceeds towards their interior, with a rapidity and extent proportioned to the degree of congestion by which it is preceded.

The rapid development of some of these accidental formations often depends on the destruction of the surrounding tissues by mortification, whereby they are relieved from the restraint imposed on them by external pressure. They now shoot forth with surprising rapidity, and undergo such a change in their conformation and other physical characters, that, although still the same disease, they are no longer recognised as such, and receive new names, which not a little embarrass the student of pathology.

3. *Mortification from obliteration of the arteries.*—Although this form of mortification, confined as it is almost always to the extremities, be regarded as the exclusive object of surgical treatment, we shall give a short outline of the pathology as it occurs in two distinct morbid states of the arteries of these parts, that the physician may be the better prepared to distinguish it from that which arises from disease of the heart, and another form of mortification of the extremities which still remains for us to describe,—viz. that occasioned by the use of unsound rye as an article of food.

The two forms of mortification of the extremities to which we here allude, originate, the one in spontaneous rupture of the internal and middle coats of the trunk of an artery, the other in the obliteration of a similar vessel or of its principal branches by the presence of organized fibrine, fibrous or osseous substances.

Mr. J. W. Turner, professor of surgery in the University of Edinburgh, was the first who directed the attention of the pathologist to the occurrence of spontaneous rupture of the internal and middle coats of an artery. There is, however, nothing in the histories of the cases which he has published which throws any light on the morbid condition of the arteries which precedes the rupture of their internal and middle coats. That such must have been the case is obvious from the following facts. One of the patients, whose case is related by Professor Turner, was in the act of raising himself in bed by resting on the palms of his hands, when he experienced a sensation as if something had given way at the joint of the right arm. Five days afterwards, the same patient, while in the act of moving his right leg, perceived a sudden sensation of numbness and weight extending from the ham downwards. Another patient, while turning his hand behind his back to put it in his coat-pocket, felt a sudden acute pain in the bend of the elbow joint, and a sensation of numbness in the hand and fore-arm. It is, therefore, obvious that in none of these cases the rupture, which was afterwards found to have taken place in the internal and middle coats of the brachial and popliteal arteries, could have been produced had there not existed a previous state of disease of these vessels. In one of the cases only did mortification take place. Half an hour after the rupture of the popliteal artery, no pulsation could be felt in any of the arteries of the foot, or in the ham. The foot was cold: no pain was excited by pressure on any part of the limb, but the patient complained of occasional cramp-like pains in the calf of the leg. The morning after the attack the foot was pale and cold, and below the ankle the integuments were entirely void of sensation when pressed, pinched, or tickled, and the muscles of the foot seemed to have lost the power of contraction. The next day several mottled purple patches appeared on the instep and fore-part of the ankle, which gradually extended over the whole foot, till the surface, by the fifth day, became

entirely livid. As the discoloration advanced, the foot swelled slightly, and became œdematous, and appeared to acquire an increase of temperature. Soon after the attack the patient complained of severe burning pain in the foot, and a feeling as if it were crushed, which continued till near his death. About the ninth day the soft parts above the ankle began to swell, and to be hot and painful on pressure; the swelling gradually increased, and extended till it reached the upper part of the calf of the leg. The integuments above the ankle began to become discoloured at the same time, and the discoloration increased till the lividity reached the calf of the leg, and at last rapidly extended nearly to the knee. The soft parts adjoining the discoloured skin were swollen and very painful on pressure; but no redness appeared, nor any inflammatory line between the dead and living parts. The parts discoloured were completely sensible, and the cuticle raised into globular vesications, filled with limpid or reddish serosity. The constitutional symptoms in this case were greatly aggravated by a previous state of disease. Death, however, did not take place until eighteen days after the pulse had ceased in the leg. The coats of the artery were found torn, thickened, and obliterated in several points by coagulated blood, fibrine, and lymph.*

The second form of obliteration of the arteries which gives rise to mortification, consists, as we have said, in the presence of fibrine, fibrous, or bony substances formed in these vessels. When the quantity of these substances is such as to interrupt or prevent entirely the circulation of the blood through the principal arterial trunk or branches of one of the inferior extremities, mortification is almost always the consequence, because of the advanced period of life at which this form of the disease generally occurs, and the very unfavourable state of the arteries to the formation of a collateral circulation.

It is to this form of mortification that we would confine the term *gangrena senilis;* the *idiopathic* and *dry* gangrene of authors.

We have already stated one of the reasons which have induced us to give a general outline of the kind of mortification which we are now describing, and we might have added a still more weighty reason for our doing so; viz. the important pathological evidence with which it furnishes us in regard to the production of mortification, independently of the previous existence of local inflammation; a subject on which it would appear some doubt is still entertained. We should not have thought it necessary to recur to this circumstance, having already shewn that mortification, from a mechanical obstacle to the return of the venous blood, and produced in a variety of ways, is not an uncommon occurrence in internal organs, were it not that the facts then adduced might be regarded as incomplete, from their being chiefly founded on the results of post-mortem examinations. In the form of mortification which we are now about to describe, no such objection can be raised, as all the facts which the pathology of a disease can afford as evidence of its seat and nature, are, in this case, equally conspicuous and decisive.

The first change which announces the occurrence of local death from obliteration of the arteries of one of the inferior extremities, occasioned by the presence of the accidental products which we have named, is a dark-red, purple, or almost black discoloration of the skin of the fleshy or under portion of one or more of the toes of the foot. There is, in general, no previous swelling of the affected toes, no increase of their temperature or sensibility. The discoloration alone is often the first circumstance which attracts the attention of the patient to the existence of the disease; and we have seen two cases in which the discoloration had gained the upper surface of the toes before the patients were aware of the presence of this insidious and fatal affection. In some cases, however, a prickling or tingling sensation, or a certain degree of numbness and cold, are perceived in one or more of the toes, and which, when examined, are already found to be discoloured; not red, hot, swollen, and painful, but of a purple or livid colour, colder than natural, not painful when pressed, and shrunk rather than increased in bulk. An increase of temperature, sensibility, and bulk of the affected toes, is, however, occasionally observed at or near the commencement of the disease; but as they are not constant, so are they not necessary changes. This, the first period of the disease, presents, indeed, none of the local characters of inflammation, if we except the circumscribed accumulation of blood on which the discoloration of the skin of the toes depends, the isolated existence of which is, however, of no value, inasmuch as its presence can be accounted for from interruption to the arterial circulation of the limb.

The discoloration extends slowly until it has pervaded the whole of the skin covering the toes, then proceeds upwards over the back and sides of the foot, and sometimes mounts nearly as far as the knee, although more frequently death takes place from the constitutional disturbance which ensues, before it has passed the foot or ankle joint. During its progress the discoloration generally presents the same purple or livid tint which it did at the commencement; and although it may be preceded by some swelling and congestion of the skin and subcellular tissue, its progress is seldom marked by the bright red colour of inflammation; and when inflammatory redness of the skin takes place, accompanied with heat, pain, and tumefaction, these phenomena must be regarded as effects of the disease which more frequently tend to increase than to interrupt or arrest its progress.

The bulk of the affected parts depends chiefly on the situation and extent of the obstacle to the circulation. If the obstacle be extensive, the quantity of blood admitted to

* On the sudden spontaneous Obliteration of the Canals of the larger Arteries of the Body, &c. by J. W. Turner, Professor of Surgery in the Royal College of Surgeons, Edinburgh. Edinburgh Medico-Chirurg. Society's Transactions, vol. iii.

the foot is too small to give rise to congestion; and this not taking place, there is little or no effusion of serosity. Hence there is no increase of bulk in mortification from this cause; and if the obstruction has been effected slowly, the foot and leg may even be atrophiated previously to their being attacked with mortification, the dead parts being shrunk, dry, and indurated. These physical characters of the disease are entirely owing to the hydraulic conditions to which we have just alluded; for if the obstruction to the passage of the arterial blood be only partial, and particularly if it has occurred suddenly, a considerable degree of congestion is induced, and consequently the effusion of a greater or less quantity of serosity, whereby the bulk of the foot, and more frequently of the leg, is more or less increased: even in this case, however, there is not any marked increase of bulk in the toes, the primary seat of the disease. It is in its progress upwards that the congestion and œdema become manifest; that the skin becomes tense and painful; and that the febrile symptoms, if they have not yet occurred, appear, increase rapidly in severity, aggravate the local affection, and hasten its fatal termination.

From the nature of the obstructing cause, and the unfavourable conditions under which it occurs, the progress of the mortification is seldom arrested; and if it is so, the separation of the dead parts is rarely accomplished, and perhaps a cure never effected.

It is stated by some pathologists that this form of mortification sometimes occurs in young persons, and is much more frequently met with in males than in females. The former statement we believe to be an error originating in an imperfect knowledge of the causes of this disease; for as we ourselves have never seen it in young persons, and as this statement has not been supported by other than mere negative facts, and these too very incomplete, we must continue to regard it as a disease peculiar to persons advanced in life, and occasioned by morbid states of the arterial system, which occur only in such persons, at least to such an extent as to produce local death.

With regard to the greater frequency of the disease in males than in females, we should say from our own personal observation, that this statement is correct only in so far as it regards its occurrence in the inhabitants of towns and cities; but that in those of agricultural districts, where the occupations and mode of living of both sexes are much of the same kind, it appears to occur as often in females as in males.

In every case of gangrena senilis which we have examined after death, we have found the arteries of the diseased limb obliterated in such a degree as to interrupt the circulation of the blood. The obstructing cause consisted, in five or six cases, of a fibrous tissue formed either in the walls or cavities of the arteries, whereby these vessels were converted into nearly solid cords of ligamentous consistence. This state we have traced from the toes more than half way up the leg: it was always connected with ossification of the larger branches and trunks of the thigh and other parts of the body. In other two cases, the obstruction depended on extensive ossification of the principal arteries of the limb; and in several others it was produced by solid fibrine formed around spiculi of bone projecting from the internal surface of the arteries.

Connecting this state of the arteries with the external appearances of the mortification with which it is accompanied, we can have no hesitation in admitting that this form of the disease is the immediate consequence of a deficient supply of arterial blood, and that therefore, if the facts already adduced were considered insufficient to prove that some of the other forms of mortification which we have described may also take place without being preceded by inflammation, those which we have now brought forward will, we trust, remove any doubts that may have been entertained on this highly important part of our subject.

The description which we have given of these two forms of mortification from rupture of the internal and middle coats of the arteries, as well as from obliteration of these vessels, is, we hope, sufficiently characteristic, and such as will enable the physician to distinguish them from other forms of this disease which belong especially to his department of the healing art.

III. Mortification from local and general debility.—As a state of local debility capable of inducing mortification is always connected with, and essentially depends on, a state of general debility, we shall confine the observations which we have to make on this form of mortification to the affection as it occurs under the influence of the latter condition of the economy.

Whatever may have been the causes of the general debility, we regard this state as constituting the essential condition of the disease;—a state in which the physiological and physical properties of the solids and fluids of the body are so modified, (we commonly say enfeebled or debilitated,) that every function of the economy is slowly, ineffectually, or imperfectly performed: innervation and nutrition in particular are so circumstanced, that even those agents on which the varied phenomena of health and life more or less immediately depend, now become the causes of disease and of death. Illustrations of this important fact meet the eye of the physician in the every-day occurrence of diseases of various kinds, but they seldom arrest his attention unless they occur under extraordinary circumstances,—such, in fact, as are observed in those cases of decay and death of the solids to which we shall presently more particularly allude. We have seen that mortification of various parts of the body may be produced by mechanical causes whose operation is entirely limited to the vascular system, in which they impede or arrest the circulation of the blood. This fluid, as well as the solids in general, may be in the healthy state up to the moment at which the local mechanical cause begins to operate and manifest its effects, and these are characterized by a diminution of

all those properties, the extinction of which is the death or mortification of the part thus circumstanced. A similar healthy condition of the solids and fluids may precede mortification from inflammation, but the phenomena of the disease are the opposite of the former. Local death does not take place until after the morbid stimulus has increased every property of the part to which it has been applied, to its maximum. The part is thus exhausted of its strength, if one may be allowed the expression, and being deprived also of the means of renewing it, from the changes which have taken place in its more essential elements, it soon sinks into a state of absolute death. In the form of mortification of which we have now to speak, the fluids of nutrition as well as the solids are, as we have said, in a previous state of disease, and this state is the cause of the general debility which constitutes the essential character of this form of mortification. Notwithstanding, we have classed it with the two former, because of their being all preceded by the same state of the circulation. In none of these three forms of mortification does local death take place without being preceded by cessation of the circulation ; a circumstance, we believe, of sufficient importance to authorize our having brought them all under the same general head.

The most marked examples of mortification from general debility are met with in individuals whose strength is greatly reduced by want and fatigue, by the violence of acute diseases of an adynamic character, and by chronic diseases accompanied with much pain, extensive suppuration, or which compel the patient to remain for a long time in the same position. Under these circumstances the local phenomena of mortification present, no doubt, considerable variety ; but those which constitute the type of the disease, whether local or general, are always the same, unless in so far as they vary in extent and degree. Thus, mortification from debility may be preceded by a certain degree of pain, increased sensibility and temperature of the part affected ; but these changes are not constant, and therefore not necessary to the production of the disease. A local accumulation of blood constitutes, in general, the first perceptible change in the part which is about to be deprived of its vitality. This may take place from the part being submitted to pressure from its own weight or that of the body, from slight friction, puncture, or similar causes. In some of these cases the blood accumulates, partly from the influence of gravitation, and partly from compression of the veins ; as, for example, in mortification of the soft parts covering the sacrum, heels, elbows, &c. of persons who have escaped the dangers of typhoid fevers, and who are left in that state of prostration which precludes the possibility of changing the position of the body. It is, perhaps, still more conspicuous in some patients similarly confined with paraplegia from injury of the spinal cord. Sloughing, or at least sphacelus, may have proceeded to a considerable extent before its existence has even been suspected ; the patient seldom complaining of any uneasiness till inflammation has been induced by the presence of the dead tissues.

A state of local congestion is also frequently the only change which precedes the sphacelus of the skin to which leeches have been applied, or which has been scarified or punctured. The skin around the leech-bites assumes a dirty purple, livid, or almost black colour ; looks sometimes as if it had been injected with ink ; presents no previous redness, heat, or pain, and is not swollen except where the blood is accumulated ; it drops off in the course sometimes of twenty-four hours, leaving a number of circular openings, which unite and spread by similar succeeding congestions and sloughing of the contiguous skin ;—effects which are always to be dreaded when it is found necessary to apply leeches to weak scrofulous children, greatly debilitated by confinement within the walls of an hospital, or low, damp, obscure, ill-ventilated dwellings.

The occurrence of mortification in scorbutus affords another striking example of the influence of general debility in the production of this disease. Portions of the skin often become gorged with blood, die, and slough, without our being able to discover that these parts have received any previous injury. The prostrate condition of all the functions of the economy, indicated by an unwillingness or the incapability to move ; the feebleness of the pulse, the fluidity of the blood, and the imperfect state of nutrition in the worst forms of this disease, convert, as it were, the natural and healthy influence of physical agents into a means of destruction. Even the mastication of the food necessary for the support of those affected with this disease, cannot be performed unless at the risk of inducing mortification of the gums, and other soft parts of the mouth. The sloughing of these parts from this cause is sometimes very extensive, accompanied by a continual oozing of blood, and occasionally terminates by the loss of the greater part of the teeth, and even portions of the alveolæ. For a more detailed description of the varieties of form, extent, progress, and termination, as well as the treatment of this form of sphacelus, we must refer the reader to the article Scorbutus.

There is one other form of sphacelus from general debility which requires to be more particularly noticed in this place. It is that which has received the names of *noma ; cheilocace ; stomocace gangrenosa seu maligna ; necrosis infantilis ; pourriture des gencives ; gangrène scorbutique aux gencives ; wasserkrebs der kinder ; gangrenous aphthæ ; water-canker.* The gangrene and sphacelus which have been described under these various appellations occur generally in infants, and in children from two to five years of age, attack the mouth and cheeks, and the external parts of the female organs of generation. Their occurrence in the mouth may be owing to the presence of several diseased states of the mucous follicles, mucous membrane, or walls of this cavity. Thus gangrene and sphacelus may follow inflammation of the follicles or mucous membrane of the mouth,

the inflammation being limited to these parts, as in follicular aphthæ, or combined with pharyngitis, scarlatina, small-pox, or scorbutus, examples of which will be found under these several heads. But the form of mortification to which we wish to direct the attention of the reader occurs in the parts which we have named without being preceded by any of these lesions. It commences, however, in the mouth, in the mucous membrane, and, perhaps nearly at the same time, also in the cellular tissue, generally of one, rarely of both cheeks. The general and local phenomena of the disease have been well described by Baron,* Isnard,† Billard,‡ Richter,§ and others, of which the following are the most important.

Symptoms.—In the first stage of the disease, the mucous membrane of one of the cheeks presents in some cases a small superficial ulcer without pain or discoloration. Sometimes there may be two or three ulcers, seldom more. In other cases, instead of an ulcer, a small whitish or yellowish grey spot appears on the mucous membrane, which sloughs, and gives rise to an ulcer similar to the former, or presenting the same colour as the slough by which it was preceded. It is not certain whether the disease commences by ulceration or sphacelus of the mucous membrane, but we are inclined to believe that it commences by the latter process. But, however this may be, there is observed nearly at the same time a greater or less degree of tumefaction of the cheek, opposite the ulcer or slough of the mucous membrane, which increases with great rapidity, and soon extends to the eyelids and lips. The skin of the swollen parts is pale and glistening, resembling wax, hard towards the centre of the swelling, and more or less elastic. A copious discharge of fluids takes place from the mouth, consisting at first of glairy saliva, and afterwards of a dirty sanies, which gives a strong offensive odour to the breath. There is no pain in the cheek, little or no increase of its temperature; and so little are the functions in general disturbed, that children affected with the disease in this stage are sometimes able to amuse themselves with their companions, and partake of their ordinary meals without any apparent inconvenience.

The commencement of the second stage is marked by the appearance of a dull yellowish grey discoloration of the skin on the centre of the swollen cheek, where it is hardest, and opposite the sphacelated mucous membrane of the mouth. The portion of skin thus discoloured soon becomes black, and sloughs; the whole substance of the cheek undergoes the same successive changes, and in the course of a few days, sometimes less than a week, the cheek, lips, and eyelids are converted into a soft putrid mass, which, falling off, destroys sometimes nearly the whole of one side of the face, lays open the cavity of the mouth, and exposes the gums in a state of sphacelus, the inferior and superior maxillary bones denuded or necrosed, and deprived of their teeth. In milder forms of the disease the sphacelus may be arrested before it has proceeded far in breadth or depth, or after it has destroyed only a limited portion of the cheek and lips, and without having attacked the bones. The general symptoms which accompany this the last stage of the disease, are sometimes so mild, so disproportioned to the local ravages of the disease, that one cannot help being struck with astonishment. There is even a craving for food, which the little victims devour with greediness and apparent relish, and which they continue to do even until within a few hours of their death. The intellectual faculties are seldom much affected. In other cases there are from the commencement a low state of fever, a weak quick pulse, heat of the skin, thirst, and loss of appetite. The fatal termination of the disease is likewise sometimes announced by a state of great prostration and colliquative diarrhœa, excited probably by the absorption of the putrid fluids, and their passage into the stomach and intestines. When this form of mortification attacks the labia, it presents the same local and general phenomena, commencing with a sloughing or ulcerated state of the mucous membrane of these parts, accompanied with the same kind of tumefaction and discoloration, and terminating in sphacelus, which spreads with great rapidity, and destroys to a greater or less extent the neighbouring parts.

From the above description of this form of mortification, little doubt can be entertained as to its being a disease arising in that state of general debility which we have already endeavoured to explain. All the phenomena which it presents are also so characteristic, that it is not likely to be confounded with any other disease except malignant pustule, from which however it may be distinguished, as has been observed by Rayer and others, from the latter disease, when it affects the cheek, always commencing on the external surface.

Prognosis.—The prognosis of this disease is extremely unfavourable when it attacks children in hospitals, for few of them survive its ravages. We have, however, seen its progress arrested in a few instances, and in two cases the patient survived the loss of a large portion of the cheek and a part even of the inferior jaw. When children are placed in more favourable circumstances, where they enjoy fresh air and receive all the care that their situation requires, the remedial means are more efficacious, and the mortality of the disease less considerable.

Treatment.—As soon as the disease is perceived, the slough or ulcers of the mucous membrane, whether of the labia or mouth, are to be touched with a mixture composed of equal parts of honey and muriatic acid, or with the latter alone. But when the disease is more advanced, when the swelling is conside-

§ Der Wasserkrebs der Kinder, Berlin, 1828. Journal des Progrès, &c. tome iii. 1830.

rable, and the stage of sphacelus has arrived, Mons. Baron strongly recommends that the sphacelated tissues be divided, and the actual cautery, heated to whiteness, carried deep into their interior.* This treatment is said to be by far the most successful. Marjolin states that he has employed it with complete success, and also the nitrate of silver, in the state of powder, introduced into the incised sphacelated tissues.† The muriate of soda is also an efficacious remedy, as it is found not only to arrest the progress of the disease, but likewise removes the stench by which it is accompanied.

Every precaution ought to be employed to prevent the putrid fluids from being swallowed, and perhaps the best means of doing so is to wash out the contents of the mouth with a decoction of bark, or a gargle of muriatic acid and honey; and to prevent them accumulating, the patient should be made to lie on the affected side of the face, so that they may find a ready exit. The swollen parts should be covered with cloths dipped in an aromatic fomentation, and occasionally rubbed with the liniment of ammonia, or other stimulating substances. Although this disease originates in a state of general debility, the local treatment which we have pointed out is regarded as the only certain means of arresting its progress. The operation of general remedies is too slow to have any control over a disease which proceeds with such rapidity, and therefore general remedies must be regarded only as auxiliaries. They should consist of nutritious fluids and small quantities of wine, but the administration of the latter in particular must be regulated by the state of the digestive organs, which in this disease are often greatly disordered and highly irritable, and therefore require to be remedied by means suited to the kind of derangement which they may present in each individual case.

II.—Mortification from the violent operation of mechanical, chemical, and physical agents.

The mechanical agents which occasion mortification are violent blows and contusions of various kinds; the chemical, powerfully stimulating substances; and the physical, extreme heat and cold. All these agents produce the same ultimate effect in the part of the body which has been submitted to their influence; that is to say, they deprive, to a greater or less extent, such a part of those properties on which its existence depends. The effect of a contusion produced by a heavy weight falling upon or passing over a part of the body, may be partial or complete death of such a part; and that produced by a bullet, instantaneous death of the soft parts, to a certain extent beyond the limits of the solution of continuity which it occasions in its passage through them. Strong stimuli, intense heat and cold, may operate precisely in a similar manner. The destructive effects of these agents are, however, not always the same in degree or extent, nor are they always produced in precisely the same manner. In one case there may be no gradation of change, no intermediate state of disease which separates these destructive effects from the previous healthy condition of the tissues in which they are produced: local death may be the immediate consequence of the violent operation of such agents. In another, the vitality of the part which has been exposed to the operation of these agents is not entirely destroyed. In this case the part may be regarded as in a state of gangrene; and in the former, in a state of sphacelus. In the present case it may or may not be susceptible of recovery, the result being dependent on the subsequent changes which may take place in the affected part itself, or in those parts with which it is connected. Congestion and inflammation are the changes which always take place, to a greater or less extent, in gangrene of this kind. If they can be prevented from taking place, moderated or removed when present, the suspended functions of the part may be restored; otherwise the gangrene terminates in sphacelus.

The state of congestion and inflammation to which we have just alluded originate in opposite states of the vascular system. The congestion takes place in the gangrened tissues, because of the vessels being deprived of those properties by means of which they were enabled to propel the blood through them. They have ceased to contract, and consequently the blood, although carried into them in the usual quantity, accumulates in, and distends them to a greater or less extent. On the contrary, the bloodvessels situated beyond the gangrened tissues having received little or no injury, are stimulated either by the presence of the disease acting as a foreign body, or have been previously excited by the cause which produced the gangrene, to such a degree as to give rise to an increased influx of blood, to an increase of the sensibility and temperature, and other phenomena of inflammation. Under these circumstances the remaining vitality of the gangrened part is soon destroyed, and consequently a state of real death produced.

However important it may be in a practical point of view to be fully acquainted with all the changes which take place in the structure and functions of a part which has been submitted to the violent operation of mechanical, chemical, and physical agents, we shall not enter into a more detailed description of them than may seem necessary to our present purpose, as this part of our subject belongs almost exclusively to the department of surgical pathology.

We may, however, observe,—1. that the degree and extent of these changes of structure and function are proportioned to the intensity of the agent by which they have been produced, the degree of energy with which it has acted, and the duration of its operation;—2. that the recoverable or irrecoverable condition of the structure and functions of the injured part are essentially determined by similar modifications of the efficient cause;—3. that congestion or inflammation are subsequent changes depend-

* Loc. cit.

† Dictionnaire de Médecine, tom. x.

ing on the primary lesion or its agent, always effects and complications but never causes of the disease, unless secondarily and under those circumstances to which we have alluded, that is, when the part is left in a recoverable state, or in a state of gangrene;—4. that, therefore, mortification from the violent operation of mechanical, chemical, and physical agents, differs from that produced by inflammation, an obstacle to the circulation of the blood, and local and general debility; the disease, in the former case, consisting essentially in a simultaneous lesion of all the elements; in the latter, of one element only of the part in which it is produced. There are, no doubt, slight exceptions to these general conclusions; but considering them in a general point of view, they appear to us to be drawn from a series of facts sufficiently broad and distinct to render it necessary to consider apart these two forms of mortification, independently of the advantage of doing so in a practical and scientific point of view.

For the reason before stated, we shall confine the few observations which we have still to make on this form of gangrene, to some of the more remarkable phenomena which it presents when produced by the action of intense heat and cold on the external parts of the body, and strong stimuli on the digestive mucous membranes.

1. *Mortification from intense heat.*—The effects of intense heat on the surface of the body are a greater or less degree of excitement, a temporary or permanent suspension of the functions of the part to which it has been applied; or in other words, there is produced a state of inflammation, gangrene, and sphacelus. The states of inflammation and of gangrene do not require to be described, as the phenomena which they present in the present case do not differ materially from those which accompany the same changes when they occur without any obvious cause, if we except the rapidity of their progress, and also the more sudden and extensive development of phlyctenæ, bullæ, or blisters, particularly when the heat is applied by means of a fluid. The state of sphacelus produced by the direct application of heat presents several very characteristic appearances. The skin is of a yellow, grey, brown, or black colour; dry and hard; sunk below the level of the surrounding surface, and quite insensible. These are, sometimes, the only appearances which are at first perceived to follow the action of intense heat, and are certain indices of the complete death of the skin to a greater or less depth. The deeper-seated tissues may also be deprived of their vitality, but to what extent cannot be determined by any change which the cutis may have suffered. The inflammatory redness which succeeds to this state appears almost immediately, and indicates by the rapidity of its course and the peculiar colour which it assumes, the extent both of the gangrene and sphacelus, the existence of which could not be determined by any previous change of the cutis produced directly by the heat. We do not wish it to be understood that we are speaking of gangrenous inflammation. The degree of inflammation produced by intense heat may, certainly, be such as to give rise to mortification; but in the present case we wish to shew that both stages of this disease may be, and often are, the immediate effects of the physical agent in question, and, consequently, whether capable of being detected or not by any peculiar change in the affected part, precede the inflammation to which they are often ascribed.

The extent of the sphacelus may be said to be always increased by the subsequent inflammation; and parts that were only in a state of gangrene are, by means of it, converted into a state of sphacelus; and hence the necessity of preventing the extension or modifying the violence of the inflammation which succeeds to burns or scalds.

Whether the state of sphacelus may have been produced by the action of the heat or the subsequent inflammation, the limits of the disease are seldom defined before the end of a week or ten days. The dead are then separated from the living parts, and an abundant suppuration takes place from the denuded surface. The solution of continuity is often imperfectly repaired in consequence of the exuberant production of granulations, which, instead of acquiring the organization of the cutaneous texture, assume that of contractile tissue, which often gives rise to great deformity of the parts with which it is connected. The general as well as the local effects of intense heat in case of burns and scalds, are proportioned to the extent and violence of the injury produced by this agent. They are characterized by excessive pain, great mental agitation, and extreme thirst; the pulse is rapid and hard, the skin hot, and the secretions in general are diminished in quantity.

If a remission of these symptoms does not take place soon, the pulse becomes small and feeble, and the skin covered with a cold sweat; the sufferings of the patient are announced by wild delirium; or he sinks into a state of stupor accompanied with convulsion. In some cases of violent and extensive burns, these symptoms make their appearance almost immediately after, and are followed by death in the course of a few hours.

The general symptoms are greatly modified by the situation of the burn or scald, independently of the age, constitution, and temperament of the patient. For it has been observed that a burn of any of the extremities gives rise to much less constitutional disturbance than a burn of the walls of the chest or abdomen, although it may be of the same degree and extent in each of these parts. The greater functional derangement in the latter case depends, no doubt, on the vicinity of the disease to the important organs contained in the abdominal and thoracic cavities.

It has been asserted that the mucous membranes, and especially the digestive mucous membrane, are not only inflamed in all cases of burns of any considerable extent, but that the secondary fever that follows is chiefly owing to this lesion of the digestive organs.

With regard to the latter statement, nothing can be more obviously erroneous, as the intensity of the pain in all such cases is in itself sufficient to produce the secondary fever. However far the former statement may be correct, we have not had sufficient opportunity to determine. We have seen the respiratory and mucous membranes red and vascular in one fatal case, the patient having died at the end of four days. In two other cases this membrane in both of these organs was pale, and without any appreciable lesion. These two patients were females, and had the inferior half of their bodies severely burnt from their clothes having caught fire: both of them lived seven or eight days. It is possible that the difference in the duration of the disease in these cases may have had some share in effecting the difference observed in the state of the mucous membrane after death. But it is of greater importance to observe that the secondary symptoms were equally severe in all the three patients.

With regard to the local and general treatment of burns and scalds, we shall only observe that, in the latter, antiphlogistic measures, carried to the extent which the individual case demands, must always be had recourse to, although the secondary fever, when it occurs at an early period, and depends more on the shock which the system has received and the violence of the pain, is but little under the control of such measures. More benefit is derived from the administration of anodynes, and the use of those means which the surgeon has found to be most successful in allaying the local heat and pain of the injured part. Opiates are particularly useful in abating the great nervous excitement which accompanies this form of fever, and in procuring a temporary respite from suffering.

It is of much importance to distinguish between the febrile excitement which immediately follows the injury, and the secondary fever which is the consequence of the subsequent inflammation. As in the latter case, general bloodletting is always more or less useful. The same indication is pointed out when inflammation of an internal organ has taken place, although leeching and cupping are oftener to be preferred to the lancet. In stout young persons of a sanguine temperament it may be necessary to employ both.

2. *Mortification from cold.*—The local and general effects of intense cold are, in many respects, very similar to those produced by intense heat. If the degree of cold be not very great, the circulation and temperature, of the skin for example, when submitted to its influence, are increased, as is shewn by this tissue assuming a redder colour, and feeling warmer than before. On the contrary, if the cold be very intense, it may not give rise to any appreciable degree of local excitement; the vitality of the skin, and even of the deeper-seated tissues at the same time, may be either greatly reduced or entirely destroyed by the direct operation of this physical agent. There is, however, this difference between the local effects of heat and cold, viz. that the former may produce complete disorganization of the tissues submitted to its action; whereas the latter never produces such a change. In the former the local redness rapidly increases, in the latter it rapidly diminishes; and in the same manner does the sensibility increase and decrease under the influence of these agents respectively. (We are now speaking of the immediate, and not the subsequent effects of cold.) The general effects, or functional disorder produced by the immediate operation of cold, are very different from those produced by heat. If the cold has been limited in its operation to the extremity of a limb, complete death of the part may ensue without any general functional derangement being induced. But if the whole body has been exposed to its operation, every function becomes depressed, and a state of lethargy soon succeeds, from which the patient is often not to be roused, either by the entreaties of his friends or the best directed efforts of the physician.

The symptomatic fever which follows the local effects of cold does not take place until inflammation has succeeded to these effects, for it depends exclusively on the presence of this morbid state; and hence the similarity said to exist between the symptoms of mortification from cold, and those of mortification from heat. It is, in fact, only after the occurrence of inflammation that the local and general symptoms of mortification from these two causes acquire a striking similarity in kind, if not in degree.

Although a state of gangrene and sphacelus of a limb or a portion of a limb may be induced by the direct operation of intense cold, we may not be able to determine the existence of either until inflammation has taken place. It is, however, said that the toes and fingers have been seen to fall off, having been deprived of life on account of the intensity of the cold. But by far the most frequent occurrence of mortification is when a frozen limb is exposed to natural or artificial heat, as before a fire or during thaw. The blood that was before frozen thus regains its fluidity, and gangrene and sphacelus, if they were not previously, are now more or less rapidly induced. Under these circumstances, the skin assumes a dark red or livid colour, where it is in a state of gangrene or sphacelus, and the neighbouring skin acquires an erythematous blush, accompanied with a prickling or tingling sensation, and a feeling of weight or stiffness in the limb. By-and-bye phlyctenæ appear on the inflamed part of the limb, and grey, livid, or black spots on that part of it which is in a state of sphacelus. Then also putrefaction commences, and extends till its progress is arrested by the adhesive inflammation. In this kind of mortification, as well as in every other, the extension of the sphacelus depends much on the degree of the subsequent inflammation, to subdue and still more to prevent the occurrence of which every means ought to be promptly and sedulously employed.

The treatment of a frozen limb, for example, consists in rubbing it with snow or pounded ice, in order to re-establish gradually its sensibility and circulation, and afterwards the use of a circular roller carried from the toes upwards, the good effects of which depend on the obstacle which it opposes to the accumulation of the blood in the limb, and to the distention and swelling to which the presence of this fluid and the subsequent effusion of serosity give rise.

3. *Mortification from stimuli.*—The stimuli included under the present head, and which give rise to mortification, are those which exercise a chemical influence on the tissues with which they come in contact. The nitric, muriatic, and sulphuric acids may be cited as furnishing us with examples of chemical stimuli which produce local death when they are applied to the skin or mucous membrane of the digestive organs. The local effects of these substances resemble very much those produced by intense heat. Like the latter physical agent, they instantly destroy, to a greater or less depth, when strong, the cutaneous and mucous tissues. In both cases the vitality and texture of these tissues are destroyed, and the functional derangements of the economy are also very nearly the same, particularly when the former have been applied to the digestive mucous membrane. The functional derangement too, which follows the action of these chemical stimuli, does not arise in consequence of absorption, but, as is the case in intense heat, from the sudden shock which the nervous system receives at the moment they are applied, and the state of excitement of this system from the inflammation to which they give rise. Instead of a state of complete local death or sphacelus, we may have as the result of their action, when diluted, a state of gangrene, or simply inflammation, and which may, as in similar states produced by other causes, terminate in sphacelus. A state of sphacelus is, however, the far more frequent effect of their immediate operation in the undiluted state, to which inflammation occurs as a subsequent change, and which seldom proceeds, unless in the mucous membranes, beyond that degree necessary for the elimination of the dead part.

The local effects of these chemical stimuli are not often confined to one portion of the cutaneous or mucous tissues; they are generally perceived on several portions of both, the form and extent of which are subject to great variety, more particularly in the stomach; the states of vacuity and fulness, or the nature of the contents of this organ, modifying in a greater or less degree both of these local circumstances.

The changes of colour which indicate that local death has been produced by these chemical stimuli are well known; they are either yellow, yellowish brown, brown, or black, changes which seem to depend much on the quantity of blood contained in the part, and the strength of the acid which has been applied to it.

Perforation of the stomach, giving rise to a communication between the cavity of this organ and that of the peritoneum, is not unfrequently the consequence of the introduction of these acids into this organ, and we believe that when it does take place, it is generally soon after their introduction, and before the peritoneal inflammation which ensues has been sufficiently long established to furnish coagulable lymph, and unite some neighbouring organ with the stomach opposite that part of it which has been acted upon by the acid. Under these circumstances, therefore, the perforation is not the consequence of the separation of the sphacelated tunics of the stomach by their subsequent inflammation, but is the result of their immediate and complete destruction.

There are several important points connected with this part of our subject which merit particular consideration, more particularly the changes of colour and consistence to which chemical stimuli give rise in the mucous membrane of the stomach, to the former of which we have already alluded, but into the consideration of which we do not think it necessary to enter in this place, as we have already insisted on similar changes in the article Melanosis, where we have endeavoured to show that they may be produced by the action of the gastric acid after death, and present appearances so similar to those of the former as to lead the toxicologist and medical jurist to commit the most serious mistakes. As these chemical stimuli are classed among the poisons, we refer the reader to the article Toxicology for a description of the symptoms to which they give rise, and the treatment which they require.

III.—Mortification from the deleterious influence of certain poisons.

The poisonous substances which we propose to include under the present head are those which are derived from the animal and vegetable kingdoms. Some of these substances are natural, others morbid products. The former consist in a peculiar healthy secretion of certain animals, which is capable of producing disease or death in other healthy animals, and for which we have no distinctive appellation except the vulgar term of *venom*. The latter, derived from the animal kingdom, are generated by a state of disease of the animal solids and fluids, are capable of producing the same morbid state to which they owe their formation, when communicated, directly or indirectly, from one animal to another, and are termed *virus*. We have no specific denomination for the deleterious agent generated by the decomposition of animal matter, and by that diseased state of rye which gives rise to mortification.

Mortification arising from these different sources may be considered with advantage under the following heads:—1. mortification from a deleterious agent generated in healthy animals; 2. mortification from a deleterious agent generated during the decomposition of animal substances, and in animals in a state of disease; 3. mortification from a deleterious agent generated in vegetables in a state of disease.

1. *Mortification from a deleterious agent*

generated in healthy animals.—We have already said that a peculiar healthy secretion of certain animals is capable of giving rise to mortification, when directly applied to the body of another healthy animal. The most striking examples of this are met with in the effects which follow the bite of the *cobra di capella*, the rattle-snake, and the viper. When the poison of these animals is inserted into the cutaneous and cellular tissues of one of the limbs, the most acute pain is produced, which rapidly extends in both directions towards the extremities of the limb; the cellular tissue becomes œdematous, much swollen, and hard. If there be any redness of the skin around the wound, it is of short duration, and is succeeded by a livid discoloration, which increases in extent, followed by the formation of phlyctenæ, and diminution of the temperature of the affected part. The hard œdematous swelling of the skin and cellular tissue then becomes soft, crepitates when pressed, and a sanious discharge of a fetid odour runs out from the wound. During the short time these local changes are taking place, the functional derangement produced by the absorption of the poison proceeds with extreme rapidity, and it may terminate in death in the course of a few hours. Almost immediately after the insertion of the poison, a sense of great oppression is felt in the region of the heart; the respiration becomes laborious; there is great pain in the head or vertigo, and frequently pain in other parts of the body, but particularly in the stomach and intestines, accompanied with vomiting and diarrhœa; vision is also sometimes much impaired, and the pulse small and intermittent. As the influence of the poison becomes more extended, to these symptoms are added extreme debility, great anxiety, the most unquenchable thirst, cold sweats, hiccup, and frequent fainting fits; the skin assumes a sallow jaundiced aspect, and the breath becomes extremely offensive. Such is a general description of the local and general effects which follow the insertion of the poison of these animals into the cutaneous and cellular tissues. Although the local treatment is strictly surgical, we may state here that it consists, as recommended by Celsus, and very recently by Sir David Barry and others, in the application of a ligature to the limb between the wound and the heart, so as to arrest the venous circulation and intercept the poison; the use of the cupping-glass, and the actual cautery. Various topical remedies are recommended, and are said to have been employed with success. Indeed, the local appears to be much more successful than any general treatment that has yet been devised, in arresting the progress, or in preventing the baneful effects of the poison of these animals. The liquor ammoniæ is regarded as the best internal remedy that can be employed. It is also said that stimulating sudorifics have been found useful; but it does not appear that much reliance is to be placed on the use of internal remedies when the poison has once entered the system, and when it possesses such a degree of virulence as to destroy the vitality of the part to which it is originally applied. It is to such cases alone that our observations apply, as in milder cases mortification seldom occurs in consequence of the direct application of the poison.

2. *Mortification from a deleterious agent generated during the decomposition of animal substances, and in animals in a state of disease.*—The production of mortification from a septic agent, generated during the decomposition of animal substances, or in animals in a state of disease, being introduced into the blood or applied to the surface of the body or of sores, is by no means a rare occurrence. The most obvious and frequent examples of mortification of this kind are met with in the bodies of those who have died from mortification of some external part of the body, from whatever cause arising. Mortification of a portion of a limb, succeeding to inflammation, to a mechanical injury, to an operation, is often followed by mortification of some internal organ. The same may be said of mortification of one internal organ, giving rise to mortification of another internal organ, although it is by no means so frequently observed as in the former case. We have seen a considerable number of cases of gangrene and sphacelus of internal organs originating in the existence of similar states on the external surface of the body. That such is frequently the origin of mortification of internal organs there cannot be the slightest doubt; for it occurs when this disease affects an external part of the body from inflammation, as urgical operation, or other causes to which the internal organs, which are afterwards found to be in a state of mortification, were in no way whatever subjected. The septic principle is carried into the blood, and appears to give rise to a state of gangrene or sphacelus, without these being preceded by any perceptible intermediate change. For when we examine the organ thus affected, we do not perceive any of those changes which accompany inflammation, such as red induration or suppuration; nor are there any symptoms during the life of the patient which indicate the presence of a local disease. The lungs and liver may be extensively affected without the functions of either undergoing any modification which indicates the existence of such a disease. They are, however, modified, as well as those of every other organ of the body, by the contaminated state of the blood, to which we have already ascribed that peculiar assemblage of symptoms which make their appearance at the close of the fatal termination of sphacelus.

The morbid appearances of this kind of mortification of internal organs present several peculiarities. The tissues of the organ do not, as we have already said, exhibit any of those changes which constitute the anatomical characters of inflammation. They are, on the contrary, found to present those appearances which we observe on a part of the external surface of the body to which a virulent poison has been applied, viz. a circumscribed dull deep-red, livid, brown, or black colour, in which state they feel firmer than natural; or

they are of a dirty grey colour, of a soft pulpy consistence, or entirely decomposed and transformed into a grey or reddish-brown fluid of the consistence of pus, around which the other tissues may not present any material alteration. These appearances are most frequently observed in the lungs and liver. They may exist in several points of these organs at the same time; may occupy an extent of surface varying from the fourth of an inch to two or three inches; and are much more frequently situated towards the external surface, than in the central parts of these organs. In the lungs they are generally seen under the pleura, and if the patient survives a certain length of time the contaminating influence of the poison to which they owe their origin, the pleura sloughs, and pneumothorax is produced. We have seen two examples of this termination of sphacelus of the pulmonary tissue and pleura, arising in, or connected with, sphacelus of the ankle-joint in one patient, and in another with sphacelus of the larynx.

The production of gangrene and sphacelus from a septic agent generated in a state of disease is no less conspicuous in what is called *hospital gangrene*. Whatever may be the causes of hospital gangrene, this local disease may be communicated by means of the fluids of the diseased part being brought in contact with the surface of common sores, a scratch or prick, and, it is said, with the healthy skin. When the disease is thus produced, for example in a sore, the surface assumes a pale or livid aspect, becomes swollen and painful, and covered with a viscid grey matter tinged with specks of blood. The surrounding integuments soon present the same appearances, are converted into dirty-grey spongy sloughs, the extent of which, as well as the progress of the disease, is marked by the preceding discoloration, which is often of an erysipelatous character, affecting at the same time the skin and subjacent cellular tissue, and thence the adjoining lymphatic glands, which are also destroyed in the manner above stated. But although the state of sphacelus be often preceded by an erysipelatous redness, the separation of the dead parts is always accompanied by more or less hemorrhage, which shows that the plastic property of the blood by means of which hemorrhage is prevented, as well as the vitality of the solids, is destroyed in this kind of mortification. Dr. Hennen, in his *Principles of Military Surgery*, states that in the last stage of the disease there is a bloody oozing from the surface of the denuded parts; that in lifting up the edge of the flabby slough, the probe is tinged with dark-coloured grumous blood, with which its track becomes immediately filled, and that at this period of the disease repeated and copious bleedings take place which rapidly sink the strength of the patient. The sloughs, whether falling off spontaneously, or detached by art, are thickly studded with specks of arterial blood; and when hemorrhage takes place from an artery which it is necessary to tie, and which is ruptured by the ligature, the application of the tourniquet or other pressure is employed in vain, for while it checks the bleeding, it accelerates the death of the limb, which becomes frightfully swollen and horribly fetid.

The constitutional symptoms of this kind of mortification sometimes precede the local affection, at other times do not make their appearance until it is fairly established. But however this may be, they are characterised by greater or less derangement of the digestive functions, a feeble and quick pulse, and great weakness of mind and body. "Men," says Dr. Hennen, "who had borne amputation without a groan, shrunk at the washing of their sores, and shuddered at the sight of a dead comrade; or even, on hearing the report of his death, predicted their own dissolution, and sunk into sullen despair." The fatal termination of this frightful form of mortification is announced by extreme prostration, vomiting, hiccup, involuntary dejections, and coma.

The treatment of the present form of mortification will depend much on the state of body and mind of the patient, and the situation in which he is placed. When it occurs in a healthy individual, his removal from the place in which it was communicated to him, and the topical application of those remedies (the concentrated acids or actual cautery) which are now found to be most efficacious in arresting the progress of the disease, will in general effect a speedy cure. In such means, also, consists the most essential part of the treatment which the situation of those patients will allow in whom the disease occurs spontaneously, that is to say, without any direct cause, and whose mind and body have suffered from the injurious influence of disappointment and privations of various kinds. Cheering prospects, wholesome food, and change of situation, are well known to be the most effectual means of preventing and checking the ravages of this disease in hospitals, or other situations, in which a greater or less number of patients are confined, and without which all our remedies are often entirely useless, or procure only a temporary or partial benefit.

The next form of mortification produced by a septic agent generated by disease is that which is called *pustule maligne*, or *charbon* by the French, and *milzbrand* by the Germans. By some pathologists this disease is believed to originate in horned cattle, among which it sometimes prevails epidemically to a very great extent, and that when it occurs in man, it is always derived from such animals. By others it is said to occur *sporadically* in persons who have no connexion, either directly or indirectly, with animals so diseased. Be this as it may, the important fact is, that a septic principle is generated in this disease, which possesses the property of communicating a similar disease from one animal to another and from person to person. Hence it is that herdsmen, butchers, and tanners, and all other persons who handle the skin, blood, and flesh of these animals, are those in whom the malignant pustule or carbuncle is generally observed. Enaux and Chaussier regarded the occurrence

of the disease in such persons as strong proof that it was communicated to them by immediate contact; and in further support of this opinion, they adduce the facts that malignant pustule makes its appearance exclusively on those parts of the body which are usually uncovered, such as the face, neck, breast, and shoulders; the hands and arms, feet and legs; and that in general it is observed in such persons when it reigns endemically among cattle.*

Numerous examples are recorded of malignant pustule being communicated in the manner above alluded to, as well as of its being communicated to persons employed in dressing those affected with the disease. The blood appears to be strongly impregnated with the septic principle generated in this disease, for parts of the body on which this fluid has been deposited have soon after been affected with malignant pustule, and similar effects follow its injection into the veins, as was the case in the experiments of MM. Leuret and Hamont.†

Those who eat the flesh are also often affected with an eruption of malignant pustules, and other symptoms similar to those which the animal from which the flesh was taken presented.

Malignant pustule commences in the form of a small vesicle, filled with a somewhat bloody serosity, accompanied with a circumscribed œdematous swelling of the skin and cellular tissue beneath it, which soon extends in breadth, followed by an erysipelatous redness of the skin. As the swelling increases, the skin acquires a glossy aspect, and presents here and there small and large phlyctenæ. The erysipelatous redness soon assumes a livid tint; the central portion becomes brown or black, hard and insensible, whilst the surrounding parts are tense and emphysematous. These changes are produced with greater or less rapidity, and sometimes extend to a considerable distance, followed by extensive sloughing of the skin and cellular tissue. The local and general symptoms of malignant pustule resemble very much those which follow the bite of the viper, &c. which we have already described, and require nearly the same treatment.

Maurand‡ relates some cases of malignant pustule produced by the flesh or blood of overdriven cattle, although their bodies presented no appearance of disease. It would appear that the flesh of such animals may be eaten with impunity when cooked, but that if the blood or raw flesh be applied to the wounded skin, or even to the unbroken skin, diffuse cellular inflammation is excited, or malignant pustule produced, which frequently terminate fatally; and M. Dupuy states that the malignant pustule or carbuncle of cattle may be produced by applying to a wound the blood of an animal that has died of gangrene of the lungs.§

The carbuncle of plague and the malignant pustule present precisely the same local characters as those which we have just described, and seem to owe their origin to a similar cause, viz. the development of a septic agent, and which in the former seems to be formed during the progress of the disease in which it is observed. The number of the pestilential carbuncles vary considerably, and are generally in proportion to the gravity of the disease which they accompany, and in which they originate. Pestilential carbuncle, like malignant pustule, may be communicated by contact or inoculation; and it is said by Diemerbroëck and Desgenettes, may prove fatal without giving rise to the general symptoms of the plague.*

There can be no doubt that a septic agent is developed during the decomposition of animal substances, apart from the living body, capable of producing mortification. This state, however, is always preceded by erysipelatous inflammation, which spreads with great rapidity and proceeds to a great extent, and followed during its progress by extensive sloughing of the skin and cellular tissue, and is accompanied by the same kind of general symptoms that characterize the action of all septic agents on the economy. It is difficult to say how far wounds received in dissection or in the inspection of dead bodies, and which are followed by diffuse erysipelatous and gangrenous inflammation, depend on the presence of a septic agent developed during the progress of disease, or after death. One thing is certain, that the frequency and severity of the disease which follows such wounds, has, so far as we can perceive, no connexion with the ordinary changes of the solids and fluids produced by putrefaction; for the results of our own experience are in accordance with the generally received opinion, that it most frequently occurs after wounds received in the examination of recent bodies, and also in the bodies of those who have died of inflammatory effusions into the serous cavities. Nevertheless similar consequences follow pricks and wounds from putrid bones, and the contact of putrid animal matter with the abraded surface of the skin; and Cullerier says that gangrene sometimes attacks the penis of those persons employed to clean out the cesspools in Paris, if they are affected at the time with gonorrhœa.

It would appear that a septic agent is developed in various grains in a state of disease, but more particularly in rye, which, when used as an article of food, has frequently given rise to one of the worst forms of mortification. This form of mortification has, perhaps, been exclusively observed in various parts of the continent of Europe, and particularly in those districts of France, Germany, and Switzerland, in which rye forms the chief article of food of the inhabitants. In these and various other parts of the continent, the local and general effects of spurred rye, as it is called, have been

observed and described by several physicians, but it was not until the year 1597 that they were traced to the internal use of that diseased grain. Since then repeated epidemics have occurred, and always during rainy seasons, and which have prevailed most in places naturally moist and of a poor soil,—circumstances to which, in fact, the ergot or cockspur owes its origin. We shall not stop to enquire into the causes of the spur in rye, and besides shall confine ourselves to a general description of its effects. The effects produced by the use of spurred rye as an article of food are very various. In some individuals the influence of the poisonous ingredient is chiefly exerted on the brain and nervous system, the most remarkable symptoms being vertigo, dimness of sight, pain, loss of sensibility, cramps and convulsions, yellow discoloration of the skin, thirst, and feeble pulse. These symptoms are greatly modified in degree in different individuals, and are sometimes slow, and at other times very rapid in their progress. In the most acute form of the disease death may take place at the end of one or two days, preceded by dreadful cramps and convulsions of the whole body. Even in the milder cases, the convulsions are more or less severe towards the fatal termination of the disease; and hence this form of the disease is called *convulsive* ergotism by French writers, and is vulgarly denominated in Germany *kriebelkrankheit*, or creeping sickness. In other individuals, placed apparently in similar circumstances, the most remarkable effect which follows the operation of the same septic agent is gangrene or sphacelus of certain parts of the body. Hence this form of the disease has received the name of *gangrenous ergotism, necrosis ustiliginea, seu epidemica.*

The local, like the general effects of spurred rye, present considerable variety. The following description of them taken from the works of those authors who have witnessed the disease in various parts of the continent, contains the principal forms under which they have appeared. In one class of patients seen by Dodart, the disease was characterized by vertigo, a malignant form of fever, great drowsiness, and gangrene of the inferior extremities. The gangrene was preceded by a sensation of numbness in the legs, which became afterwards painful, slightly swollen, but not inflamed. The skin was cold and livid, and the sphacelus commenced in the centre of the limb, and did not reach the skin till some time after.*

In a second class of patients, in which the disease was observed by Noël, surgeon to the Hôtel Dieu of Orleans, the sphacelated parts were dry, livid, or black: these appearances commenced in the toes, and gradually extended sometimes as far as the thighs. In some the sphacelated parts separated spontaneously; in others the progress of the disease was arrested by scarifications.

Lang, who observed the gangrenous ergotism in Lucerne, Zurich, and Berne, says that the disease commenced with lassitude and a sensation as of insects creeping under the skin, without fever. Soon after the extremities became cold, pale, wrinkled, and benumbed, and at last quite insensible and incapable of motion; afterwards acute pain was felt, referable to the central parts of the limbs, which was exasperated by heat and mitigated by cold applications; there was then, also, fever and headach; the pain extended from the hands and feet to the shoulders, legs, and thighs; and lastly, the affected parts became dry, shrunk, and black, and dropped off at the joints. Entire extremities were thus separated from the body without hemorrhage. Many patients lost both legs, several the arms, and a few both legs and arms.* In other cases, the chief symptoms were, at first, spasmodic contractions of the limbs, afterwards great weakness of mind, voracity and dyspepsia, which generally terminated in fatuity or sphacelus.† The parts most frequently attacked with gangrenous ergotism are the inferior extremities. Men are more subject to the disease than women, and children and old people than adults.

From the above description of the local and general effects of spurred rye, it is by no means easy to say in what manner this poisonous article of food operates so as to produce mortification. One thing, however, appears certain, that it is not by an inflammatory process of the part which becomes the seat of the disease. That cessation of the circulation and loss of the sensibility and motion of the limb observed to take place at an early period of the disease, are not the consequences of inflammation, is clearly proved by the nature of the local, if not the general symptoms which we have detailed. All these local changes appear to be produced as direct consequences of the spurred rye, acting through the medium of the blood or nervous system, or both at the same time. For we have seen that the dead parts are separated without hemorrhage, and it is stated that the blood, when taken from a vein, is dark and so very thick that it only oozes out from the orifice of the wound.

In several animals who died after having been fed for some time on spurred rye, and who presented several of the symptoms already mentioned, gangrenous spots are said to have been found in the stomach, intestines, and liver. But the morbid anatomy of this disease is extremely imperfect, and does not enable us to offer any explanation either in regard to the nature of the disease itself or its complications; or to suggest any means other than those already employed in its treatment, and which may be said to be almost entirely empirical. Bloodletting, emetics, and purgatives have been employed by some; tonics and stimuli by others; and lastly, anodynes and narcotics, all of which methods of treatment appear to have been more or less successful in one form of the disease, and of little or no avail in another. Stimu-

lating lotions, warm fomentations, and friction appear to mitigate the local symptoms, and along with the general treatment, sometimes to arrest the further progress of the disease.

(R. Carswell.)

MUMPS.—See Parotitis.

NARCOTICS, (from νάρκη, *stupor*,) syn. *hypnotica*.—These are medicines which in small or moderate doses produce temporary excitement succeeded by depression, which is generally followed by sleep. This definition does not comprehend the anodyne power strikingly displayed by many narcotics; because, although it is undeniable that many of them are capable of alleviating pain, yet, as this is not a general property of narcotics, it cannot correctly enter into a definition of the class

Narcotics are commonly confounded with sedatives, but there are sufficient reasons for separating these two classes. In the first place *narcotics* operate as diffusible excitants, and by a proper regulation of the dose, and its administration at short intervals, their exciting influence only is obtained; in the second place, the depression or collapse which follows the administration of the full dose of a narcotic is the result of the previous excitement; and although this is not in the direct ratio of the degree of excitement, yet, if the excitant effect be considerable, and raised to its acmé, the succeeding collapse is proportionate. On the other hand, *sedatives* immediately depress the vital energies by a peculiar action upon the nervous centres, without causing previous excitement; and, if the dose be sufficiently large, they destroy both mobility and sensibility. Such are the distinctions between the effects of the administration of narcotics and sedatives, —distinctions undoubtedly sufficient to authorize the separation of these classes of medicinal agents.

The first effect of a moderate dose of any narcotic is an augmentation of the action of the heart and arteries, followed by an elevation of the heat of the whole body, and a slight sensation of fulness in the head. These symptoms are accompanied with an unusual exhilaration of spirits and aptitude for exertion; effects which, however, in a little time subside, and are followed by languor and drowsiness, gradually terminating in perfect sleep. The augmented arterial action is succeeded by a small, feeble, and irregular state of the pulse; the temperature of the body is lowered; and the respiration, which in the first instance was accelerated in the ratio of the augmented vascular action, falls below the natural standard; an imperfect decarbonization consequently is effected in the pulmonary circulation; so that the blood transmitted to the brain being inadequate for due excitement, the whole system necessarily languishes. The function of the skin is, however, increased, and passive diaphoresis occurs, accompanied by itching and the dilatation of all the erectile tissues: finally, the glandular excretions are diminished, the mouth feels dry, and both the bile and the urine are evidently defective. The influence on the stomach varies according to the state of the organ; if the narcotic be taken into an empty stomach, it diminishes the desire for food; if swallowed at the time of taking food, the organ is enervated, and chymification suspended; if a short time after a meal, the process of digestion is arrested; and if vomiting be excited an hour or two afterwards, the food is ejected in the state in which it was swallowed. The same effects follow the introduction of a narcotic into the rectum: the intestines, besides, frequently lose their ordinary contractility, and costiveness ensues. This, however, is the result of a moderate dose of only some narcotics; others rather increase than diminish the peristaltic motion of the intestinal canal.* After awaking from the sleep induced by a narcotic, the individual frequently experiences slight headach, some degree of nausea, languor, and a more than usual susceptibility of impression, with tremors of the hands, which continue until some excitant, such as coffee or a glass of wine and water, be swallowed. By degrees these symptoms subside, and the system remains in its accustomed state, unless the dose of the narcotic have been more than can be termed moderate, in which case headach, sometimes vertigo and confusion of ideas supervene and continue for several hours; whilst anorexia, constipation, and a scanty urinary discharge are experienced for a considerable time, and the individual is left weak and uncomfortable.

If the dose of the narcotic substance be so large as to prove poisonous, headach, vertigo, imperfection of vision, and stupor, are experienced, without any previous apparent excitement; the person soon becomes motionless and insensible to external impressions; he breathes slowly; and for some time the expression of the countenance denotes only sound and deep repose. By degrees the features change, and acquire a ghastly character; the breathing, under the influence of some narcotics, is stertorous, as in apoplexy, under that of others it is soft and natural; the pulse becomes irregular, sinks, and at length is almost imperceptible; the muscles relax, the jaw falls, and death rapidly closes the scene. Many of the symptoms following the administration of such large doses of narcotics resemble, in some respects, those attending *apoplexy*; in others, those of *epilepsy*; and occasionally those of *hypertrophy* of the brain; but in every case the distinction is apparent, when the circumstances preceding and attending the attack are duly investigated.

* These effects of narcotics on the alimentary canal are greatly modified by disease. In subacute inflammation, or a highly irritable state of the mucous membrane, vomiting is not unfrequently induced; in a relaxed condition of that membrane, the atony is augmented, and indigestion and constipation confirmed; in cancerous ulceration of the stomach, instead of allaying pain, narcotics cause pain, and excite vomiting and rigors, and the brain becomes powerfully affected. In irritable states of the intestinal canal, however, especially when spasm is present, they allay griping, resolve spasm, and produce an anodyne and salutary effect.

Thus, in apoplexy there are generally premonitory indications of the threatened attack; and when the sopor has commenced, the patient cannot be roused to any consciousness, which is not the case in narcotic poisoning. The same kind of sopor attends epilepsy; it terminates suddenly, and the attack of the paroxysm is abrupt. Cerebral hypertrophy is a slowly progressing chronic affection.

The influence of narcotics is modified by a series of circumstances; for example, by the nature of the narcotic, the extent of the dose, the time of the day at which it is administered, the combination in which it is given, the state of health of the individual, habits of life, age, sex, and temperament; climate, and idiosyncrasy. Before entering into the consideration of these, let us examine, briefly, the questions—do the effects of narcotics result from their direct influence on the nervous system? or is it secondary to their introduction into the circulation? These are points which have been long and strenuously agitated, and on which the most opposite opinions are maintained. There is no doubt that narcotics are in many instances received into the circulation, and that they are most active; indeed, so much so as to produce almost immediate death, when they are directly conveyed into it; as, for instance, by injection into the veins: yet even in this case their influence may be propagated by nervous communication, as we are led to conclude from the experiments of Messrs. Morgan and Addison,* who discovered that they produce in the sentient extremities of the nerves on the inner coats of the bloodvessels a peculiar impression, which is conveyed to the brain along these nerves. This is also demonstrated by the rapid effects on every part of the system which follow their administration by the mouth; often in a space of time too short to be the result of absorption. It is also well known that, when the dose has been so large as to be suddenly followed by fatal effects, the whole quantity of the narcotic administered has been found in the stomach. Some striking objections, it is true, have been made to the conclusions drawn from the experiments of Mr. Morgan and Dr. Addison; but the explanation of the manner in which the effects of narcotics are diffused over the body does not rest on their experiments: the nature of the nervous system enables us to comprehend readily the manner in which this communication of impression is effected.

The primary action of narcotics is not confined to the nerves of the stomach; for if any narcotic, opium, or atropia,† or daturia,‡ for example, be applied to the surface of the body, the same results follow, although in a diminished degree, as display themselves when they are taken into the stomach. If the application be made to an entire membranous surface, the energy of the narcotic influence is not in the ratio of the absorbing power of the surface; and if it be injected into the thorax, between the lungs and the ribs, the action is more energetic than when the narcotic is taken into the stomach. The absorption, however, of narcotics cannot be doubted; and when a narcotic substance is applied to a wound, it is probable that in this case it operates chiefly by its absorption into the blood;* but although its influence can be impeded by a ligature on the bloodvessels, yet its operation does not essentially depend on its introduction into the circulation. When it is injected into the veins, the animal, as has been already stated, instantly expires, and this without convulsions. In this experiment all the muscles of the body are rapidly deprived of their contractility; and, therefore, the action both of the heart and of the respiratory muscles ceasing, death must necessarily follow. If these remarks be correct, it is evident that narcotics operate on the *brain* and the *spinal column* by entering the circulation when they are taken in moderate doses; but when they are swallowed in quantities sufficient to prove rapidly fatal, this effect is the consequence of their immediate influence on the nervous system; and when they are taken into the circulation, their effects may be still referred to the direct impression which they make on the nervous system. The nerves most particularly affected by narcotics are the respiratory; for when artificial respiration is maintained for some time in an animal poisoned by a narcotic, the animal recovers.

A question naturally suggests itself—how do narcotics produce sleep? Much difficulty attends the solution of this question; but some approach towards it may be attained by keeping in view the state of the vital functions during sleep. In this condition of the body, the pulse beats more slowly than when the person is awake; the temperature of the body is diminished, the perspiration is decreased, and nearly all the secretions are suppressed. Now on whatever principle narcotics act, if their primary stimulant influence is followed by a diminution of the force and frequency of the circulation, and at the same time of the respiratory effort, the change of the venous into arterial blood must be necessarily impeded; and this alone, by weakening the energy of the brain, will cause sleep. Such, at least, is the theory which the writer of this article is inclined to offer. It may be objected that this explanation applies equally to all stimulants; and such is really the case, as all transitory stimulants, according to the extent of the dose, operate like narcotics, and produce sleep. But there is still something connected with the anodyne influence of narcotics which we cannot readily explain, and which requires a more intimate acquaintance with the nervous system than we at present possess.

Circumstances which modify the action of narcotics.

1. *Nature of the narcotic.*—The general effects

* An Essay on the Operation of Poisonous Agents on the Human Body. London, 1829.

† The active principle of belladonna.

‡ The active principle of stramonium.

* M. Lesieur of Paris applies narcotics to blistered surfaces in preference to their internal administration.

which have been described as resulting from the administration of a narcotic are those which opium produces. When acetate of morphia is substituted for opium, and a full dose is administered, another symptom displays itself: the patient, when in the horizontal posture, is attacked with shocks, as if electrified; the head is thrown backwards as in opisthotonos; and a paralytic condition of the bladder of urine supervenes, although there is no diminution of the secreting powers of the kidney. If the muriate of morphia be employed, little or no excitant effect is perceived, whilst the sedative influence is most obvious. Belladonna, hyoscyamus, and aconitum, are more directly anodyne, and even in small doses affect the sight more than any other narcotics; and when the two former are overdosed, and delirium succeeds, it more resembles the delirium of intoxication than that of narcotism. Irregularity of arterial action characterizes the operation of conium, the pulse being in some instances sunk, in others increased to one hundred or more during the whole time of administering the medicine. When over-dosed, the breathing is more oppressed, and the thorax more constricted than with any other narcotic, while the countenance assumes the aspect of that of a man who has been strangled. Digitalis accumulates in the system, and veratria (colchicum *autumnale*) operates chiefly on the duodenum, producing copious bilious stools; thus lessening febrile action, and allaying pain.

2. *Extent of the dose.*—The influence of small and large doses of narcotics has been stated; and in many morbid states of the habit they may be employed to produce either stimulant or sedative effects. Unless the dose be large enough to diminish sensibility, they cannot be administered with the view of procuring sleep. In cases of inflammation, after the use of the lancet, large doses of narcotics are generally productive of the most salutary effects; on the contrary, small doses are likely not only to counteract the benefit derived from the bleeding, by their stimulant influence, but, if their administration be repeated, to augment the evil. In all painful and spasmodic affections the extent of the dose is to be limited only by its effects: thus in tetanus, one hundred drops of the tincture of opium have been administered every hour with the best effect; and the writer of this article, in cases of gall-stones and renal calculi, has given upwards of eight hundred drops of the officinal tincture of opium in less than twelve hours, without any effect but that of relieving pain and aiding the passage of the concretions: indeed narcotics may be persevered in to any extent as long as they display no determinate action on the habit. The dose in such cases requires to be progressively augmented; if no relief be afforded in three or four hours, it should be doubled, and so on until the benefit anticipated be obtained.

3. *Period of the day.*—When narcotics are administered in the morning, especially on an empty stomach, considerable excitement is induced, and the anodyne and hypnotic effects of the medicine seldom follow; on the contrary, if the same dose be given in the evening, little excitement supervenes, and the desire of sleep is so great that it is impossible to avert it.

4. *Combinations.*—Narcotics, when uncombined with other substances, produce the effects already described; but in combination with many different substances, their operation is greatly modified. Thus, in conjunction with tonics, instead of checking chymification, they promote the appetite and favour the digestive function; aromatics oppose their sedative influence, and delay their soporific effect; combined with diaphoretics, whilst the function of the skin is augmented, their influence on the brain is diminished. Acids promote their powers; whilst alkalies, by decomposing their active principles, and withdrawing the acids which render their alkaloids soluble, diminish them, and in many instances render the narcotic inert. We shall notice these effects of combination in describing the individual narcotics.

5. *Habit.*—Narcotics lose their influence when they have been taken daily for a considerable time; and doses have been swallowed under such circumstances which would at first have proved fatal. This effect of habit in modifying the action of narcotics has not been satisfactorily explained, although M. Charvet has attempted it in reference to opium. He assumes that the state of congestion of the brain is admitted as the effect of an overdose of opium, and supposes that the frequent use of the drug renders this less considerable; or that the brain, accustomed gradually to the flow of blood and resulting compression, at length is enabled to bear it with impunity, in the same manner as when a serous effusion gradually occurs, or a tumour is slowly developed in the brain.* There is much ingenuity in this explanation; but the power of habit in modifying and resisting the influence of some narcotics is not extended to all; and, indeed, there is little similarity of action among narcotics: each has its own specific or peculiar action on the nervous system, a circumstance which enables the physician to accommodate narcotics to the constitution of his patient. This is peculiarly striking with respect to the anodyne and hypnotic properties of narcotics: after the failure of one, the administration of another will fulfil the intention of the subscriber whether it is intended to allay pain or procure sleep. It is an equally curious fact, and one of practical importance, that this force of custom in reference to one narcotic does not render the system less susceptible of the impression of moderate doses of another: the opium-eater, accustomed to take a drachm of his favourite narcotic daily, may be lulled to rest by a few grains of henbane or conium.

It is unnecessary to mention many instances in proof of the extent to which the doses of narcotics may be carried with impunity by those who have long accustomed themselves to their use. Russell, in his History of Aleppo, states that Mustapha Shatar, an opium-eater in

* *Charvet* de l'Action comparée de l'Opium.

Smyrna, took daily three drachms of the drug, and felt a necessity for increasing the dose. Dhere, a French author, mentions the case of an officer of the same nation who took a drachm of pure opium daily, and appeared in good health, although an alvine evacuation was procured once only in eight days, sometimes once only in fifteen days. But no work affords so much curious information on this part of our subject, and so displays the extent to which the doses of some narcotics may be carried, as the Confessions of an English Opium-eater. It is, nevertheless, true that the habitual use of narcotics wears out the powers of life, and leads on to premature old age. The symptoms which follow the use of opium, for example, thus indulged in, closely resemble those brought on by excess in venery; marasmus and decrepitude supervene; the mind equally suffers; and the wretched individual sinks into the grave a deformed and slavering idiot.

6. *Age.*—The younger the person, the more energetic is the action of narcotics on the system; they even prove injurious to the fœtus, when they are prescribed to relieve cramps, or allay inquietude in the mother: thence the necessity of caution in administering them to infants, in whom both convulsions and epilepsy have followed their use.

7. *Sex.*—Narcotics exert a more powerful influence on women than on men, a circumstance which might, *à priori*, be expected from the greater susceptibility of the female constitution. To pregnant females, also, narcotics must be administered with the greatest caution, as in this condition of the female habit a state of the cerebral function frequently occurs, which is augmented by the operation of narcotics, and might be productive of dangerous consequences.

8. *Temperament.*—There is but one opinion respecting the power of temperament in modifying the operation of narcotics. In the *sanguine* temperament the nervous system is highly sensitive and susceptible of every impression, and the body predisposed to inflammatory action. There can be no doubt that narcotics will produce a more powerful impression on such a temperament than on the opposite or *melancholic*. In those persons, for example, who are easily affected by wine, and in whom inebriety is quickly produced, a small dose of opium causes powerful cerebral excitement; thence the maxim of Tralles, "Illi vero omnes qui vinum non bene ferunt vix bene ferent opium." On the same account, a condition of habit likely to favour cerebral congestion is much more likely to be powerfully influenced by narcotics than a spare habit—a fact which ought never to be lost sight of in practice.

9. *Climate.*—The action of narcotics is powerfully modified by climate. The same dose of a narcotic which produces only beneficial effects in Great Britain, has been found to operate too powerfully in Italy; some attention is, therefore, necessary, in prescribing narcotics, to accommodate the doses to the nature of the climate in which the physician is practising. On the same principles, season modifies their action, and smaller doses are required in summer than in winter. These observations seem, nevertheless, at variance with the result of temperature on opium, the brain being less affected when the patient is kept in a temperature which excites perspiration than in one which is cooler. M. Hecquet* explains this influence of temperature in the case of opium, by saying, that as heat favours the flow of sweat, the opium is carried out of the habit with it, and is thus prevented from affecting the brain. Charvet supposes that, as copious sweating diminishes the mass of the circulating fluids, and renders the cerebral compression less powerful, the sweating may be regarded as a favourable crisis which guards the brain from over-compression. Both opinions are hypothetical; and it is more likely to depend on the greater irritability of the habit in warm climates than in cold, and the consequent greater susceptibility of impression.

10. *Idiosyncrasy* is more likely to influence the action of narcotics than any other classes of medicines. In some individuals opium, for example, even in moderate doses, produces restlessness, delirium, and convulsions; in others miliary eruptions; and in some its soporific effects are never experienced until the day following that on which it is taken.

With regard to the employment of narcotics, were it consistent with our plan to enter into the history of this class of remedial agents, we should remark on the very early period in which mankind appear to have been acquainted with their effects. In every nation and among every people, from the southern islander, who chews the kava, and with his own saliva manufactures the intoxicating bowl, to the polished European who indulges in the fermented juice of the grape, all seek in narcotics, not only oblivion from pain, but a balm for the cares and sorrows of life—"ducunt sollicitæ jucunda oblivia vitæ."

When narcotics are taken in over-doses, they produce the effects which have been already described: post-mortem examinations of the body display the brain gorged with blood; and not unfrequently water is found in the ventricles. In cases of supposed poisoning by narcotics, however, care must be taken not to confound the symptoms with those arising from diseases; in particular, apoplexy and epilepsy, which, as has been already stated, display symptoms closely resembling some of those attending poisoning by narcotics.

With regard to the *practical employment* of narcotics, it is obvious that they ought not to be prescribed in cases in which their primary excitement would prove hurtful, unless the dose be large enough to induce symptoms of diminished sensibility and lessened action without any previous excitement; and experience teaches us that this is the result when a large dose of a narcotic is administered, particularly when it is taken immediately after a copious abstraction of blood; but if the dose be small, the opposite effect follows, proving

* Vide Charvet de l'Action de l'Opium, p. 58.

that the patient may be either greatly benefited or materially injured by the extent of the dose of the narcotic, which it may be thought proper to prescribe. Thus if, in a case of pleurisy, the pulse be hard, quick, and forcible, and the pain of the side so acute as almost to prevent even a half inspiration, if a free bleeding be resorted to, two grains of opium in conjunction with the same quantity of calomel and a quarter of a grain of tartar emetic may be prescribed with the prospect of much benefit; but if half a grain only were ordered, not only would no advantage accrue from the narcotic, but the stimulant effect alone being obtained, the benefit of the bleeding would be counteracted rather than maintained, and the repetition of the dose would only increase the evil. In this respect the action of narcotics does not differ from that of direct stimulants. In all cases, therefore, of increased excitement, when pain or restlessness demands the administration of a narcotic, the dose should be sufficiently large to obtain at once its anodyne effect without the primary stage of excitement.

The stimulant influence of narcotics in small doses is frequently taken advantage of in the treatment of fevers of a low or typhoid type. The tincture of opium, for example, given in doses of ten minims at short intervals, augments the strength of the pulse, rouses the vigour of the system, and sometimes supports the strength.

Narcotics may be arranged under two distinct heads, namely, *direct narcotics* and *indirect narcotics*. Under the former may be placed all those substances which produce their effects by a direct impression on the nervous system, without necessarily entering the circulation: under the latter those which enter the blood before acting upon the nervous system; for even when they enter the circulation, their influence is still exerted upon the nerves. The continental physiologists have made many experiments to ascertain the manner in which narcotics operate, and have deduced this inference, that the narcotic must be transmitted to the brain through the blood before it acts; but it is more probable that in full doses direct narcotics operate by an immediate impression on the sentient extremities of the nerves.

The number of narcotics is considerable, but the most valuable are *opium* and the salts of *morphia*, *henbane*, *conium*, *belladonna*, *lactucarium*, and *camphor*. It is incompatible with the plan of this work to enter upon the natural history, chemical properties, and pharmaceutical preparations of these substances; it is to their importance and employment as remedial agents that we have to direct the attention of our readers.

Like all other narcotics, *opium* exerts a primary stimulant effect on the living system, whether it be introduced into the stomach or into the rectum, or injected into a vein, or applied to wounds or ulcers, or rubbed on the surface of the body. When taken into the stomach in a solid form, it undergoes partial digestion; this process separating, in a great degree, the active principles, the *meconate of morphia*, the *narceine* and *narcotina*: thence the salts of opium act more rapidly than the entire opium.* During the continuance of the stimulant effect of opium and its salts, the cuticular secretion is augmented, but some of the other secretions are diminished: the urine, for instance, is scanty and high coloured; and after this state is over, the pale, clay-coloured aspect of the alvine discharges indicates a greatly diminished excretion of bile. The stimulant effects of a moderate dose of opium are soon dissipated; and the administration of a much smaller dose, after a short interval, produces more intense effects than the first dose, although the reverse of this follows the continued use of the drug. If the opium be taken on an empty stomach, the excitement is greater than when it is swallowed soon after a meal: in the first case the pulse remains small, although hard, and symptoms of cerebral congestion rarely appear; on the contrary, symptoms of congestion appear sooner, and are more obvious, if the same dose be taken just after a meal. From experiments made by Dr. Crumpt and others, it is evident that the exciting influence of opium differs little from that of other stimulants; but the sleep which follows the excitement of wine and ordinary stimulants differs from that procured by the influence of opium; nor do these possess the power of opium in relieving pain: it is therefore fair to conclude that, in its sedative influence, opium is distinguished from all other stimulants.

Although it is probable that the effects of opium on the living system are attributable to

* The components of opium are—

1. *A volatile oil*, on which the odour of the drug depends, but existing in such small quantity that it can scarcely be procured in a separate form. Water distilled from opium contains it, and is productive of slight cephalalgia when snuffed up the nostrils, but it displays no other narcotic property.
2. *Gum*, including *bassorine*.
3. *Extractive*, partly simple, partly unusually oxydized.
4. *Resin*, with which the colouring matter is closely combined; and this in conjunction with the volatile oil may be the source of the stimulant property of the drug.
5. *Caoutchouc*.
6. *Narceine*, a new principle lately discovered by M. Pelletier; it is crystallizable, is soluble in water and alcohol; insoluble in ether; and has a bitter styptic taste. Its action on the animal economy is unknown.
7. *Meconine*, another new principle, also discovered by the same able chemist; crystallizable; little soluble in cold water, but very soluble in hot water.
8. *Morphia*, in combination with meconic acid as a bimeconate.
9. *Narcotina*, which has been supposed to be the stimulant principle of the medicine.
10. *Sulphates of lime and of potassa*.
11. *A brown acid*.
12. *Lignine or woody fibre*.

† An Inquiry into the Nature and Properties of Opium, &c. 8vo. 1793.

its direct influence on the nervous energy, yet it must be admitted that there are facts which tend to shake this opinion; and one of the strongest is related by M. Barbier, from which it appears that an infant was affected by the milk of its mother, who had taken a large dose of the wine of opium. But as alcohol is undoubtedly taken up by the absorbents, it is probable that the absorption of the opium in this case is to be attributed to the vehicle; and it is only by admitting the direct influence of opium on the sentient extremities of nerves, that we can explain the relief obtained in instances of severe pain.

Many circumstances, as has been already stated with respect to narcotics in general, modify the operation of opium on the living system. The first of these is age: opium operates with most energy on the young, consequently the greatest caution is requisite in administering it to infants, in whom it often excites convulsions; even in the state of syrup of poppies, too often administered to infants by lazy nurses. A low irritative febrile state, depending on the continued cerebral excitement produced by the medicine, gradually brings on marasmus, and undermines the powers of the constitution. The influence of sex is less than that of age; but still experience has proved that women are more easily affected by opiates than men.

The effect of custom in modifying the influence of opium on the system is so well known as scarcely to require it to be noticed. The extent of the dose to which it may be carried by those in the habit of taking it daily is wonderful, but still larger doses may be given to allay pain and spasm. Dr. Chapman mentions that, in a case of cancer in utero, he has given the tincture to the extent of three pints in twenty-four hours, without any other effect than that of relieving pain.

The combination of other substances with opium greatly modifies its action on the system. When combined with antimonials, not only are its diaphoretic powers increased, but it is rendered less likely to impede the other secretions. With acids, half the usual dose will produce the effects of a full dose, an effect evidently resulting from the production of a more soluble salt, the acetate, the citrate, the sulphate or the muriate of morphia, according to the acid employed. When we order it with the view of procuring sleep, we should not combine aromatics with opium, as these increase its stimulant, but lessen its sedative influence.

Morphia, the active principle of opium, exists, as we have already said, as a bimeconate in opium; but when it is separated from the other components of the opium, it is generally administered in combination with acetic, or muriatic, or sulphuric acid, as an acetate, a muriate, or a sulphate.* Any one of these salts, when administered in doses of a quarter of a grain repeated at short intervals, causes a sensation of fulness in the head, some obscurity of sight, tingling of the ears, cephalalgia, vertigo, and a tendency to sighing and sleep. The pupils are sometimes dilated, at other times contracted, and sometimes are not at all affected; the pulse is not much accelerated: occasionally there is a sensation of itching all over the skin, frequently nausea, and a difficulty in passing urine. In large doses the cerebral excitement is alarming. From some observations made by M. Bailly, in the Hôpital de la Pitié in Paris, it appears that full doses of acetate of morphia sometimes excited shocks like those of electricity, when the person was lying in the horizontal position: the muscles lost much of their contractility, and the sight was greatly impaired. As, in these cases, the pulse was diminished both in force and frequency, Bailly was led to infer that morphia acts as a sedative on the heart, and as a stimulant on the nervous system; it would, perhaps, be nearer the truth to say that it acts as a stimulant on the nerves of sensation, and as a sedative on those of motion. It seldom increases the temperature, although sometimes its salts greatly augment the exhalent function of the skin. In over-doses, whilst the upper part of the body is bathed in a viscid sweat, the lower extremities are cold; there are violent tremors; the body acquires a livid hue; the face has a pinched and cadaverous aspect; and death ensues without convulsions.

The *black drop* has all the properties of acetate of morphia in combination with aromatics.*

From what has been said, it is evident that in prescribing opium we must always keep in view both its stimulant and its sedative influence.

Practical employment of opium.—In *in-*

* Acetate of morphia is thus prepared: a specific quantity of morphia dissolved in alcohol is saturated, accurately, with pure acetic acid; and the solution evaporated with the gentle heat of a vapour-bath to dryness. The sulphate is prepared in a similar manner, care being taken to employ the acid in a dilute state. The muriate may be readily prepared by precipitating an aqueous solution of opium by means of muriate of baryta; a meconate of baryta, which is insoluble and falls to the bottom of the fluid, and a muriate of morphia which is soluble, are obtained. By evaporation of the fluid, the muriate crystallizes in tussocks consisting of aggregations of acicular crystals; by pressing these between colourless blotting paper, the narcotina is separated, and the muriate obtained in an impure crystalline state. It is purified by repeated solutions and recrystallizations.

* The black drop is prepared by rubbing half a pound of opium, reduced to powder, with four pounds of verjuice, one ounce and a half of nutmegs, half an ounce of saffron, and three ounces of sugar. These ingredients are fermented with yeast for six days; the fluid is then to be decanted, filtered, and inspissated in the air to the consistence of syrup. The strength of the black drop compared with that of tincture of opium is as three to one. An excellent preparation, which owes its activity to the citrate of morphia, is ordered to be thus prepared in the Brunswick Pharmacopœia. "Dissolve four ounces of opium in forty-eight ounces of water, acidulated with six ounces of lemon-juice; filter and evaporate to the consistence of an extract in a water-bath." The citric acid, in this case, decomposes the bimeconate of morphia, and affords a more soluble salt, the citrate of morphia, which is conjoined with the gum and extractive of the opium.

termittent fevers the employment of opium is as old as the time of Galen. The best time for administering it is an hour before the expected paroxysm, as at this time it weakens the force of the attack, and sometimes prevents its accession; a result probably due to its stimulant property, whilst, at the same time, its sedative quality allays the morbid irritability connected with ague. The dose should be large; for example, from forty to sixty minims of the tincture. When given during the hot stage, as Lind recommended, it renders that stage shorter and milder, lengthens the intermission, and greatly promotes the influence of bark or the sulphate of quinia in curing the disease. In combination with calomel, in doses of a grain of each, it also enhances the sanative powers of tonics, in cases which resist them when given alone. But if opium fail to check the accession, it should not be given in the succeeding paroxysms, as the repetition of it in such a case only tends to induce debility.

In *continued fevers* the use of opium is more questionable than in intermittents. It should not be ordered if the temperature of the surface be much greater than natural, unless there be a tendency to perspiration, which it accelerates, and thence proves beneficial. If pain and watchfulness demand its use, the dose should be large, and it ought to be united with calomel and tartar emetic, a combination which greatly lessens its stimulant properties. In this combination and with James's powder, Dr. Currie employed it with great advantage after the cold affusion. In the advanced stages of typhus, opium is useful as a general stimulant, in doses of from six to ten minims of the tincture, or from three to six minims of the black drop, in combination with camphor and other cordials. When, in the early stage of continued fever, the pulse is full and hard, the heat of the surface greater than natural, the thirst considerable, and there is much headach. the use of opium is not admissible. Even in the sinking stage of this disease, wine is a better and more permanent stimulus. In typhus, the symptoms that chiefly indicate the use of opium are low muttering delirium, watchfulness without increased heat of skin, diarrhœa, and subsultus tendinum: the dose should be small, frequently repeated, and cool air freely admitted to the chamber of the patient. If the delirium, however, be accompanied with flushing of the face, impatience of light, and throbbing of the temples, it must not be administered.

If opium be prescribed to counteract watchfulness, it should be recollected that this may arise from very opposite causes. When it is accompanied with great heat of surface, restlessness, tossing about in the bed, and determination of blood to the brain, it proves deleterious; if none of these symptoms are obvious, then opium is the best means for overcoming such a state of watchfulness. It should be given in full doses, in a solid state combined with calomel, at the usual time of rest; and during its operation the scalp should be kept cool by enveloping the head in a cloth wet with a cold lotion. In low delirium it may be given at the same time as ammonia; but if, as sometimes occurs, it increase the delirium when it is taken into the stomach, then it may be applied by aid of friction dissolved in oil.

The best preparations of opium are the *tincture* of the pharmacopœias, the *black drop*, the *liquid laudanum of Sydenham*, the *solution of the muriate of morphia*,* and the *acetate of morphia*.

With regard to the extent of the dose, it should be held, as a general rule, that double that which is required to produce sleep in a state of health should be administered in disease; if acetate of morphia he preferred to any of the other preparations, when narcotic not hypnotic effects are desired, the following formula will be found useful:

℞ Morphiæ, gr. ii.
Acidi acetici, *m* ii.
Misturæ amygd. amaræ, *ƒ* ℥vi.
Syr. tolutani, *ƒ* ℥i.

Tere morphiam cum acido et syrupo, dein adde misturam. Sumatur quarta pars sextâ quâque horâ.

In the *phlegmasiæ*, notwithstanding the general rule that opium should not be administered during the presence of active inflammation, until the system have been relieved by bleeding, there are cases in which it proves highly useful; as for instance, when the inflammatory action is of a passive kind, as in malignant ulcerated sore throat, and in chronic rheumatism. But even when it is of the opposite description, as in pleurisy, if venesection be freely employed, nothing is so likely to subdue permanently the inflammatory action as large doses of opium in combination with calomel and tartar-emetic. When the inflammation is in the substance of the lungs, as soon as dyspnœa is relieved, and the symptoms are reduced to cough and restlessness, opium may be given with the hope of the greatest advantage: indeed, all acute inflammatory affections of the chest may be benefited by opium thus preceded by antiphlogistic measures. In peripneumonia notha, both in that variety which constitutes the catarrhus suffocativus of old age, and that in which there is a congestion of blood in the pulmonary vessels, opium is useful. In the first place it forms an active and useful ingredient in stimulant expectorant mixtures, with ammoniacum and squill; and in the second, after the congestion is partially relieved, the liberal administration of opium in combination with demulcents is productive of much benefit. It may be said that this opinion is at variance with the common idea that opium retards expectoration; but in reply to this objection, let us examine what the state of the chest is in pneumonia. We find that the pain is aggravated by a full inspiration, and that, in order to obtain this, the patient must be nearly in the erect posture. Now, under this state the necessary change cannot be effected on the blood; and in the irritable state of the bronchial membrane the secretion of its natural mucus is hurried, and the sputa consequently thin and acrid. In this condition, opium, acting

through the pneumogastric nerves, allays pain, and enabling the patient to take a fuller and more perfect inspiration, it is easy to comprehend how a thicker and more slowly secreted mucus will be coughed up more easily than a thinner and more irritating matter. It is on this account that opium, instead of restraining, frequently promotes expectoration.

Opium is indisputably a most useful medicine combined with ipecacuanha, or camphor, or ammonia, as circumstances may require, in malignant peripneumony. In ophthalmia it is exhibited under the same restrictions as in pneumonia. If pain and irritation be excessive, it may be given even before bleeding has been resorted to, in which case it should be combined with calomel and tartar-emetic. Externally no application is more useful, after the active inflammation has been subdued by topical bloodletting. The old *solutio opii vinosa* is preferable to the vinum opii of the modern pharmacopœias, as it contains only half the quantity of opium and an aromatic. It acts partly by its stimulant, partly by its narcotic properties.

Opium has now almost supplanted the use of the lancet in acute rheumatism: it should be administered in full doses, immediately after active purging, in combination with colchicum. In the chronic form of the disease the opium may be combined with sulphate of quinia, or with infusion of menyanthes *trifoliata* acidulated with muriatic acid, which gives activity to the opium by forming a muriate of morphia.

In gout, even in that variety of the disease which is named retrocedent, opium is truly our sheet-anchor, and it must be given in full doses. In some cases it has been administered in doses of ten grains twice a day with advantage; and no consequent inconvenience is experienced if the dose be not too hastily lessened. In the acute form of the disease, opium is most useful when combined with colchicum. Something in this combination is due to the specific action of the colchicum on the gall-ducts. It has been supposed that the opium diminishes or impedes the biliary secretion, because the evacuations which follow a dose of opium are frequently pale; but this only indicates a diminished excretion. In the lower animals poisoned by opium the gall-bladder and ducts are turgid with bile, although very little had found its way into the duodenum. Now, as colchicum stimulates the gall-ducts, the combination of this remedy with opium removes the objection to its employment in gout, as far as regards the biliary secretion.

It is almost unnecessary to say that in cases of biliary calculi impacted in the gall-duct, or in nephritic inflammation arising from the irritation of renal calculi, either in the pelvis of the kidney or in the ureters, the best results are to be anticipated from the use of opium, particularly when the stomach is so irritable as to reject, by vomiting, every thing received into it. In this case, on account of the advantages to be expected from proximity of action, the opium is most beneficial when exhibited per anum, dissolved in oil. In suppression of urine, also, from calculi irritating the bladder of urine, or from stricture of the urethra, opium in combination with calomel is the medicine most to be depended on; and the same combination acts as a powerful anodyne in chordee, and the painful micturition of gonorrhœa. Neither large doses of opium alone, nor large doses of calomel, produce the effect of the combination of these medicines. Two grains of each may be administered in the form of a pill every second or third hour. The writer of this article, however, has sometimes found it better to order eight grains of calomel and two of opium, to be taken every eighth hour until relief was obtained.

Small-pox is the disease among the exanthemata in which opium is most decidedly indicated; and we are indebted for this fact to the sagacity of Sydenham. In the distinct form of the disease it is not required unless convulsions occur, or the eruptive fever be accompanied with much restlessness. Perhaps the practice of Sydenham, of administering opium every night in confluent small-pox, has been too indiscriminately followed. It is not required in the greater number of cases during the progress of the eruption, although it is occasionally useful for promoting the maturation of the pustules; and after the eruption it is indicated, under the same circumstances as in typhous fever, in conjunction with cinchona bark and wine. It is also useful in the secondary fever, if diarrhœa supervene; for notwithstanding the authority of Sydenham, purging at this time ought to be restrained to a certain extent. In measles, the employment of opium is contraindicated in the commencement of the attack, but after the inflammatory symptoms are subdued, and the cough remains, then opium in combination with calomel and ipecacuanha will be found beneficial, and still more so if the diarrhœa, which to a certain extent is useful, proceed too far. In that form of the disease which is of a malignant nature, rubeola *maligna*, as the fever is of the typhoid type, opium is indicated, and may be given throughout the attack, under the same regulations as in typhous fever.

Much difference of opinion exists respecting the employment of opium in hemorrhages. When febrile symptoms exist, these should be subdued before opium is prescribed; when the hemorrhage is connected with much debility, laxity of the solids, and a thin state of the circulating mass, then opium in combination with astringents and tonics should be administered to allay the irritability which always accompanies this state. In hemoptysis, when no inflammatory state of habit exists, when the bleeding is kept up by cough, and is accompanied with watchfulness, opium is likely to prove useful: in the opposite state, if much irritation exist, it should be combined with either digitalis, or acetate of lead, or hydrocyanic acid, and cold both topically and generally applied.

In phthisis pulmonalis opium is administered to allay cough, and to moderate diarrhœa when it is present. If the accession of the hectic paroxysm be well marked, it should be

given at that period. It is usually administered at bed-time; but as it is apt to excite much perspiration, it is preferable to defer it until early in the morning, when the cough is most severe. The soluble salts of morphia, especially the acetate, are preferable to opium, as they do not excite perspiration in small doses. The following formula will be found very serviceable:

℞ Acidi acetici diluti (aceti dist.) ℥iv.
Acetatis zinci solut. P. E. ℥i.
Tinct. opii *m*xii.
Decocti lichenis Islandici ℥xi. M.
Haustus quintâ quâque horâ sumendus.

In no disease has opium been more frequently employed than in dysentery; but there is much difference of opinion as to the propriety of this practice. If pains and tenesmus continue after the bowels have been freely evacuated, opium, combined with ipecacuanha, will be found useful; but during its use the bowels should be freely evacuated once at least in twenty-four hours. When the tenesmus is very urgent, the opium should be exhibited, in conjunction with demulcents, in the form of enema; and towards the close of the attack, when the disease may be regarded as having passed into diarrhœa, opium is the proper remedy. In bilious colic, and some other affections of the bowels in which pain and spasm arise from the action of highly irritating matters on the coats of the intestines, and in which purgatives do not act freely, experience has proved the propriety of combining opium with purgatives. In conjunction with calomel in large doses, it allays the irritation both of the stomach and the intestines, removes spasm, and consequently aids the operation of the purgatives. Indeed, in almost all spasmodic affections opium is the remedy to be relied upon, whether the spasm arise from the action of some irritating substance on the moving fibre, or from irritation kept up by debility: the cure consists in removing the irritating cause, and diminishing the susceptibility of the muscular fibre by restoring its tone. The term "almost all" is employed, because in some spasmodic affections opium seems to produce deleterious effects: thus in hay asthma it augments fever, headach, and the wheezing and suffocative tightness across the chest, which characterizes that singular disease. To answer both the above intentions opium is admirably adapted, when it is given in combination with sulphate of quinia and other tonics.

In idiopathic tetanus, opium is a remedy of great power; in traumatic tetanus it is of less value even in the largest doses. In the idiopathic form of the disease, opium should be early administered, as the progress of the attack is rapid, and the power of deglutition may be soon lost. The extent to which the remedy may be given is limited only by its effects; many ounces of the tincture have been taken before its effects have been felt. Its stimulant influence quickly disappears, on which account, even after the spasms are controlled by it, the use of it should not be discontinued for some time. A case is recorded in which fifteen hundred grains of solid opium were taken in the course of seventeen days; and another in which twenty fluid ounces of the officinal tincture were swallowed in twenty-four hours: both cases recovered. In general the following rules should regulate the progressive increase of the dose, and its repetition. If the spasms be moderate, ten or twelve minims may be given every hour; but if no relief be afforded in three or four hours, the dose should then be doubled, and so on progressively until the expected benefit be obtained, after which the dose should be diminished in the same ratio. No intermission should be permitted whilst the spasms continue. When deglutition is impeded, the opium should be administered per anum, and a solution of it in oil be rubbed upon the spine. Much advantage is derived from rubbing this oily solution on the jaw in trismus—a proof of the direct influence of opium on the nervous system.

In epilepsy, except in cases which are kept up by habit, after the removal of the irritation which first caused the convulsions, opium is not useful. In such cases a large dose is required to break the habit, but a purgative should be given at the same time, as in no disease is costiveness so injurious. The old physicians, even Sydenham, relied much on the influence of opium in chorea; and if the attack be complicated with hysteria, after the bowels have been freely opened, it frequently proves useful. But the plan of treating chorea with powerful purgatives, and afterwards with the carbonate of iron or with the nitrate of silver, is so successful as to leave us little to regret, should opium fail altogether in relieving the disease. In another painful affection also, tic douloureux, opium has so frequently disappointed our hopes, that more reliance is placed on the influence of tonics than on narcotics in this disease.

The watchfulness of maniacal patients early led to the use of opium in cases of insanity: the only objection to its employment is its tendency to cause costiveness; but this is obviated by combining it with aloetics, which operate on the bowels without weakening the soporific power of the opium conjoined with them. By procuring sleep, and thereby severing the catenation of morbid sensations, opium is often highly beneficial in insanity, especially that form of it which is produced by habitual drunkenness. In these cases there is generally a pallid countenance, a cold clamminess of the surface, and other symptoms indicative of great debility, accompanying the want of sleep; under which circumstances the question of life or death is often involved in administering or withholding the use of opium, and in no situation can the judgment and discrimination of the practitioner be more seriously employed.

In syphilis, opium has been used as the sole means of cure; but although experience has demonstrated that opium cannot be relied upon for this purpose, yet as an adjunct to mercury it is of great value: it enables the system to bear a large quantity of mercury with impunity, and also allays the state of morbid irritability which frequently remains

after the cure of syphilis, and, consequently, favours the return of health.

In diabetes mellitus, opium has a powerful influence in restraining the quantity and moderating the saccharine quality of the urine. The dose must be carried to a considerable extent to effect this purpose, to six or eight grains in twenty-four hours; but too often the evil returns as soon as the dose is diminished. In one case recorded by Dr. Warren,* five grains of solid opium were taken four times a day with evident advantage. Its beneficial influence has been referred to its augmenting the action on the skin, and consequently diminishing that of the kidneys; but as other diaphoretics do not cure diabetes, this theory of its operation is not satisfactory.

Besides the benefit arising from the employment of opium in the diseases already noticed, advantage is also taken of its administration in many morbid states of the system, to lessen irritation, to relieve pain, and to induce sleep; and undoubtedly, whether it be taken into the stomach or applied to the surface of the body, its place for these purposes can be supplied by no other substance. But, like some of the choicest gifts of Providence, it is abused and frequently employed as a poison, and this statement might be closed by tracing the symptoms produced by an overdose of opium or of its salts, and pointing out the remedy; but for this information we must refer our readers to the article Toxicology.†

Digitalis is generally regarded rather as a diuretic than a narcotic, but under certain states of habit it exerts a decided and important narcotic influence. It operates directly upon the nervous system, producing first stimulant and afterwards sedative effects. This influence of foxglove was first satisfactorily observed by Dr. Hallaran in a case of insanity, in which the tincture of foxglove was given by mistake for the tincture of opium, and from the effects which presented themselves, he was led to conclude that foxglove cannot be advantageously exhibited under "the pressure of high arterial action;" a fact which, indeed, might have been inferred from the repeated observations of its uselessness as a diuretic in dropsy, when an inflammatory state of the habit exists. Dr. Hallaran, taking advantage of his accidental discovery, employed opium as a narcotic in cases of mania, attended with diminished excitement, and the benefit was such as to enable him to remark regarding it, "I am encouraged to proceed with as much confidence in the hope of recovery, as I would in cases of lues, from the mercurial influence." "Insane persons," he adds, "have repeatedly assured me, on approaching to recovery, that they within a very few minutes have had a consciousness of relief, both as to mental and corporeal sensations, from the use of digitalis. One in particular, who for a time had been intent on self-destruction, declared to me that the propensity was never present so long as its efficacy had remained."* The mode of administering digitalis in mania is to commence with ten minims of the tincture for a dose, three times a day, in a glass of water, and to add two minims to every dose until sleep be procured, or until nausea or vertigo be experienced, in which case its use should be instantly laid aside, and ammonia and cordials with opium liberally substituted. In this manner Dr. Hallaran has carried the dose "to one hundred drops with safety and advantage;" and the writer of this article has frequently carried it to sixty minims three times a day, with no other result than sleep, quiet, and the restoration of the patient to sound health and intellect. The best form of the medicine for producing these desirable effects is the tincture, made with the recently dried leaves, collected in June, in dry, warm weather, and dried without artificial heat.

In phthisis, digitalis acts also as a narcotic, but it is fitted rather for the advanced than the early stages of the disease. M. Neuman, of Berlin, has extolled its influence as a narcotic in chronic catarrh, when this depends on a state of erethism of the mucous membrane of the bronchi. He gives it in the form of infusion, made with ʒii. of the dried leaves in ℥vi. of boiling water, one table-spoonful of which is administered every hour, until nausea, or a sensation of constriction of the throat, or irregular pulse, supervene. The use of the medicine is then suspended for a week, and again renewed if the disease be not removed.

During the use of digitalis its sedative power on the circulation is to be carefully attended to, and its accumulation in the system closely watched, as by carrying it too far and producing extreme debility we may endanger the life of the patient. When the symptoms of poisoning display themselves, (see Toxicology,) in addition to the means already recommended for counteracting them, much benefit will be obtained from the application of a blister to the pit of the stomach. From the difficulty of preserving foxglove leaves so as to retain their active properties, the infusion is a bad form of preparation, and the powder should not be employed unless it retain the beautiful green colour and the peculiar odour of the recently well-dried plant. In prescribing the tincture also, it must be borne in recollection that the bichloride of mercury, corrosive sublimate, and nitrate of silver, are incompatible with it.

Henbane, hyoscyamus *niger*, is very generally employed as a narcotic in all the cases in

which opium has been found beneficial. Its active principle is supposed to be an alkaloid, which has been obtained in a separate state, and named *hyoscyamia*; it is taken up both by water and alcohol. The forms in which henbane is administered are tincture and extract. The formula of the London Pharmacopœia for the preparation of the tincture is adequate for every practical purpose; that for the extract might be improved. Mr. Plumbe has procured an extract by macerating one part of the dried plant in four parts of alcohol for four days, filtering the tincture, and evaporating to dryness in a water-bath; it has a beautiful green colour, and retains all the active properties of the plant.

As a narcotic, henbane is analogous to opium in its effects. It operates directly on the nervous system, augmenting the force of the pulse, and increasing the heat of the skin before it produces sleep. It neither confines the bowels nor affects the brain so much as opium. In large doses, however, it operates as a virulent poison, and in some habits excites a pustular eruption.

Although henbane was employed as a narcotic by the ancients, yet Stoerck first investigated its value. He employed it in all painful diseases; and owing to its tendency to relax the bowels, it has been found very serviceable in ileus and colica pictonum, in combination with colocynth and scammony. Mr. Brande recommends it as well adapted for allaying the pain and irritation caused in the kidneys by red gravel. Smoking the leaves in the manner of tobacco soothes the pain of toothache and relieves the dyspnœa in spasmodic asthma. When applied to the surface, in the form of extract, it dilates the pupil; and much comfort to the feelings of the patient is derived from henbane in the form of a poultice in scrofulous ulcers and open cancer.

The tincture is the best form of administering henbane; but it is most frequently employed in the form of extract. The dose of the tincture is from *m* xv. to *ʒ*iſs; that of the extract from *gr.* ii. to *gr.* xii. Alkalies destroy its narcotic properties; they consequently are incompatible in prescriptions with it, and may be employed as antidotes, when it displays poisonous effects either from an over-dose or from idiosyncrasy.

The results of Stoerck's employment of *conium* in cancer and fistulous sores recommended it as a narcotic to the attention of modern practitioners. It possesses considerable narcotic powers; but so much depends on the drying and preservation of the leaves, either in their entire state or in that of powder, and on the preparation of the extract, as well as the state of the patient at the time of its administration, that few narcotics have perplexed practitioners so much as conium, and to these causes we must attribute much of the varying opinions respecting its influence as a remedial agent. Keeping these facts in view, conium has been found useful in acute rheumatism, scrofula, syphilis, and especially in cancer, the pain and irritation of which are supposed to be more effectually under the control of conium than of any other narcotic. In these cases the dose should be gradually increased until indications of an overdose begin to display themselves. These are nausea, dimness of sight, headach, drowsiness, vertigo, acceleration of the pulse, sweating, dryness of the mouth, diarrhœa, and, if the system be not relieved, coldness of the extremities, sinking of the strength, and a fatal result. Some, not all, of these symptoms usually present themselves before any perceptible beneficial change in the diseases which have been named is effected by conium. In many of the cases in which conium has proved beneficial, its use has been continued for some time, and the cure has proceeded in the direct ratio of these sensible effects. On this account the dose of conium requires to be progressively augmented until the symptoms of its influence be sufficiently obvious. The pulse in some instances sinks; in others it is maintained full, and at 100 or more, during the whole time of exhibiting the medicine. Sometimes the function of the kidneys is augmented; sometimes that of the skin; sometimes no effect is produced on the sensibility of the habit; occasionally this is greatly diminished. In that variety of paralysis which is complicated with rheumatism, in which deficiency of motion is attended with acute pain, conium has been found highly beneficial. In six cases of this affection treated with conium in the Edinburgh Infirmary, by Dr. Home, three were relieved and three were cured, although two of them were of long standing, and one in an old person. We have witnessed much benefit derived from it in chronic rheumatism, in keeping down pain; and in chronic sciatica our experience authorizes us to say that it is more to be depended on than any other narcotic. In intermittent cephalea, conium has been found to be an excellent adjunct to tonics. In scrofula, notwithstanding the testimony of Stoerck in its favour, we have not been able to perceive that it effects more than any other narcotic; and except in soothing the cough, the same character may be bestowed upon it as a remedy in phthisis. In overdoses, besides the symptoms already mentioned, its effects greatly resemble those of opium.

The extract, which is the only preparation of conium in the London Pharmacopœia, is a bad form of the medicine, owing to the difficulty of preserving it; whenever a saline crust appears on the surface, it is no longer of any value. The tincture of the Edinburgh and the Dublin Pharmacopœias is a better form of preparation. We have found it particularly useful, when administered in combination with hydrocyanic acid in a light decoction of cetraria Islandica, in long-protracted hooping-cough accompanied with much debility, and when the cough is kept up by habit. The dose of the extract is from *gr.* i. to *gr.* vi.; that of the tincture from *m.* x. to *m.* xl. in any bland vehicle.

The atropa *belladonna*, deadly nightshade, possesses considerable influence as a narcotic, and some peculiar properties which require to

be noticed. According to the analysis of a distinguished German chemist, M. Brande, its active principle is an alkaline substance, which he has named atropia, and which, in combination with either sulphuric or muriatic acids, is procured in beautiful white prismatic crystals, possessing in a concentrated degree the powers of the plant. The preparation most employed is the extract, which, however, is a very uncertain medicine, unless it be prepared in vacuo, the atropia being volatile and exhaled during the evaporation of the infusion. Belladonna, in whatever form administered, requires to be given in minute doses at first, and then to be gradually augmented until symptoms of its influence on the system become apparent. These are dryness of the throat, vertigo, dilatation of the pupils, slight dimness of sight, extravagant delirium, and an eruption on the skin closely resembling that of scarlatina.

The efficacy of belladonna has been well ascertained in painful and spasmodic affections: in hooping-cough it has been found useful in doses of an eighth of a grain, gradually increased until the sight is affected, and a scarlet eruption overspreads the skin, accompanied with some degree of headach. Whilst these symptoms continue, the cough ceases, but returns as they disappear; but by renewing this state and maintaining it for a sufficient length of time, the disease is always shortened. In neuralgia, both internally administered and externally applied, belladonna has been advantageously employed. The influence of the extract on the radiated fibres of the iris, so as to dilate the pupil, was first proposed as a method of facilitating the extraction of cataract by Professor Reimarus; and for the same reason it is frequently employed for aiding vision during the progress of cataract. A small quantity of the extract, softened with water, is applied upon the eyelid: in a short time the pupil dilates, and the effect continues for many hours. An ointment formed with 3i of the extract and 3vii of lard, affords great relief in the pain of hemorrhoids; and in chordee when rubbed upon the perineum: the powdered leaves, sprinkled upon cancerous sores, greatly abate the pain of these ulcers. The narcotic influence of belladonna cannot indeed be justly depreciated. In prescribing it, alkalies should not be combined with it, as they render the medicine inert; and the same result takes place when the atropia is converted into a tannate, by administering any of the preparations of belladonna with astringent vegetable decoctions or infusions. Dr. Reisinger has proposed to employ atropia instead of the extract or the infusion of belladonna; on the ground that it exerts a direct sedative influence on the nervous energy, whilst the extract and the infusion exert a primary stimulant power like other narcotics.

Belladonna, when given in overdoses, produces such an effect on the stomach that the organ rapidly ceases to be excitable by emetics: under such circumstances the advantages of the stomach-pump are great; for it is obvious that, notwithstanding the paralysed state of the organ, we may produce much mischief by inconsiderately augmenting beyond a certain point the dose of an emetic.

Like every other narcotic, the activity of belladonna depends greatly on the manner in which it is prepared: in general so little care is bestowed on the preparation of the extract, that it is difficult to apportion the dose. When the evaporation is conducted in vacuo, as recommended by Mr. Berry, the dose must be considerably less than that usually prescribed.

The genus *lactuca* yields a white proper juice, which has much of the properties, at least of the sensible properties, of opium. When inspissated, this juice, procured from the lactuca *sativa* and lactuca *virosa*, is the lactucarium of the Edinburgh Pharmacopœia. The narcotic properties of lettuce were very early known; Galen, who in the decline of his life suffered from watchfulness, found much comfort in eating lettuce in the evening: and every one who has indulged the same luxury, must have experienced the soporific effects of this plant. Dr. Coxe instituted a set of experiments to ascertain how far lactucarium resembles opium in its medicinal effects; and his results were confirmed by the subsequent experiments of Dr. Duncan. Dr. Coxe's experiments led him to regard lactucarium as precisely the same as opium in its medicinal properties; but although it may be employed as a substitute for opium, in persons who from idiosyncrasy cannot take opium without suffering, yet its properties are not exactly the same. In our opinion it is one of those substances which may be well spared from the Materia Medica, as the same effects which it produces can be obtained from modified doses of opium.

Camphor is a narcotic, which, like opium, possesses both stimulant and sedative properties: when it is taken into the stomach in moderate doses, it exhilarates, but in large doses excites nausea, vomiting, and even inflammation of the organ. It is so penetrating, that, independent of absorption, it seems to pervade every part of the frame. It displays its stimulant and sedative powers in nearly the same manner as opium, the stimulant effects always preceding its sedative operation. Its influence is exerted directly on the nervous system, producing sleep and relieving pain; and this is so very powerful that people employed to open packages of camphor have occasionally fallen asleep. As a stimulant, camphor is extremely diffusible, its influence being rapidly extended over the system, and disappearing sooner than that of any other narcotic: it is, therefore, well adapted for procuring a sudden and transitory excitement, in cases in which this is required, and in which its continuance would prove hurtful. When it is intended that it should exert a stimulant influence, like opium, it should be given in small doses, and repeated at short intervals: when its sedative effects are required, it should be administered in large doses and at considerable intervals.

Camphor may be employed in every kind of fever: in intermittents, during the paroxysm, to allay irritation and procure sleep; in continued fever, to subdue spasmodic twitchings,

calm delirium, and remove watchfulness; but in these respects it is inferior to opium. It is, however, an agreeable and useful adjunct to opium in fever. In the phlegmasiæ, camphor is frequently prescribed on mistaken principles, under a conviction that its primary action is sedative. Thus in ophthalmia it is sometimes prescribed as an external application in the inflammatory or active stage of the disease; whereas it is only suited for that passive state which is the result of the scrofulous diathesis, and old chronic inflammation of the conjunctiva.

In the exanthematous fevers it is useful for promoting the eruption, and restoring it when it has receded: in confluent small-pox in particular, attended with much of the typhoid character and with petechiæ, it aids in maintaining the powers of the constitution, and the maturation of the pustules; abating the tendency to convulsions which frequently accompanies this form of the disease. One curious result of the external use of camphor is stated by Rosenstein: he says, that if the skin be smeared over with a camphorated ointment, no pustules will appear. In spasmodic affections, camphor may be administered so as to act either as a stimulant or a sedative; but in either case it is inferior to opium. In mania, the powers of camphor have been greatly overrated: it lowers the pulse of furious maniacs sometimes to fifty, and an evident sedative effect follows, but without any diminution of their sufferings. "By its duration," says Dr. Hallaran, "the countenance eventually assumes a livid aspect; the extremities also become cold and insensible, and equally livid with the face. The arterial blood seems as if concentrated in the vessels immediately issuing from the heart; the action of the lungs is impeded; and congestion, determining to the head, is often the inevitable consequence. The power of reaction of the heart, under such difficulties, is in fact suspended; and the torpor of the system previously existing is thus greatly aggravated."* Dr. Hallaran thence regards it as a very uncertain medicine in the treatment of mania. In nymphomania, however, camphor has been found highly beneficial; and it is also an admirable adjunct to opium in that variety of insanity which frequently follows a continued course of intoxication.

The opinion that camphor has the power of allaying the strangury which occasionally follows the use of cantharides was first hazarded by Dr. Grainger in the beginning of the last century, and is still credited by many; but it is erroneous: Dr. Heberden, indeed, has demonstrated, that when freely administered camphor causes strangury. The idea that it diminishes salivation is not better founded.

In prescribing camphor, its precipitation from the alcoholic solution, suspended by mucilage in any bland vehicle, is a good form of administering it: or it may be held in solution in water by means of carbonic acid. It has been also successfully used in the form of a vapour bath by some of the continental physicians. The patient is placed on a chair with an open cane bottom, beneath which a chafler, covered with a plate of iron, is placed; the whole apparatus is surrounded with a blanket, which is pinned round the neck of the patient. A dessert-spoonful of camphor in powder is then thrown upon the iron plate; it is instantly volatilized, and involves the body in an atmosphere of camphor vapour. The patient perspires freely; and in three-quarters of an hour afterwards he may be rolled in a blanket and carried to bed. The sweating must be maintained by tepid fluids. In chronic rheumatism this fumigation should be repeated three or four times a day, and continued for some time after the pains have disappeared. The dose of camphor is generally too small; its narcotic influence being seldom obtained from less than half a drachm: we have given it, with advantage, to the extent of four drachms in the day, in low fever. It operates with more energy when administered per anum than when taken into the stomach: the camphor is quickly felt in the breath; an indescribable uneasiness succeeds, then vertigo, with pallidness of countenance, chilliness, and a low intermitting pulse. Opium, brandy, and ammonia are the means of counteracting these effects of camphor.*

We consider it unnecessary to enter more particularly into the consideration of the narcotic agents: the *ethers*, *alcohol*, and some vegetable matters, operate by exerting a direct influence on the nervous energy through the medium of the circulation; but this does not affect their practical utility. It only remains to close our remarks on narcotics with a few statements respecting the influence of what may be termed *mental* narcotics. Mental impressions rouse or depress the nervous energy according to circumstances; we consider those impressions narcotic which at first rouse the system, but by repetition at length exhaust it, in the same manner as stimulant material narcotics exhaust, and induce sleep. *Sound* is one of these mental impressions; but it is necessary to explain that it is not the repetition of sound, but of the same sound, which produces the narcotic effect. When sound is varied, the opposite result occurs, the attention is kept awake; and it is a law of the system that the variation of the stimulus renews the excitement in such a manner, that collapse is prevented for a greater length of time than when there is a repetition of the same sound. It is the monotony of sound, therefore, such as the gurgle of rills, or small water-falls, the voice of a dull preacher, the moaning of the breeze, &c. that is followed by soporific effects; and on the same principle, slow and plaintive music has been found practically useful in the treatment of some peculiar cases of insanity. In this case, the slower, longer-continued, and less varied the impressions are, the more powerful is the sedative influence of the music; and some-

* Practical Observations on Insanity, &c. p. 130.

* The best work to be consulted on camphor is the Traité de Camphre, by M. Grauffenaur, Strasbourg, 1823.

thing is also produced by the period of the day and the situation in which the listener is placed. The stillness of evening is highly favourable to the employment of music as a soporific agent;

> "—— let the sounds of music
> Creep in our ears; soft stillness, and the night
> Become the touches of sweet harmony."

And when sleep is induced, there is much less likelihood of its being disturbed than if it occur during the day. *Gentle friction* and *titillation* produce also soothing effects, on the same principle as the monotony of sound; in cases of pain we have seen them prove useful, by transferring the attention from its seat, to the mild and agreeable impressions of the friction; and this acquires power by joining it with monotony of sound. Thus we know that patting an infant on the back, whilst at the same time the nurse hums a monotonous tune, is almost always sure to produce sleep. Were it requisite, many instances of the beneficial effects of mental narcotics might be brought forward; but enough has been said to shew the importance of not disregarding them in cases in which they are likely to prove beneficial.

(A. T. Thomson.)

NEPHRALGIA AND NEPHRITIS. In several of the morbid affections incidental to the kidneys the symptoms are, as we have endeavoured to shew in a former article, (KIDNEYS, DISEASES OF,) so nearly alike as to render it very difficult, if not impossible, to distinguish between them during the life of the patient. Nor is accuracy of diagnosis of much importance in some of these affections, the treatment of which experience has taught us is to be conducted not only on the same principle, but in the same manner as regards its minutest details. But to distinguish clearly between nephritis—inflammation of the substance of the kidneys, or of their capsules and surrounding cellular membrane—and nephralgia—pain of the kidneys from calculus—is of great moment, since the remedies most proper for the one would be unavailing or injurious in the other. In nephritis, especially in that species where the capsule is the seat of inflammation, bloodletting is absolutely necessary; but in many cases of nephralgia bleeding would do harm. Again, opiates are not proper in nephritis, at least not till the inflammation has been decidedly arrested; while in nephralgia they are often eminently serviceable from the commencement of the attack.

In order to form this correct diagnosis, let us take the definition of nephritis as we find it laid down by Dr. Cullen in his Nosology, and let us observe wherein it is applicable to both the diseases in question, and wherein it applies to nephritis only. The definition is as follows: "Pyrexia; pain in the region of the kidney, often following the course of the ureter; frequent desire to pass urine, which is either limpid and colourless, or very red; vomiting, numbness of the leg; retraction or pain of the testicle of the same side."

Now, what we are most carefully to attend to in the above definition is *the pyrexia*—the fever, and the description of fever. All the other symptoms are common to both nephritis and nephralgia; indeed the *pain* in the latter affection may be much more intense than in inflammation of the substance of the kidney, and quite as severe as when its capsule is inflamed, but the pulse is little, if at all, affected, and the other signs of inflammatory fever are absent. But if, with the symptoms of the local affection, we find a frequent hard pulse, a loaded tongue, great heat, and dryness of skin, we may at once pronounce the disease to be nephritis.

While we are careful not to mistake these two affections of the kidney for each other, we must also be upon our guard lest we confound either of them with certain other diseases which are accompanied with symptoms very similar. They have, for instance, been mistaken for lumbago; but here again the definition will assist us. In lumbago there is seldom much fever; there is no nausea; the urine does not present the appearances which indicate affection of the kidney; in lumbago the pain varies; it is most felt upon resuming the erect posture after the body has been bent, whereas in nephritic affection it remains much the same in every position.

Nephralgia and nephritis may both be mistaken for inflammation of the psoæ muscles; but in inflammation of those muscles there is neither nausea nor retraction of testicle, nor alteration in the flow or quality of the urine; the pain is increased considerably on rotating the thigh, and, if the disease have long subsisted, there is great emaciation.

Nephralgia may be mistaken for enteritis; for, as Dr. Pemberton has remarked, enteritis sometimes commences with such severe pain across the loins as absorbs all other sense of uneasiness; and in nephralgia there is often a sympathetic pain in the abdomen, midway between the os ilium and navel, which is extremely acute, and much increased upon the slightest pressure. We have met with instances where this sympathetic pain has been even greater than that arising from inflammation, and where the lightest possible covering could not be borne without distress to the patient. Now, in a case of nephralgia, should the medical practitioner fall into the error of pronouncing the disease to be enteritis, and proceed to treat it accordingly, that error, though it would prove a sufficiently inconvenient one to the sick person, and would reflect discredit upon himself, might not prove a fatal one; but how lamentable, as well as disgraceful, would be the consequence of his mistaking enteritis for mere nephralgia! The practitioner should, in every case, be cautious; he should put together all the symptoms, and carefully weigh their aggregate force, before he ventures to pronounce a decided opinion upon the disease. In severe nephralgia he will particularly remark, that though the pain and tenderness upon pressure, in the situation above mentioned, are exquisite, yet neither the pulse,

nor the temperature of the skin, nor the expression of countenance, are those of a person labouring under inflammation of the peritoneal covering of the intestines; neither is there the same obstinate constipation, the bowels being generally acted upon by emollient enemata.

Another disease, with which a nephritic attack is liable to be confounded, is colic. The mistake is not perhaps, as Galen observes, of much moment, since, at the commencement, the mode of treatment in both is pretty much the same. Still, however, it is proper to distinguish between them. In colic the pain is more paroxysmal; there are intervals of absolute ease; there are gripings and distention of the lower bowels; and the pain, instead of being in the loins, and following the course of the ureter, is chiefly about the navel; there is no numbness of the thigh or leg, or retraction or soreness of the testicle.

It is further to be remarked that a pain in the region of the kidney, extending through the ureter, and accompanied by almost all the other symptoms of a nephritic attack, will sometimes take place from hysteria, so that, to adopt the language of Sydenham, it is extremely difficult to distinguish whether these symptoms arise from calculus, or from some hysterical affection, unless perhaps some misfortune having greatly distressed the patient a short time before the disease came on, or the discharge of green matter by vomiting, should shew that the symptoms are rather to be ascribed to hysterical than to calculous affection. It is indeed very difficult to arrive at any certainty here: we should, however, carefully investigate all the symptoms; we should enquire whether the patient has previously been subject to hysteria; we should endeavour to ascertain whether the uterus and its appendages are in a healthy state, whether menstruation be performed with regularity, and whether the secretion be natural, and we should particularly observe the state of the urine.

Nephritis, as has been already observed, is no otherwise to be distinguished from nephralgia than by the symptoms of inflammatory fever which attend it; and these symptoms will be more or less marked according as the disease occupies the capsule of the kidney and its surrounding cellular membrane, or its substance. In the former case, there will be pain —burning, pungent, and great—in the region of the kidney; there will be inflammatory fever strongly marked. In the latter case, the pain will be less urgent,—it will be more of a dull heavy pain, and the accompanying fever will be more moderate; but still the pulse will be more frequent and harder than in a fit of the gravel simply; the tongue will be furred, the skin hotter than natural; the symptoms will be those of subacute inflammation. The former has occasionally been observed as an idiopathic disease; the latter occurs only in consequence of calculi retained in the kidneys, or external injury, or perhaps hydatids. The difference of intensity in the symptoms, depending upon the seat of the inflammation, seems, until of late years, to have been overlooked by authors of the highest reputation.* The late distinguished Professor Gregory, when, in his admirable lectures, he spoke of idiopathic and symptomatic nephritis, appeared to regard both as affecting the substance of the kidneys; he did not, as far as we recollect, throw out any hint of their capsules and surrounding cellular membrane being the chief or the only seat of idiopathic nephritis.

We have thus endeavoured to point out how nephritis and nephralgia may be distinguished with tolerable certainty from each other, as well as from certain affections of the surrounding parts; but no small degree of obscurity yet remains: it is extremely difficult to discriminate between an affection of the kidney itself, and disease of other parts of the urinary system; for one extremity of that system so readily and so rapidly sympathises with the other, that the same set of symptoms will often occur wherever the disease in the urinary organs may be located. Thus, a stone in the bladder may give rise to all the sensations of disease in the kidney, and a calculus in the latter may produce every feeling of disease in the bladder. We would, therefore, impress upon the mind of the young practitioner the importance of extreme caution in pronouncing upon disease of the urinary system.

We now proceed to offer a few observations upon some of the symptoms which belong equally to nephritis and nephralgia; and first as to the pain generally following the course of the ureter. This pain in the region of the kidney is a very common but not an essential symptom; it sometimes is entirely wanting, and sometimes is so obtuse that it is not noticed, until vomiting comes on and attracts the physician's attention and induces him to make minute inquiries: in other instances it is extremely severe, yet, upon examination after death, the kidney of the suffering side has been found free from all trace of disease, while the opposite one has been completely disorganized.

Another symptom which is also usually but not invariably present, is dull pain, or numbness of the thigh and leg. Attention to the distribution of nerves will enable us to comprehend this affection of the lower extremity, as also that of the testicle, which frequently occurs. We have only to bear in mind that the semi-lunar ganglion of either side sends off branches which unite together, and with branches of the par vagum, to form the solar plexus, from which may be traced nerves going to various parts, and among the rest to the kidneys and the testes. The renal and the spermatic plexuses are derived from the same source, i. e. from the great solar plexus formed by the sympathetic and par vagum; and if we trace the sympathetic

* Boerhaave, for example, says, "*Ipsos renes* verâ inflammatione occupari scimus ex dolore ardente, pungente, magno, inflammatorio, loci ubi renes sunt; ex febre acuta, continua, concomitante."

into the pelvis, we shall find that it is connected with the nerves which pass to the leg. To account for the derangement of stomach, the eructation, nausea, and vomiting which attend nephritic affection, we have also to recollect what nerves concur to form the renal plexus, and what nerve it is that supplies the stomach.

The frequent desire to pass urine may well be explained upon the principle of irritation. The secretion is either scanty, very high-coloured, and mixed with blood, or it is limpid and nearly colourless. The former appearances we may expect to find when calculus is present, or when the affection has been induced by violent horse exercise or by external injury; the latter are more likely to take place in acute idiopathic inflammation. Sometimes there is total suppression, a symptom, as we have already shown in the article Ischuria Renalis, to be of very formidable character; it is not, however, necessarily a fatal symptom where the kidneys are primarily affected: we have known it to subsist for above a week in a case of nephritis from calculi, and where the inflammation terminated in abscess, as was proved by purulent matter in considerable quantity being passed with the urine. In this case the head was little affected, and though there was great pain, with most distressing nausea and retching, the pulse was hardly more influenced than in an attack of gall-stone.

Acute idiopathic inflammation of the kidney may be produced probably by any of the general causes of inflammation, but especially by exposure to cold, or violent exercise on horseback. Cases of this description are, however, of very rare occurrence. It does not appear that Dr. Baillie ever met with an instance of inflammation of the capsule of the kidney; and the late Professor Gregory used to state in his lectures, that he never saw a case of pure idiopathic nephritis. Symptomatic nephritis, i. e. inflammation of the substance of the kidney, or nephralgia with inflammatory symptoms, is, however, far from uncommon. Its most usual exciting cause is calculous matter blocking up the tubuli uriniferi, or calculi formed in the pelvis of the kidney and obstructing that cavity, or the canal of the ureter. But it may also arise from other causes, as from a blow, or a bruise or strain, from severe exercise, long confinement in a recumbent posture, plethora, acrid diuretics, excess in the use of spirituous liquors, poisons.*

There is a great connection between nephritic affection and gout. In some individuals the two diseases make their assault simultaneously; in others they alternate: we find some members of a family affected with gravel, and others with gout; and families have been known where all the men had gout, and all the women gravel. It is to be observed that the former disease is more common in men, owing, probably, to their freer mode of living. The descendants of gouty parents seem to be hereditarily disposed to both diseases. In a family with whose history the writer of the present article is intimately acquainted, the paternal great-grandfather and his wife died martyrs to gout, the one at the age of forty-three, the other at forty-five: their elder son had occasional smart fits of gout till the age of sixty-five, when they left him to return no more till his death, which happened in his eighty-eighth year; his elder son, a man of very temperate habits, never had gout, but died at sixty-six of severe disease of the urinary organs: the two sons of the latter, who have both reached the middle of life, have hitherto been entirely exempt from gout, but both exhibit a disposition to nephritic affection.

Inflammation of the kidney may terminate in any of the ways of other inflammations: it may terminate in resolution; or a profuse sweat, or a copious flow of urine, high-coloured, thick and mixed with mucus, may carry off the disease; or the same may be effected by a considerable discharge of blood from the hemorrhoidal veins. The relief afforded by such a discharge has been noticed by the great father of medicine;* and his commentator Galen observes that the untimely checking of habitual hemorrhoids has given rise to nephritic affection.

To the intimate connection which subsists between nephritic affection and gout, allusion has been already made. That the sudden suppression of the latter may occasion ischuria renalis, or renal inflammation, is well known; and a decided attack of gout supervening upon nephritis may effectually relieve the kidneys. If, however, the symptoms be protracted beyond the seventh day, suppuration will in all probability ensue, and will be declared by its usual symptoms, as frequent irregular rigors, dull, heavy, throbbing pain, &c. The entire kidney may be thus consumed, and in its place may be found a collection of pus: cases of this kind are not uncommon. Again, the inflammation may terminate in an indurated condition of the kidney: its natural structure may be partially or totally lost; it may degenerate into what, by the most skilful morbid anatomists, has been considered a truly scirrhous state, and then permanent lameness may be the consequence. Lastly, nephritis may run into gangrene, as is well attested by Boerhaave and other systematic writers. Such a termination is doubtless extremely rare at the present day; but an example of it has been given by Dr. Turner in the fourth volume of the Transactions of the College of Physicians in London.

We now approach the subject of *treatment*; and, first, of that of pure idiopathic nephritis, which may be disposed of in very few words. The inflammation must of course be met by the same prompt and energetic measures which we are accustomed to employ for the purpose of arresting acute inflammation of other parts. Bloodletting, both general and topical, is a re-

* A peculiar irritation, it is said, has been produced in the kidneys by arsenic, especially by the fumes of that mineral.

* Τοῖσι νεφριτικοῖσι αἱμορροΐδες ἐπιγινόμεναι ἀγαθόν. Sect. 6, aph. 11.

medy of the first importance, and it should be employed early, and with freedom, lest suppuration or gangrene ensue. The whole of what is understood by the term *antiphlogistic regimen* should be strictly enforced. The warm bath and fomentations should not be neglected. Mild diluents may prove useful; and perhaps some of the class of diuretic medicines, as the infusion of digitalis; but all diuretics which possess a stimulant property should certainly be avoided. It is of importance to unload the bowels, and afterwards to maintain their action; but saline purgatives, being disposed to pass off by the kidneys, are improper in this disease. The mildest laxatives alone should, in the first instance, be tried; such as a draught with one or two drachms of oil of almonds, or castor oil with manna, repeated every third or fourth hour; should this fail, castor oil in a larger dose may be exhibited; or the compound infusion of senna with manna; or, in the event of the bowels continuing obstinately costive, recourse may be had to stronger purgatives, as jalap with calomel. It is, however, to be recollected that, owing to the nausea which is so constant an attendant of nephritis, it will frequently be found impossible to administer either oily or other laxatives by the mouth. Emollient glysters, or glysters of warm water only should then be thrown up, and we should desist from all attempts to administer medicine in another mode until the stomach become more settled. Emollient glysters are useful both as fomentations and evacuants: by this employment we may unload the colon, to unload which is of considerable importance. Blisters have been recommended by some authors of credit, but we should protest against their being resorted to.

If, after the lapse of six or eight hours, the pain and heat in the region of the kidney be not relieved, and the hardness and frequency of the pulse remain, nearly the same quantity of blood should again be drawn from the arm and from the loins by cupping or the application of leeches; and should the inflammatory symptoms still continue, a repetition of the same means may be necessary. We must be guided here, as in acute inflammation of other organs, not by the quantity of blood drawn, but by the impression produced upon the system by its abstraction.

Such is an outline of the plan of treatment to be adopted in pure nephritis. If it terminate in resolution, or by any critical discharge, little will be left for the physician to do afterwards; if, in spite of the most active measures, it run on to suppuration, the treatment must be such as will be hereafter pointed out. If the sudden cessation of pain, hiccup, clammy perspiration, feeble intermitting pulse, great prostration of strength, ischuria, or dark flaky offensive urine, indicate that gangrene has taken place, the case is indeed all but desperate; strong cordials and stimulants must then be resorted to: recovery *may* follow, but a fortunate result is a sort of miracle.

In symptomatic nephritis, inflammation of the substance of the gland, from calculi or any other of the causes above enumerated, our treatment must be conducted upon the same principles as in the foregoing species, but, as the inflammatory symptoms are less marked, the same freedom in the use of the lancet will hardly be required at the onset, and seldom will there be need to repeat venesection. Local depletion seems more applicable in this grade of the disease. When, however, the pain has come on very suddenly, and is extremely acute, blood should be taken to the amount of ten or twelve ounces from the arm; recourse should be had to the warm bath or hip-bath; and, if circumstances seem to demand it, local depletion may be subsequently employed. When the disease has been induced by a strain, or blow, or bruise, or by violent exercise, &c., a second bleeding may sometimes be necessary, and a strict adherence to the antiphlogistic regimen will be expedient; but when it appears clearly to arise from calculus, we may generally, after one moderate bleeding, and opening the bowels by mild laxatives, have recourse to opium, in the dose of a grain every second or third hour, according to the urgency of the pain. Opium is in fact the grand remedy in calculous nephritis; it moderates the pain, and checks the vomiting, relaxes the spasm, and promotes the descent of the stone into the bladder. If the affection be simply nephralgia, bloodletting will seldom be required; yet if the pain be extremely acute and long continued, it may be expedient, as a measure of precaution, to take away blood in moderate quantity by cupping from the loins, or even from the arm, since, though none of the essential symptoms of inflammatory action may be actually present, or at least none which we can detect, we can never be sure that inflammation will not supervene, or that it is not already obscurely existing; and we must constantly bear in mind that a degree of renal inflammation, not to be discovered during life, is sufficient to produce abscess of the kidney or the total destruction of the gland.

In nephralgia, having first unloaded the bowels by a brisk cathartic, or, if the stomach be in a very irritable state, by a purgative glyster, opium in a full dose, and repeated at short intervals, is of great service, and glysters of starch, with laudanum, may also be employed. Every mean should be resorted to to favour the descent of the stone into the bladder, and to afford the patient a chance of its being passed by the urethra. To increase the flow of urine, mild diluent liquids should be freely taken; with the view of relaxing the parts, fomentations should be diligently used; and, as soon as possible, the patient should be placed in a warm bath, and, while in the bath, he should endeavour to pass urine; the attempt will often succeed under these circumstances, though it has failed before. The means to be adopted, by way of obviating a return of nephralgia, are those which have been found most efficacious where the *lithic diathesis* is known to prevail. Alteratives and aperients should be exhibited so as to promote the proper actions of the organs concerned in the digestive process. Five grains of the compound calomel

pill may be given every other night, or five or six grains of hydrarg. cum creta, with an equal quantity of rhubarb and a grain of ipecacuan. In robust habits we may prescribe from two to three grains of calomel, combined with four grains of James's powder and three grains of compound extract of colocynth and of extract of hyoscyamus, to be taken at bedtime twice a week, and to be followed up the next morning by a Seidlitz powder, or by three drachms of Epsom salts, a scruple of carbonate of magnesia, and six of powdered ginger, in half a pint of tepid water. A teaspoonful of magnesia in soda-water, or twenty minims of the liquor potassæ in linseed-tea or barley-water may be given twice a day, or more frequently, according to the urgency of the symptoms. But one of the most valuable medicines we possess is the diosma crenata; the infusion of its leaves has often given decided relief to nephritic patients when various other remedies have totally failed.* We have repeatedly witnessed its soothing effects, and it appears to possess a tonic property—it seems to give tone to the stomach. It is a valuable addition to the Materia Medica, and merits a more extensive trial and more careful observation as to its effects than it has hitherto received.

In cases where there is great weakness of the loins, accompanied perhaps by dull heavy pain, mechanical support will frequently afford great relief. For this purpose a tight bandage may be applied, or a plaster, such as the emplastrum cumini, emplast. ammoniaci, or emplast. oxyd. ferri rubri.†

When an abscess forms in the kidney, it may open in the loins, or it may burst into the pelvis of the organ, and be discharged with the urine. In the former event the aid of the surgeon will be required. If the abscess be of a scrofulous nature, the termination of the case will in all probability be unfortunate. The surgeon will have to deal with sinuses, which will prove very troublesome, yet by means of setons they may sometimes be healed. If the ureters be plugged up with scrofulous matter, there is no chance of a cure, but temporary relief may be afforded; the sinuses opening at at an inconvenient part may be healed by seton, and an outlet be made in a more favourable situation. In the latter case, should the abscess be the result of common inflammation, the patient has a good chance of recovery. Balsamics, as the Chian turpentine, may be employed, and the uva ursi may be of service. Should it be, as it commonly is, of a scrofulous character, the prognosis must be unfavourable. In such cases generally the infundibula, pelvis, and ureter partake of the disease; more or less symptomatic fever attends, and the patient is worn out by the irritation and drain. Such, however, is not always the case; patients do occasionally recover against hope, whether by the resources of nature alone, or the aid of medicine, may admit of great doubt; but certainly it is the bounden duty of the medical attendant to bring into the field those remedies which have the reputation of being useful in scrofulous disease—sarsaparilla, cinchona, liquor potassæ, conium, cum multis aliis.

The termination in gangrene is happily of rare occurrence; and when such is the termination, nothing is to be expected from medicine.

We would, in conclusion, impress forcibly upon the minds of persons who have once suffered under an attack of nephritis or nephralgia, the consideration that they are extremely liable to a recurrence of the complaint, and the importance therefore of caution as to diet, exercise, &c. Their diet should be plain and of easy digestion, and repletion should be studiously avoided; they should be sparing in the use of strong liquors, and should especially abstain from acescent wines; they should take regular and moderate exercise; they should not acquire the habit of spending many hours in bed, nor should they make use of a feather bed; they should avoid exposure to cold and damp, particularly the getting wet in the feet.

(H. W. Carter.)

NEURALGIA. The term neuralgia, derived from νεῦρον, a nerve, and ἄλγος, pain, signifies pain in a nerve. The pain is in some cases felt in the chord of a nerve, and follows its track: in other cases the pain is felt in the ultimate twigs into which the nerves split, so that a space, or spot, or an organ, and not the track of any particular nerve, aches or is acutely sensible. When it evidently takes the course of a nerve, the case is clear, whatever be the character of the pain; but when it affects an organ, a space, or a spot, we pronounce the disease to be neuralgia from the character of the pain and the absence of such other circumstances as would be sufficient to occasion it.

In the most exquisite cases the pain is excruciating, sharp, sudden, stabbing, or plunging, as patients frequently express themselves; more violent at one moment than another, and sometimes greatly mitigated or absent for a longer or shorter period; induced instantly, like an electric shock, by motion or pressure, even by brushing the point of the finger along the affected part, or it being shaken or blown upon by cold air. Firm pressure is frequently borne, and gives ease. If a secreting organ is in the neighbourhood, it is excited. For example, when some nerves of the face are affected, a paroxysm of pain may be induced by masticating, swallowing, blowing the nose, or even by speaking; and a flow of tears, nasal mucus, or saliva, is frequently observed. If there are small muscles in the neighbour-

* The diosma crenata has been long known to British botanists as a plant highly esteemed among the Caffres as a remedy in nephritic complaints. It is noticed, upon the authority of Sherard, in Ray's Historia Plantarum, tom iii. lib. 30, p. 91, under the title of Spiræa Africana, or Buchu of the Hottentots, and is there stated to constitute the principal ingredient of a certain powder in use amongst them—"primarium ingrediens pulveris Cyprii Hottentottorum." It has within the last few years been favourably introduced to the notice of the profession in this country.

† Of these the best perhaps is the emplast. oxydi ferri rubri, on account of its stiffness and adhesive quality, not from any effect which we can suppose the iron to communicate.

hood, they experience twitchings; and, in the severest cases, large and distant muscles may be convulsed. From these circumstances some have called the disease neuralgia *spasmodica*, but, we think, most improperly, because they are only incidental, and the severest neuralgia may occur without them. The pain may be dreadful and occasion delirium.

Such an affection was formerly called *tic douloureux*, painful tic; the latter word signifying a sudden catching or convulsive motion, such as is noticed in the face or other parts of some persons, and is as it were a local chorea, and such as is noticed in some horses that convulsively bite the manger. Persons with such catchings experience no pain. But when twitchings occur in neuralgia, they are attended by pain, and therefore to their name—tic—in this disease, the epithet douloureux was added. As the disease was first noticed and distinguished in the face, where there is an abundance of small muscles and consequently twitchings usually attend it, the twitchings attracted as much attention as the pain, and the disease obtained its designation from both symptoms. Sometimes, between the shooting pains, there is constant aching; and sometimes the part feels painfully benumbed. We have known the neighbouring parts, which were not in pain, benumbed.

The attacks may last days, weeks, or months; and may recur after intervals of days, weeks, months, or years. They may occur chiefly after exciting causes, or without any obvious reason. They generally occur without warning, but have been preceded by peculiar sensations and some kind of indisposition. The disease may be suspended or may cease, by nature or through art, or may end in apoplexy, insanity, emaciation, and death.

It most frequently attacks the ramifications of the fifth pair, and the first and second branches of the nerve suffer oftener than the third. We notice it therefore particularly over the orbit, under the orbit, in the cheek where the pes anserinus is spread, in the mouth, and along the lower jaw, and in the lower teeth. Some doubt that it is ever felt in the portio dura; others declare they have known it in that nerve. An hospital patient of ours complained of it not only in the cheek, but in the course of the portio dura from the stylo-mastoid foramen. We do not see why the disease should be confined to nerves of sensation. Two, or even all the three, branches are sometimes affected, and the pain may extend even to the other side of the face. We have known it extend down the neck to the shoulder, and along the inside of the arm to the ends of all the fingers and the thumb. Various nerves of the legs, arms, fingers or toes, are occasionally the seat of the disease; and an intercostal, a lumbar, and even the spermatic, nerve, has been attacked. The pain may be confined to one nerve, or to it and its branches, may extend to other nerves in the neighbourhood or at a distance, or it may affect nerves distant from each other, simultaneously or successively, and change its seat backwards and forwards. The pain does not always shoot in the course of the nerve, but frequently in the opposite direction. It may not shoot from a nerve through all the twigs, but only through some.

Neuralgia of this character was perhaps first distinctly described in 1756 by André, the French surgeon of Versailles, in his work upon the diseases of the urethra. Dr. James Fothergill, in the fifth volume of the Medical Observations and Inquiries, published in 1776, described it as occurring in the face, and without being aware that André had anticipated him—and no wonder, when we consider the singular mode in which André promulgated his facts—and he tells us that he never saw more than fourteen instances of it. We have not seen so many. He observed it oftener in women; but this greater frequency is not a general fact. He never noticed it in persons much under forty years of age, and this observation, we believe, is confirmed. It is rare in children, yet continental writers record cases of it in subjects but seven and nine years old.

Pain of exactly this character, and not to be accounted for by inflammation or organic disease of the part, now and then attacks organs or spots, and not the track of any nerve. The breast, for example, the heart, the testis, may so suffer; and once we witnessed it apparently in the kidney. The character of the pain, and the absence in the part of the ordinary causes of pain, justify us in regarding it in these cases as neuralgia.

In other cases it is not the character of the pain, but the evident situation of it in one or more nerves, that proves it to be neuralgia. Pain is frequently not stabbing and sudden, not of the description above given, but equally deserving to be called neuralgia, because affecting the course of a nerve. It may be acute, though not electric nor excited by the slightest friction; it may be a constant aching. When a nerve is inflamed, there is great pain. When a portion of a nerve has been seen of an uniform dark red colour after death; when a portion has been found diseased and enveloped in gangrenous cellular tissue; or about double its natural size, of a violet red colour, and strewed with ecchymoses of the size of pins' heads; or a serous, bloody, or purulent effusion has been discovered among its fibres; or nerves have been found hypertrophied and connected with fungous ulcers; when a nerve has been bruised, lacerated, or half divided;—pain of greater or less intensity had been felt in the nerve or the parts upon which it is distributed.* Cotugno, Cirillo, Chaussier, Bichat, &c. have seen similar appearances after neuralgia. In some cases of disease of the brain or spinal marrow, even where paralysis is produced, pain is felt at a distance: the paralysed parts sometimes ache severely in hemiplegia. In epilepsy and hysteria pain is sometimes felt in the course of nerves. A portion of the pain in structural disease of all organs may occasionally occur in the branches and twigs of the nerves irritated by

* See Abercrombie's Researches on the Diseases of the Brain, &c.

it. Nerves also frequently suffer pain from rheumatism. There is decidedly a rheumatic neuralgia. The exquisite neuralgia, described as tic douloureux, may arise from those vicissitudes of temperature that occasion rheumatism, and may be rheumatic. But pain, not of that description, though perhaps very acute, perhaps dull and aching as is usual in rheumatism, is every day witnessed in the situation of nerves, in persons who have rheumatism in those situations, and who have been exposed to cold, or perhaps cold and wet; and it yields as readily to the treatment of rheumatism as the ordinary rheumatism of other parts. The neurilema, which is a fibrous membrane, is probably still more affected than the nerve, since rheumatism is chiefly a disease of the fibrous membranes. In rheumatic neuralgia we observe all the varieties of suffering occasioned in other parts by rheumatism: sometimes acute pain, with tenderness, heat, and even throbbing, and aggravation of the pain by heat; sometimes dull aching only; sometimes pain on motion, pressure, or other modes of mechanical irritation; sometimes remittent, intermittent, or even periodical, pain. The pain is sometimes exquisite and sudden, assuming the character of tic douloureux, which, we may remark, not only when rheumatic, but sometimes when not apparently so, may assume a periodical type. It is the clear situation of the pain in a nerve, and not the character of the pain, when it is not like the pain called tic douloureux, that justifies us in rheumatism to pronounce it neuralgic. The nerves chiefly attacked by rheumatism are the sciatic and the branches of the fifth. It is frequently very inflammatory, so that the surface is tender, hot, swollen, and even red. Sometimes no marks of inflammation are discoverable, and warmth and other stimuli relieve. In the case of the face especially, (one side only of which is usually affected, and perhaps not only the nerves, but some of the surrounding parts,) there is a great tendency to periodical intermission, and the paroxysms usually occur in the evening.

In hysterical females, portions of the surface occasionally become exquisitely tender, so that the least pressure with the extremity of the finger, such as would not occasion pain were the peritoneum or viscera inflamed, even the sudden falling of the bed-clothes upon it, causes anguish. The surface of the front of the body is most frequently affected, sometimes only of the abdomen, sometimes only of the chest; sometimes portions of the back only suffer, particularly at the spine; and sometimes nearly the whole surface of both the trunk and extremities. As no pain is felt while the part is not compressed, perhaps this condition ought not to be called *neuralgia*. But the absence of heat, swelling, redness, and of all signs of internal no less than of external inflammation, and of structural affection and serious disease, the perfect inutility of all the remedies of inflammation, the power of the remedies of pure nervous affection and neuralgia, prove it to be a morbid sensibility of the nerves of touch, and perhaps make it merit the epithet *neuralgic*. Cases of this description are occasionally mistaken for chronic peritonitis and other inflammatory diseases; and, when the tenderness is felt in the course of the spine, it is too often set down as a mark of disease of the spine or its ligaments, or perhaps the whole case is referred to an affection of this portion of the spinal chord, while the morbid sensibility of the spot is merely one of the number of symptoms. We saw this tenderness in an *hysterical* and neuralgic middle-aged *man* who had been exposed to malaria.

The nature of neuralgic affections may be evident during life, and immediately, or not till after a lapse of time; may become evident after death only; or may never be discovered.

Inflammatory conditions of the nerves and structural changes, as well as mechanical causes of irritation, may be detected during life if the seat of these conditions is within the reach of observation: and symptoms may be induced which clearly point out inflammation or structural change, even should these be beyond our observation. Occasionally, however, the seat and cause of the irritation is not only beyond observation during life, though discoverable afterwards, but no symptoms are produced which indicate them. After exquisite neuralgia, or that kind denominated tic douloureux, the cranial bones have been found of unusual thickness, so that it was fancied that probably they had in some degree compressed the nerves. There is, however, no proof that the neuralgia was the effect of the growth of the bone. The latter might have been only one of several morbid changes going on in the head, and some of which caused neuralgia. The state of all the nerves should have been accurately ascertained. In insanity and idiotism the bones are sometimes of enormous thickness through the general tendency to disease in the head, and the insanity is not ascribable to it, but the whole is the result of the tendency to disease in the head. Here, too, there is generally no neuralgia. To show that in some cases of neuralgia the cause becomes obvious after a time only, we may state that Dr. Abercrombie quotes one case of exquisite neuralgia of the face that ceased on the removal of a piece of china which had been there fourteen years, and another of ten years' duration that ceased on the extraction of a tooth. Sir Henry Halford mentions the case of a lady who laboured under violent tic douloureux till an apparently sound tooth was extracted on account of the attacks being frequently preceded by uneasiness in it, and that a large exostosis was found at its root. He relates the case of a nobleman who was liberated from the disease by the exfoliation of a portion of bone from the antrum maxillare. To ascribe neuralgia, however, to these causes in most cases is very unpathological. In ordinary rheumatism, which is not inflammatory, in that form which is unattended by heat, and in which there is mere aching relieved by warmth and all stimulants, and probably greatly influenced by atmospheric changes, the real condition of the part is unknown. The same is true, not only of this rheumatism when affecting nerves, not only of the corresponding

form of rheumatic neuralgia, but of that exquisite neuralgia, when not rheumatic, and when no inflammation nor structural change, nor mechanical cause, can be detected before or after death. Good pathological anatomists declare they have frequently been unable to detect any unhealthy appearance on careful dissection. Occasionally the pain may be sympathetic, may depend upon no fault of the nerves or even the nervous centres, but upon disorder of the digestive organs. Even such an origin cannot always, in obscure cases, be presumed; and we confess that, allowing some of the blame to be deserved that is laid upon the digestive organs as causing all kinds of diseases of all parts—a vulgar assumption easily made and saving a world of investigation and accurate reasoning,—we have never seen one case of neuralgia referable to such an *origin*.

Since this is true of the nature and causes of neuralgia, we see how various must be its course and its termination, and how various the prognosis as well as the mode of treatment required in different cases.

When inflammation is obvious or presumable, whether rheumatic or not, local bleeding, mercury, colchicum, and the whole antiphlogistic plan, general and local, are appropriate. Should these not succeed soon, anodynes may be added; and the pain may, from an inflammatory commencement, degenerate into pain without inflammation, and demand at last solely the treatment of another form of the disease. When rheumatic and yet not inflammatory, the remedies of this form of rheumatism in other parts are required;—stimulants internal and external, tonics, mercury, and all modes of counter-irritation. Coldness indicates stimulants. Among internal stimulants, besides generous diet, the ammoniated tincture of guaiacum is one of the best. It should be exhibited in such quantity and frequency as to keep the patient comfortably warm. A dose of half a drachm may be sufficient, or six drachms may be required; and a frequency of three times in the twenty-four hours may be sufficient, or the dose may require repetition every two hours; and in general both may be diminished after the remedy has been continued for some time, because it stimulates more and more, and its effect lasts longer. When there is debility, and especially paleness, iron in full quantities operates in the most salutary manner, much more so than quinine. The hot bath, of water or vapour, the douche, electricity, blisters, moxas, smapisms, tartarized antimony, croton oil, and acupuncture, frequently cure, if combined with all other appropriate means. Mercury carried to ptyalism frequently cures, provided the strength will bear it, and the rest of the treatment is well conducted. Even the cold shower-bath or cold douche, if followed by good friction, will cure. A warm temperature of the atmosphere around the patient, and warm clothing, may be indispensable. Anodyne narcotics may be absolutely necessary; and the salts of morphia, stramonium, and belladonna, carried to a due extent, are by far the best, and sometimes alone will cure.

If the disease is seen to depend upon any organic affection, or upon a mechanical cause, the treatment will be evident. Should no structural or mechanical cause, and no inflammation be discoverable, and should the disease be of the exquisite character, then iron is the best remedy. The use of the subcarbonate of iron was discovered by the late Mr. Hutchison of Southwell. The old dose of half a drachm or a drachm will sometimes succeed. But while exhibiting this remedy in various diseases, we soon discovered that it might be given without any inconvenience in far larger quantities than was imagined.* Even children of eight years old will often take half an ounce or six drachms every four hours. If given in twice its weight of treacle, it rarely constipates. But strict attention should be paid to keep the bowels open during its employment, because, being an insoluble substance and bulky, if it is not regularly discharged, its accumulation may be considerable and produce inconvenience. If doses of a drachm every six hours fail, it should not be relinquished till those large quantities also have failed. Although it is the best medicine at present known under these circumstances, it frequently fails altogether, and still more frequently the disease returns, but perhaps yields again and again to it. In all cases of neuralgia, whether exquisite or not, unaccompanied by inflammation or evident existing cause, iron is the best remedy. Probably other forms would answer as well as the subcarbonate. When iron fails, or affords but imperfect relief, it may be serviceable by improving the general health. Less frequently curative as is this medicine than we had hoped from Mr. Hutchison's statements to find it, the power it was proved by this gentleman to possess over the disease induced us to try it in other nervous affections; and in those which are less frequently connected with an inflammatory or structural condition, its power is very great. The first other disease in which we employed it was paralysis agitans, and the first case was cured. In most other cases we have been disappointed, and probably from organic change of the nervous substance frequently existing. The next disease was chorea, and as that is comparatively seldom dependent upon structural change, we have never once failed in curing it with iron, except when it has been partial or of very long standing—circumstances in which structural change is highly probable. Even in two cases of tetanus out of three we were successful with it; and in the third, which was fatal, there was too little time to exhibit it.

Quinine, arsenic, belladonna, stramonium, colchicum, are said sometimes to cure this exquisite form. The want of attention to the stomach and bowels, and of the observance of good habits, will aggravate it. Relief is said to be obtained occasionally by the application of steam to the part, and sometimes by ice. The application of the strongest narcotics, and all irritants and escharotics, as well as the actual cautery, have occasionally done good.

* See a Paper by the author of this article in the 13th Volume of the Med. Chir. Transactions.

When all has failed, the division of the nerve, or the removal of the part, if possible, may be proposed, provided no cause in another part is obvious, and provided the pain is invariably limited to one part. Galen was acquainted with the division of the nerve as a remedy in the disease; but a royal French surgeon-maréchal appears to have been the first who performed the operation. Unfortunately it very rarely cures. One portion of the divided nerve suffers again, or the disease reappears in some other part. Too often there has not been even temporary relief. Yet amputation of the finger or thumb, in which the disease was seated, has succeeded, when the cause of the affection was local.*

When neuralgia arises from malaria, whether ague has also been produced or not, quinine or arsenic, long continued in the largest and most frequently repeated doses that can be borne without the least inconvenience, are the best remedies; and when it is periodical or intermittent, without evident connection with malaria, they are excellent. But sometimes a full dose of extract of stramonium or belladonna, repeated every hour or two from just before the attack is expected to the termination of every paroxysm, succeeds better.

(John Elliotson.)

NIGHTMARE.—See Incubus.

NOLI ME TANGERE, or LUPUS. The name of *lupus*, which was occasionally used by the older writers on medicine and surgery to signify any ulcer having a destructive tendency, (quasi, voracious as a wolf,) was appropriated to the particular disease of which we now treat by Sauvages, who considered it a species of cancer, and called it "cancer lupus." The other term by which it is equally well known is of a still older date; and it is no longer certain in what it originated. Some authors affirm that, the ichorous matter which was formed by the ulcerated parts being supposed to be contagious, this name was given to include an expressive warning to beware of the contact of a thing which produced such fearful and unsightly effects. Others state, with greater appearance of probability, that "touch me not" refers to the inutility of using topical remedies in its treatment. However this may be, the terms lupus and noli me tangere are synonymous in British medicine, and have always signified the same thing since they have been used in any definite sense. Biett, indeed, uses the latter term to express malignant ulcers of a cancerous origin; but he will not, we hope, be imitated in this, as this application of it would only serve to add to the confusion which already exists as to the proper comprehension of this disease. We shall revert to this, and to other names which have been used indifferently with it, as we proceed.

There is scarcely any disease of so formidable and obvious a nature about which such uncertain and ill-defined notions prevail. It must have been known to the earliest antiquity. Celsus clearly and forcibly distinguished it from cancer under the name of *cacoethes;* and it is not a little remarkable that the remedies which he recommends are the same which at the present day are most relied on. While other diseases of the integuments have been investigated and described with a minuteness of research which some have considered superfluous, systematic writers have slurred over this with a scanty and superficial notice quite inconsistent with its importance. Some writers pass it over altogether, and others handle it in a manner which gives us as imperfect a notion of the malady almost as if they had left it altogether untouched. This does not surely arise from the rarity of its occurrence, or from the insignificant nature of the affection. A slight acquaintance with the practice of any considerable hospital or dispensary affords a melancholy proof both of its frequency and its ravages. In Dr. Good's "Study of Medicine" we find the subject dispatched in about a page, in which short space he has contrived to insert so much of error that no person acquainted with the disease could recognise it from his description. Bateman, in his valuable "Synopsis," devotes ten pages to aphthæ; but lupus he is also content to dispose of in one. For the comparative neglect of this subject he excuses himself by stating that he is not aware of any medicine which has been of essential use in its cure. We suspect, however, that one chief reason why the subject has been treated in so insufficient a manner lies in the essential difficulties connected with it. And these are in fact very great. Nature herself does not appear to have assigned in many cases accurate limits to it; at least in the study of these destructive ulcerations the observers of nature are frequently at a loss to find means for drawing the line of demarcation between true lupus and diseases considered to be of a different pathological nature. In our description of the varieties, or rather species of this malady, we shall observe a somewhat similar plan to that of M. Biett, whose lectures, detailed in the work of MM. Cazenave and Schedel, deliver the best digested history of it to be met with in any language.*

Lupus commences by the slow development of a tubercular induration in the tissue of the true skin or mucous membrane; sometimes, perhaps, in the subcutaneous or submucous cellular tissue. According to its situation this

* Med. Chir. Trans. vol. iv. and vol. viii.

* Abrégé pratique des maladies de la peau, d'après les auteurs les plus estimés, et surtout d'après les documens prises dans la clinique de M. le Docteur Biett, par MM. A. Cazenave et H. E. Schedel, &c. &c. We wish to acknowledge our obligations to this book. It is written in an unpretending style, but is now justly reckoned, both in this country and Germany, to contain more enlightened information on cutaneous diseases than any other recent work. We cannot but express a wish that Great Britain afforded such an opportunity for the cultivation of this branch of medical study as the Hôpital St. Louis at Paris does.

tubercle is either single, or else several appear together. While it makes its slow progress towards the surface, the skin takes on a violet colour, which spreads before the advancing tubercle, and seldom yields except to destructive ulceration. After an uncertain time the tubercle makes its appearance on the surface, cracking the cuticle, and forming a coarse laminar scab, from under which exudes a foul ichorous discharge. The crust, which is the surface of the tubercle, is very closely adherent; it spreads and sometimes falls off, exposing an ulceration of a malignant aspect underneath. The latter extends *pari passu* with the tubercular crust; but sometimes it spreads beyond the space which this occupies: every time that this falls off, a greater extent of ulceration is visible; and thus it proceeds, unless checked by art, till it commits the most frightful ravages.

This general character of the disease applies to it more particularly when it has its seat on the face, which, in genuine lupus, is the case in nineteen instances out of twenty. But even in this situation it has much variety which a general description cannot include. In describing it more particularly then, we will separately consider it in three forms:—*first*, lupus in which the ulcerative process destroys chiefly in depth; *second*, that in which the destruction and cicatrization do not manifest any open ulceration, and are accompanied by an hypertrophied state of the skin; *third*, lupus which spreads mostly superficially. This division of the subject differs but in the succession from that of M. Biett. It appears the most practical, and therefore the best adapted for closing with the difficulties with which the subject is attended.

1. *Deep or erosive lupus.*—The first species in our division is that in which the ulcerative process proceeds from the surface towards the centre. We have placed it first because it is the real type of the disease, the undisputed lupus or noli me tangere. The French writers have given to the disease the name of "dartre rougeante" after M. Alibert, who has divided the latter into three species. His *dartre rougeante idiopathique* agrees with this species, which is more especially the lupus of the nose. It very rarely occurs in any other place; but having run its destructive course on that organ, it not unfrequently spreads to the adjacent parts. On the alæ nasi, or at the point, a small tubercle makes its appearance, having its seat more or less deep in the true skin. As it advances, it assumes a livid colour. The skin around it becomes somewhat swollen and painful, and also assumes more or less of a livid or violet hue. After a period, which is various in different cases, a crust forms on the surface of the tubercle, of some thickness, and under this an ulceration extends. The crust falls and is renewed; and at every time that it is detached, it is found that the ulceration has destroyed a deeper layer of the skin. This proceeds very slowly for a long time, the loss of substance taking place nearly insensibly. Although new portions of the incrustation are frequently falling off, and always carry away with them a part of the subjacent tissue, it is not till this process has been going on for a considerable period that the destruction which it has caused is perceived.

In most cases this ulceration is accompanied by a constant discharge, from the nostril of the side affected, of a thin fetid matter. This latter phenomenon may originate in two ways. It may arise from inflammation of the Schneiderian membrane, propagated from the irritation of the tubercle producing the destructive ulceration of the skin. This is a frequent origin of the discharge; and where it is caused in this manner, it is neither so unremitting nor of such a bad quality as in the other case: it partakes here, in fact, more of the character of a common mucous coryza. The other source of the discharge is the actual commencement of the tubercular development in the mucous membrane of the nose itself. It is an indubitable fact that the disease very often commences here. It even sometimes produces much internal destruction without manifesting any morbid alteration in the skin. The history of its progress, when the disease begins in the mucous membrane, is different from that of its cutaneous origin; and we are disposed to think that, not considering this, it has been erroneously stated that it sometimes begins without any tubercular formation. But when we take into account the different structure of the two tissues, the process is quite analogous, whatever apparent difference the first stage of their progress may present. Its beginning in the mucous membrane is after the following manner. After some redness and inflammatory swelling in one of the nostrils, a thin, dark scab forms on the lining membrane, which, if it be torn off, is soon reproduced in the same way as the crust of the external tubercle. The destruction goes on under this thin layer until it corrodes the mucous membrane and the subjacent tissues just in a way corresponding with that in the tubercles before described. The difference lies not in the character of the disease, but in the nature of the tissues. In the mucous membrane, from its soft, pulpy texture and moist surface,* it is impossible to have the solid induration, denominated a tubercle, which the firm structure of the skin, covered by its dry cuticle, permits, unless by the deposition of a foreign structure, which does not take place in lupus; but there does take place a degree of condensation of its tissue; and in some places where it is most firm in structure, as the hard palate, we have known small tubercles to be formed. The crusty exfoliation takes place in both situations;

* In other cutaneous diseases a similar relation exists between the mucous membrane and the skin when the former becomes invaded by a disease proper to the latter. Papular eruptions, as lichen, sometimes extend inside the mouth; but here they take on the appearance of aphthous vesicles. In squamous diseases not unfrequently the internal membrane becomes affected; but instead of scales, which, from the nature of the mucous membrane, could not form on it, excoriations take place.

but it is modified as to its density and thickness by the nature of the membrane which secretes it. It is in this form, where the tubercular deposition commences within, that the discharge is sanious and fetid, being in this case the actual secretion from the ulcer; whereas in the former case it is mucus produced, as we have explained, by the irritation propagated to the pituitary membrane.

But whether it be in the cutaneous or mucous tissue that the disease begins, after a short period the progress of it becomes identical. The subjacent cellular tissue and the muscles yield to the ulceration and are destroyed; the cartilages follow in their turn, and very frequently the bones themselves are not protected from its ravages, but partaking in the general destruction, are corroded *pari passu* with the soft parts on the same level. This seems to be the distinguishing property of lupus, and of this particular species more especially. In most other diseases (where there is no actual deposition of morbid structure, as in cancer, &c.) the morbific action affects one tissue in particular, and is more or less confined by its specific irritability to this. But in lupus this does not by any means hold; its ravages have no respect to contrariety of organization: having destroyed the seat of its original development, it continues to eat its way through every tissue which opposes itself in its progress, until its further course is limited either by the destruction of the organ or by artificial means.

To return to the history of its progress. The destruction is generally complete in one of the alæ, or the point of the nose, before it spreads farther on its surface; but sooner or later the disease extends so as to embrace both sides; and wherever it takes up its ground in advancing, it is by the same tubercular deposit with which it began. Sometimes after having destroyed the tip of the nose or one of the alæ, it forms a puckered cicatrix, and seems to be nearly healed up; but it rarely stops in this manner. More generally, after a while, new tubercles become developed in the midst of the cicatrix itself, which ulcerate and destroy with all their original virulence. While the destruction spreads externally in the manner described, in general the internal parts are not exempted from the disease. In the majority of cases some part of the nasal fossa is simultaneously affected with it. The inner surface of the alæ corresponding to the external disease is a common place to find it internally; but the septum narium is the part where its ravages are most generally met with. In such cases the discharge is constant, and becomes an additional subject of disgust to the poor patient. The crusts which collect on the septum and on the turbinated bones nearly block up the passage of the nostrils. Sometimes, indeed, union takes place by adhesive inflammation between the alæ and septum, which has to be divided by the knife and cauterised. Where the disease is not checked by the appliances of art, nature seldom interferes to make its ravages but partial. The soft parts of the nose being destroyed by a gradual external progress, and the internal disease having broken up the septum, the entire organ is thus carried away, and in its stead remains but a square aperture partially divided by a partition, a hideous memorial of its devastating course. The bones sometimes limit its course after it has destroyed all the soft parts; but if it be not arrested before it has gone so far as this, these are also involved. It is at least common for the ossa nasi to be affected; and cases are met with where the destruction invades the superior maxillary bones: usually, however, when the ossa nasi fall, and the septum has been destroyed, it pursues its course no further among the bones.

This is the general account of its ravages, and it seldom stops, unless checked by art, till it fulfils it. Some variety will of course be met with in its course and in its terminations. Instances will be met with where it has disappeared after carrying away one of the alæ nasi; others where it went no further than to carry away the point of the nose. These are singular cases, and will be generally found to have been brought about by art. We have lately seen a case, however, where the alæ nasi on one side was taken clean away by the disease, which then stopped spontaneously. In other instances it has run a more superficial course from the beginning, and having eaten through some of the layers of the skin, becomes cheeked. In such a case it sometimes leaves the nose thinned on the sides, and running into a sharp-pointed tip. It is in these cases that the orifices are liable to be closed by the adhesive inflammation of the internal surfaces.

With respect to the stages of the disease, and the time which they take to run their course, they are by no means definite. The tubercles remain indolent for many months, but when they ulcerate, the disease generally makes quicker progress. No corresponding relation exists between the duration of the malady and the destruction which it produces. While in some it remains without effecting any important loss of substance for several years, in others the whole nose is destroyed in a few weeks.

We must again notice the frequency with which lupus occupies the pituitary membrane. Bett describes with exactness the case where it commences internally, and eats its way from within outwards, its arrival at the skin being preceded by a livid colour. The same author states that it sometimes commences in the skin, and having in its course reached the opening of the nares, it traverses their floor; it then descends along the soft palate, and having destroyed it, returns along the palate bone, eating away the roof of the mouth. But no author has, we think, dealt sufficiently on the disease as running its course entirely within. It has been long known, indeed, that ulcerations of a bad kind occur at the back of the pharynx, destroying it deeply, and carrying away the uvula and soft palate. These too are often called in surgical works by the improper name of "herpetic ulcers," which infers that they partake of the nature of lupus, as this was

and is still too often designated by the term "herpes exedens."* But they often occur in other parts of the nasal cavity, where they are less obvious; and the insidious latency with which they commit extensive ravages is sometimes very extraordinary. A great part or the whole of the septum narium may be destroyed without its even being discovered by the patient or by his friends. The chief complaint which is observed is a stuffing in the nose and head, which at length proceeds so far as to alter the voice. This is generally attributed to cold or catarrh. It is always accompanied by a foulness of breath, which might lead to an investigation of its real source; but this is attributed to worms by the patient's friends; for it is to be observed that this internal lupus occurs almost always in children under twelve years of age.

Its insidious character we have seen strongly illustrated in some cases that occurred in dispensary practice, particularly in two observed by the author's friend, Mr. Smyly. A child about three years of age was brought to the dispensary by its mother, who asked for some worm medicine to give it. She said that the child's general health was tolerably good, but that she had a habit of picking her nose, and she was certain that worms was her ailment from her foul breath. Her nostrils were examined, and it was found that the septum was quite perforated by a lupoid ulceration, which reached nearly to its anterior extremity, and extended backwards so far that its termination could not be discerned. Mr. Smyly applied a strong solution of nitrate of silver to the edges of the ulceration, and enjoined that the child should return frequently to have it treated with the necessary vigilance. She did not return, but was met accidentally some time afterwards by Mr. Smyly, who examined the ulceration anew, and found it stationary. She did not go back, she said, because there was nothing the matter with her nose. She had been brought to an apothecary who gave her medicine for worms, and assured her that this was the whole origin of her complaint. The details of the other case are so remarkably similar, that it would be needless to recount them. Superficial examinations in such cases will often betray the medical practitioner into deep error. We were impressed strongly by the above facts with the necessity for circumspection. In another case of this internal lupus which occurred to the author last summer, in a girl of fourteen years of age, the voice became completely changed into a nasal tone, and a curious convulsive heaving of the respiratory muscles took place during sleep. A constant coryza, with some fetid discharge, led the author to suspect lupus of some part of the nasal fossa, although nothing could be discerned by inspection. It has lately made its appearance at the root of the nose near the lacrymal sac on each side, and confirmed the suspicion entertained of the source of the disease. We notice it for the purpose of calling attention to the effect which the disease appeared to have on the breathing during sleep.*

2. *Lupus with hypertrophy.*—This form agrees with the first in many points, but its progress and its results are different. Like the former, its seat is frequently the nose, but it does not affect in particular the alæ and tip. It often occurs at its upper part between the eyes and on the forehead just above it. The angle of the eye and the cheek beneath it are not unfrequent localities. It may, however, occur on any part of the face, and, according to Biett, even affect the whole face. It begins likewise with tubercles, but they are not like the round hard bodies of the former species. They are rather soft, ill-defined rugosities, having a purplish hue, which spreads from them to the surrounding skin until a circumscribed patch of the latter presents this colour. No open ulceration takes place in the tubercle, but if any single one be watched, it will be found gradually to disappear, leaving a slight furrow behind. This takes place partly by desquamation from the surface, but chiefly by an interstitial absorption going on in the body of the tubercle. Whilst this process is going on in one tubercle, others are growing beside it, and in their turn they undergo the same imperceptible destruction and cicatrization. At the same time the whole unhealthy patch of skin becomes swollen, and presents a peculiar indolent aspect and doughy feel. When this tumid state of the skin goes on to a certain extent, the tubercles are no longer prominent, but the depressions left by the cicatrices are more evident. The base of these often exhibits a white creamy streak, con-

* This name was employed before proper limits were given to cutaneous nosology. To continue to use the term herpes or herpetic in the present day in any other than the vesicular disease so called, only tends to confirm error.

* This singular effect certainly depended on the disease of the nostrils, for the lungs were ascertained to be quite sound by a careful stethoscopic examination. The breathing was performed quite naturally during the day, but the moment sleep came on, the respiratory muscles were thrown into a kind of clonic convulsion, which increased with the intensity of the sleep. The writer was called twice to witness it for the purpose of getting further light as to the nature of the disease. Two things struck us as of peculiar physiological interest in considering this spasmodic action of the muscles of respiration. First, its occurring only during sleep, and secondly, its being confined to one side. The following explanation occurred to us:—the spasm was remotely caused by the want of free respiration. The purely voluntary muscles withdrew their assistance during sleep; and the instinctive respiratory muscles having then more to do, they were easily thrown, in a weak irritable child, into spasmodic action. The spasm having for its end apparently the perfect freedom of action of the muscles of one side, and this the opposite side to which the obstruction existed in the nasal fossa, we could not help seeing an analogy between this and the cases where, an obstruction existing in one lung, the patient instinctively lies on the diseased side, to leave the muscles of the sound side perfectly unrestrained in the respiratory motion. If this be a true analogy,—and we were persuaded, whilst considering the case, that it was,—the obstructed state of one of the air passages of the nose produced a sympathetic effect on the lung and the muscles of respiration of one side,—a striking illustration of the sympathetic consent which subsists between the various parts of the respiratory apparatus.

trasting with the purple colour of the tubercles, which lie generally on each side of the cicatrices. When the disease then is of some standing, it presents the appearance of a swollen circumscribed patch of the skin, of a violet colour, and in this area there are spots of a deeper hue, denoting the surface of the tubercles, and white marks, the cicatrices of tubercles which have disappeared under the slow process before mentioned.

This form, although also a very chronic malady, spreads more quickly than the first; its manner of extending its limits is the following. On the edges of the morbid surface flat tubercles arise, similar to those by which it at first commenced; their destruction is effected by the desquamation before mentioned, while those inside the area, of an older date, are removed by the interstitial cicatrization. By this double process much destructive change takes place in the tissue of the part affected, for although there is no open ulceration, and there seems to be an actual hypertrophy of the skin, the latter has lost all the characters of healthy skin. It is not painful even to slight pressure. It evidently extends to the subcutaneous cellular tissue; indeed it would appear from feeling it, that most of the deposit which constitutes the swelling exists in the latter. This enlargement presents to the touch something of the feeling of elephantiasis; and Biett relates a case where the swelling of the face proceeded to such a degree as to present the appearance of the most frightful form of this disease, with the additional circumstance of the livid hue proper to lupus. Such an excessive tumefaction is, however, a very rare effect of the disease.

It may continue for years without producing any serious consequences of a constitutional or of a local nature, save the existence of the morbid state of the skin just described. Of itself it has not the least tendency to healing. If it does not go on increasing, it remains inert for an indefinite period. It appears to be much more under the control of internal medicine than the former species. When it begins to yield to the action of any remedy, the livid patch of skin, and particularly the tubercles, shew signs of an unwonted activity by becoming a little hot and painful, and the colour changing to a deeper red; the hypertrophy then gradually diminishes, and the skin slowly recovers somewhat of its own suppleness and texture, but it never returns entirely to its original state. Its cure has been brought about by the accidental occurrence of an erysipelas, attacking the skin beside the lupoid patch. The encroachment of the inflammation on the morbid structure roused the torpid state of the latter, upon which a new and healthy action followed, which removed the disease.

We must here notice a form of the disease in which this second species is complicated with the first. It is as frequently met with in practice as the second form, and is more difficult to deal with, because we have not the same hopes from internal remedies, which are sometimes successfully employed in the latter; nor can we use the local escharotics with the same prospect of advantage as in the first form, where the disease is more circumscribed. When the affection is of this compound nature, it begins with a tubercle of the first species, which becomes covered with the crust, as before described. A very ordinary place for its commencement is under the lower eyelid, and here it produces very serious effects by the destruction which sometimes ensues. Tubercles of the character of the second species make their appearance at an indefinite period after those of the first have been going on, and the livid hypertrophy of the skin accompanies it. Here, then, the two kinds of lupus already mentioned simultaneously exist and modify each other. The deep ulceration of the first kind is sometimes cicatrized by the hypertrophic action which accompanies the second species, but still new tubercles from which become encrusted and have the ulcerative character in the adjacent spots. This is the course of a case at present under the author's observation. In a woman aged forty-five, a tubercle of the first species appeared at the angle of the eye; it formed crusts and ulcerated during eight months, when others of a softer nature and more livid colour sprang up beside them; in its progress it reached the edge of the nose, and here took on the character of the hypertrophic lupus; but there always remained one of the tubercles with the crusts and the deep ulceration of the first species;—the disease having spread across the nose, and in one spot sunk so deeply in it that the mucous membrane became affected. About fifteen months after its commencement it developed itself on the hard palate and spread towards the velum. A perforating ulcer, which succeeded to a hard tubercle of the first kind, is now nearly closed by the cicatrization which is going on around it. This case affords a good illustration of the kind of affection which we describe as a combination of the first and second species. The double character of ulceration in depth and hypertrophic cicatrization was evinced both in its first development under the eyelid and on the nose, and in its posterior eruption on the roof of the mouth.

Besides this combined form of the malady, the first and second form may exist separately at the same time. Whilst the hypertrophic lupus is manifested on the forehead or the cheek, the eroding species may be pursuing its course on the alæ or tip of the nose. It is sufficiently common also,—and we should have mentioned this before, as it occurs not infrequently in the first form,—to find pustules of impetigo in the neighbourhood of the lupoid patches. A crop of these impetiginous pustules often form scabs across the nose, while the tip is engaged with the more intractable lupus; but generally there are observed but a few scattered pustules in some locality adjoining the latter, as, for instance, on the nose, lip, or cheek. This complication of lupus has given occasion to some writers to make use of the term impetigo erodens.

3. *Superficial lupus.*—The third form of lupus is that which ulcerates superficially. Biett de-

scribes this species first; and were we to classify the species of this disease according to the comparative frequency with which they occur, we should have followed his example. We have, however, doubts whether this species can in reality be regarded in the light of a variety of the true lupus. It appears to us to differ very widely from the first species, the real *noli me tangere*, which, as we have before stated, is the true type of the disease. It has, indeed, considerable affinity to the second form in external characters, but we think it generalizing too much to consider it as congenerous with the lupus of the nose. As the points of resemblance which it bears to the second form may induce some to regard the latter as a kind of link connecting this superficial ulceration with the first form, we shall give its description here, and superadd some considerations developing our views of its nature.

The history of this third form is not so uniform as that of the last; the superficial destruction which is essentially its character arises variously and proceeds in different ways. The variety which allies it to the second species originates by tubercles, or rather tuberosities, in the skin, large and soft, and differing little from the surrounding parts in colour. These remain for a long period indolent, but as they increase in size, and grow beyond the skin's level, they assume a dusky livid colour, which spreads to the adjacent skin for a considerable space. Ulceration at length commences on the surface of the tuberosities, and as their bases have become by this time nearly joined, as the ulcerative process spreads, it presents often, for a large extent, but one continued surface. A thin ichor is secreted by the surface, which sometimes concretes on the edges into closely adhering scabs; but these are not like the solid crusts which cover the tubercles in the first species. The ulceration has a great tendency to extend its ravages, and in doing so it does not spread by direct absorption of the skin, but by the renewed production of these tubercular indurations which had originated the disease. A circumstance which is remarkable in its history is this—that often, while ulceration breaks out in the new tuberosities, it closes up in the old places, and in this manner it has been known slowly to travel over a great space. The cicatrices which it leaves behind are of the most disfiguring kind, but they are not painful unless pressed upon, or when the patient indulges in spirituous liquors, in improper diet, or excessive exercise. If they be situated where there is a depth of soft parts, they are puckered, and evidently engage the subcutaneous cellular tissue. Even under the best directed medical efforts it is a long time before the ulcerative process entirely leaves these cicatrices. There remains generally at the inferior extremity of the cicatrising surface a spot which refuses to heal, and from this the ulceration is ready to spread again if the medical efforts be relaxed, or from very slight causes. And even when they become perfectly healed, they are often the seat of a new outbreak of the disease. In such instances they become deeper and more extended, and resemble very exactly the scars left by deep and extensive burns. If they occur near any of the natural openings, they may produce much impediment by narrowing these in their puckered growth; and besides this inconvenience, if they occur at the mouth they give rise to a very disfiguring aspect by contracting the commissure of one of the lips, and thus destroying their symmetry. These marks are often observed on the face and neck; and they are not less common on the skin of the thorax and the extremities, where they are often of a very great extent.

Marks of a similar description are often met with which have ensued on a very different process. We find on the face and on the extremities cicatrices which have not been preceded by any tubercle or even by any ulceration. The following is their manner of forming. The skin takes on a reddish hue, and appears a little swollen. After a short time, on this morbid part a slight exfoliation commences, and by this process the skin becomes plainly thinned. When this has continued for a certain period, the skin becomes pale again, and even less coloured than the sound surface adjacent to it. It becomes also smooth and glossy, and this makes a difference between the cicatrices which remain after this affection, and those ensuing upon the tubercles and ulceration, in that the latter are more or less puckered. The cause of this difference is obvious. In the affection we at present describe, the superficial layers of the skin are nearly exclusively engaged in the exfoliation; while, as we have seen, the morbid process is much more deeply seated where the scars ensue upon the tuberosities and ulceration.

There is another affection of the skin, of an analogous character, which deserves to be placed in juxta-position with the last variety. In this the deep layers of the skin and the subjacent cellular tissue are exclusively the seat of the disease. It manifests itself by the skin assuming a livid colour, and becoming hard and stiff. This may remain for many months without showing any actual disorganization. At length, probably by the formation of a small abscess arising from the irritation of the sloughing cellular tissue, the destruction which has been going on in the deep parts of the skin is brought to light. From the opening made by the abscess, which is generally enlarged by the practitioner, if he has not originally made it, a large quantity of sloughing cellular tissue of a yellow colour and firm consistence will be discharged. On the dislodging of these sloughs and the use of appropriate dressings, deep cicatrices slowly form, similar to those above described. The few cases of this affection we have witnessed occurred on the leg. We notice it under the head of the superficial form of lupus, notwithstanding that it affects the deep layers of the skin and the subjacent tissue, because it bears an analogy to it in progressing in a horizontal direction. It appears in fact to differ from the variety last described only in affecting the deep layers instead of the superficial.

These are the varieties of the form of lupus which destroy superficially. Doubtless the chronic nature of its progress, the purple colour which generally more or less attends it, and its frequent origin by what we have denominated tuberosities (to distinguish them from the tubercles of the first form), are circumstances which show a seeming analogy between it and the other species, particularly the second; but notwithstanding these, we imagine that those who have given attention to the subject will think that we are justified in doubting the propriety of making it congenerous with the other forms, at least with the lupus of the nose. It appears to have a different constitutional origin; it is curable by different remedies; and it terminates differently. In several cases of this nature which we have observed, it happened in persons who were at one time the subjects of venereal disease. In some others we think it could be traced to that analogous state of the system produced by courses of mercury. But much more frequently it depends on scrofula. In short it appears to us that it is decidedly a scrofulous disease. This idea is rather strengthened than opposed by what we have just remarked as to its sometimes being found connected with a syphilitic or mercurial taint in the system, as it is known that the sequelæ of mercury or of syphilis are easily developed in a scrofulous constitution, at the same time that the latter modifies the nature of the resulting affection. The variety of this third form, which spreads by the superficial ulceration of the tuberosities, is evidently the same with the so-called scrofulous ulcer. Biett does not recognise this in terms, but we apprehend that it is easily to be collected from his description of the affection. It is without doubt to this species that Rayer alludes in his list of synonyms, where he enumerates "ulcères scrofuleux, scrophule vulgaire vasculeuse." But it appears of still more importance with respect to the nature of this superficial ulceration to establish its identity with the esthiomenic or corrosive scrofula of M. Lugol, in which the iodine has proved such a powerful agent. And with regard to this we know that some practitioners have been successfully employing this remedy against it without being aware that there existed any doubt as to its scrofulous origin, or that it was included under the name of lupus in the works of writers of authority.*

The success of iodine in this superficial ulceration, while it seems an evidence of its scrofulous nature, may be regarded as one criterion of the difference of its nature from the two former species, for against these it is found to possess little or none of the virtues which have given it such a high place in scrofulous affections. Where we state our opinion of the relation which subsists between the two first species and scrofula, it will further appear what connexion this third form stands in with the other two.

Having thus described the phenomena and course of the different species of the disease, we have here to mention some particular accidents which its destructive nature sometimes gives rise to from its occurring in certain localities. One of these, which has attracted much notice from its disastrous consequences, is the destruction or eversion of the lower eyelid. This occurs in the first form, or probably still more frequently in that combination of the first and second which we have described. One or two tubercles having formed just under the eyelid, their ulceration perforates the conjunctiva, and goes on to destroy a great part or the whole of the lower lid. Besides the shocking disfiguration which this produces, more serious effects follow. The protection which the palpebræ afford the eyes is by this interrupted; the tears escape through the broken surface instead of by their natural channel; and inflammation of an unmanageable kind ensues, which causes loss of sight on this side by producing opacity of the corneæ. The puckered cicatrices sometimes form under the lid, drag it down, and thus produce its eversion. Epiphora and its consequences follow here as inevitably as where the lid is destroyed, if it be not prevented by surgical means, which are more available in this case than the former.

When the nares, the velum, or the palate are the seat of the disease, the voice is always more or less altered. It is only, however, when the destruction is very great that the articulation is entirely lost. Partial deafness is sometimes produced when the disease affects the Eustachian tube, as occurred lately in a case which happened to the author, where the disease spread from the nares and velum. When the disease has its seat in the superior parts of the nasal fossa, it may produce destruction of a fatal nature. Lallemand* is of opinion that in many of the cases recorded by old authors, where abscess of the brain broke and discharged pus by the nostrils, the latter was produced by caries of some of the bones forming the roof of the nares. This is a situation in which lupus occurs more frequently than is at all supposed. The considerations which this writer offers in proof of his positions, are, we think, quite satisfactory, and apply to lupus; for we are persuaded that caries of the bones of the

* Confusion must daily occur as to this malady from our inattention to precision in names. Rayer's synonyms are, "Dartre rougeante, herpes esthiomenos (herpes exedens, *Biett*), ignis sacer, formica corrosiva, lupus vorax, noli me tangere. Scrofule vulgaire vasculeuse, ulcères scrofuleux, &c. Every day adds to these, for it would appear that every one relating a case considers that former appellations may be disregarded, and that he may change or add according as some peculiarity of the case or his own ingenuity supplies him with new terms. Thus, in the account of two interesting cases of this superficial ulceration detailed in the Medical Gazette, December 15, p. 367, they are denominated "strumous phagedenic ulcers." A copious supply of names is a proof that the subject has not been reduced to clear limits; but adding to them of *libitum* only increases the difficulties, and in fact virtually does away with the utility of nosological arrangement altogether.

* Lettres sur l'Encéphale et ses dépendances.

nose is much more frequently the effect of this disease than of all the other causes to which it might be referred. The occlusion of the nares has been already referred to. This event may occur even in the early stages, where the destruction commences by the falling of the crusts from time to time, and all throughout its course there is a tendency in the swollen edges to unite by cicatrization.

Such accidental results of lupus are amongst its most important consequences. Some of them are rare, but it appears highly necessary to know beforehand the tendency to their occurrence, that we may be watchful when the disease exists in any locality exposed to them, if by any means we may be able to devise a treatment calculated to arrest them ere they proceed to such disastrous effects.

There is in lupus little or no sympathetic disorder of the system: it is quite unaccompanied by fever. The gastro-pulmonary mucous membrane, which is so frequently either primarily or secondarily affected in other diseases of the cutaneous tissue, is very rarely affected. The disease may exist for several years, and in this period effect a great destruction, while the general health retains a perfect integrity. Biett mentions that in cases of extreme malignity, where its ravages proceed unchecked by nature or by art, death has been known to happen from the supervention of a chronic gastro-enteritis attended by a slow fever and colliquative diarrhœa. This termination has, however, been so rarely observed that it may be doubted whether the internal affection and fatal result should not be considered as accidentally occurring during the progress of the lupus rather than depending on it. However this may be in certain peculiar instances, it is a well ascertained character of the disease that its ravages give rise to a remarkably trivial amount of general disorder, although it usually happens in individuals of weakly constitutions.

Causes.—It is very rare to meet any of the varieties beyond the age of forty, so that it is to be considered a disease of youth. Between the ages of six and sixteen it is more common than at earlier or later periods. It appears that the female sex is more subject to it than the male. This has been satisfactorily established to us from the observation of a considerable number of cases. It is also a fact that it is particularly prone to occur in those weakly lymphatic habits in which the period of puberty arrives late, and the menstrual function is feebly performed. Authors assert, and we believe experience proves it to be true, that it is much more common in the country than in town, and in places where vegetables and fruits form the chief food. In the city of Dublin, where the poor are inured to poverty and uncleanliness, it is very commonly met with, although some of the worst cases which are found in the hospitals come from the country parts of Ireland.

Pathology.—The predisposing causes are important elements in considering the pathological nature of lupus; and in treating of the latter we would be understood as particularly referring to our first two species, for we regard the third, as we have before stated, to be a true scrofulous malady. We must consider also that Rayer had in mind this form of the disease exclusively, when he asserted that nearly all the individuals in whom the tubercles of lupus occur have been known to be subject to scrofulous affections in their youth, such as glandular swellings in the neck, groins, or axillæ; for such an incontestable proof of its scrofulous nature can refer only to the superficial ulceration, and can by no means be truly predicated of the first two species. But, although this be the case, we cannot overlook the fact, which is evident from considering the last paragraph, that the state of constitution in which scrofulous diseases manifest themselves, and the circumstances which predispose to their development, are also particularly favourable to the production of lupus. On the other hand, it is also certain that the latter considerations are quite insufficient to establish it as a scrofulous disease, as it is found in persons of quite the opposite diathesis, and more particularly because it resists the remedies which are found so beneficial in scrofula. It was for a long time reckoned to be a cancerous disease; and it would be wrong in a discussion concerning its nature to omit mentioning this opinion. The progress and result of lupus give some colour to the notion of its affinity with cancer. Such loose resemblances, however, have never been sufficient to allow accurate pathologists to recognise their identity. Many of the oldest physicians already marked some of the distinctions between them. Celsus, as we have seen, distinguished them with particular accuracy. Wiseman, and others of our early writers, also laid down excellent rules for making a diagnosis between them. Without entering here particularly into their differences, we content ourselves with remarking that the symptoms, both local and constitutional, are quite different in the two diseases; and that lupus is as decidedly distinct in character from cancer as it is from scrofula.

But notwithstanding that it is impossible to identify it on the one hand with scrofula, as some writers do, or to reckon it as a form of cancer, it seems to us that in searching for its true nature, it may be profitable to recollect the frequency of its occurrence in scrofulous constitutions, and not to lose sight of the circumstances in which it resembles cancer. Now, with regard to the latter, it may be remarked that the hypertrophic state of the skin in our second species is not unlike the deposit of a new tissue, and also that in our first, which we have often laid down as the type of the true lupus, the ulceration is as unsparing in its destructive course as cancer. Besides the true cancer, there are cancerous ulcers which come still nearer the lupus of the nose in character, and cancerous tubercles which differ indeed from the tubercles of lupus in some important

particulars, but still they appear to shew an approximation in the character of the two maladies. Dr. Jacob has given the history of three cases of an interesting kind in the fourth volume of the Dublin Hospital Reports. Notwithstanding his arguments to prove that they are neither cancer nor lupus, it appears to us that their description answers perfectly to the character of the latter carried to a great extent. At that time the history of lupus was comparatively but little known, and scarcely any good account of it was to be found in books. Ravages to so great an extent are seldom found in this situation resulting from lupus or even from cancer, but the description answers so well to the former disease that no doubt exists in our minds but that it was really lupus.

Were we called on to declare our opinion of the essential character of lupus, we should say that it is an intermediate pathological state between cancer and scrofula, partaking somewhat of the nature of both, but constituting a state in which, by the blending of these two diseases, many of their peculiar characteristics are lost. In the lupus of the nose the double nature appears so proportioned as for each to neutralize the other more perfectly than in any other of the forms; and departing from this on either side, pathological gradations can be traced which degenerate to true cancer on one side, and on the other, passing through the hypertrophic and superficial lupus, lose themselves in scrofula. Besides the considerations offered above in support of this view of its nature, we consider that it is much strengthened by other circumstances, as, for instance, the action of iodine, carbonate of iron, and arsenic on the respective varieties. The first of these is found to possess signal virtues in the third form, which is a scrofulous disease; it is much less useful, if it have any effect, in the second form; and it is quite inert in the first. Whatever powers the arsenic and carbonate of iron possess are almost exclusively available in the first form; and it may be remarked that, while they have no efficacy in scrofulous diseases, they sometimes are found to palliate affections of a cancerous nature. Although this view of the pathology of lupus has not, as far as we know, been advanced before, we put it forward with some confidence, as we think it accords with the facts which are known on the subject. But the question demands much ulterior discussion, in accordance with that cautious spirit of laudable scepticism which the modern cultivators of medical science have been taught to use in weighing the worth of pathological doctrines.

The influence which a syphilitic taint in the constitution has in the production of lupus acts in two ways. One, the most obvious, is, where it gives rise to a secondary syphilis, assuming the character of lupus, but to be distinguished from it, as we shall immediately point out. Another effect is to predispose to the true lupus. How far these may be really differences only in degree of the syphilitic infection of the constitution we will not pretend to say, but in practice the two states occur. A striking case, which the author has observed, will illustrate our meaning. A woman, aged forty-seven, came from the country with an extensive lupus of the nose and of the palate; it was that combination of the first and second species which we have described above. She had had primary venereal symptoms seventeen years before, but no secondary disease of the skin, throat, &c. ever followed. She has borne eight children since, of which the first six died either before or immediately after birth. This was the way in which the disease showed itself. She herself attributed the death of her offspring to the contagion of syphilis, and there is no doubt but that she was right, as two of them came away in the putrid state, which is not an uncommon effect of this virus on the fœtus in utero. Her two last children, however, lived and enjoyed good health. The lupus has now existed two years, and has never exhibited any of the external characters of the venereal affection, which it is sufficiently easy to distinguish. This, then, is an instance where the original syphilitic taint predisposed to the formation of lupus, without impressing on it the marks which denote it to be a form of secondary syphilis.

A vague opinion was once entertained that the scanty pus which the ulcerating tubercles supply is contagious, and that it propagates the malady on any part of the body with which it comes accidentally in contact. This notion survived the old error which was so long a time prevalent in the schools, that all pus was corrosive; for even when it became established that purulent matter was a bland instead of an irritating fluid, exception was made in respect of that formed by some kinds of ulceration, and lupus was amongst the number. In fact, it is still imagined by many that the pus which oozes from the ulcerating tubercles is the means by which the slow destruction is effected. That it produces any specific effect as a direct chemical corrosive, is, however, no longer tenable; nor can it even be admitted that any considerable action is to be attributed to whatever irritating properties this discharge possesses. If it drop from the nose upon the hand or arm, it produces no perceptible effect. A patient with lupus of the nasal fossæ, in whom we had an opportunity of confirming this, yet complained of a smarting from it as it trickled through the nose. While, then, it is denied that the pus has any specific agency in the destructive results of this disease, it must be supposed to maintain more or less irritation on the ulcerating surface, as is the case with common ulcers which discharge an ill-conditioned sanies.*

Diagnosis. — It may be easily imagined

* See the sixth number of the Edinburgh Medical and Surgical Journal for an account of a curious case related by Dr. Grenville, under the name of "Herpes exedens vermiculatus," in which a very copious discharge which an ulcer furnished was proved by experiment to possess the power of generating the same ulcer in a part inoculated by it. On microscopically examining the pus, it was found to be full of animalculæ of various shapes and sizes.

that the diagnosis of a disease of such obvious characters as lupus will be made with facility. This will be rendered more certain if a clear knowledge of its different species and their stages be kept in mind. But, as it has been often confounded with other diseases, it will give us much confidence in our diagnosis to be forewarned of the affections which might lead us into error. We shall, therefore, point them out briefly with their diagnostic marks.

The pustules which constitute the elementary form in acne are succeeded by round indurations, which have a deeper purple colour than the surrounding skin. When these collect in clusters, as they sometimes do, near the point, or on the alæ of the nose, they have some resemblance to the tubercles of lupus in their first stage, and have been mistaken for them. This error will be avoided by attending to the different nature of the tumours in question. In acne they have been preceded by pustules, some of which are probably still to be met with in parts where the affection is least advanced, and besides this there exists round the base of the tubercle in acne a dull redness from which the lupoid tubercle is quite free, as the latter makes its way slowly over the skin without any marks of inflammation; for the violet discoloration which precedes it does not deserve that name. The hypertrophic lupus, when situated on the nose or forehead, is also not unlike acne, but the history is very different, and even a slight attention will discover the cicatrices which lie between the tuberosities in the former, and thus at once distinguish it.

It might be sufficient to mention the possibility of mistaking the crusts which form in certain kinds of impetigo and porrigo for lupus; but notwithstanding their general dissimilarity, the mistake has been made. The mind is preoccupied with the idea of lupus in every incrusted appearance which is met with on the alæ nasi or its immediate neighbourhood, and these pustular affections sometimes occur here in a very chronic form. In examining the case then, we must search for the primitive form of the eruption which has furnished the crusts. Small pustules will be more or less obscurely detected, with inflammation in the skin diffused between them, if these belong to porrigo or impetigo. Moreover, the crusts which might cause the mistake are quite opposed in their character to those of lupus, being irregular, soft, and easily detached; while in the latter, as we have frequently had occasion to state, they are of a firm consistence, and confined for the most part to the surface of the tubercle which forms them, and to which they generally adhere with great tenacity.

It is stated by authors that the elephantiasis of the Greeks is liable to be confounded with the hypertrophic form of lupus. But the tuberosities which occur in elephantiasis are round, knobby, and of a dusky sallow or fawn colour, which overspreads the whole face. If even they be confined to the face, they spread over it here and there, not affecting (as this form of lupus) the arrangement of a circumscribed patch. In some aggravated forms of this disease the tuberosities ulcerate, and furnish black crusts, which might impose on an unwary observer for lupoid incrustations; but tuberosities will be found, which have not gone on to ulceration, presenting the marks of distinction before laid down. This malady, besides, is rarely confined to the face, and when it has made some progress, it is attended with constitutional symptoms which do not belong to any form of lupus. Finally, its great rarity in this country prevents us from being often put to the necessity of making the comparison, while our knowledge of their points of resemblance will keep us from being off our guard.

Cancer is an affection which must be carefully distinguished. Whether the affinity which we suppose to exist between them be grounded in fact or not, it is of the utmost practical importance to separate the two diseases when we have to consider them with regard to treatment. Some cancerous tubercles commence with a warty tubercle, having a considerable resemblance to incipient lupus. It will, however, be observed that they are for the most part solitary, while the lupoid tubercles are scarcely ever so, at least for any length of time. Their bases too are deep-seated, and attached by a root which ramifies in the surrounding tissue, which is not the case in lupus. The most striking difference is the pain, which, as we have seen, is nearly totally absent in the beginning, and indeed throughout the whole course of lupus. Cancer is the seat of deep lancinating pains almost constantly, which are easily increased by improper applications, and permanently removed by none. Without multiplying points of difference, one more, with those already recited, will be amply sufficient to diagnosticate the two maladies. The circumstance to which we allude is the age of the individual. We have seen, with respect to lupus, that it is a disease of youth; but cancer is seldom or never met with below the age of forty. Biett is desirous of appropriating the name *noli me tangere* to cancerous tubercles, but at the same time insists that it should be carefully distinguished from lupus. We have not adopted his suggestion on this head, because we think it would only serve to confound the affections, which we are desirous with him to keep separate. There has always existed much discrepancy between the French and British ideas of cancer, and it would undoubtedly only serve to increase it were we to assign to this disease a term which has been hitherto uniformly appropriated to lupus.

Syphilis assumes the guise of this malady, as it does that of most other cutaneous diseases. We shall not here discuss the important theoretical question, whether we are to consider diseases of the skin produced by a venereal infection of the constitution the same actual diseases as when they occur unconnected with any constitutional taint, or whether we are to regard them as a class *per se*. For the exposition of this problem we refer to the article Syphilis. It is, however, of undeniable importance to have the means of distinguishing ordinary lupus from that of venereal origin.

The crusts which form in the syphilitic affection are much darker-coloured than those of the genuine lupus, and the surrounding skin is of a dark copper hue. The tumefaction which more or less attends the real lupus is absent, and the crusts are dry and permanent, and very seldom give place to any open ulceration. If the latter do ensue, it is to be recognized by the well-known characters of the syphilitic ulcer which infallibly attend it, viz.—the deep centre, and the raised, hard, and swollen edges. We have lately seen a case of syphilitic rupia, situated on the point of the nose, which at the first view we mistook for lupus, but on a little closer examination we found that the only point of agreement was the situation of the scabby crust. It was dry, hard, and flat, adhering to the tip of the nose with still greater tenacity than the crust of lupus. There were present also symptoms of venereal affection in the throat, and the patient had had venereal iritis. These were quite decisive of the question in themselves. In investigating doubtful cases, these additional constitutional symptoms should always be sought for, and the history of the disease obtained. But as to the latter, it must be remarked that negative evidence is not to be held decisive, nor is it even of much value if the other marks be present, as it is well known that patients will often refuse to admit the possibility of their having had syphilis, while undeniable proofs of its existence are manifest. There is a syphilitic affection which commences in the cartilages and bones of the nose, and having destroyed them by caries, attacks the soft parts. The bones having yielded, the nose becomes flat, and the alæ expanded. In this state the affection might be confounded with the hypertrophic lupus, for the root of the nose becomes somewhat swollen and livid; but it will be seen that this description differs from lupus in its progress, its appearance, and its results. It will be unnecessary to compare them more minutely.

Treatment.—The treatment of lupus has from the earliest periods of medicine been an object of great importance in practice. It does not put the life of the patient in jeopardy, but the hideous ravages which it effects, and the sure though slow progress with which it marches, render it a formidable disease. Yet intractable though it be, its sanability by the efforts of medical art is perfectly ascertained. Cases are even to be met with where a spontaneous cure has taken place by the cicatrization of the surface. Where this does occur, it generally belongs to the first form, and the cicatrix is perfect and permanent. There is much less security in the cicatrices of the other species. When the malady is left to itself, such a termination is very rare, and must be regarded as the exception; for the destruction seldom ceases till the nose is nearly level with the face, and then, which is a remarkable circumstance, it sometimes does show a tendency to stay its ravages. In many cases, however, it continues its progress on the cheek to a fearful extent. Experience teaches us, on the whole, to employ the means in our power sedulously and with vigour, and encourages us never to lose hope of arresting its progress; but it also lays before us the difficulties of a most obstinate disease, and cautions us against being too sanguine in our prognosis.

The treatment resolves itself, in this as in most cutaneous affections, into general and local means. We have seen that the system shews but little sympathetic action in this disease; we should not, therefore, *a priori*, expect that internal remedies would avail much; they form a part, however, of every well-digested plan of treatment. In some cases their efficacy is more considerable, and many cases will occur where they will demand our first and most particular care. On the other hand, the disease will be found in some patients who are in such good general health that it would be inexpedient to lose any time in the exhibition of general remedies. In these the local means will form the main resource, and whatever others may be employed will be directed rather to obviate particular symptoms than to make any impression on the disease through the constitution.

a. Internal remedies.—When a cachectic state of the system accompanies the malady, if its cause be recognized we must apply all our resources to remove this. If this ever stands to lupus in the relation of cause and effect, it is where it happens in the poor, when indigence exposes them to unwholesome and insufficient diet, with cold and uncleanliness. The low torpid state of the system which these induce will be evidently best obviated by reversing as much as possible the condition of the patient, substituting a light animal diet, and all the comforts which hospitals and other public or private charities afford. If we can detect any diseased action in the chylopoietic viscera, this will receive a particular attention; for whether this be regarded as a cause or merely as a concomitant effect, no favourable change in the local malady should be anticipated as long as it remains. Gentle aperients and tonics will tend much to the gradual improvement of the system. Occasional doses of the pilula hydrargyri and pilula rhei composita will be a useful remedy when the liver is found to perform its functions torpidly. The old authors, who looked so much to the state of the blood in pathology, attended much to the use of such remedies, and their practice in this disease is not thrown into the shade by any in the present day.

If the individual be obviously of a scrofulous habit of body, he should be kept steadily under the use of appropriate internal remedies for some time. This should be done whatever be the form of the malady with which the patient is affected. But, as we have already stated, the superficial lupus will be the form usually met with in such constitutions, and therefore that for which an anti-scrofulous treatment is particularly calculated. For the remedies proper to be used, we refer to the article Scrofula. We may mention here, however, that our experience of iodine has inspired us with great confidence in its efficacy.

We have seen striking amelioration produced by the use of the solutions which Lugol recommends. The proto-ioduret of mercury is one of the preparations of iodine which has proved of most utility. The ulceration has been observed to heal under its use with a rapidity which is quite foreign to its indolent character. The fourth part of a grain was given twice a-day to a girl of fifteen years of age, who had a large patch of deep ulceration with tubercles on the front of the leg. After ten days of its use the mouth became affected, contrary to the intentions of the physician, and in three weeks time an ulceration which had been forming a year and a half was almost cicatrized. We should add that the iodine was used externally also as a lotion, and in cataplasms. Its efficacy, however, appears to be confined to the third form, as whatever trials have been made with it in the lupus of the nose, or even in the hypertrophic form, have quite disappointed expectation.

The muriate of barytes was commended by Bateman for its efficacy in promoting the resolution of the tubercles. It does not appear to what species the latter belonged in which he employed it, but later authors object to its use, that it is a dangerous remedy from its energetic action on the stomach. The muriate of lime has been proposed as a substitute, having the same properties, and free from these objections. One drachm of the *solutio muriatis calcis* is to be mixed in a pint of water, of which a table-spoonful may be given once or twice a-day at first. This is to be progressively increased after a few days, till ten or twelve spoonfuls be taken daily. Preparations of iron have been at various times extolled. The muriated tincture and the carbonate are more relied on than any other. The latter, particularly, has been set forward with a zealous advocacy by writers who confounded the noli me tangere with cancer. It is doubtful whether they are entitled to any confidence in either, but as the cases in which they have been reported to have effected a cure were undeniably lupus, they deserve a trial.

Arsenic is a remedy which has been extensively employed, and the authority of most writers agrees in recommending its internal use. It is found to exert considerable influence in checking the progress of the tubercles, and even in altering the character of the ulcerated surface. It is variously administered. It forms the active ingredient of *the Asiatic pills*, a medicine which enjoys great reputation on the continent.* Fowler's solution is the preparation which is most approved of in these countries. This is to be commenced with the small dose of three drops, to be taken thrice a-day: it may be gradually increased to ten drops, but the greatest vigilance is to be observed during its exhibition. (See Lepra.) Practitioners of merit prefer minute doses of corrosive sublimate, carried to the extent of touching the gums, to any other internal means. It would be unprofitable to swell our catalogue by recounting other internal remedies whose effects are more doubtful, and we believe that those above mentioned comprehend all that have gained any merited reputation.

b. External applications.—These form by far the most important part of the treatment, and indeed often constitute the whole of it. It is always in combination with these that the efficacy of internal remedies has been developed, for no one would think of relying on the latter without using some of the local applications which have been at all times the essential therapeutic resource.

The local applications are of two kinds: *first*, those which are intended to exalt the vitality of the part, and thus to promote the resolution of the disease; *secondly*, those which, acting as cauteries, destroy the morbid part, and excite a healthy action in the surface beneath it.

The stimulating applications may be tried where the disease presents itself in the stage of tubercle. The attempt to effect the resolution of the malady will be more feasible in proportion to the earliness with which it is made, and also to the activity which the surrounding skin appears to possess. If the skin shew that the circulation is actively carried on, it will be often useful to apply a few leeches to the neighbourhood of the tubercles before commencing the use of the resolvent applications. Dr. Mac Farlane has experienced the good effects of such a plan, and recommends it in these words: "Sometimes the progress of a lupoid tubercle may be arrested and the ulceration prevented by the application of leeches round its base, especially when the tumour is painful and covered by inflamed integuments. This, followed by evaporating lotions and alterative doses of calomel, will not unfrequently subdue the inflammation upon which the progress of the disease depends, and reduce it to that indolent and chronic state in which friction with an ointment, containing the ioduret of zinc or mercury, may be beneficially employed to promote its absorption." These iodurretted ointments are topical applications of decided efficacy. Besides these, Biett is in the habit of using the ioduret of sulphur, made, as the metallic iodurets, into an ointment, in the proportion of fifteen grains to an ounce of simple ointment. This is to be applied with gentle friction to the tubercles and the skin surrounding their bases. It stimulates the skin powerfully, and has a greater resolvent effect on the nascent tubercles than any other similar application. Rayer objects to its use in this manner that it is apt to produce erysipelatous inflammation of the surrounding skin; but this is an infrequent consequence, and when it does occur is not to be deemed an injurious effect; on the contrary, it has been observed to be a means of dissipating the disease by communicating its sthenic action to the torpid tubercles.* In the hypertrophic lupus

* They contain about one-thirteenth of a grain of white oxide of arsenic, and somewhat more than half a grain of black pepper in each pill.

* See an interesting observation quoted in the Archives Générales de Médecine, t. xxiv. p. 584,

ıe employment of these resolvent ointments is articularly indicated; indeed, in this form ur hopes of cure must depend chiefly on such pplications, aided by an appropriate internal nedication.

When the tubercles are once ulcerated, or hen they are already far advanced towards is point, those stimulating applications are too eeble to be further of any efficacy. There is ne lotion which comes under this head, which ome experienced practitioners still confide in; e mean a solution of arsenic of such a rength as to produce only its specific stimuting effects on the sore, in the hope of changg its action. The solution of Fowler conins the arsenic in the best proportion for this pplication; with this the surface of the tuberles should be sopped twice or thrice a day, hen this method is judged expedient. It s generally agreed, however, that it is the isest practice in such stages to have recourse t once to escharotic applications.

Arsenic is the substance which is almost niversally allowed to be the most suitable scharotic which we have the command of in upus. This has been anciently established, s we find it first on the list of the "*medicamenta aduventia*," which Celsus proposes. ts superiority over the other caustics appears o consist in this, that it produces a slough romptly and certainly, which confines itself o the parts immediately touched by the arsenial preparation. The methods of employing his powerful mineral have been varied by lifferent practitioners. Justamond's application was once a very favourite form. This s made by fusing in a crucible two parts of ulphuret of antimony and one of white oxide f arsenic. The resulting compound, being ulverized, is of a blue colour. Sir A. Cooper s accustomed to use an ointment consisting of white arsenic and sulphur, a drachm of each, nixed with an ounce of spermaceti ointment. le directs some of this to be spread on lint, nd to be applied to the ulcer for four-and-wenty hours, at the end of which it is exected that a black slough will be formed, and when this falls, the surface is to be dressed with simple ointment. Other eminent practiioners employ it mixed with simple ointment lone, rejecting the admixture of any other ubstance to modify its action. When we desire to apply it to indolent tubercles, it is sometimes found that these are covered by a thick uticle, which impedes its action, for the rsenic has scarcely any effect on the cutaneous surface as long as the cuticle remains entire. Some advise that in such a case a small blister should be raised previous to its application; but this end will be probably better answered by mixing some cantharides with the arsenical ointment. Mr. Adams has successfully employed the following ointment:

℞. Unguenti cetacei, ℥ß.

Oxydi arsenici, ʒi.

Emplastri cantharidis, ʒiii. M. fiat unguentum.

He has also found that the callous edges of an old lupoid ulcer, which had resisted other arsenical applications, yielded a slough freely under the use of this for a few days.

Whichever method may be selected for applying arsenic externally, a certain degree of caution will be requisite. It will be prudent to apply it at one time to no larger a surface than a shilling would cover, and having produced in this space the desired eschar, a new portion may, if necessary, be attacked. This way of proceeding is found to be very effective in establishing a healthy action in the new surfaces, as well as to fulfil the end for which it was adopted, that is, to obviate any unpleasant consequences which might arise from spreading the arsenic over a large surface. While it will be prudent to make use of this remedy with that vigilance which our acquaintance with its powerful action on the animal economy must inspire, it is to be recollected that it is a perfectly safe application. All practitioners who have been accustomed to use it testify that they have never witnessed any of its dangerous effects produced on the constitution by its regulated use. There are indeed two cases mentioned by Dr. Mac Farlane, where, being spread upon extensive ulcerations, it was followed by severe inflammation of the gastro-enteric mucous membrane, apparently in consequence of its absorption into the system. These examples are, however, exceptions, and serve rather to exhibit the rarity of constitutional disorder consequent upon its use; but they also shew us the necessity of observing the cautions in applying it which we have suggested.

The arsenical paste is the application which has the most decided caustic powers, and on this account it is by many preferred to the other less energetic escharotics.* In the old cases of extensive destruction the edges acquire a degree of callousness which it requires the most potent remedies to affect; in these it is found advisable to produce a prompt and decided slough with rapidity, as it is found that less energetic means, which act more slowly, only allow of new productions under the imperfect slough, which increase the ravages sometimes to a prodigious extent, of which one of Dr. Jacob's cases is an example.† In these instances and wherever the strongest cautery is required, the arsenical paste may be used. Its employment demands particular caution not to surpass a limited area in its application, as besides the results alluded to in the last paragraph, it almost invariably causes a severe erysipelatous inflammation of the face. This may in some cases be of little consequence, but it must in all

where, during the treatment of a lupus of the nose in the state of tubercles, an erysipelas which was epidemic in the ward, attacked the patient's face. It had been very fatal amongst the individuals whom it had seized, but in this patient it proceeded no further than the face, where it ran its course safely, and at its disappearance brought about the complete resolution of the tubercles.

* The arsenical paste is made by mixing the "poudre arsenicale" of Frere Côme with saliva into the consistence of a paste. This powder consists of arsenic, cinnabar, and burnt leather. (See Rayer's Formulaires.)

† Dublin Hospital Reports, vol. iv.

be prevented from running too high by the ordinary means of leeches and proper remedies. Some habits could not safely sustain this. We should, therefore, confine the use of this energetic caustic not only to the kind of ulceration which requires it, but also to individuals whose constitution will enable them to bear the erysipelas which attends its use.

In cases where the effects of the stronger arsenical applications might be injurious, M. Dupuytren recommends a powder, whose action is, he says, specific, not caustic. It is composed of calomel and arsenic in the proportion of one part arsenic to two hundred of calomel. The quantity of arsenic may be doubled if it be required more active. It is sprinkled directly on the ulceration by means of a dossil of lint, or made into a paste with thin mucilage. It is to be left on till it falls away of its own accord, and renewed several times till it produce a new action in the ulcerated surface, and a tendency to cicatrise. This is found to be a very suitable application in children, females, and individuals of a delicate habit and irritable skin. Dupuytren applies it to unhealthy cicatrices, having in the first place produced a new surface by cauterising them, and this appears a very excellent method of employing it. Although this powder is much milder in its action than the other arsenical applications, the same cautions are to be observed in its employment, for whatever is to be apprehended from the absorption of the mineral, may as readily occur from this as from the more concentrated preparations.

The nitrate of silver and the muriate of antimony, which are so commonly used in other ulcerations, seem to be superseded by the arsenical cauteries; but the former does not deserve to be neglected; we can answer for its efficacy in changing the unhealthy surface. The concentrated nitric acid is a favourite escharotic with some experienced men. In that variety of the third form where the deep layers of the skin and the cellular membrane are the seat of the destruction, it is amongst the best applications for causing separation of the sloughs and cicatrisation.

A preparation, called "le nitrate acide de mercure," is in high repute at the Hôpital St. Louis, from the success with which MM. Richerand and Cloquet employ it in producing healthy cicatrices. It is made by dissolving a drachm of the proto-nitrate of mercury in an ounce of nitric acid. The ulcerated surface is to be touched with it by means of a dossil of lint, and some scrapings of lint moistened with the same solution to be also laid upon the part. Its immediate effect is very painful, but this does not continue. It is also an excellent application for the soft flabby edges of unhealthy, half-formed cicatrices, which, we should remark, are always to be treated with the same energy as the open ulcer; they are certain otherwise to relapse sooner or later into this condition.

The actual cautery was formerly much esteemed in this malady, but now is but seldom employed. We believe, nevertheless, that it is sometimes amongst the best methods for obtaining a satisfactory eschar that we possess. It should never be employed, however, in lupus of the nose, for the cartilages become affected by a bad kind of inflammation and swelling from its use, which increases the evil. Their defective vitality is not capable of producing a slough. But where the disease occupies a different situation, it is still used with much success.

These methods of destroying the diseased surface are generally preferable to extirpation by the knife, which has, however, been practised with the most favourable result.* Cases may happen where it can be had recourse to, in which the mineral escharotics are inapplicable, as, for instance, where a solitary tubercle is situated very near the eye. It is of particular importance to arrest its progress as soon as it can be recognized in this situation; but the cauterising substances would be dangerous applications in the vicinity of the eyeball; so that here, if other things permit it, excision by the scalpel will be the preferable practice.

In employing the escharotic applications, it must be a rule with the practitioner to persevere in their use till the whole of the morbid structure is destroyed. In order to effect this, it will in general be required to repeat them several times, for when the eschar falls, although the new surface present a healthy aspect, the cicatrix may form imperfectly, and afterwards break out again into open ulceration. To diminish the chances of this event, it will be wise not to trust to the destruction of the mere face of the ulcer, but rather to repeat the cautery, to procure a deeper and healthier surface, which will give us better confidence in its cicatrisation. During the progress of the latter, attention must be frequently given to the opening of the nares, as their edges have a great tendency to unite during this process. It is sufficient here to revert to the frequency of this accident, and in individual cases the ingenuity of the practitioner will suggest means to promote or to remedy it.

When the cicatrisation is accomplished, every means should be put in practice to fortify the constitution against the risk of a relapse. To this end it has been proposed to insert an issue or seton in the nape of the neck. This would be, doubtless, particularly in young persons, a wise precautionary measure. It may, however, be stated in general, that if the remedies be steadily persevered with till the malady be quite removed, the cicatrices will stand sound. The Tagliacotian operation has been performed where the nose had been destroyed by lupus. Fears were entertained that the skin taken from the forehead for the new nose would not form a junction with the old cicatrized edges cut to promote union by the first intention, and that the dormant malady might be reproduced by the operation: the union was, however, completely established,

* Nouveau Bibliothèque Médicale, t. iv.

and the cicatrix maintained its integrity, because the cure had been complete.

(James Houghton.)

NURSING.—See Lactation.

NYCTALOPIA, Νυκταλοπία, *(th. νὺξ, ὄψ,) Night-blindness.*—A considerable degree of confusion has prevailed among authors in the use of the term *nyctalopia*. Some have employed it to signify blindness by night, and others blindness by day; while it has also been used indiscriminately to denote either of these conditions. The most approved acceptation, however, among the best and by far the most numerous authorities, would appear to be that of night-blindness, while the opposite condition of blindness by day is properly designated by the word hemeralopia. This is the sense in which the terms are used in the present article.

History and causes.—Nyctalopia is little known in this country, but in the torrid zone, and in those parts of the globe where the heat and light of the sun are powerful, it is frequently met with. It occurs in Africa, in Asia, and in America, and is said to be more common in China than in Europe. In the East and West Indies, and in the Mediterranean, it is no unusual disease among our soldiers and seamen; and on the eastern shores, and in the islands of the Adriatic, it is at times very prevalent. It has also occasionally assumed an epidemic form in different parts of France, Germany, Poland, and Russia; and in some situations it appears to be endemic. Wherever it occurs, it preserves the same characters, varying only, in individual cases, in the severity of its attack, in the length of its duration, or from constitutional peculiarities of the patient.

In persons affected with this disease, when the sun sets, vision begins to be indistinct, and becoming gradually more imperfect as the light diminishes, it is at length entirely suspended. The blindness continues during the darkness of night: in proportion as the day-light returns, sight is restored, and it again becomes perfect when the sun appears above the horizon. Blindness and vision continue, in this way, to correspond with the setting and rising of the sun, and the approach and the remission of the paroxysms are in general gradual; but in some instances the blindness comes on suddenly at sunset, and disappears at sunrise in a similar manner.

The degree of blindness varies. In the early stages of the disease it is in general partial, and the patient can see objects in a clear light; but as the complaint advances, the powers of vision become more impaired. Some patients are incapable of discerning the moon or the stars, or even the light of a candle when placed close before their eyes; and some can perceive these bodies, but not the objects which are illuminated by them; while others can barely distinguish light from darkness. After a lapse of time, varying in different cases, the blindness is often complete, and the patient cannot perceive any object after sunset, even in the brightest artificial light.

According to Mr. Bampfield, if the disease is allowed to continue in this degree of severity, the sight will, in the course of time, become weak during day-light, and the eye will not be able to bear the direct or reflected rays of the sun, without pain and temporary blindness being induced.* Such cases, however, are not of common occurrence.

But even when this irritable state of the eye has not been induced, it would appear that, on some occasions, the patient, when placed in an obscure situation,† is incapable of distinguishing objects by day as well as by night; but this state does not seem to have been often remarked, and it would appear that a condition exactly the reverse of this has also been sometimes observed.‡

In general there is no uneasy sensation, or visible alteration in the eye, to indicate the presence of any morbid affection. Some authors, however, describe the pupil as being immoveable and contracted; whilst others say that it becomes immoveable and dilated, particularly during the night. These discordant accounts may, perhaps, have arisen from examinations of different states or stages of the disease; for Mr. Bampfield, whose opportunities of observation were extensive, says, that after it has continued long, and in the worst stages, "the pupil is often contracted, and the eyes and actions of the patient evince marks of painful irritation, if the eyes are exposed to a vivid light, or if he look upwards." In another place he observes, "the pupil of the eye is considerably dilated both by day and night, in the proportion of about one case in twelve, and at night the pupil is often dilated, and does not perform its expansions and contractions when exposed to the moon or artificial light."§ These were also generally cases which had been long protracted.

Although no medical treatment has been employed, the disease, after continuing for a longer or shorter period, frequently undergoes a spontaneous cure. In temperate climates, its usual duration is from one month to six weeks; but within the tropics its continuance is generally much longer, extending from a few weeks to three, six, or nine months, and even occasionally to a still longer period. On some occasions it would appear to be congenital;‖ and it is also alleged to be at times hereditary.¶

¶ Rees's Cyclopædia, art. Nyctalopia.

The natives of cold countries who reside within the tropics are said to be more subject to this complaint than the indigenous inhabitants; and those Europeans who have once had an attack are very liable to a recurrence of it while they remain in a warm climate.

Within the tropics, the disease may be almost considered as endemic, and does not appear to be more prevalent at one season than another. But in temperate climates it most generally occurs during or after the protracted heat and dazzling light of summer and autumn. In Germany it prevailed as an epidemic in the months of July and August;* and in Russia Dr. Guthrie says it is most frequent in June and July during the hay-harvest.† All the cases which the writer of this article met with in the Mediterranean took place in the end of summer and in autumn. It is, however, by no means confined to those seasons. Hippocrates names it among the diseases that occur "circa brumam," and adds that the greater number had relapses "ante æquinoctium."‡

Even at the season of the year when the heat has not arrived at its greatest height, but when the sun is long above the horizon, the disease has appeared as an epidemic among troops exposed to much watching and fatigue. The most remarkable instance, perhaps, is that recorded by Dr. Guthrie in the Edinburgh Medical Commentaries. "I was lately desired," he says, "to give an opinion on a curious phenomenon that happened last war in Finland, where a Russian detachment, ordered to attack a Swedish post during a light night in spring, had like to have mistaken one another for enemies, and occasioned bloodshed, owing to some hundreds in the column being *blind after sunset*. The complaint seized the soldiers in spring, when the nights, from the short absence of the sun, and the strong reflection from the snow, must have been very fatiguing to the eyes, at a period of much martial vigil and alarm; surprises on both sides being then very frequent, more especially nocturnal."§

Night blindness has been described as endemic in different countries. We have an interesting account by Chamseru,‖ of its annual occurrence in this form in France, at Roche Guyon and the neighbouring villages, in some of which it occasionally affects as many as one in nine or ten of the inhabitants. It appears every year in spring, about the middle of March, and continues for three months; sometimes also returning in the autumn. The soil is here composed of chalk and marl, upon beds of burrstone (meulière) and flint (caillou), and the disease principally attacks those who are much exposed by their labours in the fields to the reflected heat and light from this dazzling surface. As the summer advances the ground becomes covered with verdure, and being no longer capable of reflecting the brilliant light of the sun, the disease disappears for the season.

According to Richerand, the inhabitants of the northern regions, where the ground is covered with snow during the greater part of the year, become, at an early age, the victims of this disease. He also says that among artisans the same morbid state of the vision is sometimes produced from long exposure to a great intensity of artificial light.*

Nyctalopia is a disease more common to the labouring classes of people, and those who are exposed to much fatigue, watching, and other debilitating influences—whose diet is often scanty, or even unwholesome.† The epidemics which are referred to above were confined to persons of this description; and its frequent occurrence among our seamen leads us to the same conclusion. A few instances are recorded of its affecting individuals among the better ranks, but in such cases the habits and mode of life of the patients have not been described with precision, so as to justify us in forming a different opinion.

In many cases nyctalopia appears to be a purely local or idiopathic disease; but still more frequently it is the consequence, or at least the concomitant, of some other affection. All the instances of it which came under the observation of the writer, happened to individuals more or less affected with sea scurvy; and several medical authors and surgeons of the navy have remarked the frequent co-existence of the two diseases.‡

It is very often symptomatic of derangement of the digestive organs, so much so that Scarpa,§ Schmucker, Richter, and several other authors, seem to consider the disease as almost entirely originating in this cause.

Some morbid condition of the brain would likewise appear to be occasionally present; for headach and vertigo, pain and watering of the eyes, &c., have been enumerated as precursory or concomitant symptoms.‖

Hippocrates¶ and Celsus** state that females, whose catamenia are regular, are not subject to attacks of this disease, but later observations sufficiently prove the general inaccuracy of this opinion. It is indeed true that the proportion

of males affected is in general greater than that of females; but this arises from the circumstance that the latter are usually exempt from the same degree of hard labour in the fields, and other debilitating causes. For similar reasons young children are seldom affected by it.

Persons of different temperaments are equally liable to nyctalopia; and it is not peculiar to those who have eyes of any particular size or colour.

Nyctalopia has been attributed to various other causes, such as eating rice, sleeping in the sun, the use of poisonous vegetables, a fit of anger,* &c. It appears from Haller† that the inhabitants of Bavaria ascribe the disease to the use of bread in which darnel is present; and this opinion is one of great antiquity; for both Virgil‡ and Ovid§ mention that "lolium" was believed to be hurtful to the sight; and Plautus‖ expressly says that it produces nyctalopia.

Pathology.—In order to produce distinct vision, a due proportion of light is necessary to excite the retina. The quantity required for this purpose depends much on the impressions which have been previously made on the organ. When the eye has been exposed to a strong light, a fainter illumination will not suffice to enable it to discriminate objects; while, on the other hand, vision will be painfully acute, even in a comparatively obscure light, to those who have previously been in a state approaching to entire darkness. Thus the prisoner becomes gradually enabled to perceive the objects in his cell; while the man who has been exposed to the reflection of the sun's rays from the snow is rendered for some time incapable of seeing in the less dazzling though clear light of day. From the operation of the same law, the eye, in nyctalopia, after being exposed to a long and brilliant sunshine, is not excited by the feeble light which continues after sunset, and vision entirely ceases.

When an organ is often and highly stimulated, its sensibility, it is well known, becomes impaired. The long-continued action of light accordingly produces a state of torpor or insensibility of the retina, which becomes greater in proportion to the degree of predisposition and length of time during which the exciting causes continue to operate. In the early stages of the disease, before any considerable insensibility of the retina has been induced, vision is observed to be more or less perfect in a clear light, and according to the degree of illumination. But after a lengthened attack, the increasing torpor of the retina renders it insensible to the stimulus of even a bright artificial light. While this torpid state of the organ remains, the pupil continues dilated and immoveable on the approach of a light which is not of sufficient intensity to excite the retina in the degree requisite to produce vision.

Nearly the same explanation applies to that state of protracted disease in which the eye has become unable to bear the direct or reflected rays of the sun. The heat and light which occasion the insensibility of the retina, at the same time stimulate the vascular portion of the eye, so as to produce a degree of inflammation. It is in this state that the eye becomes irritable, and the pupil contracted, in order to exclude the excess of light. For while the retina preserves its natural sensibility, the contractions and expansions of the iris in most instances go on unimpaired, and the eye appears as in perfect health.

Perhaps it may be thought that, if the disease be owing to an insensibility in the eye produced by the intensity of the sun's light, the patient ought also to be blind when removed to an obscure place during the day, seeing that in both cases the stimulus of light is withdrawn from the eye. This, however, we find, is not always the case. In explanation it may, perhaps, be alleged that the action of the sun's rays, for the *whole duration* of a long day, will more effectually contribute to produce that state of the organ which constitutes the disease than when they act only for a shorter period. The inference seems to be reasonable, but it would require to be confirmed by repeated observations.

Diseases of the brain, and such other causes as induce repletion in that organ, may also produce nyctalopia by injuring the optic nerves, either at their origin or in their course, and thereby so impeding their functions as to render them incapable of transmitting the slight impressions which are made on the retina by a faint light. The last stage of this form of the disease would constitute complete amaurosis.

The well-known sympathy which exists between the stomach and the organs of vision will readily account for nyctalopia appearing so often as an attendant on disorders of that viscus.

The varied illusions and other affections of vision familiar to persons subject to dyspeptic disorders, are analogous in many respects to this disease.

A very different and almost mechanical cause has been assigned for this disease by different authors, namely, a rigid and contracted state of the pupil, whereby a sufficient quantity of light is prevented from reaching the retina. It is very evident that such a state of the pupil might occasion the disease; and it seems to be sometimes observed, as several authors have mentioned its occurrence.*

Diagnosis.—Nyctalopia can scarcely be con-

founded with any other disease. Yet in a complaint of such frequent occurrence in the navy and army, and which affords such facilities for carrying into effect the schemes so often devised by seamen and soldiers to enable them to evade their duty, it would be an object of importance, if any sure diagnostic symptoms could be pointed out. The present state of our knowledge does not, however, enable us to do so with any thing like precision. If contracted or dilated pupil were an invariable concomitant, this would afford a ready mode of discrimination; but these states of the pupil have been rarely observed, even in cases of long duration. As there are no direct means by which the disease can be detected,* attention must, therefore, be paid to the character, habits, and conduct of the individual, and there are few instances in which investigation and experiment will not suffice for its discovery. For some remarks on this point, see the section on *Blindness*, in the article Feigned Diseases, vol. ii. p. 136.

Prognosis.—The prognosis in nyctalopia may generally be considered favourable; and, when proper means of treatment are speedily adopted, the disease is seldom protracted. It even frequently undergoes a spontaneous cure; and the instances are rare in which it is followed by any bad effects. It has also been occasionally removed by the supervention of diarrhœa, of hemorrhage from the nose, and of abscesses and eruptions about the head and face. In two of Dr. Forbes's cases,† epiphora succeeded; and according to Mr. Bampfield,‡ lippitude and myopism are sometimes consequent upon it. This author also states that total loss of sight has been known to ensue, and refers to Bontius in support of this opinion. But from the passage in Bontius,§ it is somewhat doubtful if the disease which is alluded to was nyctalopia. Some authors, however, have been of opinion, that the treatment of the disease is not always successful. According to Sennertus,‖ and Etmuller,¶ it is seldom cured, and Boerhaave** says, "nullum remedium scio, quod hoc malum tollere possit."

Treatment.—Physicians have very generally endeavoured to adapt their mode of treating a disease to the theory which they have formed respecting its cause. This remark has been fully verified in the treatment of nyctalopia. The *humoral* pathologists, who supposed the disease to depend upon a superabundance, thickening, or congestion of the humours, had recourse to such remedies as they considered adapted for diminishing, altering, or evacuating the various humours of the body in general, and of the eyes in particular. For these purposes they recommended *attenuant diet* and bleeding, both general and local. They employed also purgatives, particularly those which they considered as suitable to diseases of the eyes—"oculis appropriata." Nor were other evacuants omitted—*sternutatoria*, *pituitaria*, and the like. Various local applications were also made use of, such as collyria, unguents, and powders, elaborately compounded with all the superfluous science, and multifarious ingredients resorted to in ancient pharmacy. Some things were recommended as remedies on principles evidently the most absurd. Thus, according to Galen and Celsus, *hieracion* was advised, because "accipitres aiunt scalpendo eam, succoque oculos tingendo, obscuritati visûs mederi; ob idque vocant hieracion."* *Euphrasia* was thought good for the sight, from an imaginary resemblance between the spots on its petals, and the eyes. Many other equally fanciful examples might be adduced, but it may suffice to quote the following from an author of high celebrity:—"Capras negant lippire, quoniam eæ quasdam herbas edant: item dorcadas: et ob id fimum earum cera circumdatum nova luna devorare jubent. Et quoniam noctu æque quoque cernant, sanguine hircino sanari lusciosos putant, nyctalopas a Græcis dictos."† Thus it would appear that, from the visual faculties possessed by those animals, of seeing by night as well as by day, the employment of their livers in the cure of nyctalopia took its rise. This is a remedy, the astonishing powers of which have been extolled, both in ancient and in modern times, and in countries the most widely separated, with a confidence truly inexplicable. The livers of various animals were occasionally employed; but those of he-goats, of bullocks, and of sheep, were preferred. Sometimes the vapour of the heated liver was applied to the eyes; at other times the viscus itself was given to the patient to eat; in both cases frequently after it had undergone the most complicated preparations, particularly with various stimulating substances. It is difficult to believe in the production of a cure by such means; and yet it would require no small degree of incredulity to set aside altogether the evidence which has been adduced in favour of these remedies.

A recent German writer has given a remarkable instance of the apparent power of this hepatic treatment of nyctalopia. As the account is altogether curious, we give the narrative at length. The author, Dr. Edward Meissner,‡ informs us that in a small town in Podolia, on the banks of the Bug, having a

population of about 2000, some weeks before Easter, in the year 1816, he met with more than a hundred cases of nyctalopia. "I discovered this," he says, "accidentally one evening, when my surgeon, a Jew, came home hurt, having been overturned by the man who drove him, and who had suddenly become blind as the sun set. Upon inquiring why none of these people were brought to me, I was told that they very well knew how to cure themselves, and would do so as soon as they were at liberty to use the means. It was then the time of fast, when those of the Greek church use no animal food, but live chiefly on bread and grits prepared with oil. I was assured that at the same period every year a great many people were seized with nyctalopia, but that when Easter came they ate the liver of a black cock or black swine, and were cured in a few days. I had ten of these people brought to me both during the day and in the twilight, but could perceive nothing particular in their eyes, except a great immobility of pupil. In other respects they were all in perfect health, and would submit to no other kind of treatment, assuring me that they knew they would be quite free from their malady within fourteen days without my medicines. On Easter day they began to eat liver *and other animal food*. Two of those I had examined, on the third day saw as well as ever; and all were completely cured by the following Sunday."

The writer of this article has repeatedly seen a cure *apparently* produced by fumigating the eyes with the vapour of bullock's liver. The disease occurred in persons who were in some degree affected with scurvy; and various measures had been employed for its removal without benefit. The patients themselves had recourse to the bullock's liver, and declared that one or two fumigations entirely cured their complaint.

We are as yet but little acquainted with *nervous* diseases, and are too well aware of their intermitting nature to put implicit faith in the efficacy of such a remedy. The disease in these as in many other instances, may have undergone a spontaneous cure; or it may have owed its removal to some cause which was unknown or unobserved. It must be acknowledged that the *minute* history of nyctalopia is still very imperfect.

Could any remedial exhalations have proceeded from the broiling liver? or, did the application of heat alone suffice to excite the torpid retina into healthy action?

In the case of the Podolians above mentioned, it is obvious that we are entitled to attribute the case as much, *at least*, to the general change in their diet, as to the specific influence of the black pig's or cock's liver.

Viewing nyctalopia in the light of a more rational pathology, it is hardly necessary to say that, to give hopes of successful treatment, regard must in all cases be had to the nature of the causes which immediately induce the disease. If it appear to proceed from fulness of blood in the head, or any affection of the brain, bleeding and other means, tending to remove such a condition, are of obvious propriety. If derangement of the digestive organs give rise to the complaint, emetics, purgatives, or such other remedies as are suitable for removing the primary disease, must be employed; and when scurvy, or any other general affection of the system prevails, the appropriate means for its removal will be adopted as the first step in the treatment; and after the chief predisposing cause has been subdued, attention will then be paid to the treatment of the local affection. Nyctalopia, however, is often unaccompanied by any specific or formal disease, and appears to depend upon general and local debility. In such cases our efforts will be directed to restore the general strength of the body, and more particularly of the eyes; and this will be most readily accomplished by avoiding the exciting causes, and by employing tonics and stimulants, both general and local. Dr. Guthrie informs us that, in a week or fourteen days, the disease "is cured by the use of a bitter tonic infusion,* although the patient continue his daily hard labour, providing he sleeps as at other seasons during the night." Although the complaint may certainly be in this way removed, yet a cure is induced still more speedily by the application of blisters to the parts immediately adjacent to the local affection. They stimulate the eyes more effectually than general remedies do; and as during their application the patient is usually allowed to go to rest at night, they constitute an important part of the remedial process in the case of seamen or others subject to night-watching. The merit of more particularly recommending blisters, and determining their efficacy in the cure of this disease, belongs to Mr. Bampfield, though the remedy is not new, as they are known to have been employed from a remote period. His words are, "A succession of blisters to the temples, of the size of a crown or a half-crown piece, applied tolerably close to the external canthus of the eye, has succeeded in every case of idiopathic hemeralopia which I have seen. Under their application, the retina appeared to regain its irritability, and sensibility to impressions from light, in the same gradual manner as it was deprived of it."† In his practice, one or two applications were often sufficient to remove the complaint; but the third, fourth, or fifth generally produced a complete recovery. The instances are but few in which there was occasion for a greater number of blisters; or by keeping them open, the cure was generally completed within a fortnight. During the time in which they are applied, exposure to a bright light ought to be carefully avoided; and the patient should be allowed a sufficient time for sleep. The eyes may also be frequently bathed with cold water, or some tonic and astringent lotion.

* Made, he believes, from the "Centaurea Cyanus" of Linnæus. Edin. Med. Comment. loc. cit. p. 288.

† Medico-Chirurg. Transactions, loc. cit. p. 47.

Besides blisters, other local stimulants have been employed, particularly the vapour of ammonia; frequently, however, with indifferent success. The stimulus of electricity has been used with advantage; and, reasoning from analogy, it might be expected to prove highly beneficial, as also galvanism.

It may be proper just to notice in this place the analogous but reverse lesion of vision, termed *Hemeralopia* by those who give the name of nyctalopia to the affection of which we have been treating, in which the patient is blind during the day, but sees comparatively well at night. This disease is noticed by Hippocrates, and many other authors, both ancient and modern; but as it has never fallen under our own observation, except as a mere symptom of ocular inflammation, and as its occurrence as an idiopathic affection is, we are convinced, extremely rare, we deem it unnecessary to give any particular account of it. It may no doubt arise from such local affections of the retina of an organic though unknown kind, as to entitle it to be considered idiopathic; the relative excess of light producing here the same effect as its relative deficiency did in nyctalopia. When, however, not the immediate consequence of inflammation of the eye, it has commonly been observed as the temporary attendant of hysteria, or as a symptom of worms, or other irritation sympathetically affecting the brain generally, or the optic nerves in particular. It therefore deserves no separate consideration in this work as a distinct disease.

(James Grant.)

OBESITY.—This term, from the Latin obesitas, *fatness, corpulency*, its synonym *polysarcia*, from πόλυς, *much*, and σὰρξ, *flesh*, and many others of similar import, are used to signify an excessive development of fat in the body.

Of all animal solids, fat may be named as that which may vary most in quantity without material infringement on the health. Thus we see persons in very various degrees of fatness or leanness enjoying the best health; and even the same individual, under different circumstances of diet and regimen, may become fat or lean without any corresponding change in the well-being of his body. There is, nevertheless, in most individuals, a certain degree of stoutness which best comports with that regular balance of functions which constitutes perfect and permanent health. This degree in some persons may not rise above leanness; and in these even a moderate degree of embonpoint is often a precursor or a sign of disorder; whilst in many, a fulness and rotundity of person is natural, and not only consistent with, but indicative of perfect health. This statement shews the impossibility of defining absolutely what degree of obesity is to be considered as morbid, although in its excessive degrees it is unquestionably a disease and a cause of disease. Cullen describes obesity as morbid "when it renders persons from a difficult respiration uneasy in themselves, and from the inability of exercise, unfit for discharging the duties of life to others."*

Fat may be developed in excess at any period of life, but some ages are much more disposed to obesity than others; and these are infancy and maturity. Infants at the breast sometimes acquire a prodigious size from the deposition of fat. Usually this is chiefly confined to the subcutaneous tissue, and very little affects either the cavities or the interstices of the muscles; but when such children are affected with somnolency and a shortness of breath, which renders sucking difficult and movement laborious, the accumulation of fat may be supposed to be more general, and to oppress by its mass the organs of respiration, circulation, and motion. This condition is almost uniformly caused by an excess of nourishment, and is not unusually attended by a torpidity of the bowels. Fat infants are generally good-tempered; and it is difficult to say whether this be a cause or a consequence of their fatness; but a fretful disposition is generally consorted with an irritability of the secretory organs, which is opposed to any superfluous growth. The obesity of infancy generally diminishes after the second year; and it is not unusual to see the subjects of it become as thin as other children before the age of puberty. The demands of other solids of the body, which the increasing exercise at this period produces, operate against the superfluous deposition of fat; and the fuller development and greater activity of the mental faculties perhaps have a similar effect. In some of the most remarkable cases on record, however, the inordinate development of fat continued and increased regularly from infancy upwards. A German girl, who was exhibited some years ago in Paris on account of her prodigious size, at her birth weighed 13 lbs.; at six months, 42 lbs.; and 150 lbs. at four years. She shewed great physical strength as well as size, for when six years old she was able to carry her mother. She ate much milky food in her childhood, and afterwards drank large quantities of tea, but did not eat more than another person. She menstruated at the age of nine years, and always enjoyed very good health, being active and lively in her disposition. At the age of twenty she weighed 450 lbs.; she then could carry in each hand a weight of 250 lbs., and could walk for an hour without requiring rest, but her breathing was short on going up stairs. Her arms measured eighteen inches (French) in circumference; and the fat formed annular rolls, as in the thighs of very fat infants.† Many similar cases are related in Mr. Wadd's amusing monograph on *Corpulency*, from which we extract the following.

Isaac Butterfield, born at Heightley, near Leeds, Feb. 20, 1781: in November 1782 he measured three feet in height, thirteen inches round the arm, two feet two inches round the thigh, sixteen inches across the shoulders, and

* First Lines, ed. by Cullen and Gregory, vol. ii. p. 208.

† Dict. de Médecine, art. *Polysarcie*.

weighed near one hundred weight. He died Feb. 1, 1783.

A child named Thomas Hills Everitt was publicly exhibited in London in 1780. He was not remarkably large when born, but began to increase rapidly when six weeks old, until his death, which happened at eighteen months. At eleven months he measured three feet nine inches in height; two feet six inches round the breast; three feet one inch round the loins; one foot ten inches round the thigh; fourteen inches round the leg; eleven inches and a half round the arm, and nine inches round the wrist.

Mary Tate, aged twelve years, the daughter of a publican in Cambridge, and one of twins, weighed thirteen stone; the other child died at two years. When Mary was born, she was not larger than is usual, but began to increase at five years; and at six she was publicly exhibited. Her parents were corpulent. She was attacked with a fever which prevailed at Cambridge a few months before her exhibition, and recovered without any apparent diminution of size. Mr. Wadd has collected a great number of other instances of obesity, but as they are merely named, with scarcely any particulars of their history, they are objects of curiosity rather than of medical interest. In most of the well-recorded instances of obesity in early life, there has been an uncommon development of muscular strength; and in this respect the obesity of childhood differs from that supervening in after-life.

A remarkable case of obesity in early age was lately brought before the Royal Institution by Mr. Pettigrew. It was a boy, twelve years of age, who weighed 198 lbs. The great increase of his bulk took place after confinement in consequence of a fracture of one of his limbs. His health is now good, and his habits, appetites, and mental development present nothing uncommon for a boy of his age. He is not deficient in activity, but he says that he cannot lift more than five stone weight.

After the completion of longitudinal growth, the adipose membrane again receives the overflow of the nourishment of the body; this is less remarkable in males than in females, in whom the nutrient function is naturally more active. In both sexes, however, the irritation of the generative organs at the early epoch of maturity seems to have a remarkable effect in diminishing the plumpness of the body; and the absence of this influence in eunuchs produces the sleek smooth surface so remarkable in their bodies, in which the inequalities of bone and muscle are buried in a bed of fat. It is a familiar fact that some of the lower animals fatten much more readily after the removal of the testicles or ovaries. It is perhaps partly in connection with this circumstance, and partly from the abatement of other excitements of youth, that obesity more frequently and more decidedly shews itself as maturity advances; and it is after the fortieth or forty-fifth year that it attains its greatest degrees. The diminished mobility of both mind and body which is perceptible at this age, and the greater inveteracy of habits of living, render corpulency then a much more serious evil than in earlier life; for these circumstances, unless steadily and vigorously counteracted, will infallibly increase it in a degree that must abridge life by encroaching on the functions of various internal organs, and laying the foundation of fatal diseases. This we shall see sufficiently explained in the situations which fatty accumulations occupy at these ages. Besides the thick bed of fat in the subcutaneous tissue, and in the interstices of the muscles, the mediastinum, the pericardium, the mesentery, and the omentum, become the seats of prodigious adipose depositions. Such subjects, besides a largeness and rotundity of body and limb generally, have a protuberant abdomen, and the loose texture in the axillæ, under the chin, and about the mammæ of women, becomes in like manner distended with fat. The effect of these accumulations is mechanically to oppress the adjoining organs; hence shortness of breathing and asthma, weak or irregular action of the heart and palpitation, an oppression and consequent disorder of the digestive apparatus, inability of movement, obstructions to a free circulation of the blood, and dropsical effusions. The cavity of the head is the only one which escapes the deposition of fat; and this exemption exposes its contents to a still greater evil. The various obstructions to the circulation, and the increased pressure to which the mass of fat throughout the body subjects it, produce a determination of blood to the head, and congestion; whence arise somnolency, torpor of the mental and animal functions, and sometimes apoplexy and sudden death.

We have hitherto considered obesity as a simple hypertrophy, but there is reason to believe that in many cases the fatty substance encroaches on the nutrition of other structures. In very fat subjects, both in man and in the lower animals, the fibres of the muscles are often interspersed with depositions of fat, sometimes to such a degree that the latter constitutes the greater part of what once was muscle, and the remaining fibres are commonly softer and paler than is natural. All the muscles are liable to this change, and the heart among the rest; the consequence necessarily is a diminution of their contractile power. We have seen the heart thus more than half converted into fat; the adipose tissue of the base and surface having encroached on the muscular fibres, so that at the base and along a great part of the wall of the right ventricle, and at the septum of the ventricles, these fibres only formed a thin stratum irregularly terminating in the adipose tissue. Laennec describes this state of the heart, and says that "the fatter the heart is, the thinner in general are its walls; and on cutting into them the scalpel seems to reach the cavity without encountering almost any muscular substance, the columnæ carneæ appearing merely as if bound together by the internal lining membrane."* He dis-

* Dr. Forbes's Trans. p. 637.

tinguishes it from fatty degeneration by the marked difference between the muscular fibre and the fat, the latter seeming rather to have superseded the fibres than to have been formed in them. The effects of this change must be unquestionably to render the action of the heart weak, and the circulation languid and inefficient; and some of the instances of the sudden death of fat persons may reasonably be ascribed to a rupture of the organ in this weakened state. M. Bertin describes a case of the rupture of a prodigiously fat heart. But the mere diminution of power in the heart, and its oppression by a load of fat, without any rupture, seem to have caused death in some cases. Dr. Brian Higgins of Dublin, the first discoverer of equivalents in chemistry, appears to have died from this cause; and there are many similar examples on record. These forms of obesity must have a tendency to increase; for as fat is deposited in and around the muscles, they will be less disposed to that habit of exercise on which their development mainly depends, whilst obesity and its causes will increase together.

Without dilating this article with cases of extraordinary obesity, we may state generally that the fat, which is computed to constitute an average of from 1-10th to 1-15th of the weight of the body in persons of ordinary degrees of stoutness, in extreme cases amounts to 4-5ths; and the absolute weight, which runs commonly from 10 to 14 stone (14 lbs.), has been known in remarkable cases of this disease to reach to from 30 to 50 stone. Mr. Lambert, of Leicester, who is always placed at the head of the list, weighed 52 stone 11 lbs. There is detailed in the twelfth volume of Corvisart's *Journal de Médecine et de Chirurgie*, an interesting account of a case of obesity by M. Dupuytren, with a full description of the tissues affected, and the proportion of fat in various parts of the body: an extract from this has already been given in the article Hypertrophy, and it is therefore unnecessary to repeat it here.

Obesity is sometimes partial; and it has its seat in no part more frequently than in the omentum, which has been known to increase to the weight of 20 or 30 lbs. This gives the appearance of what is vulgarly called a pot-belly. The mediastinum is likewise occasionally filled with fat without a corresponding obesity of the body; and the double chin often occurs as a partial obesity. The mammæ, abdominal parietes, and nates of women are likewise sometimes the seats of fatty enlargements; the latter are so to a ludicrous degree in the Bosjesman Hottentots.

Pathology.—Fat is an oily matter contained in minute vesicles which are agglomerated together in masses in the cellular tissue of various parts of the body. Whether there is a peculiar adipose tissue, or whether the fat is deposited in the common cellular structure, is a matter of dispute amongst anatomists. Dr. W. Hunter described the adipose tissue as distinct, and as consisting of cells which do not communicate with one another. He grounds his opinion on the following facts. The parts where fat most commonly accumulates are not those which are most subject to œdematous and emphysematous swellings, nor do the forms of parts increased by fat, and of those whose cellular tissue is distended by serum, resemble each other. Adipose accumulations do not pit on pressure, or gravitate towards the most dependent part, as anasarcous effusions do: the scrotum, so commonly the seat of the latter, is scarcely ever affected with fatty enlargement. W. Hunter's opinions have been adopted by Monro, Mascagni, Bichat, and Beclard. Haller, Wolff, Hensinger, Majendie, and Meckel deny the existence of a peculiar adipose tissue, and consider that fat is merely deposited in globules in the cellular structure. Meckel supposes the fat to be a solid, manifesting itself in globules, which make cells for themselves in the mucous tissue, in which he asserts there is naturally no cellular division or communication. A minute examination of human fat does not confirm this latter opinion, for it traces its globular form to the presence of an investing membrane, while the contained oil is liquid or solid, and the animal temperature according as elain or the stearin prevails in it, which varies in different parts of the body. We are, therefore, disposed to retain Dr. Hunter's view, which is confirmed by the distinct and characteristic appearance which the adipose substance presents when surrounded by serous infiltration of the cellular tissue.

There has been an equal discrepancy of opinion as to the place of the formation of fat. Haller and Majendie consider it as a simple exhalation from the blood. Dr. W. Hunter ranks it as a secretion elaborated by the specific tissue in which it is found; whilst Sir E. Home has framed a curious hypothesis, that it is formed from the fæcal part of the food in the colon, whence it is taken up by the blood-vessels, and deposited in different parts of the body. Almost the only argument urged in favour of this last notion is a supposed resemblance between the retention of fæces in the colon, and certain cases in which decayed animal matter is converted into adipocire: this resemblance is very slender and distant; and if Sir E. Home has proved that an oily matter is sometimes present in the fæces, he has failed to prove that it is either formed there, or conveyed thence into the system; whilst on the other hand there are on record cases which prove that fat may be formed and deposited in the body without any aid from the colon. Thus the subjects of artificial anus have been known to get fat, although no fæces passed through the large intestines.*

The question whether fat exists ready formed in the blood, or is only elaborated at the point in which it is deposited, is much of the same nature as that respecting other secretions, such as urea, bile, mucus, &c. Commonly none of these are detected in the blood, but under some circumstances they may each be found to

* See Dr. Mackeever on Laceration of the Uterus, p. 48. 1824.

exist there; and the presence of fat giving a milky aspect to the serum* is not so uncommon as to exclude the probability that it always exists, but in proportions too small to be readily appreciated unless circumstances lead to its accumulation. And we have the positive testimony of Drs. Christison and Babington, and more recently of M. Lecanu, that there is always fatty matter in the blood, according to the latter chemist, in ordinary cases amounting to from three and a half to six and a half in a thousand parts.† These facts, coupled with the well-known presence of oily matter in the chyle, remove much of the difficulty of explaining the rapid accumulation of fat in the body under some circumstances, and its still more speedy reduction in others. These changes, if not the result of simple exhalation and absorption, are obviously more nearly allied to them than they were formerly considered to be; and although the secernent power of vessels is undoubtedly concerned in the deposition of fat, we must not overlook the cohesive quality of this substance, by virtue of which it agglomerates to matter of its own kind, whilst watery liquids have but little affinity for it. Hence we can perceive why blood surcharged with fatty matter from the chyle promptly deposits it, especially where adipose substance already exists; whilst for its removal there must be an augmented energy of the absorbent function. This view, which is but an hypothetical one, would assign the chylopoietic viscera as the probable seat of the formation of fat, although there may be reason to believe that it becomes modified and perfected in its progress through the circulation.

Another conjecture has been proposed by Dr. Bostock, that fat is formed like other secretions from the blood; and its production, by removing a superfluity of hydrogen, is a means of maintaining a uniformity in the composition of the circulating mass. The kidneys are the emunctories of azote, and the lungs of carbon, whilst fat, the prevailing ingredient of which is hydrogen, may maintain the balance by carrying off the superfluous hydrogen. If this were the mode of its production, the excessive development of fat ought to be accompanied by an unusually copious secretion of urea by the kidneys, a circumstance not, as far as we know, attributed to cases of obesity.‡

Of the excretions, that of the liver bears the nearest analogy to fatty matter; and this fact suggests a question whether an obese diathesis may not be sometimes connected with a comparative torpidity of this viscus.

Causes. These may, as usual, be divided into predisposing and occasional. The predisposing, as consisting in a peculiar habit or temperament of body, is frequently hereditary. At the first glance we may be led to say that the predisposing cause is the most powerful, inasmuch as no mode of diet and regimen will succeed in making some persons fat, whilst others increase to a great size, without, in these particulars, exceeding the bounds of moderation. A more comprehensive survey, however, of the symptoms in different cases suggests that the constitutional cause is not always of the same nature, and that therefore it has a varying share in the production of morbid obesity. A full diet, especially abounding in oily, carneous, saccharine, and farinaceous matter, will seldom fail to fatten a person naturally disposed to corpulency; and if to this, rest of body and mind be added, this effect is almost certain. Some individuals, having a strong constitution and good general health, require these to make them fat, and become so only in proportion as they indulge in them. These persons, in whom the predisposing and exciting causes may be said to be nearly balanced, constitute a large proportion of the cases of moderate obesity that are commonly met with. In them the circulation and other functions are effective and regular, the secretions free, and the bodily and mental powers little embarrassed. Their corpulency is merely an overflow of health, the deposition of fat being the outlet by which the bloodvessels deliver themselves from impending plethora, and is accompanied by an increase rather than a diminution of other solids. This form we would denominate *sthenic* obesity. A preponderance of the same predisposing cause, the hypertrophic diathesis, gives a more marked form of the disease, and constitutes the greater number of those cases of uncommon size and strength which are frequently shown about the country. When this form of obesity becomes much pronounced, by the embarrassment which it causes in the functions, it tends to pass into the second variety of the disease, which we would term *asthenic*.

In asthenic obesity the predisposition is still more strong, and probably consists of a greater number of constitutional causes. This predisposition is frequently hereditary, and is commonly allied with a leucophlegmatic temperament, a soft languid pulse, defective excretions, and a low irritability of the body. There is in

* We once saw this milky appearance of the serum very remarkable in the blood of a corpulent patient suffering under an attack of pneumonia; she had been largely bled previously.

† Journ. de Pharm. Sept. & Oct. 1831.

‡ We cannot omit the opportunity to express here our conviction, that a more frequent and habitual attention to the state and composition of the excretions would greatly enlarge our knowledge of the pathology of diseases. The interesting study of animal chemistry has established to a certain degree that the great excretory organs, the liver, the lungs, and the kidneys, act as balancing forces, which keep the blood of a uniform nature; and it must therefore be obvious that the inordinate or imperfect action of any of these would lead to a more or less disordered state of this fluid, which must necessarily react on the functions at large. Without advocating an absolutely humoral system of pathology, we cannot but view a disordered state of the fluids as an important link in the concatenation of diseased action, and as a main object of therapeutic efforts. For a clear insight into this subject, much patient and well-directed research is required; and had we a few more such inquirers as Dr. Prout, we might sanguinely look forward to the attainment of this point.

such individuals a sufficient activity of the first part of the digestive process; but a somnolent disposition, often present for some hours after meals, indicates the admixture of chyle in the circulation, and a tardiness in its assimilation. The chyle thus supplied probably abounds more in fatty particles than in albuminous globules. Until, therefore, the former are deposited from the circulating mass in the adipose membrane, the blood does not recover its natural and most healthy constitution. There is good reason to believe that naturally this adipose matter is always at the command of the absorbent functions, and that, in case of the excretions being augmented in a greater ratio than the supply of nutriment, it is taken into the circulating mass to make up for the waste. In a person of sanguine temperament the demand on the adipose membrane equals the supply: such an individual makes blood fast, and suffers from plethora before there is any considerable increase of fat in the body. A person of spare habit, again, is liable to neither form of hypertrophy; as either the incapacity of his digestive organs, or the activity of his excretions, preclude all superfluous accumulation. In asthenic obesity, on the other hand, there is a defect in the assimilatory process by which the oily matter is made available to supply the excretions of the body; and this defect may be either in the absorbent function, or in that action by which the matters excreted are formed; but it is most probable that the same defect of tone which manifests itself in the state of the body generally, extends to both these functions. Hence asthenic obesity resembles atonic dropsy, in which it not unfrequently terminates: it occurs towards the later periods of life, and in persons whose constitutions have been weakened by various excesses. It is not unfrequently the accompaniment of chronic disease of the liver, and more rarely of the stomach; and is sometimes a symptom of a chlorotic state in young women. It is in this form of obesity that the muscles become paler, lose their substance, and are displaced by depositions of fat.

We have already stated that good living and a life of ease are the most efficient occasional causes of obesity; this is universally acknowledged; and Dr. Arbuthnot says, "you may see an army of 40,000 soldiers without a fat man; and I dare affirm that by plenty and rest, twenty out of the forty shall grow fat." The portly appearance of butchers, landlords of inns, and butlers, is obviously referable to their good living and moderate exercise.

With respect to the quality of food which is most fattening, much variety is seen: either animal or vegetable diet being capable of producing the most marked effect, if taken in sufficient quantities. Thus the negroes of the West Indies, and the Chinese slaves, sometimes acquire an enormous size during the sugar season by drinking the cane juice; and it was remarked by Galen, that the keepers of vineyards, who live on nothing but figs and grapes, become fat. The ladies of Tunis and Tripoli are fattened, to please the tastes of their lords, with farinaceous food, and a seed called *drough*. "Among the Asiatics there is a sect of Brahmins who pride themselves on their extreme corpulency. Their diet consists of farinaceous vegetables, milk, sugar, sweetmeats, and ghee. They look upon corpulency as a proof of opulence; and many arrive at a great degree of obesity without tasting anything that has ever lived."*

Malt liquor, consisting of a saccharine and feculent infusion, rendered readily digestible by the stimulant and stomachic properties of the bitter and spirit with which it is combined, is highly nutritious, and some of the most remarkable subjects of obesity have been addicted to excessive indulgence in ale or porter. The following case is related by Mr. Wadd.

"A few years ago a man of about forty years of age hired himself as a labourer in one of the most considerable ale-breweries in the city. At this time he was a personable man; stout, active, and not fatter than a moderate sized man in high health should be. His chief occupation was to superintend the working of the new beer, and occasionally to sit up at night to watch the sweet wort; an employment not requiring either activity or labour: of course at these times he had an opportunity of tasting the liquor, of which it appears he always availed himself: besides this he had constant access to the new beer. Thus leading a quiet inactive life, in a short time he became of such an unwieldy size as to be unable to move about, and was too big to pass up the brewhouse staircase: if by any accident he fell down, he was unable to get up again without help. The integuments of his face hung down to the shoulders and breast: the fat was not confined to any particular part, but diffused over the whole of his body, arms, legs, &c. making his appearance such as to attract the attention of all who saw him. He left this service to go into the country, being a burthen to himself, and totally useless to his employers. About two years afterwards he called upon his old masters in a very different shape to that already described, being reduced in size nearly one half, and weighing little more than ten stone. The account which he gave of himself was, that as soon as he had quitted the brewhouse he went into Bedfordshire, where having soon spent the money he had earned, and being unable to work, he was brought into such a state of poverty as to be scarcely able to obtain the sustenance of life, often being a whole day without food; that he drank very little, and that was generally water. By this mode of living he began to diminish in size, so as to be able to walk about with tolerable ease. He then engaged himself to a farmer, with whom he staid a considerable time, and in the latter part of his service he was able to go through very hard labour, being sometimes in the field ploughing and following various agricultural concerns for a whole day, with no other food than a small pittance of

* Wadd's Remarks, &c. p. 89.

bread and cheese. This was the history he gave of the means by which this extraordinary change was brought about. He added, his health had never been so good as it then was."

In another case, from the same writer, more of the asthenic kind, the subject, a woman who died suddenly at the age of forty-four, weighing twenty-three stone, had subsisted chiefly on vegetables and pastry, and drank large quantities of milk and water, consuming above a gallon in the course of each night. She was totally incapable of rising from her bed, and required three strong men to place her in her chair.

While these cases shew that the quantity more than the quality of nutritious aliment supplies the disposition to obesity where it exists, it is at the same time certain that fat meats, butter, milk, the saccharine, the finer farinaceous, and the oily vegetable substances, with malt liquors for drink, are the most fattening kinds of food; and varied combinations of these are more effectual to this end, inasmuch as they are more inviting to the appetite, and more manageable, even in large quantities, by the digestive organs, than simple substances however nutritious.

Besides food there are other circumstances which contribute greatly to the production of obesity. Absolute rest is less powerful than some kinds of moderate exercise, as it can seldom be indulged in without such an interruption to health as would prevent the fattening process. The obesity which ensues on absolute rest is generally more of the asthenic kind. There is no mode of living that seems to dispose more to obesity than that of a regularly employed coachman. The gentle exercise and free exposure to the open air which their occupation entails upon them, gives a good appetite and easy digestion; and while they seldom fail to indulge these, they are rarely called upon for those exertions of the lower extremities, or of the whole frame, that reduce the body by a general increase of the excretions.

Mental repose, both of the powers and passions, has been considered a great promoter of obesity. We think, however, that the sluggish minds and easy tempers of fat people are as often the effect of the phlegmatic constitution which disposes to obesity, as a cause of this state. They are frequently accompaniments of asthenic obesity; and a somnolent inactivity of the mind, as of the body, may be the effect of an advanced state of any kind of corpulency: but the case of David Hume, the historian, who became very fat during his intellectual labours, and that of Napoleon under the most powerful excitements of passion and mental energy, and many others which we could cite, prove that fat and stupidity are not such inseparable companions as Lord Chesterfield represented them.

The national differences which are observable in the disposition to obesity are probably referable more to the temperament, diet, and habits of the people, than to any peculiarities in climate. It has been stated that obesity sometimes commences after convalescence from a fever, or after a course of mercury; and all that can be said in explanation is, that these influences seem to produce in various respects a change in the constitutional diathesis, as other morbid tendencies, not pre-existent, are occasionally developed by the same causes. We have known a partial accumulation of fat succeed to repeated attacks of erysipelas in the part; this bears more analogy to common hypertrophy.

Treatment.—It is sufficiently obvious from from all that has preceded, that diet and regimen constitute the most effectual means of cure in this disease; and Dr. Radcliffe's pithy motto, "to keep the eyes open and the mouth shut," promises more benefit than any medicinal prescription. The following cases, which are only specimens out of a very long list, will illustrate the efficacy and safety of this plan, as well as its modes of application, better than mere general rules.

Mr. Wood (the miller of Billericay, whose case is related by Sir George Baker in the Medical Transactions of the College of Physicians,) at his forty-fourth year had attained such a size that he was a burthen to himself, and incapable of performing common acts of exertion. At the suggestion of the rector of his parish he resolved to follow the example of Cornaro in a life of abstemiousness. He had been accustomed to indulge in large quantities of ale and animal food, with an unsparing proportion of fat. These he left off gradually, and substituted puddings of flour and milk; and at last, one made of sea-biscuit, eaten twice only in the day, was his only food. He first substituted water for beer, but afterwards brought himself to do without any liquid. By this plan he reduced himself ten or eleven stone, and was "metamorphosed from a monster to a person of moderate size; from the condition of an unhealthy decrepid old man to perfect health and the vigour and activity of youth."

A country tradesman, aged about thirty, of a short stature, and naturally of a fresh sanguine complexion and very fat, applied to Dr. Fothergill for assistance. He complained of perpetual drowsiness and inactivity; his countenance was almost livid, and such a degree of somnolency attended him that he could scarcely keep awake whilst he described his situation. Dr. Fothergill advised him immediately to quit all animal food, to live solely on vegetables and every thing prepared from them, allowed him a glass of wine and a little beer occasionally, but chiefly confined him to water. He pursued this plan very scrupulously, lost his redundant fat, and grew as active as usual in about six months. Dr. Fothergill recommended a perseverance for a few months longer, then to allow himself light animal food once or twice a week, and gradually to fall into his usual way of living. He grew well and continued so.

A young unmarried woman, about twenty-three years of age, of low stature and very fat, consulted the same physician, on account of great difficulty of breathing, somnolency, and incapacity for any exercise. It was a hardship to her to be obliged to go up stairs,

and at last to cross the floor of her apartment. It seemed to Dr. Fothergill that mere obesity was her principal malady; indeed she had no other complaint but such as might be accounted for from this supposition. She was ordered to pursue a vegetable diet, and in the summer to drink the waters at Scarborough. She conformed to these directions, became more agile, less sleepy, less averse to exercise: she walked up stairs at Scarborough from the Spa, a task of no little difficulty to people much less encumbered. A continuance of the same diet was urged: she was dissuaded from it by her friends, and died of fat in the twenty-seventh year of her age.*

A gentleman of great respectability in the mercantile world, who weighed thirty-two stone nine pounds, put himself upon a strict diet of four ounces of animal food, six ounces of bread, and two pounds of liquid, in twenty-four hours. In one week he lost thirty pounds weight, and in six months he was diminished the astonishing quantity of one hundred and thirty-four pounds. His health and spirits were much improved; and considering his remaining size of twenty-three stone, he was very active.†

Mr. W., of Whitehaven, at about thirty years of age weighed twenty-three stone, ate and drank with great freedom, and in great abundance. He became at length so lethargic that he frequently fell asleep in the act of eating, even in company. By the advice of Dr. Gregory of Edinburgh, he took a great deal of exercise, lived sparingly, and slept little. The prescribed diet was brown bread and tea; but the patient, finding it necessary to fill his stomach, ate a great quantity of apples: and to enable him to take the necessary exercise, he found a pint of port or sherry per diem indispensible. He retired to rest at eleven, and rose between four and five o'clock. His only medicine was three brisk purges a week. By this system he reduced himself to fifteen stone, with great improvement to his health.‡

A baker, living in Pye-corner, attained the weight of thirty-four stone, and could not move out of his chair for many years. He would frequently eat a small shoulder of mutton five pounds weight, and proportionably of other things, and drink a gallon of good beer. He was moreover of a costive habit, and required four times the strength of an ordinary purgative to operate on him. He with great resolution persisted for one year in living on water-gruel and brown bread, and lost nearly two hundred pounds of his bulk.§

These cases sufficiently prove the efficacy of a plan of abstinence; but there are cases in which its application will require some caution and modification. It is especially in relation to the treatment that we wish to preserve the distinction between the sthenic and asthenic varieties of obesity. The former will bear measures that would be insufficient or unsafe in the latter. Thus a sudden and total prohibition of animal food and fermented liquors would lower the circulation, already too languid in the asthenic form; and by retarding the absorptive process, and weakening the locomotive powers too much for exercise, change the disease from obesity to a cachectic dropsy. Experience has shewn, on the other hand, that persons of robust constitution, when affected with obesity, may with impunity even abruptly reduce the quantity and quality of their aliment, and with the most beneficial results. The inexpediency of laying down any absolute plan for the treatment of obesity will, therefore, be obvious; and the necessary distinctions may very well be comprehended in the two kinds into which we divide them.

Treatment of sthenic obesity.—The circulation is here supposed to be vigorous, the digestion good, and the absolute strength not impaired; although the activity be greatly diminished by the inroads of the disease. The indications here are, therefore, 1. to remove the accumulated fat; 2. to exclude from the system all material of nourishment beyond what is necessary to supply the demands of the excretions; 3. to ensure that the nourishment that is taken in be applied only in this way. All these indications may be fulfilled by diet and exercise.

The food should be very moderate in quantity; this is the most important point, and the next is that it be not too nutritious in quality. The breakfast may consist of tea and brown bread (not more than four or five ounces) without butter. If there should be a feeling of great exhaustion in consequence of the scantiness of this allowance, a dried herring or a hard-boiled egg may be added. The brown bread which is made by several bakers in London, containing the finer particles of bran and a proportion of rye-flour, is to be preferred, as it is less nutritious, and acts on the bowels more than any kind of bread or biscuit. As long as active exercise can be persisted in, we do not think it advisable to exclude entirely the use of animal food. A few (three or four) ounces of lean meat, white fish, poultry, or game, with a proportionably sparing quantity of the less nourishing vegetables, such as greens, turnips, pulse, sorrel, chiccory, &c. with two or three glasses of white wine if required, may constitute the dinner. If the absence of the habitual quantity produce a painful sensation in the stomach, the only supplement that may be added is cucumber or salad without oil or egg in the dressing; or, if preferred, an orange or two, an apple, or a few gooseberries, strawberries, or currants, with little or no sugar, may be taken to allay the cravings of a dissatisfied appetite. Although it is desirable not to tempt by variety, nor to allow more than three articles for the principal meal, yet the varying of these from day to day keeps the stomach in tone, and reconciles the patient somewhat to the difficult task of great moderation. Very little liquid should be taken during dinner, and the liquid meal after it should be

* Med. Obs. and Inq. † Wadd, p. 82.
‡ Wadd, p. 85. § Wadd, p. 102.

restricted to a single cup of tea or coffee with little or no sugar or milk; for we are convinced that copious libations of any kind at this time hurry the chyle into the circulation in an imperfectly assimilated state, and, therefore, more abounding in oily particles. There should be no solid food taken after dinner; or if the appetite be very craving, an orange, a roasted apple, or a cup of thin gruel with a little lemon-juice in it, taken half-an-hour before bed-time, should suffice; these contain but little nourishment, and tend to keep the bowels in a soluble state.

The habit of active exercise is quite as necessary as abstinence, and it requires as much resolution to observe it. In advanced stages of obesity, horse-exercise is almost the only kind that can be pursued, the legs being unequal to support their burthen for a length of time sufficient to be useful; but the patient must submit to the roughest paces of his sturdiest horse. When walking can be accomplished, the legs must not be spared: this is the best exercise to reduce bulk, both because it can be more readily resorted to and longer persevered in, and because, being most general, it excites the excretions more than other kinds. It may, however, with advantage be varied with digging, rowing, dumb-bell exercise, and various other gymnastic pursuits. At least two hours out of the twenty-four should be imperatively devoted to the energetic practice of some of these modes of exercise; and the more beyond this, the speedier will be the reduction of bulk. Corpulent persons ought to limit their period of sleep as much as possible, by rising early to take a walk or some exercise before breakfast; and the disposition which they frequently have to sleep during the day and after meals should never be indulged in.

A very salutary kind of exercise, and one that may conveniently be allotted for the fasting task, is vigorous friction of the limbs and body by the hands or with a flesh-brush; and this may be advantageously preceded by the shower-bath, or copious cold ablution. These means promote the action of the absorbents, and improve the tone of the cutaneous circulation.

There is little need of medicines in the slighter degrees of sthenic obesity; for the functions are generally pretty well performed. If the bowels require aid, and the dietetic means before recommended fail, a black draught or a colocynth pill occasionally will suffice. But in more advanced states purgatives may be indicated as depletories, especially if there be also determination to or congestion of blood in the head; in this case calomel and jalap, alternated with salts and senna, or the compound gamboge pill, will be required twice or three times a week. It has been thought useful in some cases to diminish the appetite for food by squill, ipecacuanha, and other nauseating medicines: we do not recommend this generally, as nausea is a weakening influence, and renders exercise a painful effort; but there may be cases in which the natural appetite cannot be stinted without real suffering: in these, small doses of ipecacuanha, or, what is better, dissolving in the mouth a camphor lozenge or smoking a cigar, may occasionally be resorted to, to relieve this craving sensation. As to vinegar and other acids, which formerly were reputed remedies in obesity, we cannot but follow Cullen in condemning their use, since their effect is only in proportion as they counteract the digestive process; and the risk which they entail, of exciting chronic diseases of the stomach and bowels, far outweighs their thinning powers, which often fail when unsupported by diet and exercise. Soap and alkalies were highly recommended by Dr. Flemyng;* and as they have a certain chemical affinity for fat, and increase the secretion of urine, they seem to promise advantage: but the illustration of their efficacy in the case described by Dr. Flemyng falls greatly before the numerous examples of cure by abstinence and exercise. As adjuncts to these means, alkalies may prove beneficial, and especially in the common complication of gout with obesity, ten to twenty grains of soap in the form of pills, *m*xv. to xxx. of the liquor potassæ, or four to eight grains of the subcarbonated alkalies in ℥i. of camphor mixture, may be given twice or thrice in the day.

Treatment of asthenic obesity.—The indications here are to increase the activity of the functions of circulation and absorption, and to improve the tone of the digestive and locomotive organs.

Abstinence is an important agent in this as well as in the other kind of obesity, and the outline of the diet before sketched may be followed here; but the reduction of the quantity of the food must be made more gradually, and the quality with greater care adapted to the powers of the digestive organs. Thus, if there be a disposition to gastric irritation, the milder and more farinaceous articles are to be chosen, their quantity being still limited; but if a nervous dyspepsia accompany the obesity, which is the commoner case, such kinds of animal food which have been already recommended, together with a little spiced rice and a small quantity of white wine, once a day, are more eligible; no salads or supplements of any kind being allowed, and the breakfast being restricted to biscuit or dry toast, with tea or coffee. The quantity of these articles must be gradually but steadily diminished as far as the strength and general health of the patient will permit.

The defect in muscular power which commonly attends asthenic obesity considerably limits the means of exercise. Horse-exercise is still generally practicable; and the oftener it is resorted to the better. An important substitute may be obtained in friction of the body and limbs; this is a powerful mean of promoting the absorption of superfluous matter, and of giving vigour to the sanguineous circulation of the surface. Where there is a relaxed state of the body and an

* Discourse on Corpulency. London, 1780.

easily perspirable skin, friction should be preceded by the salt-water plunge or shower-bath; but where the skin is harsh, with a deficient reactive power of the superficial vessels, it may with the greatest advantage be combined with the vapour-bath in the manner of Indian shampooing, which is very effective in giving laxity and freedom to the cutaneous circulation. In proportion as the muscular strength is restored, it must be engaged in other kinds of exercise to the utmost of its power; and in the ratio of its increase will be almost infallibly the diminution of the torpid bulk of the body and its accompanying disorder.

As there is often considerable derangement of the organic functions, the aid of medicines is frequently required in asthenic obesity. Those most needed are those which increase the excretions, and improve the tone of the animal fibre; and by a judicious administration of such evacuants and tonics much good may be effected. If there be a deficiency in their action, the bowels must be moved; but strong cathartics are not eligible, as they disorder the digestive function, already weak, and weaken the whole frame. In common constipation or torpidity of the whole canal, aloes in the dose of three to five grains, with a grain of sulphate of iron, twice a day, is exceedingly well adapted to fat phlegmatic subjects with languid circulation. If the colour of the evacuations indicate a defective secretion of bile, a very common symptom in this form of obesity, calomel or blue pill must be occasionally combined with these medicines; and if there be such a torpidity of the absorbent function as to cause œdema, pitting on pressure, in the fat of the legs and feet, two or three grains of gamboge may properly be added. Great advantage may in some cases of the same kind be derived from a course of a saline chalybeate water, as that of Cheltenham.

Of tonics, the alkaline preparations of iron are the most eligible, as they seem to facilitate the conversion of chyle into blood, and promote the secretion of urine, without increasing the appetite for food. The mistura ferri composita, and the tinctura ferri ammoniata are the most convenient preparations; and an attenuant and diuretic effect may also sometimes be usefully obtained by joining with them a little carbonated alkali and nitre. In no cases is this treatment more beneficial than in the obesity which occasionally accompanies defective menstruation in females; and whether this disorder be a cause or only a concomitant, it is highly important that the periodic evacuation be restored to its normal proportion.

Analogy suggests that considerable benefit might be obtained from the use of iodine, in its known sorbefacient capacity, in the asthenic forms of obesity; but we are not authorised by direct experience to recommend it. Where other complaints, such as dyspepsia, dropsy, &c. are complicated with obesity, they must be treated in the usual way. Obesity may, however, furnish a reason for modifying our practice when the subjects of it are attacked with other diseases. Fat persons do not generally bear bleeding well; purging suits them better: but they are often more readily lowered by any evacuation than their appearance would lead us to expect.

The period during which it is necessary to pursue the treatment recommended above can only be determined by the effect produced. It may be useful and satisfactory to the patient to put to the test of the balance the beneficial operation of his plan; but a restored activity, and the removal of the discomforts of obesity, give a surer criterion of his improvement; if these are accomplished, although he should still retain some largeness of bulk, there is no longer reason to consider it a disease. The return to a more generous method of living should, however, be made very gradually, and with circumspection; and nothing should deter the individual from pursuing those habits of active exercise that have mainly contributed to free him from his burthen.

(C. J. B. Williams.)

ŒDEMA, (*οἴδημα*, from *οἰδέω*, *to swell.*)—This term properly signifies a swelling of any kind, but is now confined to a swelling of a dropsical nature, situated in the cellular tissue. When the œdema is developed under the skin, it appears in the form of a tumour, which retains the impression of a finger or any other body that has been applied with a slight degree of force to the surface. It has usually been regarded as a species of anasarca; and unquestionably it has much analogy with this affection. In the present article, however, we shall confine ourselves to the consideration of those œdematous affections which are not connected with a general dropsical diathesis, and which may exist for an indefinite length of time without extending beyond the original site.

Œdema appears under very different circumstances; and we are inclined to believe that, at different times, the nature of the effusion into the cellular membrane is different; the external appearance certainly is so. We are not, however, able to prove that such a difference does exist; and we shall therefore content ourselves with stating the different circumstances under which a swelling, having the character we have assigned to œdema, may happen, and the variation of treatment which such differences demand.

Œdema exists in the commencement of phlegmonous inflammation through the whole extent of the affected part; and throughout the progress of inflammation, it occupies the extreme boundaries of the diseased part in a greater or less degree. In some instances, in consequence of the nature of the affected parts, the inflammation does not pass beyond the œdematous stage before it proves fatal. Such appears to be the case in the disease to which the term *œdema glottidis* has been assigned, the cellular membrane of the glottis being the seat of a serous infiltration, which gradually closes the rima glottidis, and destroys the patient by suffocation. In pneumonia, also, portions of

the lungs are found in the œdematous stage, the similarity of which to anasarcous effusion has been remarked by Laennec. More commonly, however, the inflammation proceeds to induration and suppuration, at least of the centre, and the œdema is found only in the circumference. M. Gendrin has given an account of the pathological state of the cellular tissue in this which he terms an active œdema. He has derived his information from observing the processes set up in the cellular tissue in the neighbourhood of a wound.

The cellular membrane close to the wound is hard to the touch; its areolæ are infiltrated with a reddish, opaque, and gelatinous matter, and pressure gives issue to a reddish, opaque, and mucus-like serum. Beyond the inflammatory redness, there exists during life a serous infiltration which is rather elastic; and this infiltration is greater in proportion to the natural relaxation of the cellular tissue, and the inferior situation of the part. After death the œdema increases, but the elasticity diminishes. The œdema extends into the intermuscular cellular tissue, and the vessels of the part are evidently enlarged.

Of the treatment of this kind of œdema we need say no more than that it is that which is appropriate to inflammation, of which indeed it is only a stage. (See Inflammation.)

The affection which has been termed "skin-bound," and which occurs in infants, is also a variety of œdema; but as Dr. Carswell has given an excellent account of it under the head Induration, we shall refer the reader to that article for information respecting it.

Œdema is a common consequence of rheumatism, particularly of that form which is called *arthritis rheumatica*. It may either be the remains of the active inflammation of the joints, or it may from the first appear as simple œdema. It may occur in the knees and ancles, but the most common situation is the back of the hands. It forms a cold, thick, puffy swelling, and generally white, and it is sometimes, but not always, rather tender. It is frequently the seat of dull aching pain, and the patient can make very little use of the limb. The fingers are stiff, and the hand cannot be closed. When the affection is recent, fomentations frequently repeated, and continued for half an hour at a time, will sometimes remove it very quickly, and the patient is cured as it were by a charm. More commonly fomentations are useless, as also are local warm and vapour baths; they do not even afford a temporary relief. Stimulating mercurial liniments are more useful, and generally succeed in removing the œdema in the course of a month. Dr. Elliotson appears to have employed the hydriodate of potash, but we have ourselves had no experience of it in these cases. When, however, the mercurial liniment fails, as sometimes it will, the preparation in question may make a good substitute. Its property of increasing absorption certainly points it out as a probable remedy. Occasionally a certain degree of œdema will remain during life, the patient having at the same time a tolerably free use of the limb.

While the treatment is thus directed to the local affection, the state of the general health must not be neglected. Few diseases, perhaps, are more manifestly attended with disorder of the digestive functions than rheumatism, and this disorder is not unfrequently aggravated by the remedies which are employed in the acute stage. Unless, however, when this stage is past, immediate attention be paid to the state of the digestive organs, the disease, even in its acute form, is very liable to return. The treatment of rheumatism becomes, therefore, the treatment of dyspepsia, and only by success in relieving this latter affection can we hope permanently to relieve the former. (See Rheumatism.)

Œdema is one of the most common attendants upon amenorrhœa. Amenorrhœa itself depends upon two opposite states of the system, a state of plethora, and a state of debility and exhaustion. In both these œdema may exist. In the former, or the plethoric state, together with the common symptoms of plethora, there is usually much pain in the lower extremities, particularly in the lower part of the leg and round the ancles; and this pain is worse towards night, at which time also the œdema is much more considerable than in the morning. Upon examining the legs, the parts corresponding to the pain are usually cold to the touch, hard, and of a purplish colour; and this colour varies from a very light tint to an actual livid hue. It sometimes resembles purpura so far as the colour is concerned, but there is evidently no extravasation. At other times real purpura exists, and many petechial spots are present. The œdema is usually in these cases very firm, not readily yielding to the finger, and the impression is very quickly effaced. Frequently there is considerable tenderness in the course of the femoral vein, and the most common site of this tenderness is just before the vein pierces the tendon of the triceps to pass into the ham. This variety occurs in girls of a florid appearance and plethoric habit, and the usual period of its occurrence is between eighteen and twenty-five years of age. The tenderness of the vein, which probably depends upon some inflammation of the vessel, is not, however, peculiar to this diathesis, nor to this period of life. It frequently occurs in that condition which is neither very evidently plethoric nor feeble, and which equally resists an extreme mode of treatment, whether depleting or tonic. The countenance of these individuals is sallow and unhealthy, but does not exhibit that fair and pellucid appearance which distinguishes those who are the subjects of œdema in consequence of exhaustion.

The individuals last mentioned exhibit the common symptoms of amenorrhœa from debility, the quick, rolling, and easily compressible pulse, the palpitation of the heart, excessive nervousness, &c.; and the œdema of the lower extremities is both more considerable than in the former varieties, and much softer. It yields

readily to the fingers, and retains their impression for some time. In some persons the œdema is so great that the swollen part overhangs the shoe excessively towards evening; and though it disappears during the night, when the patient is in bed, it returns in two or three hours after rising, gradually increasing till evening, when, from the weight and stiffness of the limbs, the patient is compelled to place them in the horizontal position, the only position in which she can obtain ease.

Œdema occurs also in women at that period which is known as *the change of life*, and is in this case, so far as our experience extends, always dependent upon a plethoric state of the system. It varies from the œdema which we have described as occurring in young persons of a florid complexion, by the absence of the livid colour, and by the swellings being much less firm and resisting.

The description above given of the different circumstances under which œdema occurs, sufficiently points out the proper mode of treatment. In the first, or plethoric variety, not only must the general remedies be employed, as bleeding and purging, but if there be any tenderness in the course of the femoral vein, leeches should be applied to the tender part, and they should be repeated again and again, so long as any tenderness remains.

The second or middle variety requires a mixed treatment, as we have already indicated; leeches, if any tenderness is present in the course of the femoral vein, and alternate tonic and depleting remedies as the symptoms vary.

The œdema in the third variety, in which the system is suffering from exhaustion, is most benefited by the exhibition of steel; but for a more complete direction for treating these cases we refer to the article Amenorrhœa, of which disease œdema is usually one symptom.

When œdema occurs at the change of life, there are so many symptoms which intimate a plethoric state, that there can be no hesitation in recurring to depletory measures, both bleeding and purging; and as the œdema is very liable to return, till the catamenia are entirely suspended, the repetition of these remedies will be required as often as this happens.

Old persons are frequently subject to œdema of the lower extremities, and which, as their debility increases, extends higher and higher towards the trunk, yet seldom assumes the general phenomena of dropsy, there being neither a decrease in the flow of urine, nor any other inconvenience experienced excepting what is the consequence of the weight and stiffness of the limbs. Sometimes it seems to become at length connected with a dropsical diathesis, and after many years have elapsed, during which this œdema has remained stationary, ascites and general anasarca ensue.

So long as the disease remains merely in the state of œdema, nothing more is required than to support the integuments by means of a laced stocking or bandages; when, however, dropsy supervenes, it must be treated upon the principles which have been laid down in the article Dropsy.

Excessive fatigue is also a cause of œdema. Soldiers, after long marches, are subject to swellings of the ancles, and the œdematous state of the legs of horses after over-work is well known to horse-keepers, who are also aware that it is merely a state of debility; hence they bandage the legs of such horses in the stables, that the cellular tissue may have an opportunity of recovering its tone.

Œdema will also be caused by any thing which obstructs the circulation of the blood through the venous system; hence it is common in the latter months of pregnancy, from the pressure of the uterus upon the iliac veins. Ligatures also have a similar effect. The presence of œdema in the arm in cancer of the breast is probably to be accounted for on the same principle. It seldom happens till the disease has made considerable progress, and in the cases which have fallen under our notice, the axillary glands have been much affected. In our experience this œdema is much more common after the removal of the breast, and upon the recurrence of the disease, than in those cases in which no operation has been performed.

These appear to be the principal forms under which œdema may appear. How far this is an affection really different from anasarca may certainly be questioned; there is, however, in all the cases we have referred to, this peculiarity, that the affection is entirely local; that it by no means necessarily leads to dropsy; and that life may terminate without any apparent progress being made in converting it from a local to a general affection of the system.

(John Darwall.)

OPHTHALMIA. Under this head it is proposed to consider inflammation of the conjunctiva only, although, strictly speaking, the term is more applicable to inflammation of the eye itself. The universal use of the term to designate inflammation of this membrane has probably arisen from this being the most frequent and obvious inflammatory affection of the organ. In approaching the consideration of this subject the student should first pause to ascertain whether his knowledge of the structure and functions of the conjunctiva enable him to announce the changes reasonably to be expected from inflammation of its texture, and afterwards should determine whether observation justifies his anticipations. The conjunctiva being a modification of the common tegumentary membrane, intermediate between the skin and mucous membrane, the changes produced by inflammation are of the same character as those induced by the same cause in these two structures. These changes are, increased vascularity, tumefaction, pain, and altered secretion. The increased vascularity is characteristic: when the inflammation is slight, the enlarged vessels present the appearance of a distinct red network spread over the white sclerotic; when more intense, the appearance of distinct vessels is lost, and the surface assumes a uniform deep

red colour. The tumefaction is inconsiderable unless the inflammation be very severe, in which case the vessels become enormously distended with blood, and the subjacent and surrounding cellular membrane loaded with serum, constituting the appearance technically denominated *chemosis* on the globe of the eye, or producing a most distressing prominence of the lids. The pain is uniformly at first such as is produced by the presence of a grain of sand beneath the eyelid, but it subsequently is accompanied by a sensation of heat, producing the same description of distress as arises from a scald. The intense aching pain experienced in violent inflammation arises from the globe of the eye becoming involved in the disease. The conjunctiva being lubricated by a fluid derived from a source different from its own surface—the lachrymal gland—the first alteration in the nature or quantity of the secretion from the surface cannot be ascertained. The alteration, however, becomes speedily obvious, and is as characteristic of the disease as the other changes enumerated, purulent matter in considerable quantity being poured out. It must not, however, be assumed that the secretion of purulent matter is a necessary consequence of conjunctival inflammation; instances of the contrary will presently be adduced.

Inflammation of the conjunctiva presents the distinct characters above enumerated, because it is inflammation of a structure of equally distinct anatomical character, but it is so completely modified by circumstances, that few other inflammatory diseases appear in so many different specific forms. The inflammation of this membrane is either circumscribed in the form of pustule, or diffused, as in the different varieties of purulent ophthalmia. Either or both of these are again modified by the presence of other diseases, and hence gonorrhœal, variolous, and other distinct species.

Inflammations of the conjunctiva may, therefore, be divided into *pustular* and *diffused;* the *pustular* into common pustular and variolous, and the *diffused* into catarrhal, severe purulent, gonorrhœal, and the purulent of infants. The grounds upon which these specific distinctions are established will be stated as each is submitted to inquiry.

While considering the nature of conjunctival inflammation in general, it is expedient to consider also the principles which are to guide us in the treatment of that inflammation. The resources available for the removal of inflammation in other structures are equally available in this. The activity of the circulation is to be diminished by general and local bloodletting—the contents of the stomach and bowels removed by emetics and purgatives—the condition of the system which nauseating medicines produce is to be induced—inflammation in the vicinity, or counter-irritation as it is called, is to be excited by blistering—the temperature of the inflamed part is to be lowered by cold applications—or the condition, whatever it may be, which warm moisture causes, should be encouraged by warm fomentations. In conjunctival, more than in any other form of inflammation, the practitioner has had recourse to the immediate application to the part of those remedies to which astringent, sedative, or irritating properties are attributed, and in considering their application to each form of disease, their comparative value will be submitted to inquiry. Particular circumstances may demand additional remedies or peculiar management—the inconvenience arising from accumulation of purulent discharge is to be avoided—the gumming together of the lids obviated—the vessels of the surface may require to be opened by scarification, or the serum of *chemosis* discharged by puncture. It may be necessary to produce the peculiar constitutional effects of mercury—to encourage the secretions of the skin, intestines, or liver—to restore the flow of milk from the breasts—to regulate the functions of the uterus—or to reproduce suppressed discharge of blood from piles. The consideration of conjunctival inflammation in detail will prove the importance of paying the most careful attention to the differences of constitution presented by different individuals, in order to substitute tonic medicines, and invigorating diet and regimen, for a system of depletion and abstinence. It is obvious that each specific form of this disease will require a corresponding variation in the application of these principles, and that the treatment must be modified with every modification of the symptoms induced by circumstances.

In studying the progress and treatment of conjunctival inflammation, the practitioner should never lose sight of the marked and important distinction to be drawn between the inflammation and its consequences. Hitherto this distinction has been so far made as to form a division of the disease into the acute and chronic stages, but it is worth considering whether the condition which is called the chronic stage should be considered analogous to that which exists during the inflammatory or acute stage. The alteration in the treatment to be adopted when the disease assumes the chronic form, and which is carefully inculcated by every practical writer, proves that those symptoms which are to be subdued by depletion and other similar means have disappeared. It is true that the increased vascularity, augmented and altered secretion, and even painful sensation still exist, but in a very different degree, and of very different character. The tense, tumid, glazed chemosis subsides, and is succeeded by a soft, pulpy, villous vascularity; the secretion from the surface is profuse, and its purulent nature more remarkable, and the painful sensation is mitigated and unaccompanied by the scalding which characterizes the distress of the inflammatory period. The eye is not injured or destroyed by conjunctival inflammation unless the inflammation extend to the other textures, producing sloughing of the cornea, or suppuration of the eyeball; or unless it produce the altered or disorganized state of the membrane which leads to vascularity or opacity of the conjunctiva covering the cornea, or granular condition of the lining of the lids.

1. *Mild inflammation of the conjunctiva.*—That there is a form of conjunctival inflammation entitled to the above appellation, which presents a specific character perfectly distinct from every other, there can be little doubt. It is rather vaguely defined by authors under the title of catarrhal ophthalmia, but does not appear to be considered so completely different from the severer purulent ophthalmia as its history, at least according to the writer's experience of the disease in Ireland, warrants. It is distinguished, as the title implies, by the comparative mildness of its symptoms, the vascularity never passing into true chemosis, or inducing sloughing of the cornea; the pain not being so severe, and the purulent discharge being much less copious. It occurs in spring and autumn, is epidemic or endemic, and, whether contagious or not, attacks several individuals in the same family. It affects young persons more frequently than adults, and sometimes seizes a great number of children in schools or other institutions where they are collected. The following is the history of the disease. The patient experiences a sensation of itching, with slight uneasiness, as if a mote or eye-lash had passed beneath the lid, which is greatly aggravated by the efforts made to remove it by rubbing or handling the eye. If the organ be now examined, nothing more can be discovered than an increase of vascularity with a copious flow of tears. Next day all the characteristic symptoms may be recognized. The conjunctiva lining the lids, especially the lower, has acquired a uniform deep red appearance, and that covering the sclerotic presents an equal vascular network, permitting the white structure of the former membrane to appear in the meshes or areolæ; the vessels not crowding together so as to produce the deep general redness of the chemosis of severe ophthalmia. This vascularity is well represented in Mr. Wardrop's work on the Morbid Anatomy of the Eye, which contains more well-drawn and faithful representations of diseases of this organ than any other accessible to the student. There can be no difficulty in distinguishing this characteristic vascularity from the equally characteristic vascularity of the sclerotic in internal inflammation of the eye. The high degree of vascularity, with prominence of the membrane from effusion of serum beneath it, constituting the appearance denominated chemosis, never perhaps exists in mild purulent conjunctival inflammation, and therefore, when it does occur, must be considered evidence of the presence of the severer form of the disease. The secretion of purulent matter from the surface is most obvious after the night's rest; the eye-lashes are gummed together by it; clots produced by the evaporation of the more fluid parts of the discharge are formed at the angles; and when the lower lid is depressed, flakes and films of it may be observed in considerable quantity. The existence of purulent discharge is not so obvious in the course of the day, especially if the patient has been in the open air, the irritation of the surface causing such a flow of tears as removes it as fast as it is secreted. In this case inquiry should be made as to the state of the eye upon awaking in the morning, and the patient should be allowed to remain for a quarter of an hour with the eyes closed, when, upon depressing the lower lid, flakes of yellow matter may be seen floating in the tears. The sufferer experiences repeated attacks of scalding pain, with copious flow of tears, so much resembling the effects of a mote or grain of sand beneath the lid, that he can scarcely be persuaded that such does not actually exist. Vision is not very materially impaired during the prevalence of these symptoms, but there is generally a slight degree of haziness experienced, especially when looking at the flame of a candle, and occasionally alarm is excited by tenacious films of purulent matter adhering to the cornea.

The symptoms here enumerated continue for two or three days; the period depending much upon the circumstances under which the patient is placed: they then begin to yield and alter, the painful sensation of a foreign body beneath the lids, with scalding and flow of tears, becomes less frequent, the vascularity loses its intensity and shining appearance, and the purulent discharge is more freely secreted. Subsequently, these symptoms gradually diminish and finally disappear, leaving the parts somewhat more vascular and irritable than before this attack; but in a few weeks this condition disappears, and the recovery is complete. That this is the true history of the symptoms, progress, and termination of mild conjunctival inflammation in a healthy subject can scarcely be denied; but it is not the history of the disease as it is observed in daily practice. This simple form of inflammation must obviously disappear after passing through its different stages, unless the natural processes tending to recovery be interrupted. This interruption, however, generally takes place. The disease is frequently exasperated, and the efforts of nature to restore the healthy functions of the part suspended by injudicious, unnecessary, or injurious interference; or it is so modified by scrofulous constitution or by neglect, filth, and deficient food and clothing, that its character is totally altered.

The treatment of mild conjunctival inflammation is as obvious as the disease is simple. The bowels should be emptied, and the secretion from the mucous membrane of the intestinal canal excited by purgatives in moderate and repeated doses. The infusion of senna and tamarinds, with the addition of sulphate of magnesia and of tartrate of antimony in the proportion of a grain to eight ounces, may perhaps be preferred for this purpose. The abstraction of blood by the lancet is seldom required; but it is frequently necessary to apply eight or ten leeches to the hollow of the temple behind the external angular process of the frontal bone, or over the cheek bone. The bites of leeches in the thin and flaccid skin of the eyelids generally produce so much irritation and inflammation, that their application there is often injurious. Locally, cold or warm applications may be resorted to, ac-

cording to the relief the patient experiences from one or the other. If there be much heat and scalding pain, a light fold of old linen wrung out of cold water may be laid over the closed lids, and changed as it becomes warm; or a soft sponge or scrap of flannel wrung out of hot water, and held in the hollow of the hands beneath the eyes, may be used to induce the soothing effects of warm moisture. At bed-time the edges of the lids should be smeared with cream, unsalted butter, or any other oily application not rancid or burned. Rest of the lids should be enjoined, as the constant friction of the surface greatly increases the irritation; the eyes should be kept closed as much as possible; but the patient should not be immured in a dark room, or have his eyes covered with a shade, as is frequently practised. The propriety of applying astringent washes to the inflamed surface during the first stage of the disease may be justly questioned. It is not to be denied that such applications may have the effect of arresting the progress of the disease at once; but if they have not that effect, they are liable to produce an increase of irritation. In Dublin, where no adequate relief is afforded to the destitute poor in their own homes, it is often expedient to endeavour to cut short the disease by the direct application of a strong astringent solution, to prevent the establishment of that chronic vascularity and opacity of the cornea which filth, starvation, and rags would otherwise produce. For this purpose a saturated solution of acetate of lead or alum may be resorted to with perfect safety and decided effects, and a few drops introduced between the lids every night and morning. To remove the vascularity and that condition which accompanies the secretion of purulent matter, weaker astringent solutions may be used more freely. Five grains of alum or of the acetate of lead to an ounce of water make a wash as efficient and safe as any other of the various salts resorted to for this purpose: the comparative value of these will, however, be presently considered.

In addition to the above observations, an abstract of Mr. Lawrence's valuable account of catarrhal ophthalmia, delivered in his lectures, may not be inappropriate. He observes that it originates from atmospheric causes or peculiarities, is caused by exposure to cold, and corresponds to catarrhal affections of other mucous membranes. In individuals predisposed to this affection, being out in an east wind for a quarter-of-an-hour, or half-an-hour, will sometimes infallibly bring on an attack. He enumerates the following symptoms:—stiffness, smarting, uneasiness from exposure to light, watering, and external redness, followed by mucous discharge, without considerable pain or intolerance of light. The conjunctiva becomes of a scarlet colour in mottled patches at first, but subsequently of uniform appearance, the redness commencing at the circumference, and extending to the cornea. Sometimes spots of ecchymosis occur in the vascular network from the activity of the inflammation, and occasionally pustules round the margin of the cornea; but true chemosis never exists. The characteristic symptom of a sensation of a foreign body beneath the lid he attributes to the irregularity of surface produced by vascular distention. The secretion from the surface is at first thin, but subsequently becomes of a thicker consistence and whiter colour, resembling pus, at first confined to the inner angle of the eye, or to the fold of reflection of the conjunctiva, but afterward is poured out in sufficient quantity to agglutinate the lids at night. These symptoms are accompanied by those of inflammation of other mucous membranes, and are found to remit by day and to become exasperated at night. The affection, he says, passes through a certain course and then subsides, yields readily to treatment, and is, generally speaking, free from danger unless improperly treated. It is distinguished from the severe purulent ophthalmia by its milder character; and although the appearances of the two approximate, yet the difference is rather in degree than in kind. The disease, he observes, demands mild antiphlogistic treatment: cupping and leeching in ordinary cases, and occasional venesection in full habits; an active aperient, sometimes an emetic, followed by saline and sudorific medicines and diluent drinks. Locally, he recommends warm in preference to cold applications; but observes that the latter are sometimes comfortable to the patient, and not injurious; and after the inflammation subsides, suggests the application of blisters, exposure of the organ to the air, and he objects to shading the eye unless there be intolerance of light.

2. *Severe inflammation of the conjunctiva, commonly called purulent ophthalmia.*—The severer form of conjunctival inflammation presents itself in three different shapes, the *Egyptian*, or, as it is called for distinction, the *purulent* ophthalmia, *gonorrhœal* ophthalmia, and *purulent* ophthalmia of infants. These three forms, if not specifically distinct, and characterized by peculiar symptoms, are at least distinguished from each other by origin, history, progress, and consequences. The common severe purulent ophthalmia is to be now considered. This disease probably always existed in the form in which we at present occasionally observe it; but the attention of the profession was particularly called to it upon the return of the troops from Egypt, among whom it spread with such uncontrollable violence and destructive consequences, that it acquired the title of Egyptian ophthalmia. The following history of the disease, as it occurred at that period, is extracted from Dr. Vetch's Treatise on Diseases of the Eye. "The British army which formed the first expedition to Egypt left that country in three divisions. Great part of the whole touched at Malta, and a considerable portion also at Gibraltar, at which places ophthalmia not only continued to present itself in the regiments which had brought it with them, but was communicated at the former place to several women with whom the soldiers associated; and at Gibraltar it became from that

time by no means an unfrequent complaint among the troops who had never been in Egypt. On the whole, however, the climate of Gibraltar has proved rather favourable than otherwise to the amelioration of the complaint. From Malta and Gibraltar the greatest part of the army proceeded to Great Britain and Ireland. In two regiments of fencibles disembarked at Portsmouth, the disease continued to present itself from the time of their landing until they were disembodied a short time afterwards. The regiments disembarked in Ireland having been placed in the same barracks and garrisons with the Irish militia regiments, the infection appears, from such evidence as I have been able to obtain, to have been communicated to them. If the disease existed at all in England, it seems to have been entirely overlooked till the summer of 1804, when it appeared with alarming violence in the second battalion of the fifty-second regiment, at that time stationed with the light infantry division in barracks, near Hythe in Kent. Not a man of this battalion had been in Egypt, and it was entirely composed of a body of volunteers received in one draft from the Irish militia, and very shortly after their arrival at Hythe the disease made its appearance. It continued to disseminate itself more extensively in this regiment during the remaining part of 1805; and in the following summer of 1806 it also began to prevail in the first and second battalions of the forty-third regiment, and the first, second, and third battalions of the 95th, all stationed at the same place and under the same command. Whether the disease was spread from the battalion in which it first commenced, or was derived from the same source, that is, the Irish militia, of which the others were equally composed, it would be now difficult to determine. The battalion in which this renewal of the infection first shewed itself in this country was the second of the fifty-second, and a very considerable number of cases had occurred in the first battalion when it embarked for Sicily in 1806. From the time of their landing in Sicily the disease continued to cripple this otherwise fine battalion. Part of the army of Sicily was dispatched to Egypt, and on its return to Sicily a fresh stock of the infection of ophthalmia was brought with it; but the disease, or an infectious ophthalmia of the same character, was in the first instance carried to Sicily from this country by the first battalion of the fifty-second regiment. From this station alone, I believe more than one hundred and thirty cases were sent home totally blind. When the disease had existed for some time in the light infantry brigade, composed as I have already stated, of the fifty-second, forty-third, and ninety-fifth regiments, stationed in Kent, it broke out in other regiments which had no communication with the former, but had formerly suffered much from the disease in Egypt, though till this period it had remained either altogether dormant, or prevailed in an extent so limited as to escape attention. Three hospital stations were established for the exclusive reception of those affected with the disease, towards the latter end of 1807, to the superintendence of which I was appointed. The numbers were chiefly composed of men from the regiments already mentioned; but in the summer of 1806 it contained no less than nine hundred cases, consisting of detachments from more than forty different corps. Previously to the sailing of the expedition to Walcheren in 1809, the number of acute and highly purulent cases was also very great, but as they were received in an early stage of the disease, there was little or no eventual loss, and from that period the disease continued to decline."

Dr. Vetch proceeds to account for the disappearance, temporary suspension, and recurrence of the disease, by attributing such recurrence to relapses with return of purulent discharge occurring in crowded barracks. He ascribes the comparative exemption from the disease enjoyed by the French army to the circumstance of their not being confined to barracks or subjected to fastidious discipline, but bivouacking in the field, or being quartered on the inhabitants of the towns they occupied; and in proof of it, instances the exemption enjoyed also by the English troops in the peninsular war. In Ireland, at the period alluded to by Dr. Vetch, the disease raged with perhaps still greater violence, and in consequence of want of sufficient accommodation for the numerous cases in the military hospitals, wards were opened for their reception in Stevens's hospital under the direction of Mr. Colles, where the writer had an opportunity of observing its extensive ravages, and the comparative value of the different means adopted for its removal. That the disease here spoken of is the same as that now observed, and commonly denominated purulent ophthalmia, can scarcely be doubted; and although its appearance among the troops in Egypt, and its subsequent history, has conferred upon it a certain distinction of character, yet it can scarcely be denied that it existed previously, and perhaps more particularly in Ireland.

The condition or symptoms which characterize the severer forms of conjunctival inflammation or purulent ophthalmia, whether Egyptian, gonorrhœal, or infantile, are the chemosis or turgid vascularity with effusion of serum into the subjacent cellular membrane; sloughing, abscess, or ulceration of the cornea; and alteration in the structure of the conjunctiva leading to granular lids and vascular and opaque cornea. The symptoms as they actually occurred in the form of the disease just alluded to are so well described by Dr. Vetch, who enjoyed ample opportunities of observing the disease, that his account is here introduced. "The first appearance of inflammation after the application of the virus is observable in the lining of the lower eyelid. It assumes first a mottled appearance and then a fleshy redness. A little mucus is generally present at the doubling of the conjunctiva at its lower part. The disease I know from observation may remain in this state for twelve hours before it invades the conjunctiva covering the eye;

sometimes it may be longer; and in some cases where the contact of the virus has been slight, or removed by immediate washing, the disease never went farther than producing the redness of the lining of the palpebra. In sclerotic inflammation the lining of the eyelids preserves in some degree its natural whiteness, especially just under the tarsi, for days and weeks. The progress of the inflammation, when it extends from the conjunctiva of the eyelid to that covering the globe of the eye, is often so rapid as to elude any distinct observation; but frequently it advances more gradually, preserving a defined line, till it extends over the whole membrane as far as the cornea. No part can be said to be more vascular than another, as the whole seems equally injected, and no space unoccupied. The disease is often thus far advanced before the attention of the patient is so much excited as to make him complain; a certain degree of stiffness being sometimes the only sensation which accompanies it. The first and chief uneasiness in this stage of the disease is described as arising from the feeling of sand or dirt rolling in the eye. This sensation is not constant, as it comes on suddenly and as suddenly departs, confirming to the patient the idea of something extraneous being lodged in the eye. I have always observed that its attacks are in the evening, about the time of going to bed, or very early in the morning. Their duration varies; sometimes an attack abates in an hour, and sometimes continues the whole night; those coming on in the evening being always the most severe. This symptom requires particular attention, as its accession is a certain index of the disease being on the increase. From the observations I have already made, its exacerbations and remissions are easily explained. When a vessel on the globe of the eye is first injected and rendered turgid, it excites an uneasy sensation in the conjunctiva of the palpebra, the same as if it moved over a particle of sand or extraneous matter. As the tone of the vessel diminishes, and the lining of the eyelids becomes accustomed to the new feeling, the painful impression ceases. A farther increase of the turgidity of the vessels already distended, or the distention of others, serves to excite afresh this feeling of uneasiness. The time at which I have said that this symptom generally comes on is when the patient is preparing for sleep, because he is then confined to a closer atmosphere; and not only is the eye deprived of the beneficial effects of the open air, but the temperature is farther increased by the closing of the eyelids in the attempts to sleep. The first stage of the disease may be, therefore, characterized by its great and uniform redness, without that pain, tension, or intolerance of light which accompanies most other forms of ocular inflammation. Exactly the reverse of which takes place when inflammation affects the sclerotic coat. From the beginning of the operation of the virus, there is a disposition to puffiness in the cellular texture between the conjunctiva and globe of the eye. This puffiness often suddenly swells out into a state of complete chemosis; and at other times it makes a more gradual approach to the cornea, advancing equally on all sides; the close attachment of the membrane at this part causes the swelling as it were to double over the margin of the cornea. While effusion is thus taking place upon the eye, œdema is likewise going on beneath the integuments of the palpebræ. This effusion ought to be considered as perfectly continuous with the chemosis arising from the internal surface of the conjunctiva, and following its reflection on the eyelids. To the œdema of the palpebræ, there is no other resistance than what the integuments afford; and, therefore, in a short time, it forms a tumour of astonishing magnitude, and the external swelling may by its pressure prevent the chemosis from acquiring the magnitude which would otherwise occur. This enormous tumefaction of the palpebræ is generally consentaneous with the complete formation of the chemosis, which is when it has reached the cornea and surrounds it. In proportion as the integuments of the palpebræ, by yielding to the œdema, swell out, they drag the tarsus to which they are attached inwards, producing inversion of the eyelid, and the integuments of the upper and lower eyelids meet, forming a deep sulcus between them. To examine the eye, it is therefore necessary, first to introduce the finger to the bottom of the sulcus, and then, by separating the swollen eyelids, to bring out the inverted cilia. Unless our treatment have an immediate effect in reducing the external œdema, few cases admit of any very minute examination of the eye itself. With the accession of the external swelling, the discharge, which was before moderate and consisted of pus floating in the watery discharge, now flows in a continued stream of yellow matter, which, diluted with the lacrymal secretion, greatly exceeds in quantity that derived from the most violent attack of gonorrhœa. The clothes, and anything within the reach of contact, soon become embued with the matter, the smallest particle of which is capable of producing infection. Although the tumefaction may be at first farther advanced in one eye than the other, it generally reaches its maximum of height in both about the same time. The patient, reduced to a state of great uneasiness by the irritation of the swelling, and by its confining the discharge, begins now to suffer attacks of excruciating pain in the eye itself. This is chiefly what indicates the mischief going on, and from which the patient must be immediately rescued, in order to save the organ. Here it is enough to observe, that the medical adviser must be careful how he allows himself to be lulled into security by any remission or palliation of this symptom. An occasional sensation, as if needles were thrust into the eye, accompanied with fulness and throbbing of the temples, often precedes the deeper-seated pain. This last is often of an intermitting nature, and a period of excruciating torture is succeeded by an interval of perfect ease. Under the latter form, I have met with it in the greatest number of cases,

and the exacerbation and remission have often occurred with great regularity. Sometimes the pain shifts instantaneously from one eye to the other, and is seldom or never equally severe in both at the same time; and sometimes instead of the eye, it occurs in a circumscribed spot of the head, which the patient describes by saying, he can cover the part with his finger. Sooner or later one of these attacks of pain is terminated by a sensation of rupture of the cornea with a gush of scalding water, succeeded by immediate relief to the eye in which this event has happened, but generally soon followed by an increased violence of the symptoms in the other. This first sensation of rupture is, when the disease is left to improper treatment, often followed by a second and a third; till exhausted by its own violence, the attacks become shorter and less severe; not, however, till after the lapse of many weeks and even months do they altogether cease. During this stage of the disease there is seldom the slightest alteration of the pulse unless the lancet have been freely employed. The patient's general health is little impaired, his appetite continues natural, but sleep almost totally forsakes him. As the pain abates, the external tumefaction subsides also, and a gaping appearance of the eyelids succeeds. This may be termed the third stage of the disease. The ciliæ, which before had been pushed inwards, are now separated, and stand outwards. The previous inversion of the cilia may be explained by comparing the palpebra to a sail bent to a rope; the more the sail is distended, the cord is drawn upwards and inwards. The swelling of the second stage having abated, the eyelids are prevented assuming their natural state, in consequence of the granulated state of the conjunctiva which lines them; and now eversion more or less takes place. This in general proceeds, however, no farther, but between this state and a complete eversion there is every degree of a diseased or granulated state of the inner surface of the palpebra. In some cases it disappears rapidly and of itself; in others it forms an inveterate disease, and, combined with some degree of sclerotic inflammation, becomes the cause of opaque cornea. The pain of the second stage of the disease arises in part from the destructive changes which have commenced in the cornea, aggravated by distention of the eye, consequent upon an augmented quantity of an aqueous humour. The formation of that fluid, I have already hinted, may take place through the medium of the ciliary processes, and the appearance of the cornea gives no reason to suppose that its internal surface partakes of the inflammation, or that the aqueous humour is increased by any morbid effusion. The distention seems entirely owing to an augmented activity in the secreting vessels; and these certainly are situated in the posterior chamber. Neither does there appear any reason to warrant the idea that the ulceration ever proceeds from within outwards. But the distention of the anterior chamber probably favours the escape of the aqueous humour sooner than it would otherwise happen. The swelling and the purulency prevent us from making any very accurate examination to ascertain the progress of the ulcer. The account I have given of it in a former chapter is an analysis of what takes place in ophthalmia. When any large portion of the cornea sloughs, an adventitious and vascular membrane is often produced, which finally forms a staphyloma. In some few cases I have seen the lens and its capsule exposed without any external covering whatever, and for a short time the patient sees every thing with wonderful accuracy; but as soon as the capsule gives way, the lens and more or less of the vitreous humour escape, the eye shrinks, and the cornea contracts into a small horn-coloured speck. This total destruction of the globe of the eye generally insures the safety of the other, and renders it less liable to be affected by future attacks of inflammation. When one eye is lost by staphyloma, and the other remains useful, it is well to do what nature has left undone, and instead of attempting to reduce the sac by puncturing it, at once to lay it open and extract the lens."

The account here given by Dr. Vetch is calculated in an eminent degree to impress on the mind of the student the importance of this disease; he is not, however, to expect to meet with it in this form in daily practice. He will not always have an opportunity of observing the first symptoms of the attack, as the patient seldom presents himself until the complaint is fully established, and he will not often find the symptoms so rapid in progress or violent in degree. The practitioner, in studying an individual case, has before him the vascularity, tumefaction, scalding pain, and purulent discharge in the severest form. His first consideration should be to recal to his memory the dangerous consequences which he is called on to avert, and which constitute the prominent symptoms of the disease. In the first or inflammatory period, he is to recollect that the eye may be lost by sloughing or abscess of the cornea, or by suppuration of the whole eye-ball; in the second stage he has to apprehend the injury or destruction of the cornea from ulceration, or that change of organization of the conjunctiva which proceeds to permanent increased vascularity, and that peculiar condition denominated granular lids. The nature of the pain experienced by the patient should receive particular attention: if it be the characteristic scalding sensation of sand beneath the lids, it is indicative of severe conjunctival inflammation only, but if this be accompanied by intense aching extending to the temples and sides of the head, it is evidence of the extension of the inflammation to the eye-ball itself; the cornea and fibrous selerotic refusing to yield to the distention of inflammatory action, like muscular fasciæ and the coverings of joints under similar circumstances.

As sloughing or abscess of the cornea is the consequence most to be apprehended during the inflammatory period, the practitioner watches with anxiety for any appearance indicative of this evil. It is not perhaps possible

o detect the first change which the cornea ndergoes in this process, but when this trans-parent structure assumes a dirty white opaque ppearance, either wholly or partially, the mis-hief is easily recognized; and when subse-quently the sphacelated portion comes to be ast off by the usual process of ulceration, and exhibits a line of separation between the dead nd living parts, no doubt of the nature of the njury can be entertained. Abscesses in the structure of the cornea are also liable to occur luring the inflammatory period, and have pro-bably been often confounded with the sloughing here described, the distinction being difficult, nd the two destructive consequences some-times being combined, and constituting a con-dition analogous to common anthrax. Abscess of the cornea is peculiar in this respect, that it does not appear to consist of a distinct sac of purulent matter, but merely a deposit in the cellular or laminated structure of the cornea; it consequently does not open at one point and discharge its contents, but breaks into an open ulcer not easily distinguished from the broken surface of a slough. The colour of the opacity of the cornea constitutes the best cri-terion; if the spot be of the usual straw-coloured tint of purulent matter, and not the dull dirty white of dead macerated cornea, abscess, not slough, is the process in progress. Abscess also probably occurs more frequently in circumscribed spots, and seldom extends to the entire circum-ference of the cornea. The secretion of puru-lent matter in the chamber of the aqueous humour is easily distinguished from abscess of the cornea at its commencement, by the puru-lent matter falling down in the aqueous humour between the iris and cornea, and by its surface assuming a horizontal level repeatedly de-scribed under the title of *hypopion*, *onyx*, or *un-guis;* but when the whole chamber is filled with pus, and the cornea consequently presents a uniform yellow appearance, the real nature of the appearance is not so obvious.

Causes.—In every day practice, where the cases are comparatively few, the inquiry into the cause of the complaint is not so important as when numbers of persons collected together are violently attacked; because the occurrence of a few instances of the disease would not jus-tify the adoption of preventative measures by a large community, which are imperatively called for where it rages among smaller numbers more crowded together, as in barracks, schools, and ships. That any cause producing irritation of the conjunctiva,—as strong light, currents of cold air, or the contact of dust blown through the atmosphere,—or any cause usually producing in-flammation of mucous membranes,—as sudden transitions from heat to cold, or peculiar con-ditions of the atmosphere,—is likely to produce purulent ophthalmia can scarcely be denied; but the extent to which these causes operate, or the circumstances under which they become in-fluential, have not been ascertained. The oc-currence of the disease in particular countries, and in barracks, schools, and ships, is notorious; but the real causes of such occurrence have not been satisfactorily determined.

The rapid extension of the disease among the individuals of crowded communities has naturally led to the belief that it is conta-gious, and not only communicated by actual application of the discharge of a diseased eye to a sound one, but even through the medium, whatever it may be, by which diseases notori-ously contagious are transmitted. The dis-cussion respecting the contagious nature of the affection is involved in the same diffi-culties and contradictions which embarrass the inquiry into the nature of contagion in general: sufficient facts, however, have been adduced to justify the separation and re-moval of communities among whom the dis-ease breaks out, and to induce the prudent practitioner to enjoin the greatest attention to the prevention of contamination by actual con-tact of the matter of the disease with the eyes of those not affected by it.

Prognosis.—The prognosis in severe purulent conjunctival inflammation must obviously be most cautious. The patient should be made fully acquainted with the immediate danger of destruction of the organ to be apprehended from sloughing or suppuration, as well as the pros-pect of slow and doubtful recovery in conse-quence of the great alteration or disorganization of the conjunctiva produced by the intense in-flammatory action. In forming his prognosis, the practitioner must of course be guided by the degree of violence of the attack, the habit and constitution of the patient, and the experience he has had as to the modifica-tion of the disease by climate or other circum-stances.

Treatment.—In severe conjunctival inflam-mation the principles inculcated in the com-mencement of this article should not be over-looked. The resources available for arresting the inflammatory action are, as has been ob-served, bleeding general and local, emetic and nauseating medicines, purgatives, diaphoretics, and, according to some, mercury. Locally, astringent, sedative, stimulant, cold or warm applications, and occasionally blisters, scarifi-cation, and other remedies directed to peculiar conditions, must be resorted to. Before the practitioner makes up his mind respecting the value of bleeding in this disease, he should pause to consider the effect of this depletion in arresting inflammation of mucous membranes generally; and having done so, he will proba-bly be prepared to admit that in many cases the lancet is not so valuable a resource as might be expected, or as it is found to be in inflamma-tion of serous membranes or other structures. The advantage of bleeding in croup cannot be denied, but it is to be recollected that this dis-ease is more liable to terminate in effusion of coagulable lymph than in secretion of purulent matter. Catarrhal inflammation of the lining membrane of the nostrils or the trachea and bronchial tubes, and dysentery in the acute form, are treated by bloodletting more with the view of diminishing the febrile symptoms than with the hope of cutting short the local inflam-matory action. Bleeding will not cure con-junctival inflammation, but it is a most valuable

auxiliary means of relief, by reducing the part to a condition in which other remedies become more effectual. The writer has seen the abstraction of blood carried to the greatest extent possible, consistent with the safety of the patient; he has seen repeated bleedings of forty, fifty, and even sixty ounces, and streams flowing from the arm and temporal artery at the same time, without generally beneficial results. More moderate bleedings, suited to the intensity of the symptoms, habits, and constitution of the patient, should, however, form part of the treatment. It is scarcely necessary to say that persons emaciated by want, enervated by drunkenness and debauchery, or debilitated by respiration of impure air, are not fit subjects for a system of depletion; on the contrary, such treatment is most destructive to them, and the very reverse of it is demanded.

The means by which blood should be removed, or the sources from which it should be drawn, deserve consideration. Many prefer opening the temporal artery, from a theoretical notion that by emptying one branch of an artery, those ramifying from the same source have the force of their currents diminished; but it never has been proved that this is actually the case, and it may even be doubted that any advantage is derived from the preference, while much inconvenience, irritation, and heat is produced by the bandage required to secure the wounded vessel. If advantage be derived from a local diminution of the circulating fluid, it may more reasonably be expected from opening the jugular vein; because in this case this vessel cannot, like the temporal artery, be instantly refilled by the heart's action: therefore, when the size of the vein, the formation of the patient, and other circumstances are favourable, this vessel should be selected. Bleeding in the arm, however, from its greater convenience, and the ease with which it may be performed, is generally preferred, and perhaps in the majority of cases without disadvantage to the patient.

The local abstraction of blood by leeches or cupping is the next resource, after the effect of the general depletion has been ascertained; it may be resorted to in the evening if the general bleeding took place in the morning, or, according to the urgency of the symptoms, may be postponed till the following day. Twelve, eighteen, or twenty-four leeches should be applied to the temple or over the cheek-bone, so as to leave an opportunity of stopping the bleeding by pressure should it become necessary. The irritation, inflammation, and tumefaction produced by the application of leeches to the swollen eyelids more than counterbalances the good, if any, derived from emptying the vessels of the inflamed part. The advantage from the bleeding by leeches appears to depend upon the continued trickling of blood, which is perhaps best encouraged by the application of compresses of old linen wrung out of warm water and removed and replaced every ten minutes, or as often as they become soaked with blood. The application of a few leeches to the conjunctiva of the lower lids has latterly been recommended and practised, and may perhaps be resorted to with safety and even advantage in the after stages of the disease; but in a case of violent purulent ophthalmia threatening destruction of the eye, the effect is too inconsiderable to risk any aggravation of the inflammation by the leech-bites.

Local abstraction of blood from the inflamed conjunctiva by scarification has been practised from the most remote periods; the same objection may be made to it as is offered to the application of leeches, that is, the small quantity of blood drawn, and the great extent of injury inflicted. When the chemosis or vascular tumefaction of the conjunctiva is very great, and the membrane projecting between the lids or overlapping the cornea, the writer, in place of merely scarifying or scoring the surface, runs an extracting knife from one end to the other of the tumour, by which the effused serum is allowed to escape, tension is relieved, and generally a considerable quantity of blood discharged. From this practice advantage is frequently derived without any injurious consequence either temporary or permanent.

As it is of the utmost importance that the practitioner should be informed as to the value of bleeding in this disease, the opinions of Dr. Vetch, Mr. Lawrence, and Mr. Guthrie, are here subjoined. Dr. Vetch observes, "A perfect command over the disease depends less on lowering the system than on the temporary cessation of arterial action by the syncope, which it becomes the object of the operation to produce. This practice, besides its efficacy, will accomplish the cure with a much less expenditure of blood than is occasioned by the repeated bleedings generally had recourse to, where this method of rendering one equal to the cure of the complaint has been neglected. Sometimes, before the approach of faintness, the redness of the conjunctiva for the most part disappears; but this is no security against the return of the disease, if the flow of blood be stopped without deliquium animi succeeding." And again, (page 217, Treatise on Diseases of of the Eye,) "Of three thousand cases admitted into the ophthalmia depôt, I am not aware of any one in which the practice of depletion, assisted by the remedies mentioned, did not prove effectual when the patient was received under the first attack of the disease." He then states that twenty-five men only were lost to the service of all those admitted into the ophthalmic depôt; "but an unfortunate feature of this very dreadful complaint is its great tendency to recur, even after the eye has recovered its healthy and natural appearance; and although it be in our power to conquer its present violence, no treatment can prevent relapses from taking place. As long as the lining of the palpebræ continues villous, this accident is liable to recur, with all the severity of the original attack." From this last observation it is to be suspected that numbers of these men were discharged as cured when labouring under pulpy and villous conjunctiva, subsequently proceeding to granular lids and opaque cornea; especially when it is known that thousands were lost to the service

notwithstanding the prevalence of the bleeding practice.

Mr. Lawrence* says, "The first measure is to take blood from the arm, and this in large quantity, so as to produce syncope: you may expect to derive much more benefit from one bleeding of this kind than from the repetition of smaller ones. It may be necessary to repeat the venesection; and if the symptoms should remain urgent, you must not hesitate to do it: you may subsequently take blood by cupping from the temple, and apply numerous leeches about the eye." In his account of gonorrhœal ophthalmia, bleeding is still more strongly recommended.

Mr. Guthrie† states, "It was deemed necessary to abstract blood in large quantities; indeed sixty, eighty, and even one hundred ounces have been drawn. It was often thought necessary to re-leech the eye and blanch the countenance to effect a cure, and I have no doubt that it has been done with success; and the extreme vessels of the conjunctiva have been so drained as to be rendered incapable of going on with the secretion. Those who find fault with this practice in all probability never saw the disease; for it is the most efficient mode of proceeding, and the best when there are no local means employed."

After the requisite depletion by the lancet, the practitioner avails himself of the other resources within his reach. If there be reason to believe that there are crudities in the stomach, with foul tongue and headach, an emetic may be administered with advantage; and when the nausea subsides, the bowels should be freely opened, and the discharge kept up by the administration of suitable medicine at proper intervals. A few grains of calomel at night, followed by repeated doses of the common mixture of infusion of senna and sulphate of magnesia in the course of the following day, may probably answer every purpose. From the advantage derived from nauseating medicines in other forms of inflammation, similar advantage has naturally been expected from its administration in purulent ophthalmia; but in consequence of their not answering the exaggerated expectations of the practitioner, they have not, perhaps, been resorted to to that extent they deserve. The effect may be advantageously secured by the addition of tartar emetic to the purgative mixture, or the same medicine alone in solution may be given after the bowels have been freely opened, in doses sufficient to produce slight nausea, and secretion from the skin encouraged at the same time by confining the patient to bed. Tobacco has been resorted to for the purpose of exciting nausea; but experience has not yet proved that it possesses any superior advantage, while we are less familiar with its effects than with the preparations of antimony. Mercury has been recommended and resorted to for the removal of conjunctival inflammation, but with little success. The opinions of Mr. Lawrence, Beer, Delpech, and others, are unfavourable to the practice. Without accomplishing any valuable object, it reduces the patient to the condition which is most calculated to perpetuate the destructive change in organization of the conjunctiva.

Whatever importance is to be attached to the opinions of English writers on the present subject—respecting the paramount value of bleeding and low living in the treatment of the disease, the Irish practitioner must undoubtedly be circumspect, in this respect, in his treatment of the poor. It may be very well to bleed and otherwise reduce those who have been well fed and have enjoyed all the comforts of life; but the practice is utterly inadmissible in a country where the poor are abandoned to a state of destitution, and, if not absolutely starved, are so ill fed, and clothed, and lodged, that frequently no healthy action can be roused until the constitution be invigorated. In Dublin it is often absolutely necessary to place a patient, a few days after the first attack of purulent ophthalmia, on full diet, consisting of animal food with ale or porter, accompanied by the administration of bark or other tonics.

In the treatment of purulent ophthalmia the management of the patient, with respect to the temperature, ventilation, and lighting of his apartment, should not be overlooked. The practice of immuring a patient in a close room, with windows shut and curtains drawn, and with the addition of an enclosure of curtains round his bed, involving him in a contaminated atmosphere loaded with the excrementitious effluvia of his body, is most pernicious. The close, stinking, crowded, and darkened ward to be found in some hospitals, called the eye-ward, is equally destructive. The author of this article has almost daily opportunities of witnessing the refreshing and salutary effects of what may justly be called a meal of fresh air, on persons subjected to such treatment; and he invariably finds that patients obliged to go out of doors are more easily managed, and escape with less injury, than those confined in the way just mentioned.

With respect to this part of the treatment, Dr. Vetch makes the following observations:—"I entertain so favourable an opinion of the effects of the free exposure to the atmosphere, that although no person can better appreciate the importance of decisive measures in the early stage of the disease, I would in favourable weather risk the delay of a journey on foot or horseback, or in a carriage, or a voyage by sea, provided the eye be freely exposed to the air. Even when the second stage has commenced, by the appearance of a chemosis and purulent secretion, I have never seen any other than the best effects to attend a change of place. Soldiers who have commenced a march with the disease completely formed, though exposed to heat, dust, and fatigue, and not abstaining even from intoxication, are invariably better at the end of the journey than when they set out. The instances of this fact which I could

* Lectures, reported in the Lancet.

† Lectures, reported in the Medical and Surgical Journal.

adduce from my own observation are innumerable; and I am informed by Mr. Murray, surgeon to the forces, that so strongly did he observe the beneficial effects of exposure to the air, when a great number of men affected with the disease was sent, under his care, to the interior of Sicily, that he was induced to march them from one place to another, with a view solely to the good effects he saw resulting from it."

In considering the local treatment of severe purulent ophthalmia, the first and most important point to be determined is the value of powerfully stimulant or astringent applications made directly to the inflamed conjunctiva in the first or inflammatory stage of the disease. The great advantage of strong astringent solutions in arresting the progress of that disorganizing change which follows violent conjunctival inflammation is undeniable; but it requires much circumspection to avoid confounding the advantages derived from astringents in the chronic stage with those derived from similar applications in the acute. The question to be determined is, whether a powerful stimulant or astringent, as ten or twenty grains of nitrate of silver in an ounce of water, or ten grains in a drachm of lard, can be with safety and advantage applied to the surface of the inflamed conjunctiva in the first attack of violent purulent ophthalmia. When a patient presents himself in the first stage of purulent ophthalmia, with severe scalding pain, and with the conjunctiva in a state of chemosis, overlapping the cornea and projecting between the eyelids, few practitioners will feel inclined to soak the eye in a ten grain solution of nitrate of silver, or thrust a portion of the ointment (ten grains to the drachm) between the lids and the swollen and turgid conjunctiva. The most strenuous advocates for the stimulating practice inculcate the necessity of allaying inflammatory action before or during its adoption. Whither incipient purulent ophthalmia of the character now under consideration can be at once cut short or not by the application in question, has not yet been established to the full satisfaction of practitioners. The circumstances under which the experiment may be made to enable the observer to arrive at a just conclusion seldom occur, because he rarely meets a case in its very onset which he can pronounce to be violent purulent ophthalmia, the severe characteristic symptoms not being yet developed. If purulent ophthalmia rages in a regiment, a school, or a ship, and the surgeon, watching narrowly the symptoms of the accession of the disease, applies this stimulating astringent to the surface with decided effect; or if a patient in the hands of a practitioner for the treatment of gonorrhœa presents the symptoms of conjunctival inflammation, and is similarly treated with similar good effects, the question must be determined in the affirmative. Several military surgeons, who have enjoyed the best of opportunities of observing and treating the disease, are decidedly favourable to the practice.

Mr. Lawrence, however, in his book on Venereal Diseases of the Eye, speaks of it with caution and reserve. After quoting the authority of Mr. Melin, Mr. Bacot, Dr. Ridgeway, and Dr. O'Halloran on this subject, he observes, "I have not seen purulent ophthalmia, whether ordinary or gonorrhœal, treated on this plan; nor am I aware that any case of the latter kind is recorded. Destructive or injurious consequences have so frequently resulted under the usual management of this disease, that I should certainly employ the local astringent if I met with a case favourable for the trial; that is, where the affection had not extended beyond the conjunctiva. Bloodletting might be resorted to at the same time. In most cases, however, our aid is not sought until the cornea has become affected; and it is, therefore, too late for the astringent plan." In a note he adds, "Since the statement in the text was written, I have employed the caustic solution in two cases of conjunctival inflammation with the best result. One of these was mild gonorrhœal inflammation. The other was catarrhal inflammation of the membrane, affecting both eyes of a gentleman who had been convalescent from gonorrhœa for a few weeks. As he was a person of robust make and full habit, and the eyes were very red and stiff, I took three pounds of blood from the arm, and purged him freely, with relief of the local symptoms, which were completely removed by a subsequent application of the caustic solution."

The practice here alluded is advocated so strenuously by Mr. Guthrie, that it is desirable to have his opinions conveyed in his own words. The following extract is, therefore, made from his lectures reported in the Medical and Surgical Journal. "In the more formidable affection which runs its course in three or four days, neither the nitrate of silver in solution nor the vinum opii are effective; it requires a more powerful local application. The disease begins externally, and is a local disease of a peculiar character. If we can set up a new action, or alter that which is going on, we check the original affection, according to the principle of John Hunter, that no two diseases or actions go on at one and the same time. Acting on this principle, I took the nitrate of silver in substance, and made it into an ointment. I did not arrive at its exact composition at once, but gradually acquired it by degrees; it was made at various times, of five, six, ten, and twenty grains to the drachm; and after trying all these different preparations, I came to the conclusion that the ten grain ointment was the best. Take half a drachm of the salt, and powder it in a glass mortar, then sift it through a bit of muslin, so that it is reduced to an impalpable powder, for if there are any grains left, they will stick in the cornea, or in the folds of the conjunctiva, and produce a slough. Ten grains of this impalpable powder should then be thoroughly incorporated with a drachm of hog's lard, on a glass slab with an ivory paper cutter; and in order to ensure

proper attention in the preparation of this ointment, I sought for something to mix with it, which would require some time for its incorporation, and selected the liquor plumbi acetatis for this purpose. Fifteen drops are to be duly mixed with the ointment; and as it generally requires some minutes to do this, there is reason to believe that the trituration is complete. There has been, as usual, some dispute concerning this ointment; the first thing said was that it was violent and useless: well, that has been got over. The second stage was to attribute the introduction of it to some other person. The third to alter the composition, and instead of the liquor plumbi acetatis to mix opium, &c. with it. I have no objection to this, if the gentlemen will only leave me the principle, which is all I contend for. I care not if they change all the component parts, or whether they apply it by a brush of the little finger, or the probe. It has been said that it is soon valueless and inert. All I can say is, let those who think so have it applied to their eyes, and they will soon change their opinion, even if it be a year old. Before the ointment is applied in this purulent inflammation, the discharge must be well cleansed out by a solution of alum; then the ointment having been inserted, the lids must be moved freely up and down so that the whole conjunctiva gets its due proportion of ointment, and this is shown by its turning white. If it does not turn white, it has not been sufficiently applied, and will not answer the purpose; if we wish to be quite sure, we turn out the eyelids, and rub the ointment on them; this application gives pain, which lasts for half an hour to an hour, or more; it is not quite so acute as the vinum opii. I had rather that the pain should last an hour or more, as the action going on is more likely to be changed. When I apply this ointment, I generally direct the patient to lose blood, not to the amount of sixty ounces, but to about twenty, and I had rather that he should faint: and I do this because the application will only alter the action in the extreme vessels, and not that which is behind them in the ball itself, and it is therefore necessary to diminish action in them by bleeding. If, however, the inflammation is moderate, I do not bleed at the time, leaving directions that if the patient is not better in the evening, or the next morning, blood should then be taken. Warm narcotic fomentations may be employed to relieve uneasiness, and opium should be given to allay pain and obtain sleep, while a solution of alum, half a drachm to half a pound, should be injected from time to time into the eye to clear it; but should the patient sleep, he must not be disturbed. A mild ointment may be applied to the lids at night, to prevent their adhering together. The next morning the discharge is again to be removed, and the ointment re-applied, for on no account should the action we are desirous of exciting be suffered to cease; the other remedies are likewise to be continued. In addition to these I would give calomel and opium, so as to affect the mouth, and the other more common remedies; and rest and diet should be attended to. When I hear of twenty or thirty persons losing their eyes from this disease, I say that it must always be so, unless they are treated on this principle, bearing in mind that some diseases in certain persons are incurable from the first, and that no one means of cure is applicable to every case. I am certain, however, from experience, that the plan I have recommended is the most generally efficient and certain of any that has hitherto been advised, whilst it is also less injurious to the constitution."

There is much difference of opinion as to the comparative value of cold or warm applications in the acute stage of purulent ophthalmia. Either in ophthalmic or any other local inflammation, the advantage to be expected from cold applications is the reduction of the temperature of the part, and consequent diminution of vascular action; but this object is very rarely obtained, and the real effect of cold in abating inflammation has as yet scarcely been ascertained. The attempt is made in conjunctival inflammation by repeated applications of cloths wrung out of cold water, but these cloths become so speedily of the same temperature as the part, that nothing more is effected than a temporary cooling, followed by perhaps greater heat and vascular re-action. To obtain the advantages to be expected from cold applications, these cloths should be changed by a nurse, sitting at the bedside of the patient, twice in a minute, or a fold of old linen may be laid across the eyes with the ends hanging into cups on each side, and cold water squeezed on with a sponge, or allowed to drop from a vessel contrived for the purpose. In this way the application of cold as a remedy in ophthalmic inflammation, and especially from wounds or other injuries, is undoubtedly of value, although many patients prefer the effects derived from warm moisture. The following objections made by Mr. Travers to cold applications, in his Synopsis of Diseases of the Eye, are perhaps more applicable to their maladministration. "Although the sensation of cold is most agreeable to an organ under acute inflammation at the moment of its application, it is generally followed by increase of heat and pain; and in familiar instances the pulsatile action of the vessels leading to an inflamed part is so increased as to evince its stimulating effect, and the reaction thereby induced. When, however, the acuteness of inflammation has subsided, and the sensibility of the part is in proportion diminished, the effect of cold is only tonic, and has a salutary tendency to restore the balance of the circulation. I therefore decidedly prefer a tepid application in the painfully acute stage of inflammation." With the reservation that cold properly applied is not to be despised, this advice is good for the purposes of general practice.

Warm applications may be made by stupes, poultices, or light compresses, all of which are generally mismanaged, and frequently do more mischief than good, unless particularly attended to by the practitioner himself. The stuping is generally attempted by wringing a flannel cloth

out of a hot decoction of chamomile or poppy-heads, and laying it across the patient's eyes, in which case the steam is dissipated, and little of it comes in contact with the eyes. It is best accomplished by the patient himself, who, sitting up in bed, should receive a small piece of flannel, wrung out of the hot water, from the nurse, and hold it in the hollow of his hands under the eyes, changing it as it ceases to give out steam. Many little contrivances may be made for the purpose with sponge or other materials, but holding the eyes over vessels of hot water, or exposing them to steam extracted from a boiling apparatus contrived for this purpose, is not found advantageous, as the heat applied is generally too great. Whether any benefit be derived from the addition of sedative or other medicinal ingredients to the stupe, remains to be proved: it is not, however, attended with disadvantage, and a medical man of any sagacity will see the necessity of yielding to prejudices for the attainment of objects directed to the relief of his patient. If the practitioner determine to add opium to the stupe, he should give the patient the advantage, whatever it may be, of its efficient application, which is, perhaps, obtained in a neater and more perfect manner by the addition of a drachm of the tincture, or a few grains of the watery extract to a pint of hot water.

Whatever difference of opinion may exist with respect to the extent to which stimulating or astringent applications should be employed in the inflammatory stage of conjunctival inflammation, there is little doubt entertained of the value of astringents in the chronic stage, or that condition of the conjunctiva which may be considered the necessary consequence of the violent inflammation above described. The salts most commonly used for this purpose are acetate of lead, alum, sulphate of copper, sulphate of zinc, corrosive sublimate, and nitrate of silver. Notwithstanding the length of time these salts have been in use, it does not appear that any conclusive experiments have been made to ascertain their comparative value, or the best proportions in which they should be used. The practitioner has little more to guide him in the selection than the vague and uncertain evidence of expressions of confidence in some one or other by different practical writers. The most generally valuable, safe, and efficient, are the acetate of lead, alum, and nitrate of silver, the sulphates of copper and zinc being more stimulating and irritating, with less astringent properties. Weak solutions, however, of sulphate of zinc or copper are unquestionably of value in the slighter vascularity of the conjunctiva following catarrhal ophthalmia, or arising without preceding inflammatory action. Saturated solutions of acetate of lead or alum may be used with the greatest safety, and without producing any such effect as follows the introduction of other salts. Saturated solutions of sulphate of zinc may also be applied to the conjunctiva without any other destructive consequence than a temporary increase of vascularity, pain, and weeping; but a saturated solution of sulphate of copper produces violent inflammation, probably acting chemically, and producing superficial destruction of the surface. Nitrate of silver, in the proportion of ten or fifteen grains to the ounce, appears also to act chemically, causing whiteness of the vascular conjunctiva, but without the irritating and stimulating effects of sulphate of copper. Nitrate of silver, even in the proportion of three or four grains to the ounce, if used for a month or six weeks, will produce an olive-coloured indelible stain of the conjunctiva, and lamentable deformity; or both it and acetate of lead, applied while ulcers of the cornea exist, produce the worst form of opacity by being decomposed by the tears and deposited on the flocculent surface, and there detained until permanently fastened by cicatrization, as has been described by the author of this article in the Dublin Hospital Reports. None of these disadvantages attend the application of the alum solution, and its powerfully astringent qualities are undeniable. The condition of the conjunctiva to which the reader's attention is called with reference to these applications, is that which exists from a fortnight to six weeks after the first attack, when the acute inflammatory symptoms have subsided, and before the membrane has acquired the extreme condition of disorganization denominated granular conjunctiva. At this period there is occasional pain, flow of tears, purulent discharge, and a pulpy villous vascularity of the conjunctiva. In this state a solution of from five to ten grains of nitrate of silver in an ounce of water, or the ointment recommended by Mr. Guthrie, will prove of great advantage; but the practitioner should not allow the praises exclusively bestowed upon it to induce him to discard the saturated solutions of alum or acetate of lead, as he may be assured that they will often be found preferable in practice, although the particular condition in which they are so may not have been ascertained. The effects of the saturated solution of acetate of lead, when such cases, modified by scrofula, are accompanied by vascularity of the conjunctiva covering the cornea, are frequently most remarkable. Dr. Vetch expresses the following opinion respecting the solution of acetate of lead. "The liquor plumbi acetatis in its undiluted state is the application which I can recommend as the most efficacious, and at the same time incapable of doing harm in this, and in every stage of purulent ophthalmia. The sensation it occasions is that of some dust or sand having got into the eye, which lasts from ten to twenty minutes; there is generally a copious lachrymation, and the eye afterwards feels cool, and the sight is clear."

Whichever of these solutions is preferred should be fairly dropped into the eye, after it has been cleansed with sponge and warm water, on awaking in the morning, and the patient should remain quiet with the lids closed for half an hour. This may be repeated in the evening, if not found to produce increase of pain or irritation, and the patient should be allowed a weaker solution to wash the eyes with more frequently in the course of the day. At night the edges of the lids may

be smeared with cream, fresh butter, or some mild ointment. On the continent a compound salt, called the *lapis divinus*, is much used; it is made by heating eight ounces of nitre, alum, and sulphate of copper in a crucible, and, when fluid, adding half an ounce of camphor, and closing the vessel until cold. It is used in the proportion of three or four grains to the ounce, and appears to have the same effects as sulphate of copper.

The application of the vinous tincture of opium was first recommended by Mr. Ware, in his "Remarks on the Ophthalmy." He gives the following account of the method of applying it and its effects: "I would particularly recommend the thebaic tincture of the old London Dispensatory; a medicine composed of opium and warm aromatics, dissolved in mountain wine." "When first applied it causes a sharp pain, accompanied with a copious flow of tears, which continues a few minutes, and gradually abates, after which a greater and remarkable degree of ease generally succeeds. The inflammation is often visibly abated by only one application of this tincture; and many bad cases have been completely cured by it in less than a fortnight, after every other kind of remedy had been used for weeks, and sometimes months, without any success. But this speedy good effect is not to be expected in all cases indiscriminately. In some, the amendment is more slow and gradual, requiring the tincture to be made use of for a much longer time; and a few instances have occurred, in which no relief was at all obtained from its first application. In cases of the latter kind, in which the complaint is generally recent, the eyes appear shining and glossy, and feel exquisite pain from the rays of light. However, notwithstanding these symptoms, the application is sometimes found to succeed; and whether it will or not, can only be determined by making the trial, which is attended with no other inconvenience than the momentary pain it gives. When it is found to produce no good effect, the use of it must be suspended, until evacuations and other proper means have diminished the excessive irritation; after which it may again be applied, and bids equally fair for success, as in those instances in which it never disagreed. If two or three drops of the thebaic tincture are dropped at once on the globe of the eye, the pain they occasion will be considerably greater than if they are placed in the inner angles of the eyelids, and made to glide gradually on the eye, by gently drawing down the lower lid. At the same time that this latter mode of applying the tincture is much less painful than the former, I have found, in a great variety of cases, that it is equally beneficial." Experience has fully established the character here given by Mr. Ware of the vinum opii; it is, however, most applicable in those cases where there is much scalding pain, lachrymation, and intolerance of light.

If the pulpy villous vascularity produced by the inflammation above described be neglected, or be not removed by the applications alluded to, it degenerates, in about six weeks or two months, into a still more destructive condition; the conjunctiva lining the lids acquiring a rough irregular vascular appearance, which, from its resemblance to the granulating surface of a sore, has been named the granular conjunctiva. This condition, if not altered or removed, is followed by red vascularity and opacity of the conjunctiva covering the cornea, and almost total loss of vision. To remove this state of the membrane, the resources of ophthalmic surgery have been nearly exhausted, and frequently without effect. It even unfortunately happens that the destruction or removal of these warty prominences or granulations is not followed by recovery. In fact, the organization of the conjunctiva is destroyed by the severe inflammation, and, if ever restored, requires a great length of time to return to its original condition. These granulations may be removed either by the knife or escharotics, and the question respecting the preference to be given to either method has been the subject of much controversy. They certainly may be shaved off by the dexterous use of a small cimeter-bladed knife, and their removal in this way is accompanied by the advantage of local bleeding, and consequently less subsequent pain, irritation, and inflammation than attends the use of escharotics. The partial use of escharotics, however, is often necessary to complete the removal, as it is impossible to reach all the granulated surface with the knife. The escharotics commonly employed are the nitrate of silver, or sulphate of copper, in substance. The former is preferable, its effect is more decisive, and the inflammation and irritation from its application are less: the latter is, however, preferred by some.

The operation of applying the escharotic must not be carelessly performed. Much mischief has been frequently done by allowing an inexperienced pupil to rub the inside of the lids with a piece of sulphate of copper in a slovenly manner. The upper lid should be everted and the surface dried with a cambric handkerchief; the whole of the granulations should then be repeatedly touched with a pencil of nitrate of silver until the surface becomes of a deep ash colour; it should then be carefully washed with a plentiful stream of water from a syringe, lest any particle of nitrate of silver should adhere undecomposed, and be turned in on the cornea. If the sulphate of copper be used, it will require a more continued application to produce the escharotic effect, and the washing must be performed with equal care. The application of the escharotic must be repeated as often as the granulations are observed to remain after the surface becomes clear from casting off the coat produced by the nitrate of silver.

Ointments are frequently resorted to for the removal of the vascularity and tenderness of the lids produced by purulent ophthalmia, especially where the skin at its meeting with the conjunctiva becomes red and destitute of cuticle, constituting lippitudo, a condition which, it is to be recollected, arises often without pre-

ceding acute inflammation. Where the object is merely to obviate the inconvenience arising from the dryness produced by exposure to the air, or the scalding from contact of the tears, it may be accomplished by the application of a little cream, fresh unsalted butter, or the spermaceti ointment. It is often, however, necessary to combine astringent or stimulating ingredients with the ointment. The ointment of nitrate of mercury, diluted with five or six times its weight of oil or lard, is very commonly used, and frequently with good effect if continued for a few days only. The stimulating effect appears to be salutary as a first and temporary impression, but when persevered in for a length of time, seems to have a contrary result. The ointment of oxyd of zinc is a very safe and efficient astringent application, as is also the mixture known as the ophthalmic ointment of *Janin*, composed of four drachms of lard, two of tutty or impure oxyd of zinc, two of Armenian bole, and one of calomel. These ointments should, however, be made with such a proportion of oil as will give them so soft a consistence that they can be applied with ease to the lids with the point of the finger or a camel-hair pencil; they should also be properly and carefully ground on a flag with a muller, not merely mixed on a tile with a palate knife, and great care taken that the oily ingredient be not rancid or burned. Ointment of acetate of lead, or a mixture of oil or lard, with liquor subacetatis plumbi, is another application frequently employed with advantage. As oily applications are sometimes found not to agree with the surface, the practitioner may find it necessary to combine astringents with some tenacious ingredient of a different description; for this purpose clarified honey may be used, with the addition of alum or Armenian bole finely levigated. Honey alone will often afford relief in the slighter degrees of vascularity following conjunctival inflammation.

In the treatment of purulent ophthalmia the advantages to be derived from blisters should not be overlooked. The extent to which they may prove beneficial in any particular case can perhaps scarcely be ascertained; but as their value generally in contributing to the removal of local inflammation is admitted, it is not reasonable to disregard such a resource. They may be applied at any period of the disease, but they probably are more efficacious after the more acute symptoms have subsided, or before they have set in, and appear most indicated where there is much irritability, intolerance of light, and scalding lachrymation. They should not be applied too near the eye, as in such case the cutaneous inflammation sometimes spreads to the lids and increases the mischief. A patch of the scalp from the temple to the top of the ear should be shaved, and a blister of size sufficient to secure a decided counter-irritating effect, applied and allowed to remain on until the skin is fully inflamed. A scrap of blister behind the ear does not produce sufficient impression to compensate for the annoyance it occasions to the patient.

Gonorrhœal inflammation of the conjunctiva—Mr. Lawrence, from whose valuable work on venereal diseases of the eye it will be necessary to make copious extracts in treating this subject, considers that there are two varieties of gonorrhœal inflammation of the conjunctiva, the acute and mild. The acute gonorrhœal ophthalmia is perhaps to be considered specifically distinct from the common severe purulent ophthalmia, on account of its origin and consequences, rather than from any decided difference in the character and symptoms of the disease. There is the same scalding pain, intense vascular chemosis, profuse purulent discharge, sloughing, abscess, and ulcer of the cornea, and permanent disorganization or granulation of the conjunctiva, observed in the Egyptian and other severe forms of purulent ophthalmia. Mr. Lawrence says, "the local symptoms are not sufficient to establish a distinction between this affection and common purulent inflammation of the most violent kind, and its peculiar nature is indicated by the concomitant circumstances, that is, by the preceding or existing gonorrhœa." He considers, however, that it generally attacks only one eye, while common purulent ophthalmia affects both; that it commences in the conjunctiva of the eyeball oftener than in that of the lids, that the symptoms are more violent, and that its progress is more rapid.

Notwithstanding the similarity of symptoms between the severe purulent and the gonorrhœal ophthalmia, a repetition of the account of those symptoms as they occur in the latter in the words of Mr. Lawrence may not be unacceptable. "There is the greatest degree of vascular congestion, the most intense and general external redness; excessive tumefaction of the conjunctiva; great chemosis, with corresponding swelling of the palpebræ; and profuse yellow discharge. In the first stage of the disease, which is short, the inflammation is confined to the conjunctiva, and is attended with soreness and stiffness, with the sensation of sand or dirt in the eye, and with more or less uneasiness on exposure to light or using the organ. The affection soon extends to the cornea, with severe and agonizing pain in the globe, orbit, and head, augmented to intolerable suffering on exposure to light, and with febrile disturbance of the system of inflammatory character. The danger to the organ is now most serious and imminent; and indeed, when the disease has thus advanced from the mucous membrane to the globe itself, we can hardly expect by any kind of treatment to avert entirely its destructive consequences. The violent inflammation, which causes the yellow puriform discharge from the mucous surface of the conjunctiva, produces effusion into the cellular texture connecting it to the surrounding parts. Hence the general swelling of the membrane, and that more considerable tumefaction on the front of the sclerotic, round the cornea, which is called chemosis. The latter is often so considerable that the swelled conjunctiva overlaps the cornea all round, so as nearly to hide it. Similar effusion takes place

into the cellular texture of the eyelids, enlarging them considerably, more particularly the upper, which hangs over and completely covers the lower. The palpebral swelling is sometimes œdematous, with the integuments but little redder than natural; in other instances it is firmer, with the skin, particularly of the upper eyelid, bright red. The latter state denotes more active inflammation, and greater danger to the organ. The chemosis and the swelling of the lids make it often difficult, and sometimes impossible, to get a clear view of the cornea. Although it is desirable to do this, in reference to prognosis, when we first see the case, we should not persist in our efforts at the risk of augmenting the inflammation or the patient's sufferings. The œdema of the eyelids declines in the progress of the affection, and then one or both of them may become everted, the convex edge of the tarsal cartilage being pushed forwards by the swollen conjunctiva. The inflamed membrane exhales at first a thin whitish mucus in small quantity; as the inflammation proceeds to its full development, the discharge becomes thicker, yellow, and abundant; the yellow tint and the quantity of the exhalation being in proportion to the violence of the inflammation. When the latter is at its height, the discharge closely resembles in its appearance, and in the stain communicated to linen, that which proceeds from the urethra in venereal gonorrhœa. Although the pain is generally most severe both in the eye and in the head, as in other instances where the dense and unyielding texture of the cornea is the seat of inflammation, and although patients often complain of burning pain, of tension, as if the eye would burst, of deep-seated and intense agony, with extension of these distressing and almost intolerable sensations to the brow, forehead, and head generally, there are some instances in which little or no pain is experienced. The symptoms of acute gonorrhœal ophthalmia are not equally violent through the whole course of the affection: it begins with swelling and increased redness of the conjunctiva, and some pain in the organ: then the puriform discharge takes place, with increased uneasiness: and, lastly, the inflammation extends to the cornea, with great aggravation of suffering. Thus the course of the affection may be divided into three stages, of which the limits cannot be marked very accurately. In the first there is vascular distention and swelling of the membrane, with swelling of the lids; the commencement of the second is marked by the occurrence of the puriform discharge, and that of the third by extension of the inflammation to the cornea. The duration of each of these varies in different instances according to the constitution and state of health of the individual, and perhaps still more according to the nature of the treatment adopted. This variety, however, is observed less in the first and second than in the third stage; the two former, and more particularly the first, usually passing off very rapidly."

In gonorrhœal ophthalmia, the immediate destructive effects of the inflammation, sloughing, abscess, and ulceration of the cornea, are more to be apprehended than in common purulent ophthalmia as it now occurs. The appearance of the cornea when about to slough or suppurate has been already described; the process, as it occurs in the present form of inflammation, is described as follows by Mr. Lawrence. "The cornea becomes dull and hazy before it sloughs, or indeed before undergoing any of the changes above enumerated. Its transparency and polish are completely destroyed where it has sloughed; and it is converted into a dirty yellowish or brownish opake surface, which is immediately recognized as deprived of life. At first it looks like a portion of wetted leather; it is soon separated from the living parts, when it has a loose, soft, and ragged appearance. As the lens and capsule which are exposed by this separation are transparent, the patient sometimes recovers for a short period tolerably good vision. After the slough is detached, the chambers of the aqueous humour may be exposed by ulceration; the humour will then escape, the empty coats will collapse, and the globe remains permanently shrunk in the socket. More commonly, although the whole cornea seems to slough, the entire thickness does not separate, and the anterior chamber is not exposed." The slough of the cornea, when it does cast off, leaves an ulcerated surface proportioned to the size of the slough, with or without an opening into the anterior chamber. If the slough or ulcer does not extend through the thickness of the cornea, the consequence is simple opacity or staphyloma; if it does not penetrate into the chamber of aqueous humour, the iris passes through the opening, and the patient suffers from closed, contracted, or irregular pupil in addition to the opacity. But it is not by slough alone that these evils are produced: suppuration or abscess is also liable to occur. It is thus described by Mr. Lawrence: "Suppuration of the cornea may be general or partial: it is usually the former. The cornea first becomes white, and then assumes a yellow colour. The effused substance is not a fluid, nor is it collected into a cavity: it is a thick viscid matter deposited in the texture of the cornea. Ulceration takes place, and exposes an opake yellow substance, which looks like ordinary matter, but it cannot be wiped off." The abscess of the cornea thus opened by progressive suppuration goes on to ulceration, and may extend to the anterior chamber as in the sloughing process, and with similar consequences. The successive changes in the ulcer are thus described. "If the ulcer should be spreading, the inflammation remaining unchecked, its surface is whitish and ragged or flocculent, or of a dirty yellowish cast with surrounding haziness. When the inflammation subsides, it becomes transparent. The commencement of the restorative process is marked by the surface of the excavation assuming a light greyish tint with a jelly-like appearance. A soft semi-opaque substance fills up the breach, when the surface becomes smooth, and the regular figure of the cornea is restored."

The *prognosis* in gonorrhœal ophthalmia must obviously be most cautious, and the pa-

tient should at once be informed respecting the nature of his disease, and the dangers to be apprehended. The first and most destructive consequence to be feared is the sloughing of the cornea; a change of appearance in the eye indicative of such disorganization is therefore to be watched for with great attention. This change is a haziness, or loss of the natural transparency of the cornea, proceeding rapidly to complete dirty white opacity, subsequently becoming total or partial slough, with edges defined by the suppurative process, which separates dead from living parts. The appearance of abscess is later than that of slough, but, when observed even in the slightest degree, should be viewed with nearly equal apprehension, as it is impossible to determine the extent to which it may enlarge either in depth or breadth, while in the state of abscess or that of ulcer. After the more acute period has passed over without either slough or abscess, the appearance of even a small speck of ulceration is also calculated to excite alarm, as it is often most difficult to arrest the progress of this process before it produces irreparable injury of the organ. After the patient is relieved from apprehension respecting these destructive consequences, he should still be taught to understand that his recovery is to be slow and ever doubtful; the change of organization in the conjunctiva, and its conversion into the peculiar granulated condition, with permanent red vascularity of the conjunctiva of the eye-ball and opake cornea, may still prevent recovery; or even without such disorganization, the cure may be greatly retarded by the influence of scrofulous constitution or the local disease. Mr. Lawrence says, "of the fourteen cases which I have related, loss of vision took place in nine from sloughing, suppuration, or opacity of the cornea. In two of these one eye was lost, and the other recovered. Sight was restored in the other five, with partial opacity of the cornea, and anterior adhesion of the iris in three of the number. So short a period intervenes between the commencement and the full development of the complaint, that in many instances irreparable mischief is done to the eye before our assistance is required. If we see the complaint in the first or second stage, we may expect to arrest its progress by active treatment; but success does not invariably attend our efforts. Our prognosis will principally turn on the state of the cornea: if that should possess its natural clearness, the eye may be saved. If it should become hazy and dull, and more particularly if it should have assumed a white nebulous appearance, consequences more or less serious will inevitably ensue. Great swelling of the conjunctiva, more particularly great chemosis, profuse discharge of a yellow colour, and bright redness of the swollen upper eye-lid, are unfavourable circumstances, as indicating a high degree of inflammation. When both eyes are attacked in succession, the disease is less severe in the second, which, therefore, is usually saved. Sometimes, however, the inflammation is equally violent in both."

In investigating the *causes* of gonorrhœal ophthalmia, inquiries highly interesting, even in a general point of view, are suggested. It has been supposed that the specific form of gonorrhœal inflammation existing in the urethra is transferred to the conjunctiva by that obscure and inexplicable transition which is denominated metastasis, respecting which we know little more than the fact of its occurrence. This metastasis never has, and perhaps never can be proved to occur, because there can be little doubt that the contact of gonorrhœal matter with the conjunctiva produces the disease of the eye, and it is impossible to prove positively that such contact does not take place in all cases of gonorrhœal ophthalmia. Every individual affected with gonorrhœa must have the fingers contaminated by the discharge, notwithstanding the most scrupulous cleanliness and care; and the application of the fingers to the eyes for the removal of any irritation there is so habitual, that it becomes an involuntary act, which nothing but continued watchfulness could prevent, and which may occur even during sleep when the patient is unconscious of it. It is true that a person may be so attentive to the prevention of this occurrence, by the utmost precaution and cleanliness, as to render it highly improbable that a particle of matter has been applied to the eye, but the attendant can only say in such case, this is most probably metastasis of gonorrhœa to the eye, but cannot safely assert positively that it is so. While it appears thus impossible to say with certainty that metastasis has occurred, it is equally impossible to prove that it has not; and many facts and arguments may be adduced in favour of the conclusion that this is the mode in which the disease originates.

The disease of gonorrhœa affords other apparent examples of metastasis. The violent inflammation of the testicle produced by suppression of the discharge from the urethra is surely rather of this character than an extension of the mucous inflammation along the lengthened and tortuous tube of the vas deferens. Irritable bladder, produced by the same cause, is also most probably independent of a continuous extension of the specific inflammation along the whole length of the urethra to the lining membrane of that organ; and even sympathetic buboe generally presents characters so different from that which arises from the extension of irritation along the absorbents to the lymphatic glands from simple injury, that it is not unreasonable to attribute it to metastasis. These metastases are of comparatively rare occurrence; so is gonorrhœal ophthalmia, notwithstanding the probability of the frequent application of the matter to the conjunctiva or its vicinity. The occurrence of the disease in one eye without extending to the other, notwithstanding the profuse discharge so likely to come in contact with the unaffected organ, makes it highly probable that the disease depends on a cause different from mere contact of infectious matter. Whatever doubt may be entertained respecting the occurrence of metastasis, evidence sufficient to prove that the disease can be produced by the contact of gonorrhœal matter, both in

the individual labouring under the disease of the urethra as well as others, is on record. Mr. Lawrence, Mr. Wardrop, M. Delpech, Mr. Bacot, and others, state instances in which there could be no doubt of the fact. The writer of this has had this assigned as the cause of the disease by a young man, who, without any leading question or knowledge of the usual production of inflammation of the eye by such a cause, stated circumstantially the fact of gonorrhœal matter having been projected into his eye while retracting the prepuce, which confined a quantity of the discharge. Dr. Vetch details a solitary case in which the experiment was made to determine this matter by an hospital assistant; and where gonorrhœal matter was applied to the conjunctiva with impunity. It does not, however, appear that Dr Vetch himself conducted the experiment; and it is obvious that much confidence could not be reposed in the accuracy of an individual so imprudent and thoughtless as to incur such a risk. While it may be admitted that the contact of gonorrhœal matter to the eye produces conjunctival inflammation, it is by no means proved that it uniformly has this effect. Some individuals may possess this dangerous susceptibility, and others not; and even the same individual may at one time suffer from the contamination, and at another time not. Should it be established by observation that this is the fact, it would be an important illustration of the general question of contagion, proving that a morbid poison directly applied to a circumscribed spot produces effects at one time and on one person, which are not observed on other persons or on different occasions. Upon a candid consideration of this subject, it must be admitted that it is the duty of the practitioner to warn patients labouring under gonorrhœa, of the danger they incur by negligence or inattention, with respect to the precaution necessary to prevent the communication of the disease to the eye.

With respect to the *treatment* of gonorrhœal inflammation, it is scarcely necessary to observe that the plans suggested for the relief of common severe purulent ophthalmia should be carried into effect with the utmost vigour. Mr. Lawrence observes, in alluding to the advantage of depletion, "The only chance of arresting this violent disorder, and preserving the eye from its destructive effects, is afforded by the boldest antiphlogistic treatment, particularly by the freest abstraction of blood, locally and generally. We must bleed largely from the arm, and take blood by cupping on the temples, or by numerous leeches applied round the part; and these measures must be repeated at short intervals, until the vascular congestion is relieved and the attendant pain removed. The other parts of the antiphlogistic treatment must be combined with the free abstraction of blood; but our great reliance must be placed on the latter. I think that as much blood should be taken from the arm as will flow from the vein; and that the evacuation should be repeated as soon as the state of the circulation will allow us to get more." Mr. Bacot and Mr. Wardrop concur in the opinion respecting the value of depletion. Mr. Guthrie, on the contrary, places little confidence in its effects, and relies upon the application of the ointment of nitrate of silver, as administered in severe purulent ophthalmia. He even attributes the loss of the organ in this disease to inordinate bleeding: he says, "The history of all cases of this disease, hitherto recorded, is but a melancholy story of lost eyes. The reason of this loss is, that they all pursued a similar plan of treatment; viz. they invariably bled the patient to a very large quantity; one hundred, one hundred and fifty, and even two hundred ounces, are stated as having been drawn, until the patients were blanched as white as a sheet, or a piece of white wax. This was accompanied by a due proportion of purgatives, emetics, and emollient fomentations, with mild astringent lotions and leeches, until in time the eye or eyes were lost, and the case was brought to a conclusion. As long as I followed this course I fared no better than those around me, but successive failures led me at last, almost in despair, to adopt a very opposite method, which has proved, at least in my hands, much more effective, and will, I trust, in those of others, remove the opprobrium which has been attached to this part of surgery." He then proceeds to describe the mode of application of the ointment of nitrate of silver formerly alluded to, and observes, "I do not mean to say that one application will alter the action and restore the parts to a healthy state, it must be re-applied; neither is the ointment to do every thing; it may and must of course occasionally fail." These conflicting opinions may perhaps be reconciled. Bleeding is undoubtedly a resource of the utmost value and importance in the general treatment of gonorrhœal ophthalmia, and the ointment recommended by Mr. Guthrie is an application also of value. The practitioner will therefore avail himself of both, as circumstances require. Even Mr. Guthrie, relying as he does on the stimulating astringent, recommends moderate bleeding in conjunction with it; and in the application of the nitrate of silver ointment in common severe purulent ophthalmia, enjoins venesection as an accompaniment. It is certain that a coarse, brawny, plethoric, carnivorous man must be freely bled to save his eyes from destruction in this complaint; while a similar practice adopted towards a pallid, languid, feeble individual, would prove at least inefficient, if not injurious. The experienced practitioner will, therefore, proportion his efforts to the resistance, and adjust his treatment to each case according to its symptoms.

It is unnecessary to repeat the observations respecting the treatment of severe purulent ophthalmia, except to remind the reader that they are equally applicable to the form of disease under consideration. It is obvious, however, from the specific character of the gonorrhœal inflammation, that mercury, from its influence on disease at least allied to this, deserves more consideration as a remedy in this than the common form. It is, however, noto-

rious that whatever necessity the practitioner may see for the administration of mercury to correct the mischief to be apprehended from the specific disease, he cannot rely upon it to cut short the inflammation. Mr. Lawrence says, "I have seen both the ordinary purulent and gonorrhœal ophthalmia proceeding apparently unchecked under the full mercurial action." Some practitioners, however, place reliance on this remedy, and some, assuming as a matter of course that it ought to cure the disease, administer it in every instance. The writer of this, considering that mercury is a poison which should not be introduced into the system without absolute necessity, and positive evidence of its beneficial effect in correcting morbid action, feels no inclination to recommend its administration in gonorrhœal ophthalmia.

On the supposition that this disease depends on metastasis, and relying on the unproved assumption that it is accompanied by a suppression of the discharge from the urethra, it has been proposed to reproduce that discharge by irritating or stimulating that passage. This resource has been recommended by the German writers in particular, who have perhaps weakened the confidence reposed in their opinions by practical men in this country, by their proneness to mould practice on preconceived theories and unauthenticated facts, as well as by their reliance on antiquated doctrines, authorities, and nostrums. There is no evidence before the profession to prove, either that the discharge from the urethra ceases with the appearance of the ophthalmia, or that, if it does, its restoration removes the affection of the eye. Mr. Lawrence observes, after quoting the authority of Richter, Scarpa, and Beer, as to the expediency of reproducing the urethral discharge, "In spite of the confidence which one is inclined to repose in the practical knowledge and judgment of those whose advice has just been quoted, I cannot help thinking that the measures in question have been recommended rather on theoretical grounds than from experience. At least these writers do not mention any results of their own practice; nor have I met with any cases in which the employment of such means is mentioned. In none of the instances which have come under my own observation has the gonorrhœal discharge been suppressed, so that the reason for this kind of practice has not existed. Again, when the violence and rapidity of the disease are considered, in contrast with the slowness and uncertain operation of this treatment, we cannot doubt that irreparable injury would be done to the organ during the time lost in such attempts.

Purulent ophthalmia of infants.—This is a most formidable disease; indeed it is probable that the loss of vision from this cause is four times greater than that from all the cases of common purulent and gonorrhœal ophthalmia put together. It is particularly necessary that the young practitioner, especially the accoucheur, should be aware of this, because some writers describe the complaint as trivial, and its treatment as attended with little difficulty. This opinion has probably arisen from the circumstance of the frequent occurrence of a very mild form of conjunctival inflammation in new-born infants, unattended by any destructive consequences, and generally disappearing without medical aid. The disease now under consideration presents all the characters of the severest purulent ophthalmia. The vascularity is enormous, but in consequence of the organization of the parts, and the yielding of the texture of the lids at this early period of life, there is less of chemosis than general tumefaction of the coverings of the eye. The pain, if a judgment may be formed from the extent of the inflammation and the sufferings of the infant, is very great. The purulent discharge is as profuse as in the worst forms of common severe purulent or gonorrhœal ophthalmia. The consequences are equally formidable; and destruction or injury of the organ by slough, abscess, and ulcer of the cornea, prolapse of the iris, staphyloma, or escape of the contents of the eye-ball, equally to be dreaded. There is one consequence, however, most destructive in purulent ophthalmia in adults, not encountered here; this is the permanent alteration in the structure of the conjunctiva, proceeding to red vascularity of the transparent part of the membrane, and granular lids. The escape from this description of disorganization, of such frequent occurrence at more advanced periods of life, arises probably from the high degree of vital energy and active operation of the functions of growth and nutrition existing at this period.

The disease generally commences within the first three days after birth. The eye first appears moister than natural; redness of the lids ensues; a small quantity of purulent matter collects in the inner canthus, the white of the eye is slightly bloodshot; and the child shuns the light and becomes restless and peevish. All these symptoms are speedily aggravated; the vascularity becomes intense, causing tumefaction of the lids externally, and a pulpy villous condition of them internally; but the redness of the conjunctiva over the ball seldom extends to chemosis. The purulent discharge becomes profuse, completely glueing up the lids during sleep, and often accumulating beneath them in such quantity as materially to increase the distress; and when the eyes are drawn asunder, it so completely fills the space between the lids as to prevent the observer from obtaining a view of the cornea: it accumulates with such rapidity, that if completely washed away with a syringe, it is replaced by a fresh secretion in ten minutes or a quarter of an hour. The discharge is usually of the colour of common purulent matter, but is sometimes tinged with blood; or if the child be jaundiced, has a greenish tint. When the infant cries, the tumefaction of the lids increases enormously, and sometimes they become everted, exposing the red vascular surface to the air. This is the period at which the sloughing process takes place; it is well described by Mr. Saunders in his Treatise on Diseases of the Eye published after his death by Dr. Farre. His

words are quoted here because they are obviously those of an accurate observer enjoying ample opportunity of acquiring correct information; and because they are the observations of the man who first applied the sound principles of Hunterian or English surgery to the investigation of ophthalmic diseases. He says, "As the disease advances, the cornea becomes more or less cloudy, and by the extent of this cloudiness the degree of approaching slough is marked: for the whole of the cornea, if the whole become cloudy, will ultimately slough, and the form of the eye be totally destroyed. I do not mean to say that in every instance in which opacity of the cornea is apparent, the cornea is about to pass into a sloughy state; on the contrary, opacity is often the mark of a healthy action, commencing around the breach of the cornea, for the purpose of restoring the part, and ought to be hailed as a happy omen. I am now speaking of a peculiar duskiness of the cornea, which begins during the progressive state of the inflammation, which is antecedent to any loss of substance, but is indeed a sure sign that such loss is about to take place. When this duskiness comes on, supposing only a portion of the cornea about to slough, the extent of it in the space of twenty-four hours becomes definite; in the same space of time it becomes elevated and apparently lessened in extent; a groove or fissure forms between it and the rest of the cornea, portions of it are carried off by the discharge and tears, or sometimes it separates altogether in one mass. I have several times washed out with a syringe these little sloughs entire. But although I am as certain of the fact as the most frequent observation can make me, I am equally sure that most commonly when this disease destroys vision, the destruction is accomplished in a more gradual manner, not by a slough of very considerable extent and through the whole depth of the cornea at once, but by a succession of sloughs. In other words, the ulcer left by the casting off of the dead piece of cornea becomes in turn sloughy, and extends itself by a succession of sloughy surfaces, until the last lamina of the cornea sloughs, or being protruded by the pressure from within, ulcerates, and the aqueous humour escaping, the iris passes through the breach of the cornea. Already the whole surface of the eye has been in an ill-conditioned inflammation; the ulcer, or rather the surface of the cornea, around the protruding iris is indisposed to heal, so that more and more of the iris protrudes; this in turn ulcerates, and the crystalline and vitreous humours all issue at the orifice. That the inflammation itself immediately destroys the parts by sloughing or ulceration is a truth of which I am perfectly convinced."

Mr. Mackenzie, in his treatise on Diseases of the Eye, observes with respect to these opinions of Mr. Saunders, "It is scarcely necessary to spend time in refuting Mr. Saunders's notion of its being an erysipelatous inflammation. His opinion regarding the mode in which the cornea is destroyed in this disease appears of more importance and equally incorrect. He maintains that it is by sloughing, not by suppuration and ulceration, that the destruction of the cornea is effected. The opportunities which I have had of watching the progress of the affection of the cornea have convinced me of the contrary. Onyx or infiltration of pus between the lamellæ of the cornea is the uniform harbinger of destruction; the lamellæ exterior to the pus give way by ulceration; the ulcer spreads and deepens till the cornea is penetrated, and often almost altogether destroyed. Any thing like mortification or sloughing I have never seen. The coming away of the purulent infiltration exposed by ulceration must have given rise to Mr. Saunders's notion of successive slough."

Whether the inflammation be erysipelatous or not may be ascertained when pathologists have determined what the term erysipelatous so applied means. If the cornea ever sloughs in severe inflammation of the conjunctiva, it may be admitted that it does so in this, especially if men of experience agree that such is the case. Mr. Mackenzie is undoubtedly right in stating that the eye is lost in this disease frequently by abscess; and the fact perhaps is, that the two processes are often combined; the dirty ragged ulcer consisting of open abscess with sloughy surface, and being very much of the character of anthrax. Whatever opinion may be entertained respecting the precise nature of the destructive process, the practitioner should never lose sight of the danger to be apprehended from it. It commences during the active period of the inflammation, but continues after it is mitigated, and, if not arrested, terminates in destruction of the organ.

The investigation of the *causes* of purulent ophthalmia in infants is not attended with much difficulty. It may readily be admitted that the exposure of the infant to cold, immediately after its expulsion from the uterus, will probably produce inflammation of this description; and to this cause may reasonably be attributed the frequency of a milder form of conjunctival inflammation at this time of life, which does not assume the violent character of the other. The resemblance between this severe form and Egyptian or gonorrhœal ophthalmia justifies the suspicion that it is of equally distinct specific character, and to be traced to a cause equally peculiar. This cause may be the application of the matter of leucorrhœa or gonorrhœa to the eyes during labour. The extent to which this cause operates, however, has not been fully ascertained, and the proof of its influence exists more upon conjecture and reasonable inference than actual practical evidence. The practitioner knows, from daily observation, that women labouring under leucorrhœa and even gonorrhœa produce children unaffected by this disease; but he should be equally aware that in the majority of cases of purulent ophthalmia the mother labours under one of them. The accoucheur should, therefore, make himself acquainted with the truth as to this matter, and direct

that a sponge and basin of warm water be ready to cleanse the face and eyes of the infant immediately after birth, and if possible before the lids are opened. If it be known that the mother labours under gonorrhœa, the practitioner should watch the approach of inflammatory action in the first three or four days after birth, and immediately resort to those vigorous measures already enumerated to arrest its progress. These precautions may possibly be superfluous, and disregarded or neglected in the common routine of extensive practice; but if one child be preserved from blindness by them in the course of a practitioner's life, it is sufficient return for the trouble.

The *prognosis* in this purulent ophthalmia is a matter of considerable importance to the professional welfare of the practitioner. In consequence of the frequent occurrence of the mild form of the disease, those who have not experienced the destructive effects of the other are liable to overlook its approach, and allow the processes of slough or abscess to proceed without interruption. As soon as the disease has appeared in the virulent form above described, the parents should at once be informed that it is liable to terminate in serious injury or destruction of the organ. Persons of the lower order, unprovided with medical assistance at their confinement, generally allow the disease to proceed without interruption during the period at which any hope could be entertained of averting the destructive consequences. They seldom seek relief until a week or fortnight after the first attack, and then in consequence of not finding the purulent discharge and tumefaction subsiding, as they were led to expect. When an infant, at this period of the complaint, is presented to the practitioner, he should at once satisfy himself whether the cornea be safe from slough, abscess, or ulceration, or, as this is attended with some trouble, if leisure does not permit him to do so, he should inform the parent in plain and intelligible language, that there is danger to be apprehended, and that the child may have its vision impaired or destroyed by opacities of the cornea, which cannot at the moment be perfectly distinguished. If he dismisses the patient without this precaution, or if he makes any application to the eye without explicitly announcing the extent of the injury, the reproach of having blinded the child will be fastened on him by those who, from culpable negligence, ignorant confidence in their own opinions, or sordid love of money, had caused so lamentable a misfortune. If, upon examination in this after period of the disease, the cornea be found perfectly clear and free from ulcer of any kind, the practitioner may entertain sanguine hopes of perfect recovery, but he should not even then give expression to these hopes, as relapse may occur, or some accidental circumstance interfere with the cure. If slough, abscess, or ulcer have not taken place in the first week or ten days, there is every reason, from experience, to expect that no further bad consequence is to be apprehended than the troublesome and distressing vascularity with profuse purulent discharge, which often, especially if not checked by astringents, continues for six weeks or more. It has already been observed that the high degree of vascularity which accompanies this disease does not degenerate into permanent disorganization of the conjunctiva with opaque cornea and granular eyelids; at least this is the result of the experience of the writer of this article: further observation may, however, enable others to correct or modify this assertion.

To the *treatment* of purulent ophthalmia in infants, the principles laid down respecting the other severe forms of conjunctival inflammation are applicable. As soon as the existence of the disease is fully ascertained, a leech should be applied over the cheek-bone at the edge of the orbit, and blood allowed to flow until the effect of the bleeding becomes obvious by the paleness or sickness of the infant. One or two leeches, at most, on each side, is sufficient for this purpose; and as all the effects of general bleeding are produced by the application of leeches at the earlier periods of life, and as the flow of blood does not usually cease spontaneously in infants, on account of the great vascularity of the skin, the medical attendant should not lose sight of his patient until he has secured such arrangements as will prevent the possibility of the child's life being endangered by hemorrhage. It is on this account that the leeches should be applied on the cheek-bone at the edge of the orbit, where, from the resistance of the bone beneath, circumscribed pressure may be made without delay. The bowels should be emptied completely; and for this purpose a grain of calomel, with castor oil or any other purgative to which the practitioner may be partial, may deserve a preference. If it be admitted that the administration of calomel influences the biliary secretion, its use is particularly indicated at this period of life, when the liver performs an office in the animal economy of still greater importance than it does at more advanced periods. If the child continue to suck voraciously, it may be desirable to rid the stomach occasionally of the accumulated milk by the administration of a small quantity of ipecacuanha or other emetic medicine. As soon as the purulent discharge becomes profuse, care must be taken to prevent it from accumulating with the tears beneath the lids, and producing by mechanical distention an increase of the irritation and distress. This accumulation is frequently produced by the eyes becoming sealed up by the evaporation of the fluid part of the discharge which has collected on the outside of the lids. To prevent it, the eyes should be perpetually sponged gently with luke-warm water, and by laying a scrap of old linen squeezed out of warm water over the eyes as the infant lies on its back in bed. The edges of the lids may be touched with a little cream when the child settles for a longer sleep, and when it awakes the lids should be gently drawn open, and the accumulated matter forced out by light pres-

sure and motion of them. Repeated syringing of the eye is unnecessary, and is often injurious by adding to the irritation: the purulent discharge causes no mischief but by its bulk producing distention in the way above stated, and is probably the best, being the most natural, protection of the surface against the contact of the tears. When the practitioner makes his visit, it is however necessary to wash away the discharge completely, in order to obtain a perfect view of the cornea; this may be done with a syringe, for which purpose a neat silver one with a fine orifice should be used; but as this may not be at hand, and as many may not wish to run the risk of spattering the discharge into their own eyes, a more simple and equally efficacious method may be adopted: the infant's head being laid on the knees of the operator while the body is supported by the nurse, the eyes should be well sponged externally, and the lids drawn open and closed repeatedly, so as to extricate the discharge, which should again be removed with the sponge. After the child ceases to cry, a few drops of warm water should be allowed to flow into the eye between the lids out of a large camel-hair pencil, and the lids opened and pressed as before, after which the child should be, if possible, set asleep, and then the eyes being suddenly drawn open, a full view of the cornea may be obtained.

Local applications may be resorted to with two objects,—the alteration of the nature of the inflammatory action altogether, or the diminution and removal of the purulent discharge. For the former object the nitrate of silver is recommended, and it cannot be denied that it may effect it; but it must at the same time be confessed that the practice has not yet been fully submitted to the test of experience. The question for consideration is, whether a practitioner, as soon as he has ascertained beyond doubt the existence of this severe form of inflammation, can with safety, and a fair prospect of advantage, introduce a solution of nitrate of silver of ten grains to the ounce, or an ointment of ten grains to the drachm, between the lids. That this and other astringents may be used with success to put a stop to the purulent discharge, after the first symptoms of inflammatory action have been subdued, cannot be doubted. With this view a five-grain solution of nitrate of silver, or saturated solutions of acetate of lead or alum, may be resorted to: the acetate of lead cannot, however, be employed if slough or ulcer be present. A large drop of saturated solution of alum may be put into the eye once or twice in the twenty-four hours, and the nurse may be allowed a weaker solution of four or five grains to the ounce to use occasionally. Mr. Mackenzie recommends a solution of one grain of corrosive sublimate in an ounce of water as a wash to be freely used.

If slough or abscess has taken place, it does not appear that any other than the plan of treatment above stated can be adopted, or that any local application can be made likely to suspend the progress of either one or the other. Mr. Saunders, reasoning on the fact that bark and other tonics are employed with advantage in gangrene, and that the slough of the cornea is of this character, directed the administration of extract of cinchona in such cases. It does not, however, appear that the cases are analogous, or that the remedy does actually prove of advantage. The slough or abscess is, in the present case, a consequence of intense inflammatory action not followed by any diminution of vital action locally or generally, consequently not requiring remedies intended to invigorate the constitution, or accelerate the functions of circulation and nutrition. The suggestion of Mr. Saunders does not appear to have been much acted upon in general practice. After the slough of the cornea has been cast off, or the abscess completely converted into healthy ulcer, or if the iris be prolapsed and has assumed a red granulating appearance, the greatest service the practitioner can afford his patient is to prevent any injudicious interference with the natural processes of reparation which are in progress.

Scrofulous ophthalmia.—The consideration of what is called scrofulous ophthalmia need not detain the reader long, if it be admitted that there is no inflammatory affection of the eye which displays at its onset such characters as entitle it to be considered specifically distinct. In fact there does not appear to be any such disease strictly speaking, and what is commonly called scrofulous ophthalmia is nothing more than the modification of any of the preceding forms of conjunctival inflammation by that condition of constitution which we denominate scrofulous. There can be no doubt that every one of the preceding forms of inflammation, and indeed every form of inflammation of the eye, is liable to assume the scrofulous character, except the purulent ophthalmia of children, which is not so modified in consequence of the organization of the system at that time of life.

The symptoms considered characteristic of scrofulous ophthalmia do not present themselves for some time after the first attack, and when the inflammatory period has subsided and the chronic stage fairly set in: then it is that the progress to recovery is interrupted; the conjunctiva does not return to its natural condition; light becomes painful; the tears flow copiously; the purulent discharge is diminished; and the continued vascularity causes opacity of, and extension of red vessels to, the conjunctiva of the cornea. To correct this destructive condition, the obvious resource is in those means universally admitted to exercise a salutary influence on the functions of circulation, secretion, and nutrition. They may be summed up in a few words—respiration of a pure atmosphere, warm clothing, generous diet, bark and other tonics, warm salt water-baths, and bathing in the open sea. It is in this condition of the eye that the chronic vascularity may be most effectually removed by the daily application of a saturated solution of acetate of lead, or the aqua lythargyri acetati dropped between the lids night and morning. It is also in this modification of the chronic vascularity, with great in-

tolerance of light and profuse scalding lachrymation, that the vinous tincture of opium affords most relief. Blisterings, which may be resorted to in any of the preceding forms of inflammation, appear particularly serviceable here, and should be repeated as often as they heal, either on the temples at some distance from the eye, or behind the ears. Free exposure of the eyes and face to the air and light is an important part of the treatment, although a part generally neglected or actually interdicted. There can be little doubt that the miserable condition in which neglected or mismanaged children are frequently found, with the face scalded with tears, the head averted, and crying or sneezing on exposure to light, is produced by confinement to a dark close room, and covering the eye with a green shade.

OSSIFICATION.—See Tissues, Adventitious.

OTALGIA AND OTITIS, (from οὖς, *auris*, gen. ὠτὸς, and ἀλγέω, *doleo*.) Ear-ach; pain in the ear. The ear-ach, which on all occasions results from a morbid congestion of some part of the organ of hearing, cannot be intelligibly explained without first considering the affections of which it is a symptom; and as the diseases of the ear have not yet been spoken of in this work, it is proposed to give a concise account of them in the present article.

Until the publication in 1821 of the admirable *Treatise on the Ear*, by M. Itard of Paris, physician to the Royal Institution for the deaf and dumb, the profession was in a deplorable state of ignorance respecting the pathology of this organ; an ignorance which has been lamented by every author who has taken up or happened to allude to the subject. The situation of the organ deep in the skull, the intricacy of its general structure, the minuteness of its various parts, added to the difficulty of tracing them in their bony case, and the supposed obscurity and unmanageable nature of its diseases, have all contributed to deter professional men from bestowing their attention, as well upon the anatomy as upon the pathology of the ear; and the consequence is a deplorable want of knowledge on these subjects. This is the less excusable since the work of Itard affords a very complete and masterly account, not only of the diseases, but of the anatomy and physiology of the organ. Itard, indeed, whose treatise cannot be too highly praised, has done for the organ of hearing what the illustrious Laennec has done for the organs of respiration: and yet so little known in this country are the labours of this author, that in a small volume just now published on "The Organ of Hearing," we do not find the name of Itard quoted. The writer's attention was particularly called to the ear many years since by the occurrence of cases of chronic disease of the tympanum producing a purulent discharge from the external meatus, penetrating the skull, and destroying the individuals by disorganization of the brain. Subsequent experience has only tended to confirm the interesting and important nature of the subject; and it is with some degree of confidence therefore that we invite the members of the profession to study this department of pathology. We can assure them that the path which may appear intricate and impracticable, is so only because it is untrodden and unfrequented.

The diseases of the ear may be conveniently arranged, according to the anatomical division of the organ, into those which are seated respectively in the external, the middle, and the internal parts of the ear.

The diseases of the middle ear are the ordinary cause of otalgia, strictly so called; on which account, as well as because they are the most frequent and formidable, we shall enter upon the consideration of them in the first place.

1. The middle ear comprehends the cavity of the tympanum with its contained chain of ossicula, its proper membrana tympani and its dependencies, the mastoid cells and Eustachian tube; all which parts, lined with a mucous membrane, present an extensive continuous surface, apt to be involved in the affections of the tympanum. Of the five openings leading to and from the tympanum, three are closed, the fenestra ovalis and fenestra rotunda by their proper membranes, the large opening to the external meatus by the membrana tympani; while the other two are open, the one leading to the Eustachian tube, the other to the mastoid cells,—which cells, forming as they do a cul-de-sac, leave the Eustachian tube the only open channel of communication with the tympanum from without. Hence it happens that in inflammation of this cavity, it and the mastoid cells become filled with the usual product of inflammation of a mucous membrane, a muco-purulent effusion, which has no means of exit, because the Eustachian tube, the only channel by which it could escape, is involved in the inflammation and closed by it. In this manner the delicate fabric of the ear is exposed to the pressure and other bad effects resulting from matter confined in a close cavity; and hence arise ulcerative perforation of the membrana tympani, puriform discharge from the meatus externus, destruction of the organ by caries, and eventually cerebral abscess and death.

The inflammation of the cavity of the tympanum, like the inflammations of the other parts of the body, may be intense, or it may be subacute.

a. The subacute internal otitis is an affair of common occurrence, and constitutes the pathological condition of nearly all those cases which pass under the denomination of ear-ach. The patient complains of pain in the ear, perhaps of the head in some degree, accompanied with singing noises and dulness of hearing. There may be a slight impairment of the appetite, which appears to arise rather from the pain than from any febrile movement, the sanguiferous system and the organic functions scarcely sympathizing in this affection. In the corresponding side of the head there is a sus-

ceptibility to the impression of a cold atmosphere, which induces the patient to wrap up the head; with this precaution he is content to bear the pain for several days, when it usually subsides, leaving the sense of hearing less acute for a short period; after which the organ soon recovers itself, and the affair is ended.

b. Very opposite to this are the symptoms, progress, and termination of the acute internal otitis, or intense inflammation of the tympanum. This inflammation is characterized by an intense, acute, unremitting pain, deep-seated in the ear, attended with loud, clanging, metallic noises, the pain affecting the whole head, but in an especial manner the side corresponding with the seat of the inflammation. As the inflammation attains its height, so does the pain in the ear become distracting, and excites nocturnal delirium; and with this dreadful pain is a sense of violent distention, as if the part were on the point of bursting. The pain of the head is proportionably aggravated, and attended with heaviness and weight. The face manifests great anxiety and distress; the constitution sympathizes deeply, but the character of this sympathy is less marked by the high febrile movement which usually accompanies inflammation, than by great general exhaustion, the effect of continued pain. The pulse is frequent, but not remarkable for fulness or strength, nor is there much increase of heat; nevertheless all the organic functions are troubled, and the tongue is furred, the taste vitiated, and the appetite lost.

This state of things having persisted for twenty-four or thirty-six hours, the inflammation begins to decline, the pain to diminish in intensity, and the metallic noises change to a violent hissing; the sense of distention and of bursting continues though in a less degree, but the delirium passes away, and the pain and uneasy sensations of the head gradually subside. The taste and appetite return quickly, and the patient is soon convalescent; though the hissing in the ear and the sense of distention and bursting are troublesome for two or three weeks, and various noises are perceived occasionally for some months. The organ, however, recovers its proper function, but slowly; the patient experiencing an indistinctness of hearing, often of sight, for a considerable period.

Such is the happiest termination of an acute inflammation of the middle ear.

Instead of this termination in resolution, if the violent symptoms, present at the height of the inflammation, do not abate, the sense of distention increases to a most painful degree, the general headach continues urgent, and the delirium manifests itself at times by day as well as at night, and in the course of two or three days matter is observed to discharge from the ear. In this case the cavity of the tympanum has become filled by a puriform fluid, the product of the inflammation, which has effected a passage by ulceration through the membrana tympani, and is discharging itself by this channel.

Should the perforation of the tympanum be large, and the discharge free and copious, then the fever and other urgent symptoms quickly subside, and a chronic puriform discharge, the *otorrhœa purulenta*, is established. Should the perforation be small and the discharge trifling, it proves insufficient to relieve the sufferings of the patient; the distressing signs of matter confined in the middle ear continue; and now it becomes the duty of the practitioner to recommend an operation to enlarge the opening in the membrana tympani. If a free outlet is thus accomplished, complete relief is afforded; the puriform discharge becomes abundant; and, as in the former case, an otorrhœa is established.

The establishment of the purulent otorrhœa is not always preceded by a form of inflammation so acute as that described; it is often brought about gradually by a subacute otitis of a chronic kind, in which case the symptoms are less severe, are more confined to the ear itself, and the perforation of the membrana tympani is slowly effected. This consecutive affection deserves further notice.

Otorrhœa purulenta, a purulent discharge from the external meatus, may arise from some disease of the meatus itself as a porriginous affection of the lining membrane of the tube; in this case the affection is of little importance. The otorrhœa about to be described proceeds from the middle ear, is the result of a suppurative inflammation of the tympanum with perforation of the membrana tympani, and is a very serious complaint. Inflammations of the tympanum having terminated in suppuration, and the matter having worked itself an outlet, it may be reasonably supposed that all diseased action would subside and cease; and such, no doubt, would be the favourable issue, were it not that, from the peculiar conformation of the organ, part of the matter is retained in the cavity of the tympanum and mastoid cells, and thus becomes a cause of extensive mischief.

The opening of the Eustachian tube being situated at the anterior and internal angle of the floor of the tympanum, may appear to offer a natural and depending outlet to the retained matter; but this channel is either closed altogether or much obstructed by its lining membrane having been involved in the inflammation; and although a free outlet may have been formed by the perforation of the membrana tympani, yet some matter is still retained in the cavity and in the mastoid cells. It is retained in the latter because they form a blind irregular cavity; and in the tympanum because of the peculiar form of the meatus externus, which being arched, and having the crown of the arch on a level with the middle of the tympanum, resists rather than favours the spontaneous emptying of the cavity. Under these circumstances the matter lodges in the tympanum as in a well, and gives rise to a train of formidable symptoms which constitute the second stage of the disease.

The perforation of the membrana tympani giving access to the air, the retained matter undergoes decomposition, becomes highly irri-

tating, and induces ulceration of the lining membrane of the tympanum and mastoid cells; the osseous structure is now exposed to the influence of this irritating matter, and a carious disorganization commences. The insidious advance of the caries is indicated by a dull pain seated principally in the region of the middle ear, but diffusing itself over the corresponding side of the head, by the sense of hearing being blunted, and by a dull and rather vacant expression of the countenance.

The disorganization proceeds more rapidly in the mastoid cells than in the tympanum, because of their less compact structure, and is made apparent by the mastoid process becoming tender on pressure, and the integuments puffy and vascular; by-and-bye the perforation of the bone is completed, and an abscess manifests itself behind the ear. The point where the carious perforation happens is usually at the anterior part of the groove which gives origin to the digastric muscle. The abscess does not burst readily, but extends itself upwards behind the ear, the soft parts offering less resistance in this direction; examples, however, occur, in which the abscess directs itself downwards under the sterno-mastoideus when it points low in the neck; it never extends backwards, because of the resistance of the digastric and trachelo-mastoid muscles and of the deep cervical fascia.

The caries of the mastoid cells is not limited to this outward direction, but extends on every side, and next affects the posterior wall of the cells, and perforates the petrous portion of the temporal bone which forms the fossa of the lateral sinus: the bone is here naturally thin, and, when carious, presents a worm-eaten appearance. Through these carious perforations the matter penetrates, and by irritating and detaching the dura mater gives rise to decided cerebral symptoms. The same process sometimes goes on in the roof of the mastoid cells formed by the superior surface of the petrous portion; but the bone being here thicker is less easily perforated. Should the patient still live, the caries will destroy the chain of ossicula in the tympanum, and they will be discharged through the external meatus; eventually the caries will ravage the whole internal ear, destroying the membranes which close the fenestra ovalis and the fenestra rotunda, and disorganizing the vestibule, semicircular canals, and scalæ of the cochlea. In this way all the sinuosities and cavities and bony fabric of the ear are broken down and confounded together, and the interior of the petrous portion and of the mastoid process of the temporal bone presents one large carious excavation.

To such an extent did the disorganization proceed in the case of a child two years and a half old, that the entire labyrinth, consisting of the semicircular canals and cochlea, was discharged by the meatus externus. In this instance the course of the disease was marked by the various stages of inflammation of the internal ear, succeeded by the chronic puriform discharge, by the dislodgement and evacuation of the ossicula of the tympanum, and, lastly, by the coming away of the labyrinth itself through the meatus externus, occupying in the whole a period of several months.*

In the course of the devastation above described, the portia dura becomes also involved, and the disorganization of this nerve gives rise to neuralgic pains, convulsive twitchings, and paralysis of the muscles of the corresponding side of the face.

At the period when, in the progressive caries of the temporal bone, the dura mater becomes exposed to the irritation of the corrupt secretion from the ear, the membrane inflames and suppurates, and becomes detached by the matter burrowing between it and the skull; the patient is then sometimes carried off at once by meningitis, or the destructive process may proceed and induce ulceration of the dura mater and other membranes, and, finally, of the brain itself. The ulceration of the brain may be superficial, or may penetrate deep into its substance and form a suppurating cavity, having the aspect of an abscess, which will in some cases occupy the whole of the middle lobe of the corresponding hemisphere, or the corresponding lobe of the cerebellum.

While the disease is confined to the ear, the sympathetic pain in the head radiating from this organ is the most marked symptom; but as soon as the membranes of the brain become involved the cerebral signs predominate and obscure the original disease. The patient, who probably hitherto has been in the hands of the aurist, is now transferred to the care of the physician, who, finding the signs of cerebral disease marked and decided, will often fail to trace them back to the ear as their origin, and therefore regards the case as an idiopathic cerebral affection. Nor is the error always cleared up by dissection, because the morbid appearances in the brain present a satisfactory cause for the violent symptoms and fatal termination, and the caries of the temporal bone, which is less conspicuous on the cerebral surface, either escapes notice, or is concluded to be the effect of the cerebral disease. This, we are persuaded, is no uncommon case, having ourselves seen it happen to persons much accustomed to morbid dissection.

The slow carious disorganization of the ear may be a work of many years before it reaches the brain, during which period the puriform discharge from the external meatus varies much in quantity, particularly if the Eustachian tube is not altogether closed, the discharge being at one time profuse by the meatus externus, at another taking place by the tube into the throat. This latter effect is manifested by an offensive dirk matter being mixed with the sputa, and which, collecting in the pharynx during sleep, is hawked up in the morning in considerable quantity. At times the discharge is suppressed, as when the patient takes cold in the ear; then otalgia supervenes, with headach and more or less of sympathetic fever,

* This case is detailed more at length in Mr. Tod's work on the "Organ of Hearing," p. 134.

all which signs are relieved by a return of the discharge. Attacks of this nature are frequent.

The gradual disorganization is seldom attended with dangerous symptoms so long as it is confined to the ear; but the moment it has reached the membranes of the brain, pain in the head becomes the prevailing symptom, and is no longer referred to the ear as its cause. If, now, from any accidental cause the otorrhœa is suppressed, the patient experiences an inflammation of the membranes of the brain more or less severe. The more extensive the disorganization, the more severe is the attack and the more dangerous. Some patients survive many such attacks, and die exhausted by long suffering, while others are cut off by the attack which supervenes on the disease first penetrating to the dura mater. In this case dissection will discover traces of inflammation of the detached membrane, with a little pus effused between it and the skull. A sympathetic but fatal inflammation of the membranes of the brain may occur at the period of the formation of the external abscess at the root of the mastoid process, of which we have seen an example.

It is at one of these periods of the supervention of a meningitis that the physician is called in, and his first impression of the complaint, as we have already stated, is apt to favour the idea of an idiopathic inflammation of the brain, the patient and friends directing his attention to the cerebral signs without alluding to the affection of the ear, they themselves not being aware of their connection.

The *diagnosis* in such cases is very important, inasmuch as the bloodletting required to save the patient in the one instance would destroy him in the other.

In the sympathetic inflammation of the membrane of the brain in cases of otorrhœa, there are prominent local signs as regards the head; there is a deep-seated, severe throbbing pain in the middle of one side of the head, with great tenderness of the scalp on the same side, which prevents the patient lying upon it; there is no marked suffusion of the face and conjunctiva; the expression of the eye is rather dull; the delirium is little active, and is complicated with heaviness of the head and some stupor; the fever is not severe in proportion to the local signs, nor is the force of the circulation great, the pulse being rather tight than full, and rather sharp than strong; the fever is moderate in the day, with a marked exacerbation at night.

In the idiopathic inflammation of the membranes of the brain, on the other hand, instead of local pain, there is a sense of constriction over the whole head without tenderness of the scalp; the suffusion of the face and conjunctiva is very marked; the eye vivid, the delirium violent, without heaviness of the head or stupor; the fever runs high, and though it may have exacerbations, it is continually urgent, and the force of the circulation is decided, the pulse being full and strong.

These distinctions cannot fail to strike the physician if he is cautious and circumspect in forming an opinion.

The *cause* of the otorrhœa is invariably an inflammation of the tympanum, which may be excited by a current of air playing upon the side of the head, or may arise, as it more frequently does, from the spreading of inflammation by the sympathy of continuity from the throat along the Eustachian tube. Hence the origin of the disease is often referred to the period when the patient had the small-pox or scarlet-fever. The deafness, which is a common consequence of the scarlet-fever, is produced in this manner.

Treatment.—In speaking of the treatment of the affections of the ear, described in this article, viz., of the otalgia, the otitis interna, the otorrhœa, and of the occasional attacks of inflammation which supervene on the otorrhœa, all which affections are stages of the same disease, we cannot do better than retain the order already adopted, it being the one in which these stages naturally succeed each other.

It is scarcely necessary in this place to advert to the means of relieving the otalgia, or ear-ach, which has been shewn to depend on inflammation of the tympanum, more or less acute; we shall therefore pass on at once to the treatment of the otitis interna, reserving what few remarks we have to offer on the cure of otalgia for the conclusion of this article.

Treatment of the acute internal otitis.—This intense inflammation of the tympanum can be controlled only by very decided antiphlogistic measures, adopted without hesitation or delay, the object being to arrest the inflammation, and, by procuring its resolution, to prevent all those disastrous consequences which accrue from its termination in suppuration.

In detailing the symptoms of this otitis, we stated that the local signs of pain and so on were intense, while the general febrile movement, though fully developed, was not urgent in an equal degree; and as we hold it to be a principle in the treatment of all diseases, that the more the local signs exceed the general the greater will be the relief from local depletion, we shall be guided by this principle in our recommendation of the treatment to be pursued. In place, therefore, of relying chiefly on the abstraction of blood from a vein, we urge the free and repeated application of leeches to the ear affected, premising, however, that one bloodletting should be practised to an extent consistent with the age, sex, constitution, and spare or plethoric habit of the patient. Let blood then be first drawn from the arm or from the external jugular vein, which is preferable, to the amount of ten, fifteen, or twenty ounces, according to the circumstances above mentioned, and, guided by the same circumstances, let it be followed up by leeches applied over the mastoid process of the ear affected, to the number of from six to eighteen. Repeat the application of leeches once in six hours at least; and that time may not be lost, let a blister be placed

on the nape of the neck, which will leave the region of the ear free for the use of more leeches if required. Fomentations can seldom be borne early in this inflammation; they accumulate heat and aggravate the sufferings of the patient; nor is any medicament to be introduced into the external meatus for the same reason. In addition to the abstraction of blood and to the counter-irritation, an active aperient, consisting of calomel and jalap, in the proportion of four grains and ten, or of a dose of calomel quickly followed by a purging draught of ten drachms of infusion of senna and two drachms of tartrate of potash, should be administered; and in the course of four hours give one or two grains of calomel, with a quarter of a grain of tartarized antimony, every two hours through the first day, and every three or four hours through the second, when it will generally be necessary to omit the antimony on account of the exhausted powers of the patient; the calomel to be continued in such quantity and as frequently as the then existing symptoms demand, remembering that, next to the abstraction of blood, our main reliance is to be placed on the mercury to procure the resolution of the inflammation. Opium is not admissible in any form or quantity; it distracts the patient.

If by this treatment the urgent signs should gradually abate and the inflammation pass away, the patient's appetite will quickly return, and a speedy convalescence be established. If, however, the symptoms do not yield to the vigorous treatment adopted, it is to be feared that suppuration of the tympanum will ensue, which will be further indicated by the increase of the sense of bursting of the part, by the throbbing character of pain, the delirium, and general headach. Fomentations and poultices may now be had recourse to; the anti-inflammatory measures should be relinquished; and as soon as the ulcerative perforation of the membrana tympani has been effected, and the matter begins to discharge itself by the external meatus, the powers of the patient should be supported by ammonia, and sleep procured by opium.

If, with the discharge from the meatus, the throbbing pain, sense of distention, &c. do not manifestly and speedily subside, it is to be concluded that the perforation of the membrana tympani is too small to admit of the free exit of the matter, and an operation to enlarge the perforation is at once to be contemplated; and being effected, the sufferings arising from the matter hitherto confined in the cavity of the tympanum will be alleviated, a copious discharge ensured, and an otorrhœa established.

Treatment of the otorrhœa.—In the foregoing part of this article, we have remarked the untractable nature of the chronic puriform discharge from the ear, and that its dangerous tendency depends on the decomposition and retention of the matter in the cavity of the tympanum, that cavity, owing to its peculiar construction, holding the matter as in a well. The indication, therefore, in the treatment is to prevent this lodgment of the irritating matter; and the manifest and only means of accomplishing this end is by cleansing the cavity of the tympanum by the aid of injections. As to the composition of the injections it matters little; warm water or milk-and-water will answer the purpose as well as any thing more medicated. Care must be taken in the first use of the injection, which should be administered without much force until the parts are become habituated to it, otherwise a shock from the syringe might be very distressing to the patient. Should the discharge persist and become chronic, then astringent injections would be very proper. Itard recommends the caustic potass dissolved in rose-water. The sulphate of zinc offers a good remedy, so does the nitrate of silver; the proportions to be weak in the first instance, and increased in strength as circumstances indicate.

Although the injections may not be effectual in restraining or curing the otorrhœa, they have the power to counteract its destructive and dangerous tendency to disorganization, an apposite illustration of which we are able to furnish in the case of an old lady, now near seventy years of age, who has been affected with otorrhœa from both ears, and deafness, since she had the scarlet fever in childhood, and who, by the daily injection of warm water, has preserved the organs from further disorganization, and has escaped the disastrous effects and premature death which a progressive caries inevitably leads to.

Treatment of the attacks of inflammation which occasionally supervene on the chronic otorrhœa.—The violence and danger of these attacks will be proportionate to the extent of the caries of the ear and the disorganization of the membranes of the brain at the period of their occurrence. While they affect the ear only, they need not excite alarm, because they subside in a few days by the application of leeches to the mastoid process, and by mild antiphlogistic measures. But when the disorganization has extended to the dura mater and brain, the inflammation affects these parts in common with the ear, and the symptoms assume a very formidable aspect. Yet it must be remembered that the cause of these attacks is the check given to the discharge either by cold or accidental obstruction, and that, therefore, the symptoms of the cerebral affection are more or less sympathetic, and partake of those of irritation. There is a train of actions set up in the brain depending on a local cause, which cause being done away, the undue actions subside. For this reason every means must be sedulously adopted to encourage a return of the discharge, as fomentations and poultices to the side of the head, and blood-letting must be employed only so far as to restrain the inflammation within limits consistent with life; for if blood is drawn ever so freely, it cannot put an end to the attack, as in an idiopathic meningitis, and it will sink the patient as soon as the discharge returns. In these cases mercury is not required; it is worse

than useless if carried to any extent. In every attack of this nature the practitioner should not neglect to examine the affected side of the head attentively, as such an attack is apt to supervene at the period of the formation of an abscess behind the ear from the carious perforation of the mastoid process. Should an abscess be discovered in this situation, a very free perpendicular incision is to be made, not only down to the process, but through the carious walls of the process itself into the cells, and relief will be immediately afforded to the cerebral symptoms. The writer was once called to a case of this description, which had been viewed and treated as an idiopathic phrenitis, when he discovered a large abscess presenting behind the ear; it was opened, and discharged a quantity of most offensive pus. The patient was relieved, but she sunk from the copious bloodlettings practised under the erroneous diagnosis of cerebral inflammation.

In one case in which a free opening was made into the mastoid cells by incision, as we have advised, a spontaneous cure of the otorrhœa followed.

The administration of injections in the chronic otorrhœa must not be adopted without some precaution; not without first estimating the extent of the carious disorganization; for should this have penetrated the skull, and a fluid be forced into contact with the dura mater, or this being ulcerated, into contact with the brain, a fatal inflammation would be the result. The extent of the disorganization may be determined correctly by the character of the symptoms. While the disease has not extended beyond the ear, the sufferings are referred to this organ by the patient, the pain being deep seated in the ear, and radiating from it over the side of the head; but as soon as the dura mater and brain are involved, the signs of cerebral affection predominate, the complaints now being all referred to the brain. This diagnosis will be a safe guide, and should be borne in mind. The disease being limited to the ear, will be benefited by the use of injections, and further mischief may by them be probably guarded against; but when it has reached the brain, injections are not justifiable.

The treatment of the otalgia does not call for any particular measures further than such as are appropriate to the relief of the inflammation, be it subacute or acute, of which the otalgia is a sign. The remarks it is of consequence here to make are, that the otalgia, or ear-ach, is indicative of an inflammatory congestion of the tympanum, which should not be neglected however trivial it may appear. Though the patient may not estimate the importance of an ear-ach, the practitioner should do so, and not be content until he has removed it by the use of leeches to the mastoid process, by aperients and so forth; not trusting to popular remedies placed in the meatus, but rejecting them; and taking a proper pathological view of the nature of the affection, of the dependence of otalgia on inflammation of the tympanum, he should combat it by appropriate remedies accordingly, and so preserve the patient from impairment of the sense of hearing, or from that disorganization of the ear of which even a very subacute otitis may be the unsuspected forerunner.

(John Burne.)

OVARIA, DISEASES OF THE.

I. *Of the structure and functions of the ovaria.*—In the human subject, after the age of puberty, the ovaria form two oblong flattened bodies, about an inch and a half in length, which are situated on the sides of the uterus in the posterior duplicatures of the broad ligaments. They are placed a little below the fallopian tubes, near the superior angles of the uterus, to which they are fixed by a short ligament. Their surface, except at the inferior margin where the bloodvessels enter, is smooth and convex. In the fœtus at the full period, the ovaria form long, slender bodies of a prismatic form, and are placed above the brim of the pelvis. In advanced life, they become hard and shrivelled, with deep irregular fissures in their surface.

Each ovarium consists of a peritoneal coat, and a dense fibrous or parenchymatous structure. In this latter texture are imbedded from twelve to twenty vesicular bodies of various sizes, which are named, from their supposed discoverer, the Graafian Vesicles, or Ovula Graafiana. They are composed of a fine membrane, which is separable into two layers, and contain within their cavity a clear coagulable fluid.

Branches of the spermatic arteries and veins are distributed to the ovaria, and they are also abundantly supplied by nerves and absorbents.

The remarkable changes produced in the intellectual and physical constitution of women, at the age of puberty, by the development of the ovaria, have been accurately described by Harvey in the following passage: "nec minus notum est, quanta virgini alteratio contingat, increscente primum et tepefacto utero; pubescet nempe, coloratior evadit, mammæ protuberant, pulchrior vultus renidet, splendent oculi, vox canora, incessus, gestus, sermo, omnia decora fiunt."

There are certain facts which seem to prove that it is not to the influence of the uterus, but of the ovaria that we are to attribute all the changes which take place in the female pelvis, in the mammæ and uterine system, at the period of puberty; and it seems not improbable from the following facts, that it is also to certain changes in the Graafian vesicles at the time of menstruation, that all the phenomena of that singular process are to be referred.

The case of a young woman who died at the age of twenty-nine, in whom the ovaria were wanting, was published by Mr. Charles Pears, in the second part of the Transactions of the Royal Society of London for 1805, and the following appearances have been recorded. "Having ceased to grow at ten years of age, she was in stature not more than four feet six inches high. The breadth across the

shoulders was as much as fourteen inches, but her pelvis measured only nine inches from the ossa ilia to the sacrum. Her breasts and nipples never enlarged more than in the male subject. She never menstruated; there was no appearance of hair on the pubis, nor were there any indications of puberty in mind or body at twenty-nine years of age."

In the young woman, whose ovaria were extirpated by Mr. Pott in an operation for inguinal hernia, menstruation ceased, the voice became hoarse, the mammæ shrunk, and hair appeared on the chin and upper lip. Before this period this female was stout, large breasted, and menstruated regularly.*

Mr. Yarrel has shewn that where there is a shrinking and shrivelling of the ovaria from disease in young birds, the hen bird assumes in many instances the plumage of the male. "Thus, in several mules (hen birds with male plumage) the ovarium has been found variously diseased; sometimes the oviducts appear to have been inflamed, and adhesions to have taken place between their opposite sides, so that they become obliterated; at other times the ovaria are shrivelled and of a black colour, and appear as if they had never been in progress to maturity. This black colour also pervades the oviduct, which is smaller than natural, and often impervious in some part. In old birds it might fairly have been alleged that the destruction of the ovarium and the change of plumage followed only the general obliteration induced by age, and that the one was not dependent on the other; but the fact that destruction by disease of the ovarium in the young bird induces a similar change, and the destruction of the oviduct by art being followed by an alteration incomplete indeed, but in many respects resembling the one mentioned, sets the question at rest."†

Dr. Elliotson related to the writer of this article the history of the following interesting case, which came under his notice upwards of ten years ago. "A young woman," he says, "consulted me for amenorrhœa; she had never menstruated, and yet had violent pains every month. I strongly suspected there was some organic disease, and wished to obtain permission to examine, but to this she would not consent, and did not return to me for a considerable period. She informed me when she again consulted me, that she had been married for a year, but had never menstruated. I then thought I must have been wrong, and that there was no organic cause. I asked if she was happy with her husband, and from her answer concluded that sexual intercourse went on. The husband afterwards came to me and stated that he had not encountered any impediment to connexion, but that he gave her violent pain at the time. I afterwards was permitted to examine, and then found there was no vagina; the part on opening the labia being as flat as the palm of my hand. She had most excruciating pains in the pelvis every month; there was every symptom of menstruation except the discharge. At my desire she was examined by Mr. Henry Cline, who plunged a lancet between the labia, but found nothing. She went on with these monthly pains, which she had experienced ever since puberty, and her life was rendered utterly wretched. I begged Mr. Cline to make another attempt, and he put in a bistoury as far as he dared go, but found nothing. Every sort of examination was afterwards made, and no uterus could be discovered. She remained several years in this situation, when her husband died, and she has married again. Though there was no uterus, it was evident from the appearance of the mammæ and other circumstances, that the ovaria had been fully developed."

Through the kindness of Mr. Girdwood, of Paddington, we had an opportunity in 1831 of seeing a case in many respects similar to the preceding, in which there appeared to be a deficiency of the uterus, and an effort at menstruation every monthly period. The patient was twenty-five years of age, and had been married two years, though she had never menstruated. Every month there was great pain in the region of the pelvis, which lasted for several days and then went off, without any menstrual discharge taking place. The mammæ and external sexual organs were fully developed. On examination at the posterior part of the vagina, the finger readily passed into a short cul-de-sac about an inch and a half in length. From ocular inspection, it was evident that this cul-de-sac did not reach the meatus urinarius, but between them was a narrow opening which admitted the catheter, and which could be passed up four or five inches. This canal was gradually dilated so as to admit the finger the whole length, but not the slightest trace of a body like the uterus existed at its upper extremity.

Mr. Cæsar Hawkins has related to us the case of a woman who had the vagina and uterus completely obstructed after parturition, and in whom there was a monthly effort at menstruation, though no menstrual fluid was secreted. No swelling of the abdomen took place; and though incisions were made through the vagina into the uterus, no fluid escaped.

In Beck's Medical Jurisprudence, somewhat similar cases are referred to.

On the 11th of March, 1831, we examined the body of a young woman who died during menstruation from inflammation of the median basilic vein. The left ovarium was larger than the right, and at one point a small circular opening with thin irregular edges was observed in the peritoneal coat, which led to a cavity of no great depth in the ovarium. Around the opening, to an extent of three or four lines, the surface of the ovarium was of a bright red colour, and considerably elevated above the surrounding part of the peritoneal

* Pott's Works, vol. ii. p. 210.

† Dr. Seymour's Illustrations of Diseases of the Ovaria, 8vo. 1830. p. 36.

coat. On cutting into the ovarium, its substance around the opening and depression was vascular, and several Graafian vesicles of different sizes were observed. The right ovarium was in the ordinary state. Both fallopian tubes were intensely red and swollen, and their cavities were filled with menstrual fluid. The lining membrane of the uterus was coated with the same fluid, and the parietes were soft and vascular. The size of the uterus was not increased.

In the autumn of the same year a woman, under twenty years of age, died suddenly from acute inflammation of the lungs while menstruating. The body was examined by Mr. John Prout, and the uterine organs were brought to us for inspection. A red, soft, elevated portion of the right ovarium was also here observed, and at one part the peritoneal coat to a small extent had been removed. The edges of the opening were extremely thin and irregular, and in the substance of the ovarium under the opening was an enlarged Graafian vesicle, filled with transparent fluid. Numerous small bloodvessels were seen running along the peritoneal coat of the ovary to the opening. When the substance of the ovarium was laid open, several vesicles of various sizes, and at different depths, were found imbedded in it. The left ovarium presented a natural appearance. The free extremities of the fallopian tubes were gorged with blood. Their cavities were filled with a red coloured fluid. The uterus was not enlarged, but the parietes were gorged with blood, and the lining membrane of the fundus was coated with menstrual fluid. A small coagulum of blood likewise adhered to the upper part of the uterus.

On the 2d of July, 1832, Sir Astley Cooper, to whom the writer had mentioned these cases, sent him the ovarium of a woman who died from cholera while menstruating. The ovarium was much larger than natural, and at one point there was a small irregular aperture in its peritoneal coat, through which a portion of a slender coagulum of blood was suspended. On cutting into the substance of the ovarium, it was found to be occupied by three small cavities or cysts, one of which was filled with a clear ropy fluid, another with semi-fluid blood, and the third, which communicated with the opening in the peritoneal coat of the ovarium, with a firm coagulum.

On the 18th of November, 1832, the uterine organs were removed by Messrs. Girdwood and Webster, from the body of a young woman who had died suddenly the preceding day when the catamenia were flowing. Both ovaria were remarkably large, and both fallopian tubes were red and turgid. The peritoneal coat of the left ovarium was perforated at that extremity which was nearest to the uterus by a circular opening, around which aperture for several lines the surface of the ovarium was elevated and of a bright scarlet colour, like extravasated injection. The margin of this opening was thin and smooth, and did not appear to have been produced by laceration. Its centre was slightly depressed below the level of the edges, but there was scarcely the appearance of a cavity beneath. The right ovarium was much larger than the left; and when cut into, a cavity or cyst was found which was filled with half coagulated blood. The peritoneal coat of this ovarium was entire.

The uterus was large, and when cut into, the parietes appeared to contain an unusual quantity of blood. The inner membrane was of a bright red colour, and coated with a thin layer of catamenial fluid. Both fallopian tubes were red and turgid, and the interior of the left was filled with menstrual fluid, but nothing in the form of a Graafian vesicle could be detected in the tube. The appearances now described have been accurately represented in a drawing made from the parts within two hours after they came into the author's possession.

In a paper by Mr. Cruikshanks, published in 1797, there is an account of similar appearances having been observed by him in a young woman who had died at the monthly period. "I have also," he says, "in my possession the uterus and ovaria of a young woman who died with the menses upon her. The external membranes of the ovary were burst at one place, from whence I suspect an ovum escaped, descended through the tube to the uterus, and was washed off by the menstrual blood."

Dr. Power has likewise conjectured that an ovum escaping from the ovarium at every monthly period is the cause of menstruation, which he has defined to be "an imperfect or disappointed action of the uterus in the formation of the membrane (decidua), which is requisite for its connexion with the impregnated ovum."* This hypothesis does not appear to have been formed from actual observations on the ovaria during menstruation, as Dr. Power has made no allusion to these in his work, and does not state that he has ever examined the body of any individual who died with the menses upon her. That an ovum, by which is usually meant an embryo enveloped in membranes, does not pass from the ovarium during menstruation, is evident from the fact that an ovum is never formed but as a consequence of impregnation, and that conception does not take place at the menstrual period. The facts which have now been related render it, however, extremely probable that all the phenomena of menstruation depend upon or are connected with some peculiar changes in the Graafian vesicles, in consequence of which an opening is formed in their peritoneal and proper coats. Whether an entire vesicle, or only the fluid it contains, escapes through this opening at the period of menstruation, further observations may hereafter determine. There is no proof whatever that an ovum passes along

* An Essay on the Periodical Discharge of the Human Female, by J. Power, M.D. 1832.

the fallopian tube into the uterus during menstruation, and it is not clearly established that this takes place even subsequent to conception.

Menstruation probably does not take place during infancy because the ovaria are not then developed, and it is absent during pregnancy and lactation because at these periods they are in a quiescent state. After the age of forty-six the catamenia cease, because the parenchymatous structure of the ovaria has partially disappeared, and the Graafian vesicles have degenerated into thick opaque cysts.

In many cases of disordered menstruation, chlorosis, and hysteria, which we have observed, the symptoms have been clearly referable to certain morbid states of the uterine appendages, and decided benefit has resulted from the application of those local remedies which were employed with the view of subduing the irritation, congestion, or inflammation which appeared to be present in these parts of the uterine system.

II. DISEASES OF THE OVARIA.

1. *Inflammation and its consequences.*—In the unimpregnated state the ovaria are not very subject to those severe attacks of inflammation which produce an alteration in their structure. In most cases of puerperal fever the peritoneal and parenchymatous textures of the ovaria become inflamed, and not unfrequently their structure becomes completely disorganized. In the article PUERPERAL FEVER in this work, a full account has been given of these morbid changes, and of the varied symptoms to which they give rise during life. The adhesions between the ovaria and fallopian tubes which are so frequently met with in examining the bodies of women of different ages and conditions of life, prove that slight attacks of inflammation of the peritoneal coat of the ovaria are not of rare occurrence, and that their presence is seldom discovered during life. Abscess of the ovarium from chronic inflammation of the parenchymatous structure, though a rare disease, does sometimes occur, as the following cases will shew.

A woman, æt. 17, of the lowest and most unfortunate class of females, was a patient of Guy's Hospital, under the care of Dr. Bright, in the autumn of 1823. She was greatly emaciated, had a very quick and feeble pulse, a shining red tongue, and constant watchfulness. She suffered from constant and irresistible diarrhœa, and for many successive days vomited both food and medicine: the catamenia were absent. After having been in the hospital about two months, she suddenly complained of most acute pain over the abdomen, and in a few hours expired. On opening the abdomen death appeared to have been produced by the effusion of a large quantity of pus into the peritoneal cavity, which escaped from an abscess in the right ovarium, which abscess appeared to arise from suppuration in the substance of the viscus, similar in every respect to phlegmonous abscess in any part of the body, and not connected with any cyst, or change or addition of structure the product of morbid growth.* A woman, whose case has been recorded by Dr. Taylor of Philadelphia, had an abdominal tumour, which was considered to be an encysted dropsy of the ovary. On inspecting the body after death, the tumour, which occupied the whole abdominal cavity and weighed seventeen pounds, was found to be formed by one of the ovaries, but in no respect did it resemble ovarian dropsy, being a large cyst, containing twenty pints of pus.†

2. *Cysts and tumours of the ovaria.*—There are perhaps no organs in the human body in which cysts containing a fluid are so frequently found developed as in the appendages of the uterus, and particularly in the ovaria. These sacs or cysts, which have not unfrequently been confounded with hydatids, constitute the disease termed encysted or ovarian dropsy; and it scarcely admits of a doubt, from the progressive enlargement observed in the Graafian vesicles, that these cysts often originate in a morbid distention of these bodies. In other cases ovarian dropsy arises from the development of a solitary serous cyst in the neighbourhood of the uterus, in the folds of the broad ligaments, or connected with the ovaria, if not imbedded in their substance. The whole substance of the ovarium is converted into a large bag containing a fluid, or into a congeries of cysts of different sizes, which have no communication with each other. These cysts, which differ considerably in the density of their coats, contain fluids which vary in colour and consistence. In some it is serous, mixed with a slimy ropy fluid, like jelly; in others it is a purulent fluid, or dark-coloured like coffee grounds, and in two instances observed by us the matter contained in these cysts resembled custard or soft cheese. A small ovarian cyst contained a thick dark-brown fluid like treacle, which did not become decomposed by exposure.

Dr. Hodgkin has recently investigated the structure and mode of formation of some of the more complicated varieties of ovarian cysts and tumours. He has given the following description of the compound serous cyst, which is often complicated with malignant disease of the ovaria.

"In this form we observe on the interior surface of the principal cyst elevations, more or less rounded and of various sizes, projecting into the interior of the cavity, and covered by a membrane which is continuous with the lining of the principal sac.

"On making an incision into these tumours, we find they also consist of cysts of a secondary order, filled by a secretion, often serous, but almost as frequently mucous. It is not, however, merely by this secretion that these cysts are filled. On looking more minutely into them, we shall generally find that from one or more points on the interior of these cysts there grows a cluster of other or lectiary cysts, upon which is reflected the lining membrane of the

* Dr. Seymour's Illustrations, p. 41.

† North American Med. and Surg. Journ. 1826.

cyst in which they are contained. Cysts of the secondary order not unfrequently afford as complete specimens of a reflected serous membrane as either the pericardium or tunica vaginalis, the lining membrane of the containing cyst corresponding to the reflected portion, as that covering the contained bunch of cysts does to the close portion.

"The proportion which the contained cysts bear to the cavity of the membrane reflected over them is extremely various. Sometimes the fluid, especially when it is of a serous character, nearly fills the containing cyst, whilst the bunch of cysts is of very considerable size. At other times the superior cyst is almost entirely filled by those of the inferior order, in which case we may generally find that the nodulose or tuberose elevations, which we may have observed on the exterior of the containing cyst, are occasioned by the unequal development of the contained cysts; for those which have grown most rapidly and have attained the largest size, forcibly dilating that part of the cyst which is reflected over them, produce a kind of hernia at that part. It sometimes happens that the distention occasioned by the growth of the contained cysts is sufficient not only to disturb the even surface of the containing cyst, but actually to produce a rupture, which admits both of the escape of its fluid contents and of the unrepressed growth of the secondary or tertiary cysts, which took their origin from its internal surface."*

Dr. Hodgkin endeavours to explain the formation of the different heterologe deposits or accidental structures on the same principles. Ovarian cysts are not unfrequently combined with a great enlargement of the organ, by which it becomes converted into a whitish, hard, cartilaginous mass, like the fibrous tumour of the uterus. These diseases are indeed not unfrequently present in the same individual, and they commence and run their course in the same manner. Portions of these fibrous tumours of the ovaria are sometimes converted into calcareous concretions like those of the uterus, or a process of softening commences in different parts, in consequence of which the fibrous structure is completely destroyed, and large irregular cavities are formed, containing a dark-coloured gelatinous fluid. Dr. Seymour in his valuable work has described ovarian tumours of the above description under the term scirrhus of the ovaria, though they are not of a malignant nature, and have no tendency to degenerate into cancer. "In the museum of the College of Physicians there is a preparation," Dr. Seymour observes, p. 59, "which has received the sanction of Dr. Baillie as a specimen of this rare disease. It is a section of a scirrhous ovarium, (resembling more a section of scirrhous testicle than the ordinary appearance of the ovarium under this disease,) which was in various parts beginning to soften, the substance breaking down into thick brown fetid fluid. This preparation was taken from a patient who died of cancer of the stomach' and Dr. Baillie says in his Catalogue is the same disease. It does not appear whether any distinguishing symptoms either of the locality of the disease or its peculiar nature existed during life."

The following example of this disease of the ovarium, which Dr. Seymour considers to be extremely rare, and the history of which he has recorded in his work, came under our notice several years ago.

At Blandford Mews on the 9th of August, 1828, we opened the body of a woman upwards of seventy years of age, who had died after long suffering from a tumour in the hypogastrium with ascites. An induration had been first perceived in the abdomen, between the navel and right ilium, nine years before, after she had suffered considerably for some months from sense of weight and dull pain in this situation. The size of the tumour gradually increased, and some years before death, (the belly being greatly distended with fluid,) the operation of paracentesis abdominis was performed by Mr. Blagden, and several pints of water were drawn off. In the course of the succeeding years the operation was frequently repeated; but the quantity of fluid evacuated gradually diminished, whilst the large indurated moveable mass came to occupy the whole of the lower part of the abdomen. She sank gradually from the interruption to the circulation caused by the tumour. On opening the abdomen, there was found attached to the fundus uteri, on the right side, an ovarian tumour weighing seven pounds, of a dense and fibrous structure. Several large cysts, containing a fluid varying in colour and consistence, adhered to the upper surface of the tumour. The peritoneum, in contact with its anterior surface, was converted into a cartilaginous substance, about a quarter of an inch in thickness. In the proper tissue of the uterus, at its fundus, was observed a fibro-cartilaginous tumour about the size of a large orange. In other respects the uterus was healthy.

The affections of the ovaria which have now been described do not partake of the nature of cancer, and have no disposition to degenerate into a malignant form. The injurious effects upon the system which they produce result entirely from the pressure and irritation which they excite in the abdominal and pelvic viscera, and some of the remote organs of the body. The cysts may descend between the bladder and rectum, and becoming firmly fixed by adhesions in this situation, interrupt the evacuation of the urine and fæces. In a case which lately came under our observation in the Saint Marylebone Infirmary, an ovarian cyst having become firmly impacted between the bladder and rectum, produced all the symptoms of stricture of the rectum. In a lady now under our care, the presence of an ovarian or uterine tumour in the pelvis, which presses upon the neck of the bladder, renders it impossible for the bladder to be emptied without the introduction of the catheter. The effects of

* Med. Chir. Trans. vol. xv. p. 282.

these tumours in impeding the progress of the child through the pelvis during labour have been fully described by Dr. Park and Dr. Merriman in the third and tenth volumes of the Medico-Chirurgical Transactions.

When the ovarian cysts remain at the brim of the pelvis, in the progress of their enlargement they gradually produce all the usual consequences of interrupted circulation in the pelvic viscera and lower extremities. Attacks of inflammation occasionally take place in their capsules, by which they contract adhesions with the surrounding organs, and pus is poured out into their cavities. After a time effusions of dropsical fluid take place into the peritoneal sac, and sooner or later the patient dies exhausted from the long-continued pressure and irritation of the abdominal and other viscera.

Encysted dropsy of the ovarium can generally be distinguished from ascites by the following symptoms. The tumour commences on one side of the abdomen, its surface is unequal, and its fluctuation, if felt at all, is very obscure. The health is at first but little impaired, and the thirst, scanty urine, and other symptoms which characterize general dropsy, are wanting. The catamenia are usually extremely irregular or altogether wanting. When both ovaria are diseased, Dr. Seymour states that the menses are always absent. Great difference is observed with respect to the progress of the disease in different individuals; in some it would appear to become stationary, or altogether cease to extend; while in others it goes on much more quickly to a fatal termination. In some cases, if we are to credit the histories which have been given by authors, recovery has taken place from a fright, blows, or from sudden exertion. Dr. Mead relates a case where eighteen pints of water escaped by a rupture of the sac through the umbilicus; Dr. Blundell relates that a lady afflicted with ovarian dropsy, falling from a carriage, struck her belly against a stone, and that a considerable discharge of urine occurred: she recovered, married, and dying subsequently of retroversion of the uterus, the cyst of her former complaint was found to have burst, and its contents effused into the abdominal cavity to have been absorbed.

Cysts containing a fatty matter intermixed with hair and teeth have frequently been met with either in the substance of one of the ovaria, or adhering to them by a narrow neck. They have been found before the age of puberty, and consequently do not arise from impregnation. In Ruysch's Museum was a tumour of teeth and hair which he found in a man's stomach. A little under the right kidney of a dead gelding, Mr. Colman met with a cyst containing fatty matter, hair, and teeth: and Mr. Brodie found a jaw, with full-grown teeth, in the bladder. Dr. Gordon met with a tumour in the thorax of a woman, which was considered during life to be aneurismal, but on examination after death appeared to be composed chiefly of the debris of a fœtus, which was situated in the anterior mediastinum, and adhered strongly to the sternum. It contained a sebaceous matter mixed with hairs, and a portion of a bone which appeared to be the superior maxillary bone. We are inclined to consider all these singular productions as wholly unconnected with conception in the bodies of the individuals in whom they have been found, and to view them as examples of that species of monstrosity which has been so fully described by Ollivier and Breschet, under the term *Diplogénèses par pénétration*.

Dr. Baillie states that the hairs are most of them loose in the fatty substance, but many of them also adhere to the inside of the capsule. Andral describes these hairs as sometimes intimately mixed up with the fatty matter, at other times as isolated from one another, or re-united into inextricable tufts. Their two extremities are usually alike, and in all the cases which he has examined there has been no bulb.*

Meckel, however, observed their bulbs in one of the cases which he examined, where the hairs were short and isolated, and were almost implanted into the walls of the sac which formed the envelopment of the tumour. He relates also from Tuniati, a case where the hairs had a white oval extremity covered by a fine skin, which was confined to the bulb, and was separated from it by an oleaginous fluid.†

These hairs differ greatly in length and colour; some are only a few lines in length, some several inches; others have been seen which measured two feet three inches. Andral states that these hairs have not always a colour analogous to that of the hair of the individual in whom they are found. A negress had a cyst with cartilaginous walls in the mesentery. This contained a sebaceous matter, in the midst of which were numerous hairs, of a colour entirely different from the woolly black locks of the African woman. They were smooth, soft to the touch, white or red, and some of a silvery hue, like those of an infant of the European race.

In almost all the cases where teeth have been found, they have been implanted into the fragments of bony or cartilaginous matter, and have resembled the rudiments of maxillary bones and alveolæ. Meckel thinks that these accidental teeth are produced like ordinary teeth in capsules filled with a gelatinous fluid.

The presence of these tumours in the ovaria has sometimes given rise to serious obstacles to the delivery of the child in parturition, and to fatal inflammation after labour. The following example of this termination of the disease has been recorded by Dr. Seymour at page 8: "A woman about thirty years of age, some weeks after delivery, having been admitted into St. George's Hospital under the late Dr. Young with symptoms of enteritis, which speedily proved fatal, the inferior portion of the small intestines was found inflamed, which inflammation appeared to have been excited by the presence of a tumour of the

* Précis d'Anatomie Pathologique, tom. iii. p. 710.

† Mémoire sur les poils et les dents, &c. par F. Meckel dans le Journal Complementaire cahier, 15 & 65.

size of a large cricket-ball, which had become attached by a narrow neck to the left ovarium. Its proper coat was of a fibrous texture, and of a purple colour, and inclosed a mass of sebaceous matter, penetrated throughout with long fine hair; after removing which, a full-grown incisor tooth was found attached to the fibrous coat."

Treatment of ovarian cysts and tumours.—Bloodletting, mercury, iodine, diuretics, emetics, long-continued friction or percussion, and a variety of other remedies have all been employed in encysted dropsy of the ovaria, and in most cases without the slightest benefit. Though the progress of the disease cannot be arrested by these means, yet the uneasy sensations produced by it admit of considerable alleviation. Inflammation of the cyst, and irritation of the bowels from its pressure, which often arise, may both be mitigated by the occasional application of leeches to the abdomen by fomentations, and the use of cathartics and anodynes. When the distention becomes great, recourse must be had to the trocar, and by a repetition of the operation of tapping, the life of the patient may be prolonged, and considerable ease and comfort may be thus obtained under a complaint which sooner or later must terminate unfavourably. On the practice of extirpating the ovaria when diseased, it is not necessary to offer any observations, as it has been abandoned by all who have made themselves acquainted with the pathology of these organs. Several years ago, an eminent accoucheur of this metropolis made an incision through the abdominal parietes of a young woman who had a moveable tumour in the belly, which he considered to be ovarian, and which he thought it possible to extirpate, as Mr. Lizars had done in similar cases with success. On laying open the abdomen, a large fibro-cartilaginous tumour presented itself, which was attached to the fundus uteri by a thick peduncle. A ligature was applied round this, and the tumour cut off; but death soon followed in consequence of gangrene taking place in that portion of the bowel which had come in contact with the cut surface. The impossibility of distinguishing ovarian from uterine tumours, where the operation is wholly unjustifiable, was strikingly illustrated by this case.

3. *Malignant diseases of the ovaria.*—Sometimes the ovarium is affected with encephaloid disease, or it is converted into a large irregular-shaped mass of cysts and tumours, the section of which presents all the characters of hematoid fungus. This fatal affection usually runs its course with great rapidity, and soon after its commencement the constitution of the patient is much more affected than in the organic diseases of the ovaria which have already been described.

M. Andral has accurately described the changes of structure produced in the ovaria by these malignant diseases. "Sometimes," he observes, "these masses are formed of fibrous, cartilaginous, or osseous tissue; in other cases they are almost entirely composed of encephaloid matter. The walls of the cysts are thick, and their cavities gradually enlarge until a tumour is formed, which fills not only the epigastrium, but the whole abdominal cavity. The outer surface of the tumour is unequal; in some points a fluctuation can be felt, while in others it has a hardness and density equal to bone."*

Dr. Seymour has also described this affection of the ovaria, and has pointed out the connexion which often exists between it and cancerous and fungoid diseases in other parts of the body, as the pylorus, lymphatic glands, and even bony and muscular parts. This malignant disease, he remarks, may be recognized during life by the want of nutrition and broken health of the patient; the unevenness and rapid growth of the tumour, the simultaneous enlargement of glands in other parts of the body, and the occasional occurrence of lancinating pains in the part. The latter symptom is not constant. The pulse is quick and feeble, and as the disease proceeds there is hectic fever, and often aphthæ in the mouth, with an inexpressible sense of debility.†

This disease occurs even at an early period of life, and it appears to be excited in some instances by pregnancy, or to be called into activity by the process of impregnation. In the body of a young woman under twenty years of age, Dr. Carswell found on dissection an ovarian tumour of a malignant nature, as large as the gravid uterus at the full period. About five years ago we examined with Dr. Merriman and Mr. Prout the body of a woman about thirty years of age who had died from malignant disease of the right ovarium a few days after parturition. In the fourth month of pregnancy she began to suffer from a constant sense of uneasiness in the hypogastrium, irritability of stomach; the countenance became sallow, and the constitutional powers greatly reduced. The abdomen, not long after, began rapidly to enlarge, and before the end of the seventh month it had attained the size it usually acquires at the full period of pregnancy. An enormous cyst, which contained a dark-coloured gelatinous fluid, was found on dissection adhering to the right ovarium, and within this cyst were observed a number of tumours of different sizes and shades of colour, which when opened presented the true encephaloid or hematoid fungous character.

An interesting case of a similar description, in which the tumour at first offered an impediment to labour, and the performance of the cæsarean operation was contemplated, has recently been recorded by Mr. Hewlett of Harrow, in the seventeenth volume of the Medical and Chirurgical Transactions.

Scrofulous and tubercular disease of the ovaria is very rarely met with. It is the least common of all the morbid alterations of structure to which the human ovaria are liable.

(Robert Lee.)

† Diseases of the Ovaria, p. 61.

PALPITATION. Palpitation may be defined to be an increase in either the force or the frequency of the heart's contractions, or of both, whereby they become not only sensible, but sometimes very troublesome to the patient. They may vary in force, from a scarcely perceptible degree to a violence which amounts to convulsion. Not unfrequently the sound of the beats is audible to the patient, especially when lying on his side; and in this position, the second as well as the first sound may occasionally be distinguished.

As palpitation is, under all circumstances, dependent on over excitement of the nerves of the heart, the phenomenon is always essentially the same. The varieties which it presents arise merely from differences in the causes, and from the different routes which these causes pursue in order to arrive at, and convey their stimulus to the heart. Thus the blood conveys the stimulus *directly;* and this it does in three ways; first, by arriving in excess, as from violent exercise, plethora, &c.; secondly, by gorging the heart, in consequence of its transmission being impeded by a disease of the organ, or an obstacle in some other part of the circulation; thirdly, by being of too stimulant a nature, in consequence of the diet being exciting. The nerves, on the contrary, convey the stimulus to the cardiac plexus *indirectly*, as is the case in emotions of the mind, in dyspepsia, in hysteria, &c. The nerves and the blood may also convey the stimulus conjointly, as happens in fever, and in all other cases in which morbid nervous irritability co-exists with an organic affection, or a state of the blood leading to palpitation.

We have now to take a more particular view of palpitation in connection with its several causes; and we shall first glance at the causes of a physical or organic nature, and those dependent on states of the blood; and subsequently dwell at more length on nervous palpitation.

I. *Palpitation connected with physical causes.*—Of these causes, some are inherent in the heart itself, and others are exterior to it. The causes inherent in the heart fall under the following heads:—

1. Hypertrophy, and hypertrophy with dilatation. In these affections palpitation consists in an increase both of the force and the frequency of the heart's action, the physical characters of the impulse and sounds being merely an exaggeration of those which the heart presents during a state of calm. (See Hypertrophy and Hypertrophy with Dilatation.)

2. Dilatation with attenuation. Palpitation in this case consists in an increase of the frequency, but often not of the strength of the beats, though the patient may experience the *sensation* of an increased impulse. Palpitation of this kind is more obstinate than any other. Laennec cites an instance in which it lasted eight days, the pulse constantly beating 160 to 180 in the minute.

3. Disease of the valves. Palpitation from this cause varies in its characters according to the nature, situation, and extent of the valvular affection, and according to the presence or absence of hypertrophy, dilatation, or both. (See Valves, Diseases of the.) Obstructions in the arterial system fall under this head.

4. Pericarditis, carditis, and inflammation of the internal membrane. In these, palpitation is either strong and bounding, or feeble, irregular, and unequal—differences which depend on circumstances explained in the articles on the above subjects.

5. Adhesion of the pericardium. Palpitation from this cause is violent, and of an abrupt, jogging, or tumbling character. (See Pericardium, Adhesion of.)

The physical causes of palpitation exterior to the heart are as follows:—

1. Acceleration of the circulation by muscular efforts. This is the most simple cause of palpitation, and it is strictly physiological. There is an increase both of the force and the frequency of the beats. Closely allied to this is the next: viz.—

2. Plethora. It gives rise to palpitation by preternaturally distending and stimulating the heart. The palpitation which sometimes exists during the first three or four months of pregnancy is partly attributable to plethora, resulting from the suppressed catamenia, and partly to the nervous disturbance which attends so important a change in the system as that of utero-gestation.

3. Anæmia, whether from loss of blood, or from an insufficient quantity being made by the patient. In this case the blood is always attenuated and impoverished, containing more serum and less fibrine than natural. Hence it moves with greater facility in the vessels, and probably, therefore, arrives at the heart either in redundant quantity or with morbid velocity, thus constituting a physical cause of palpitation. A highly irritable state of the nervous system generally accompanies anæmia, and is partly the cause of the palpitation. Hence we shall revert to this subject in treating of nervous palpitation.

4. Convulsive, epileptic, and hysteric fits. These cause palpitation partly by occasioning too rapid a flow of blood to the heart, and partly by a participation of the organ itself in the spasmodic action.

5. Obesity. This causes palpitation in a threefold way; *a*, by the plethora with which it is usually accompanied; *b*, by the weight and inelasticity of the thoracic and abdominal parietes, whence the free expansion of the ribs and descent of the diaphragm are prevented; *c*, by the unusual resistance offered to the heart's propulsive action in consequence of the extended sphere of the circulation and the pressure of the adipose tissue on the capillaries.

6. Obstructions in the lungs; namely, hydrothorax, empyema, pneumothorax, hepatization, extensive bronchitis affecting the minute tubes, &c. These cause palpitation (so far as it is independent of a concomitant febrile movement) by obstructing the passage of blood through the lungs; whence the heart becomes gorged and preternaturally stimulated. Obstructions de-

veloped slowly, as tubercles, encephaloid tumours, aneurisms of the aorta, &c., commonly occasion little and sometimes no palpitation. For this there are two reasons: 1st, that the mass of blood is diminished by the concomitant emaciation; 2dly, that supplementary respiration is established in the pervious portions of lung, which not unfrequently become hypertrophous.

7. Asthmatic bronchial constriction. This causes palpitation by preventing the expansion of the lungs, and consequently impeding the circulation through them.

8. Acute laryngitis. According to our observation in a considerable number of cases, this affection causes palpitation in an eminent degree. We ascribe it to the same cause as in the preceding case, 7. In the last stage the palpitation ceases; for the engorgement of the heart becomes so excessive that the organ struggles and flutters rather than palpitates, and the patient, if not immediately relieved, speedily dies of asphyxia.

9. Abdominal infarction: namely, from enlarged liver or spleen, morbid growths, ascites, ovarian dropsy, advanced utero-gestation, &c. These occasion palpitation, principally by preventing the free descent of the diaphragm, and thus obstructing the circulation through the lungs, but partly also by compressing the aorta, and opposing the passage of the blood through it.

Amongst the causes of abdominal infarction is to be ranged tight-lacing. We were consulted by a military officer, who had brought on constant palpitation and slight hypertrophy by the habitual use of the dumb-bells while tightly girthed round the waist.

II. *Palpitation from causes operating purely through the nervous system.*—There are few affections which excite more alarm and anxiety in the mind of the patient than this. He fancies himself doomed to become a martyr to organic disease of the heart, of the horrors of which he has an exaggerated idea; and it is the more difficult to divest him of this impression, because the nervous state which gives rise to his complaint, imparts a fanciful, gloomy, and desponding tone to his imagination. Members of the medical profession are more apt than others to give way to these feelings; partly from their apprehensions being more keen, and partly from an impression too widely prevalent, that there is difficulty in distinguishing nervous from organic palpitation, and, consequently, that the patient must remain in a state of anxious uncertainty. It may be said for the consolation of such, that the diagnosis presents no difficulty, if to general signs is added a knowledge of those afforded by auscultation and percussion.

Nervous palpitation is dependent on dyspepsia, hypochondriasis, hysteria, chlorosis, gout, mental excitement, or a naturally irritable nervous temperament; and it presents different degrees, aspects, and habitudes, according as it depends on one or other of these causes. We shall describe its most common forms, and briefly advert to the connection between them and their causes.

1. The first and slightest degree is characterised by a tumbling or rolling motion of the heart, with a momentary feeling of fulness, tightness, and oppression. It is referable to an intermission of the heart's action, producing congestion; for the removal of which the succeeding beat is inordinately violent. This form occurs principally in dyspepsia, and it may result from so slight a degree of it, that the patient is not conscious of being an invalid. Slight acidity or flatulence, for instance, is sufficient for its production.

Dyspeptics do not in general experience a more aggravated form of palpitation, unless they are of a nervous temperament.

2. In the next degree there is a series of quick, weak, fluttering, irregular beats, with slight anxiety, acceleration of the respiration, and a quivering sensation in the epigastrium: this may last from a few minutes to half an hour or an hour, and occur only at distant and irregular intervals, or several times a day, especially when the patient is startled. It is apt to supervene at bed-time, keeping the patient wakeful and restless during a considerable part of the night.

This form presents itself in nervous and hypochondriacal dyspepsia, in hysteria, and in individuals who, either from disease or mental excitement, have fallen into a state of high nervous irritability. Amongst the latter class are to be ranked literary and scientific men, and hard students in general. This form occasionally, though rarely, occurs without any other apparent origin than a very slight degree of indigestion, the patient being otherwise strong and healthy.

Individuals, especially females, with naturally small or thin hearts,—a class characterised by a delicate frame and a languid, feeble, circulation, are predisposed to the variety of palpitation under consideration.

3. The next degree amounts to perfect palpitation, consisting in increased impulse, sound and frequency of the beats, sometimes accompanied with irregularity of action, and generally with more or less anxiety, dyspnœa, and even orthopnœa. The attack may be only occasional, or may occur several times a day, or may even last with little intermission for several days together. This form is rare in pure dyspepsia, but is of common occurrence in dyspepsia complicated with hypochondriasis, or engrafted on a nervous temperament. It manifests itself principally, however, in hysterical subjects, and those remarkable for great nervous mobility and irritability. In a lady of the latter class, we have seen it exist in an exquisite degree, being excited by the slightest causes. A word, a look, an idea, a movement, the most frugal meal, the most gentle stimulant, even a glass of water, sufficed to induce a violent fit, attended with heat and flushing; and she frequently passed a great part of the night in a state of the most distressing orthopnœa. The heart and lungs were sound, and she was restored to health by bitters, tonics, cold bathing,

sea air, and a nutritious but unstimulating diet.

There are many individuals without any definite ailment, yet calling themselves *delicate* or *not strong*, who, after a full meal, after any unusual fatigue, or any extraordinary mental excitement, became languid, listless, restless, sometimes drowsy, with heat, acceleration of the pulse and respiration, and a more or less extensive arterial throbbing. This is generally connected with slight palpitation; so slight, indeed, that the patient is seldom conscious of it. The symptoms usually subside after a little repose, especially a tranquil sleep.

Sometimes a slight degree of palpitation subsists without intermission for years, especially in young persons of a constitution at once plethoric and nervous, and more particularly in females about the period of puberty.

We above adverted to palpitation from anæmia, whether occasioned by loss of blood or by defective sanguification. In this the blood is always in a thin and impoverished condition, from a deficiency of fibrine and an excess of serum, and the nervous system is generally in a highly irritable state. The variety is highly important, as it comprises a great number of cases, and requires a peculiar mode of treatment.

When the palpitation results from loss of blood, the phenomenon is denominated *reaction*. If the hemorrhage has been restricted to a brief period, as a few hours or days, the patient soon recovers; but if it has been protracted, as is often the case from piles, chronic dysentery, menorrhagia, polypus, or cancer of the uterus, &c. the case is much more obstinate and intractable; for not only is the state of anæmia fully established, in consequence of the system being reduced to a condition which renders it incapable of reproducing good blood; but, by the impoverished state of the fluids, a train of nervous symptoms is engendered, which greatly exasperates the malady. Under these circumstances we have repeatedly seen palpitation last almost without intermission for many weeks and even months, but gradually yield to tonic medicines, diet, and regimen.

Anæmia arising simply from defective sanguification, as in chlorosis, of the male as well as the female, places the patient in circumstances very similar to those last described; and the palpitation is of the nature above noticed as the third degree. Here, also, we have seen it last, with little intermission, for several weeks and even months. In a medical gentleman, the heart bounded violently 120 to 150 times per minute for upwards of four months. Bleeding exasperated the affection, and the blood drawn was very serous, and so deficient in fibrine as scarcely to form a coagulum.

This state of the blood, in connection with palpitation and arterial throbbing, constitutes, in our opinion, an important feature in the pathology of purpura hemorrhagica; for in several well characterized cases which we have seen, and in others which have been communicated to us, the conditions alluded to existed in an eminent degree.

Nervous palpitation may give rise to hypertrophy, (see Hypertrophy, *exciting causes;*) but it is surprising how long the heart will in most cases resist this affection; and when the palpitation is subdued, how soon it will recover itself after undergoing slight enlargement. According to our observation it rarely requires less than a year, and sometimes several, of very constant palpitation, to produce confirmed hypertrophy.

Every variety of nervous palpitation may be attended with arterial throbbing; and the throbbing may be either universal, or limited to a particular part, even to individual arteries, especially the aorta and carotids. Hence, nervous palpitation is, in general, more audible to the patient than *organic*, the sound appearing to rush through his ears, especially when he reposes on his side in bed, since each arterial throb causes a rustling movement of his pillow.

The contraction of the heart in nervous palpitation is less remarkable for force than for an abrupt, bounding, and jerking character, and on this the arterial throbbing is mainly dependent; since the vessels receive the jerk communicated to the blood by the impulse of the heart.*

Diagnosis of nervous palpitation. 1. *General signs.*—Nervous palpitation may be discriminated from organic by the presence of some or all of the following signs, viz. by its not being excited, but, on the contrary, relieved by corporeal exercise of such a nature as would certainly disturb the action of a diseased heart; by its disposition to supervene while the patient is at rest, especially at the commencement of the night when he lies wakeful in bed; by a fluttering in the epigastrium; by the general prevalence of nervous symptoms; by the affection being aggravated when the nervous symptoms undergo an exacerbation, by the pulse and the action of the heart being natural during the intervals between the attacks; and by the intervals being long when the general health is good. Nervous palpitation, in short, is *intermittent*, its causes being only occasional; whereas organic palpitation deserves the epithet of *continued*, its causes being constant.

To the above category of diagnostic signs, some add, as characteristic of nervous palpitation, an increase of it after meals, or when the stomach is loaded or deranged, and an amelioration produced by dyspeptic remedies; but as the stomach produces the same effects when there is disease of the heart, these signs are not pathognomonic of nervous palpitation. To this point we would particularly direct the attention of practitioners; because many, in forming their diagnosis of the affections in

* Treatise on Diseases of the Heart, by Dr. Hope, page 74 to 78.

question, regard the dyspeptic signs as paramount in value to all others.

Though nervous palpitation is often attended with various familiar nervous affections of the head, as pain, or sensations of heat or cold confined to particular parts and coming and going suddenly, temporary vertigo, tinnitus, and confusion of the sight, not increased by lying down or stooping; it is not, when purely nervous, accompanied with genuine signs of cerebral determination or congestion: there is no universal throbbing headach, with weight and tension, increased by stooping or the recumbent position; no stunning sounds and pains in the head on suddenly lying down or rising up; no permanent somnolency, apoplectic stupor, or regular apoplectic fits, as in hypertrophy, &c.

2. *Physical signs.*—"In nervous palpitation," says Laennec, "the first impression which the application of the stethoscope to the region of the heart produces on the ear, shows at once that this organ has not great dimensions. The sound, although clear, is not loud over a great extent; and the shock, even when it at first appears strong, has little real impulsive force, for it does not sensibly elevate the head of the observer. This last sign appears to me the most important and the most certain of all when we add to it the *frequency* of the pulsations, which is always greater than in the natural state. Most commonly it is from eighty-four to ninety-six per minute." This is a very accurate description of nervous action of the heart. The impulse is analogous to that which occurs in reaction from loss of blood, and which we have elsewhere denominated *jerking*. It may be added that, in nervous palpitation, though the sounds are increased, they are not materially altered in quality, the first sound being, as in the healthy state, longer and more suppressed than the second.

The physical signs of nervous palpitation will be rendered more apparent by being contrasted with those of organic. We shall, therefore, summarily recapitulate the latter.

In *dilatation*, dulness on percussion over an increased extent indicates that the organ is enlarged; further evidence of which is derived from the dulness, and the impulse being situated lower down than natural. The first sound is short, smart, and clear, resembling, and in dilatation with attenuation becoming identical with, the second. Both sounds are louder than in an equal, and often than in a greater, degree of nervous palpitation.

In *hypertrophy with dilatation*, the dulness on percussion is increased over a still greater extent, and the dulness and impulse are also lower down than natural. Both sounds are very loud, and the first is shortened, though less so than in pure dilatation. The impulse is a smart, violent blow, possessing much more force than in nervous palpitation, and very frequently raising the head of the auscultator.

In *simple hypertrophy*, the impulse is a slow, gradual, and powerful heaving, very sensibly elevating the head. Both sounds are diminished, and in extreme cases almost suppressed. These characters are so different from those of nervous palpitation, that it is only by inattention that the two affections can be confounded.

In *disease of the valves* there is a *permanent* bellows, sawing, or rasping murmur; whereas murmur in nervous palpitation is only occasional, and of a soft character. If the valvular contraction be great, the action of the heart is irregular. Irregularity also occurs in nervous palpitation, but it is not accompanied by those symptoms of an embarrassed circulation which invariably attend valvular disease, and in too palpable a form to be mistaken. Should hypertrophy, dilatation, or both, coexist with valvular disease, their signs, as above-described, will likewise be present.

The pulse in nervous palpitation is materially different from that in organic disease. In the former it is jerking, but has little fulness, strength, and incompressibility. In dilatation it is full and soft; in hypertrophy with dilatation, it is full, strong, and sustained; and in simple hypertrophy, though less full, it is strong, sustained, and even hard. In valvular disease it presents different characters according to the situation and degree of the lesion, (see VALVES, DISEASES OF, *general signs*,) but the presence of other signs of the valvular affection will enable the practitioner to distinguish the pulse from that of nervous palpitation.

To the physical signs of nervous palpitation, may, in many instances, be added an intermittent bellows and sawing murmur of the heart and sometimes of the arteries, which we have elsewhere attributed to the morbid velocity with which the blood is propelled by the sudden and as it were spasmodic contraction of the heart.* The murmur occurs whenever the action of the organ is excited; and in some instances the slightest causes suffice to produce the effect, as a momentary mental emotion, a change of posture, (from the recumbent to the erect for instance,) a constrained position, a meal, flatus in the stomach, &c. We have often found the phenomenon to subsist for a few seconds or minutes only, that is, so long as the exciting cause continued in operation. The patient, if asked whether he is conscious of palpitation, replies in the affirmative; yet the pulse may not be strong—it may even be small and weak; but it will be sharp or jerking. It is the velocity, therefore, and not the power of the heart's contraction which causes the murmur.

III. *Palpitation from physical and nervous causes.*—Nothing is more common than a conjunction of nervous with organic affections of the heart; and these are the cases which present the greatest difficulty in diagnosis, as the one masks the other, and it is not easy for the inexperienced practitioner to assign to each the share which it holds in the production of the symptoms. He will best qualify himself for this task by acquiring a sound knowledge of the two classes of affections separately. Hence

* Treatise on the Diseases of the Heart, by Dr. Hope, p. 76.

it is unnecessary to enlarge on this subject. We have elsewhere given cases illustrating the combination.*

Treatment of palpitation.— Palpitation being only a symptom, the treatment must be mainly directed to the primary affections. To advert to it here in all its details would be a superfluous repetition, as it is discussed at large in the several articles devoted to the primary affections. Palpitation from organic disease of the heart is so intimately connected with the disease itself, that abstract observations on treatment would convey no definite information; and we therefore refer the reader wholly to the various articles on that subject—to which he will find a guide in the general article HEART, DISEASES OF. The treatment for nervous pulsation of the aorta is noticed at the conclusion of the article AORTA, ANEURISM OF. In the articles HYSTERIA, CHLOROSIS, and especially INDIGESTION, he will find ample information on the subjects to which they respectively refer. Here, therefore, we shall merely direct our attention to a few points, which, though embraced in a general plan of treatment for the primary affection, are not discussed with so specific a reference to palpitation as the practitioner might probably wish.

1. *Palpitation from plethora.*—This is to be treated in the first instance by a free use of the lancet, and by two or three calomel and colocynth purges at bed-time, worked off by a draught consisting of equal parts of infus. gentian. and infus. sennæ c. with tinct. sennæ 3i. and potassæ tartrat. 3i. ad ii. or any other purgative neutral salt. This draught should be repeated every morning for a week or ten days, until the force of the palpitation has in a great measure subsided. The subsequent part of the treatment is principally of a prophylactic nature, the indication being to prevent the regeneration of too much and too rich blood. The patient should abstain from animal food on alternate days, and should always take it in limited quantity. His diet should consist principally of farinaceous articles and vegetables, and his beverage should be toast and water. As few things are more conducive to plethora than an excessive indulgence in sleep, he would do well to restrict himself, for a time at least, to six or seven hours in the twenty-four or even less. While the palpitation exists, it is dangerous to take violent corporeal exercise, as hypertrophy might be induced; but when the symptom ceases to be provoked by exertion, an active life is eminently serviceable. We have thought it necessary to insist on the present subject, as we have found plethora to be a frequent cause of hypertrophy, especially in those who, while plethoric and subject to palpitation, are compelled by their position in society to lead a laborious life. Such is the case with a large class of female servants in the country. The luxurious and indolent, when plethoric, suffer in a scarcely less degree.

Palpitation during early utero-gestation.—Should this be evidently connected with plethora, it will readily yield to a moderate abstraction of blood, a few gentle saline aperients, a spare, unstimulating diet, and a cool air with good ventilation.

Dyspeptic palpitation.—As the palpitation generally supervenes at the moment when there is a morbid stimulus in the stomach, whether this result from ill-digested food, as is usually the case in atonic dyspepsia, or from the irritation of almost any ingesta in the inflammatory species, it is evident that a judicious regulation of the diet will constitute one of the most important features in the treatment. To the article INDIGESTION the reader has already been referred. He will there find an able account of the medical treatment adapted to all the circumstances of the complaint. So long as palpitation exists in connection with symptoms obviously demanding the exhibition of medicines, as, for instance, inflammatory irritation of the mucous membrane, complete torpor of all the alimentary functions, and with various others, it is vain to expect a cessation of the palpitation until these symptoms have been relieved. But palpitation not unfrequently remains after all urgent symptoms have been removed, and the patient scarcely looks upon himself in the light of an invalid. Often have we seen it form the most delicate test of the slightest dietetic indiscretion. Here, then, it is that diet and regimen are of the first importance: they must complete what medicine began.

They are to be adapted to the nature of each case, and to vary with the variations of its circumstances. In *atonic* gastric dyspepsia the patient should follow the rules judiciously laid down in INDIGESTION, p. 620 et seq.

At p. 622 is also an excellent account of the means to be employed in order to restore the harmonious action of the bowels with the stomach, of restoring or increasing the activity of the excretory organs, and of restoring the tone or improving the innervation of the stomach. Under the latter head the subjects of mineral waters, bathing, friction, clothing, are fully discussed.

In *inflammatory* gastric dyspepsia, not only the medical, but the dietetic and regiminal treatment is very different. Both will be found in the same article, p. 629, so ably laid down as to supersede the necessity for further remark.

Palpitation from anæmia.—When this results from a sudden loss of blood in a healthy individual, little more is requisite for its cure than patience, as the symptom subsides in proportion as blood of the natural consistence is regenerated, which takes place in the course of ten days or a fortnight, and sometimes considerably earlier.

When the anæmia results from protracted or repeated hemorrhage, or from inadequate sanguification, as in chlorotic females, persevering medical treatment is in general necessary. The palpitation, and its usual concomitants, headach and arterial throbbing, are invariably exasperated by further detraction of blood, to which some resort from a mistaken view of the nature

* Treatise, &c. p. 493.

and cause of the headach. More and richer blood must be made, and the remedies best calculated to effect this object are the preparations of iron, with aloes; the latter being useful not only as a bitter tonic, but by its aperient operation to counteract the too stimulant effect of the chalybeate. We have seldom been disappointed by the pills of Dr. Abercrombie, consisting of two grains of sulphate of iron, two of aloes, and five of the compound cinnamon powder in two pills, taken at dinner, and, if necessary, at bed-time also, the quantity of aloes being diminished if it should act more than once, or gently twice a day. Should these pills create nausea, as sometimes happens, an excellent substitute is to be found in the decoct. aloes comp. ℥ß ad ℥i (just sufficient to move the bowels gently once a day) at bed-time, with a drachm of the vinum ferri thrice a day.

The carbonate of iron in doses of from one to three drachms thrice a day, and two grains of the pil. aloes cum myrr. and pil. galbani comp. respectively at bed time, is likewise an efficacious plan of treatment. Under the use of all these remedies we have seen patients speedily recover from the most unpromising circumstances. The remedies are to be assisted by a nutritious animal diet, much fresh air and gentle exercise, and by the use of the flesh-brush, salt-water sponging, and even shower-bath.

Before the medicines begin to take effect, the patient is often importunate for some palliative to relieve the urgency of the palpitation. We have found this object best effected by the hydrocyanic acid (*m* i. ad vi.); the acetate of morphia (gr. 1-3); or by the following draught: tinct. hyoscyami ℥ß, sp. ætheris nitrici ℥ß, mist. camph. ℥x. syrupi aurant. ℥i. Fiat haustus. Each remedy may be administered once, twice, or thrice a day, according to the necessity.

Nervous palpitation.—Individuals in whom palpitation is referable to a highly irritable nervous temperament, cannot, in general, bear the stimulus of chalybeates in the first instance, though they eventually prove of the greatest advantage. With such, it is best to commence with the lightest bitters, and pass progressively to bark and mineral acids, and thence to metallic tonics. Of these sulphate of zinc is one of the least stimulant, and a grain, with extract of gentian, in a pill twice or thrice a day, will often agree as well even as bitters. In the cases in question, however, medicines are of far less importance, in the first instance, than reginimal tonics: viz. a bracing air by the sea-side, sea-bathing, the shower-bath, or salt-water friction, a regular, nutritious, but unstimulating diet, and a tranquil cheerful mind. After preliminary measures of this kind for a few weeks, chalybeates, especially in the form of mineral waters, will in general prove singularly beneficial.

(J. Hope.)

PANCREAS, DISEASES OF THE.—By the ancient writers on medicine, the use and the importance of the pancreas were, it is to be presumed, little thought of; for the venerable father of our art has not even named an organ concerning whose office such a variety of opinions were advanced in after ages. Of these opinions a short yet lucid account has been given by De Graaf.* Up to the period when the pancreatic duct was discovered by Wirsangus, the notion most generally adopted seems to have been this,—that the office of the pancreas was to afford support to the vessels, and to serve as a cushion or bolster to the stomach, to protect the latter, when in a state of repletion, from being pressed and injured by the vertebræ.† In later times, however, it has been clearly ascertained to be an important gland. Its office, we now know, is to secrete a fluid analogous to the saliva, (hence it has, by Haller and other eminent physiologists, been called a salivary gland,) and to transmit by its excretory duct that fluid to the duodenum. The pancreatic juice, mixing with the bile, probably renders it more bland; and by the agency of the pancreatico-bilious fluid, combined with the lymph of the intestines, the food, already converted into chyme in the stomach, is further changed and becomes chyle, the pabulum of the blood, which has emphatically been termed *the life*.

It is worthy of remark that many eminent persons who were ignorant of the true physiology of the pancreas, who were unacquainted with the existence of its peculiar secretion, yet considered it to be the secret source of a variety of important maladies. Thus Schenkius says that the pancreas and mesentery are the seats of innumerable and wonderful diseases;‡ and Fernelius,§ treating of the morbid affections of the same parts, affirms that in them he has generally observed the causes of diarrhœa, dysentery, cachexia, atrophy, languor, slow fevers, &c. Riolanus again supposes the pancreas to be the obscure seat of intermittents, of hypochondriasis, and of other chronic disorders.

Important, however, as the office of this gland is known to be at the present day, we cannot ascribe to it an influence so extensive and so powerful as these old and most respectable writers were disposed to assign to it, at a period when its functions were very imperfectly or not at all understood. The morbid conditions to which the pancreas is subject are in fact not numerous. Dr. Baillie remarks that it is upon the whole less liable to disease than any other important gland in the body.‖ The symptoms of its diseases are moreover obscure, being for the most part such as belong equally to morbid affections of other parts contained within the abdominal cavity. It is, indeed, very seldom that we are able to discover pancreatic disease in the living subject, and rarely do we find, upon examination after death, that this gland has been the only or even the principal seat of disease.

The deviations of the pancreas from the healthy state have been regarded by several

* Tractatus Anatomico-Medicus de Succi Pancreatici Natura et Usu, cap. 2.

† Such was the notion of the celebrated Vesalius.

‖ See his posthumous volume, p. 207.

authors of high reputation as either of very small moment, or as far too obscure to be recognised with any tolerable degree of precision. Of all those whose Genera Morborum are comprised in Cullen's Synopsis, Vogel alone says one word about the pancreas, and he barely notices its inflammation—adding the words, 'notæ deficiunt.' In the comprehensive and valuable work of Dr. Mason Good we meet with nothing respecting the diseases of the gland in question. Yet though the opinion of Dr. Baillie above referred to may be perfectly correct, and though reading and experience may have forced upon us the conviction that the diseases to which the pancreas is liable can hardly be ascertained during life, or, at all events, cannot be ascertained until they have proceeded too far to receive any substantial benefit from medicine, still, in a work like the present, the morbid affections of so important a part must not be passed over in silence. We proceed, therefore, to offer such an account of those morbid affections as the perusal of some of the best authors, conjoined with our own (it must be confessed very limited) observations, enables us to supply.

Inflammation of the pancreas is a disease of rare occurrence, at least it has seldom been described by morbid anatomists. A recent instance, however, of what would appear to have been true inflammation of the gland, has been given in the Medico-Chirurgical Transactions,* upon the high authority of Mr. Lawrence. In the case to which we refer, the pancreas was throughout of a dull red colour, which contrasted very remarkably with the bloodless condition of other parts. It was externally firm to the touch, and upon being cut into felt very firm and crisp; but after having been left for eight-and-forty hours it became soft. Mr. Lawrence does not seem to regard this hardness as a morbid condition of the gland, and for the following reasons:—1st. because persons in whom such a state of the pancreas has been observed have died of other diseases, without a symptom of morbid affection of this particular part having developed itself during life: 2dly, because in these cases the structure of the gland has been in every respect perfectly healthy; and 3dly, because the hardness soon disappears after death. With all respect, however, for the opinion of so experienced a morbid anatomist and so acute an observer as Mr. Lawrence, we cannot altogether coincide with him in his reasoning upon this point—we do not feel satisfied that the induration in question is not a morbid state. The pancreas is by no means the only important organ which may be seriously diseased, and yet during the life of the patient betray no symptom of such disease, and the individual die at last of some other malady. Induration of other organs may be discovered upon dissection—such induration as has been always deemed to be unequivocally morbid—yet it shall disappear not many hours after death. Such we have known to be the case as regards the liver. We have met with at least one example of enormously hypertrophied and indurated liver, where the induration was lost a few hours after its removal from the body. Mr. Lawrence's strongest argument is the otherwise healthy condition of the pancreas; but Dr. Baillie, while he remarks that hardness of this gland is accompanied with little appearance to the eye of its structure being altered, proceeds to observe that he believes this hardness to be the beginning of a process by which the pancreas becomes truly scirrhous. "It very seldom," he says, "in this state shews, in any part, the real scirrhous structure, but I have seen this to be the case, which renders it very probable that the one is the beginning of a change into the other."*

More frequently than with inflammation of the pancreas do we meet with what are usually regarded as its consequences. Examples of abscess and ulceration are to be met with in various authors. In the writings of Tulpius, and Bartholinus,† and Guido Patin, as cited by Dr. Abercrombie,‡ found an immense abscess occupying the whole of the gland. Portal relates several instances of this disease, and one especially deserves notice, in which the pancreas was found in a complete state of suppuration, in a man who died suddenly after two or three attacks of vomiting followed by syncope: he had previously been suffering under a paroxysm of gout from which he was supposed to be recovering.§ Another case has been recorded by Dr. Percival. Dr. Baillie never saw but one case of pancreatic abscess, and that case did not occur in his own practice, but was under the care of the present Dr. Heberden.

Gangrene of the pancreas has been mentioned by Bonetus, Portal, and others.

Remarkable instances of scirrhus of the pancreas are also on record. Riolanus found the gland in such a state, and equalling the liver in size, in the person of Augustine Thuanus. Morgagni‖ relates a case where the pancreas was of unusual magnitude, and universally unequal with round tubercles of considerable size, and itself of almost cartilaginous hardness. Similar examples may be found briefly related by Dr. Abercrombie.¶ Several cases have also occurred to the writer of the present article in which the pancreas *seemed* to be preternaturally hard; but he has met with but one instance where the gland was decidedly and greatly indurated, almost as hard as cartilage. The subject was a young married lady, who, after having for many years suffered from intense pain of head, died with immense effusion in the ventricles of the brain. The abdomen was examined in consequence of her having,

¶ See his work above cited.

a short time previous to her death, complained of excessive pain in the epigastric region. No morbid appearance was discovered, excepting the extraordinary induration of pancreas above mentioned.

Cancer of the pancreas has sometimes been noticed. De Graaf* has a striking case from the Miscellanea Curiosa, Med.-Phys. Germanorum. It occurred in the person of a surgeon. The pancreas, which had perforated the diaphragm, was two spans long, and two hands in breadth; it was decayed and putrid—an ulcerated mass resembling cancer. In this case not only was the diaphragm perforated, but the spine was eroded, and the vena cava had given way. The cancerous mass had spread further, and had contaminated both kidneys, rendering them putrid and excessively black.

We are not aware of the existence of a symptom or set of symptoms by which inflammation of the pancreas can be ascertained in the living subject, nor are those which attend ulceration or scirrhus of that gland by any means well defined. The pancreas, says Dr. Pemberton,† is endowed with so small a degree of sensibility that ulceration is found after death, when no pain or other symptom had previously existed which could lead to a suspicion that inflammation was going on. If, however, there be a sense of weight or deep-seated pain in the region of the stomach, or referred to the back, with vomiting‡ of ingesta and of watery fluid; if there be gnawing pain at the boundaries of the thorax and abdomen, urgent thirst, and emaciation,§ and yet no perceptible tumour in the hypochondria, nor other symptom, in addition to those just mentioned, to mark an original disease of the stomach, or concave surface of the liver, or of the gall-bladder or ducts, or of the small intestines, or, we may add, of the kidneys, we may safely conclude that the seat of disease is the pancreas.

When disease has so far advanced that the emaciation is extreme, the indurated gland may be distinctly felt: by placing one hand upon the back and the other upon the stomach, and employing considerable pressure, an expression of pain deep-seated under the hand will in all probability be elicited from the patient.

But, besides the diseases already mentioned, the pancreas is subject to certain other morbid affections. Thus, while tubercle of the gland is mentioned by Morgagni,* a case of tuberculated sarcoma is related in the Medico-Chirurgical Transactions;† Dr. Abercrombie has given several instances of a mixed state of disease—of hypertrophy, with partial induration and partial softening resembling medullary sarcoma.‡ "Many cases," says the latter author, "are on record, of chronic disease of the pancreas, exhibiting the same diversity of symptoms which occurred in the examples now described, and nearly in the following proportion. Of twenty-seven cases, which I find mentioned by various writers, six were fatal with gradual wasting and obscure dyspeptic symptoms, without any urgent symptoms; in eight there was frequent vomiting with more or less pain in the epigastric region; and thirteen were fatal with long-continued pain without vomiting. In some of these the pain extended to the back, and in others it was much increased by taking food. In several there were dropsical symptoms, and in three or four there was jaundice from the tumour compressing the biliary ducts. In the morbid appearances also there was great variety."

Calculous concretions have been found in the pancreas. Instances of this have been given by De Graaf, Portal, Baillie, &c. The calculi in Dr. Baillie's case were found to consist of carbonate of lime.§

The pancreas, it is said, has been entirely wanting; but we doubt the fact; we believe that in the cases adduced some portion of the gland existed. The entire pancreas, as Haller observes, cannot be removed without the duodenum.‖

After what has been said respecting diseases of the pancreas, of the great obscurity of their symptoms, &c. it cannot be expected that any thing very satisfactory can be proposed as to their treatment. To use the words of Dr. Pemberton, "the remedies for a diseased pancreas are as imperfect as the symptoms which mark its derangement." Could we ever be assured that the pancreas is the primary or the principal seat of disease, we should still perhaps be at a loss how to meet the mischief by strictly appropriate remedies, and as, in the present state of our knowledge, we never can decidedly pronounce that the gland in question is the chief seat of disease, our practice must necessarily be vague; it must necessarily be directed to symptoms which belong equally to morbid affections of other organs as well as to those of the pancreas. Pain we must attempt to relieve by leeches, or cupping, or blisters. We must

* Tractatus, &c. cap. vii. See also Bonetus, de vomitu observ. 55.

† Diseases of Abdominal Viscera.

‡ The diseased pancreas may in various ways occasion vomiting; by irritating the contiguous stomach by its hardness or roughness, or by pressing upon it by its preternatural size; or it may compress the duodenum. Or the vomiting may be caused by the secretion of the gland being vitiated by its being deficient, or altogether suppressed. It is said that dogs, whose pancreas has been removed, have died of bilious vomiting.

§ There is an observation of Prosper Alpinus which we must not pass over in silence. Speaking of inflammation of the omentum, mesentery, and *pancreas*, he says, "Necessario prædictarum partium insensibilium phlegmone oppressi in expirando angustiam sentiunt."—*De Medicina Methodica*, lib. vii.

‖ Utilitatem magnam (pancreatis scilicet) perpetuitas suadet, quâ pancreas in plerisque animalibus reperitur; *neque refutant pauca experimenta, in robusto animali facta, quod particula pancreatis extirpatæ vitale superficit, totum enim pancreas auferri nequit, nisi cum duodeno.*—Haller Visuæ Liniæ Physiologiæ.

endeavour to restrain the efforts to vomit, and we must secure at least one regular evacuation daily. Of the remedies calculated to allay the irritable condition of the stomach which accompanies disease of the pancreas, a great variety might be mentioned: we select the following, simple indeed, but often very useful:—first, a drachm of tincture of senna with five minims of laudanum, to be taken a quarter of an hour before each meal;* secondly, pulv. calumb. et pulv. rhei aa gr. v., sodæ subcarb gr. v., pulv. capsici gr. ß, in any convenient vehicle just before dinner; or gr. v. of the compound rhubarb pill may enable the stomach to retain a portion at least of the food, which would otherwise be rejected altogether. Of the other numerous remedies which are commonly employed in derangement of stomach we need say nothing in this place. They may each prove occasionally useful, but they more generally fail even to palliate the symptoms when the pancreas is in fault.

The bowels may be regulated by mild laxatives. The plan of certain old practitioners is not to be despised. When they met with cases in which pain of stomach or of some neighbouring viscus was chiefly complained of, yet no good evidence existed of actual disease of any particular part, they gave an opiate draught at bed-time, and a common laxative in the morning. This practice was, we believe, at least as useful as any of the more scientific plans which have been adopted in later times. The patients probably lived as long and their days were as comfortable as they have been under modern treatment.

In one word, respecting diseases of the pancreas, we think that, in their earlier stages, when they cannot be exactly ascertained, our practice must be in a great degree empirical; when they have reached that point that they can be pretty accurately ascertained, little or nothing can be effected, nothing probably in the way of cure, little by way of arresting the progress of the disease. Still, however, it is our duty to recommend an alterative course of medicine; at any rate we may palliate the more distressing symptoms; we may, as in various other hopeless maladies, render the closing days of our patients comparatively comfortable.

(H. W. Carter.)

PARALYSIS, from παράλυσις, *debilitas, resolutio nervorum* of Celsus.

At an early period of the history of medicine it was a surmise of Galen that two different states or degrees of nervous influence were requisite to supply sensibility and the motive power to any part of the body; but it was reserved to the present century to enlarge upon this idea, and by careful induction from facts disclosed by minute anatomical investigation, from the results of direct experiment and from the effects of certain pathological conditions, to infer that parts endowed with sensation and voluntary motion are provided with two classes of nerves, the one *sentient*, the other *motive* nerves.

If a part be deprived of the influence of one or both of these classes of nerves, from whatever cause, and to a greater or less degree and extent, that part is reduced to the condition indicated by the term *paralysis*, which we accordingly define as the total loss or diminution of sensation or motion, or of both.

Aretæus was the first of the ancients to employ the word paralysis to any extent, but he limits its signification to denote merely a loss of the power of motion, (κίνησιος μοῦνον ἐνεργείης τέ πάρεσις.) The term occurs only once in the writings of Hippocrates, and then in a letter to Perdiccas—de structurâ hominis. By him, and by many writers after him, apoplexy and paralysis were confounded together, and even by Heberden they have been considered as only different degrees of the same disease.

It is with much justice that Rostan has reprobated the custom of considering the condition of paralysis as a disease in itself, when it undoubtedly should be regarded as a phenomenon belonging to and dependent on a number of different affections; and it is much to be questioned whether such a species as that given by Rochoux,* viz. *idiopathic paralysis*, is at all admissible.

From the definition above given, it is obvious that those parts which are naturally endowed with sensation and the power of motion can alone be deemed susceptible of the paralytic state. We cannot, therefore, apply the term to that condition of a secreting organ when it is incapable of performing its function, as some writers have done when they speak of paralysis of the kidney, liver, or pancreas, &c.

From the definition we may further infer a primary division of paralysis into that of *sensation*, or *anæsthesia* (ἀναισθήσιη), and that of *motion* (ἀκινήσια), each of which may vary in degree, and may be therefore *complete* or *incomplete*.

Although the term *anæsthesia* seems to have originally been applied by Aretæus to denote absence or defect of the sense of touch, there is no reason, from the etymology of the word, why it should not be more extensively applied to signify absence or defect of sensation in general. Adopting this broader signification, then, we place under this head those affections of the senses which are denominated *amaurosis*, *anosmia*, *cophosis* or *dysœcia*, *ageustia*, as the sight, smell, hearing, or taste, may be severally deficient, and finally paralysis of the sense of touch, which is specially denominated by some *anæsthesia*.

For full details respecting *amaurosis* we refer to the article under that head. (See Amaurosis.)

Anosmia (loss of smell) rarely exists as a solitary complaint, except it be occasioned, as we believe it generally is, by an abuse of sternutatories. It is sometimes a congenital defect, an instance of which is mentioned by Dr.

* In the distressing nausea and vomiting attendant upon the early stage of pregnancy, the above is a very excellent remedy.

* Dict. de Médecine, art. Paralysie.

Good, in the person of a young lady. Another instance is known to the writer, in the case of a gentleman, now past the age of fifty.

Tumours compressing the olfactory nerves, organic alterations of their roots, acute affections, or long-continued irritation of the Schneiderian membrane, polypi, disease of the spongy or other bones of the nose, external injuries, may be enumerated as the principal causes of anosmia. Serres alludes to several cases of disease of the roots of the olfactory nerves affecting the sense of smell, and seems to think that alteration of the external root exerts a more powerful influence than that of either of the others.

The cure of this affection is accomplished by the removal of the above-mentioned causes, and is attainable only so far as that object can be effected.

Cophosis *(deafness)* is not an uncommon symptom in fevers, or in acute diseases in which there is disposition to head affection. Disease or compression of the auditory nerve—disease of the petrous bone—obliteration of some of the canals or passages connected with the auditory apparatus—otitis—are among its most usual causes. There are likewise cases of nervous deafness, as Mr. Saunders designates it, dependent on constitutional causes, producing temporary derangement of the functions of the auditory nerve.

If the deafness depend on obstruction, it is of course submitted to surgical treatment; but if it be merely a functional derangement, topical counter-irritation and a general tonic treatment have been generally found successful in the early stage.

Ageustia *(loss of taste)* sometimes accompanies local palsy of the tongue or of the face, and sometimes is produced mechanically by the deposit which covers the sentient surface of the tongue in fevers, exanthemata, &c. preventing the application of the sapid substances to the nervous extremities. It is likewise occasioned, as Dr. Good observes, by the long-continued use of tobacco, whether by smoking or chewing, or of other acrid narcotics. In the Boston Medical and Surgical Journal for May 1832, Dr. Robbins relates the case of a lady in whom the sense of taste on one side of the tongue was impaired by want of exercise. Owing to the presence of a very painful but not unsound tooth on the left side, the whole force of mastication was thrown upon the teeth of the right side. Liquids were from habit successfully passed through the mouth without coming in contact with the left side. After two years' continuance in this state, the painful tooth was extracted, and when the immediate effects of the operation of extraction had subsided, the lady observed that her sense of taste on the left side was considerably impaired in acuteness, and that she failed to perceive the true flavour of whatever was presented to its action.*

This affection, like the preceding, is to be cured by the removal of its exciting cause.

* Vide Lond. Med. Gazette, vol. x. 175.

Anæsthesia *(diminution or absence of the sense of touch or of feeling)* affords much matter of interest to the pathological enquirer. We meet with it most commonly as a precursor of paralysis of motion, either in a minor degree, a condition of numbness, or in that of total insensibility; frequently it accompanies paralysis of motion, and rarely follows it.* It more frequently precedes paralysis of motion of the lower than of the upper limbs. Sometimes it is co-existent with paralysis of motion of the opposite side, as in a case by Cullen, of a gentleman who had loss of motion without loss of sense of one arm, and loss of sense with perfect motion of the other.†

Several cases of *complete* loss of feeling are now on record. In these cases the patients are insensible to injuries of the severest kind,—wounds with sharp instruments, burns, &c. and are constantly liable to accidents of this description, the skin having lost its protecting sensibility. Dr. Good quotes a case in which the anæsthesia had its seat in the right arm; in this case the occurrence of a phlegmon on the affected arm excited no uneasiness, and some time after, when the patient accidentally fractured his arm, he received intimation of the accident merely from the crash which it produced. Dr. Yellowley gives the instance of a man who put his feet into boiling water, and was not aware of the height of the temperature till he perceived a vesication forming on one of his legs: in a similar case by Mr. Earle, the high temperature of some hot grains into which the patient put his legs was first evinced by the formation of large sloughs. We may add that in Dr. Yellowley's case above alluded to, a knife was introduced deep beneath the nail of the thumb without occasioning pain or uneasiness.

When anæsthesia occupies the external integument, in the immediate neighbourhood of any of the orifices at which that membrane becomes continuous with the mucous membranes, the latter are generally similarly affected to a greater or less extent. Thus, in the cases of partial loss of feeling of the face, the conjunctiva of the eye, so acutely sensitive in its healthy condition, can bear pressure or friction, or even pricking with the point of a sharp instrument. The eyeball having thus lost its proper sensibility, the cornea is apt to become inflamed, opaque, ulcerated, and finally destruction of the eye ensues. Hence some physiologists have, with but little show of reason, argued that the nerve supplying sensibility to the conjunctiva is likewise the nerve of sight. The mucous membranes of the nose and mouth likewise participate in the insensibility in these cases. In the nose the membrane is unaffected by pungent substances, as ammonia, &c. although the sense of smell is perfect: the introduction of a feather into the

* In a case reported by Dr. Colles of Dublin in the Appendix to Sir C. Bell's work, loss of feeling followed the cure of a partial paralysis of motion of the face.

† See also Ephem. Natur. Curios. cent. ii. obs. 196.

nostril does not produce any of the usual effects. In the mouth there is equal insensibility of the mucous membrane of the gums, lips, and tongue; the individual will bear even mustard in the mouth without being incommoded: he is insensible of the presence of food in that part of his mouth which is the seat of the disease; so much so that, in a patient in this condition, a portion of food has been known to remain in the mouth till it became putrid. In these cases the sense of taste is generally affected. Mr. Broughton* has related an interesting case, in which the anæsthesia succeeded to the recovery of paralysis of motion of the lower extremities; it occupied the skin of the nates, part of the loins, perineum, penis, and upper part of the thighs. In this case the insensibility extended to a great portion of the genito-urinary mucous membrane; the patient was unconscious of the presence of a catheter in the urethra; erections of the penis and emission of the semen took place likewise without the patient being sensible of them. But the most remarkable and interesting phenomenon connected with the case was the kind of incontinence of urine which was present: "when the bladder was full, the urine overflowed on the slightest irregular movement, and ran out of the penis unconsciously to the patient." A similar case is detailed by Ollivier, in which incontinence of urine was co-existent with anæsthesia of the inner and anterior part of the thighs, and of the penis and scrotum. In these instances we presume that the insensibility of the inner membrane of the bladder is sufficient to account for the incontinence of urine; for how can those muscular fibres, which to a certain extent perform the office of a sphincter to the neck of the bladder, be stimulated to contraction unless the mucous membrane of that viscus be sensible of the presence of the urine?

Anæsthesia is most frequently partial in its extent; we sometimes meet with persons who possess from birth a numbness of one or more fingers. Often the affection begins locally, but increases its extent gradually. Cases are recorded in which the anæsthesia was universal; in others it has been reported to occupy the whole surface, with the exception of a small portion, as in a case by Ollivier, where a patch on the right hip was the only sensible spot on the whole cutaneous surface; and in another quoted by Andral, in which the insensibility extended over the whole body, excepting a small round spot on one of the cheeks.

In partial anæsthesiæ existing on one side of the body, we generally find the insensibility limited with the utmost precision by the median line. These cases vary in extent from half the body to an extremity, part of an extremity, part of the face, &c. It has also been known to occur in numerous round spots, eight or ten in number, the surrounding skin being perfectly natural.† In the anæsthesia of the face we may here mention an invariable consequence; the patient complains that when he puts a glass or cup to his lips, it conveys to him the sensation of its margin being broken; and this circumstance is often the first to direct his attention to the complaint. When there is cutaneous anæsthesia of the extremities, we generally find that the power over the voluntary muscles is impaired; and this we might, *à priori*, expect to follow loss of sensation. A case by Dr. Yellowley confirms this supposition. The patient used to drop glasses, plates, &c. if her attention were directed from them; but so long as she kept her eyes on them, she held them in perfect safety. A precisely similar instance is adduced by Foville,* in proof of the above assertion, as related to him by Sir A. Cooper. A third case we may mention from Dr. Ley.† There was defective sensibility on one side of the body; the patient could hold her child in the arm of that side so long as her attention was directed to it; but if surrounding objects withdrew her from the notice of the state of her arm, the flexors gradually relaxed, and the child was in hazard of falling. The fact is further illustrated by an incident of daily occurrence. When a person, from sitting in an awkward position, produces numbness in his lower extremity by the prolonged pressure on the sciatic nerve, he will find it almost impossible to stand on the benumbed leg alone, and that from the absence of the consciousness that the foot is applied to the ground.

Anæsthesia varies in its mode of access. In some cases the patient's attention is first attracted by the sensation of fine sand intervening between the skin and the object touched; in others there is a feeling compared to the creeping of insects over the skin, and thence named *formication:* both these after a little merge into total insensibility. Often the anæsthesia appears suddenly and without any premonitory symptom.

We cannot always assign a satisfactory cause for the condition which we have been describing. In general, however, it is referable to some change influencing the nerves which supply sensibility to the affected part or parts; in the trunk and extremities, the sensific filaments of the spinal nerves; in the face, the ganglionic portion of the fifth pair. This alteration may exist either in the nervous trunks themselves, or in the nervous centres, where the nerves are connected with them. Thus pressure, wound, or disease of a nerve, is constantly known to affect the sensibility of the parts supplied by it. Several instances are to be found in authors where anæsthesia followed concussion of the spinal marrow: injury or disease of the posterior bundles of the same could produce a like result. Loss of sensibility is often connected, too, with cerebral disease. Local injuries of various kinds will produce anæsthesia; it sometimes has commenced from a cicatrix, or spe-

* Med. and Phys. Journ. 1827.
† Andral's Lecture, Lancet, No. 497.

* Dict. de Méd. et Chirurg. art. *Encephale.*
† Appendix to Bell on the Nerves, No. lxxxv.

ceeded the application of a blister. The sudden or continued exposure to cold is not an unfrequent cause: most of the cases related by Mr. Broughton were plainly attributable to this cause. Mr. Swan gives a case in which anæsthesia of the hand was produced by a violent pressure applied to the wrist; and Roche mentions one, in which the insensibility occupied the integument over the trajet of a ball which entered the body on the right side and ran round beneath the skin till it struck against one of the lumbar vertebræ.

Anæsthesia is likewise often connected with hysteria and hypochondriasis; sometimes it follows parturition, as in the case above quoted from Dr. Ley: it is also sometimes coexistent with mental derangement. We may add, that the condition of the circulation in a limb exerts a marked influence on its sensibility; suspended or retarded circulation removing or diminishing the sense of feeling, as is matter of daily observation.

The duration of anæsthesia is uncertain and variable: sometimes the sensibility will return when least expected; at other times it will resist all treatment. When it is the result of spinal concussion, it may be removed by the treatment generally adopted for that accident; and when produced by cold, the prognosis may also be favourable.

The treatment of this condition is founded more on experiment than on a correct pathology. It chiefly consists in local applications to the affected parts. Frictions with various stimulants; baths of different descriptions, warm or cold; douches; blisters, or epispastics of other forms; electricity; may be enumerated as the chief curative agents. If an organic cause exist, either in one of the nervous centres, or in a trunk of a nerve, it is hardly necessary to observe that primary attention should be directed to ascertain how far that is removable.

We may here briefly allude to the remarkable epidemic which appeared in Paris in the summer and autumn of 1828. The most singular and constant symptom was a numbness, passing into a total insensibility of the skin and subcutaneous tissues on the hands and feet, and sometimes on other parts, of more or less extent. This was in general preceded by some symptoms of gastric or intestinal irritation, which continued often for many days or weeks. The insensibility, which was in general preceded by formication or pricking pains, was uniformly accompanied with an œdematous state of the affected limb; vesications, likewise, formed on it in different places: the skin was sometimes red, sometimes of a dark colour, and the epidermis detached in some places. The insensibility was so great in many cases, that no pain was experienced when pins were passed into the skin. In some cases there was subsultus tendinum; in others the muscles were paralysed; yet according to the report* of M. Genest, from whom we have taken the above statement, the latter condition was not very frequent; but from the statement of Chomel to the Academy (sitting of 26th of August), it appears that considerable weakness of the feet and hands, with impossibility to move them, was a symptom very constant.

No organic lesion of the nervous system could be detected sufficient to account for this remarkable epidemic. From the examinations detailed by Genest, the intestinal mucous membrane seems to have been the seat of several ulcerations. To us there appears much analogy between this epidemic and that which is met with in tropical climates, the beriberi, or the more chronic barbiers.

Paralysis of motion.—The second form of paralysis is that of motion, to which, from its being of so frequent occurrence and so serious in its effects, the term *paralysis* is more especially applied.

Like that of sensation, paralysis of motion is either complete or incomplete. It presents some variety in its mode of invasion: it may come on instantaneously, and without any premonitory symptom; the affected parts becoming suddenly flaccid and powerless, and thrown into a state of complete resolution: at other times the paralysis is preceded by inordinate muscular action, viz. by spasms, attended with a considerable degree of pain, the muscles sometimes remaining in a state of rigidity after the invasion of the paralysis. Lastly, we find paralysis coming on slowly and gradually; the part being at first affected as to its sensibility, then becoming slightly torpid, and at length paralysed: the palsy then spreads on step by step, till it occupies a considerable extent. This is the form to which the term *creeping* palsy has been applied.

There are certain phenomena which constantly succeed to the attack of palsy. Wasting of a limb is an almost invariable consequence of paralysis. This would appear to arise more especially from the atrophy of the muscles, the result of prolonged inactivity; and, in part, from the deranged nutrition, in consequence of the removal of due nervous power. The muscles of a limb, when in a state of complete resolution for any long period, lose their colour, and are diminished in firmness as well as in dimensions; the colouring matter in some cases is completely absorbed, and a yellowish tissue, which however still retains the fibrous and fasciculated character, replaces the original muscle; a change which by some has been described as the conversion of muscle into fat.

The circulation in palsied limbs is said to be more languid than in healthy ones, and the pulsations of the arteries have been stated to be diminished in force and even in frequency. These statements, however, do not appear to have been founded on facts universally or even extensively observed, to say nothing of the sources of fallacy which lie in the way of a conclusive comparison of the relative force of arterial pulsations.

The nerves of palsied limbs do not in general present any obvious change. They have, however, been found increased in size, and of a yellowish colour; but it should be noticed that

* Archives Gén. de Méd. Oct. 1828.

the enlargement might have arisen from the thickening of the neurilemma, or from the infiltration of a fluid, and not from any increase of the medullary substance. We may, moreover, state as the result of the experience of Andral, that he has never found the nerves of paralytic limbs either atrophied or hypertrophied.* Sir C. Bell, however, is of opinion, as Dr. Cooke says, that the nerves of palsied limbs do lose some of their substance. When the nerves of a paralysed limb are diseased, it has been remarked that the wasting is more rapid and more manifest than in the ordinary cases, (see article Atrophy;) and judging from our own observation, we would infer that the atrophy is likewise more rapid when the paralysis is the result of spinal than when caused by cerebral disease. Thus how much more frequently do we observe wasting of the limbs of paraplegics than of those in whom the paralysis is in the form of hemiplegia. Yet we have seen limbs in the state of palsy, and that of some duration, in which there could not be detected any difference from sound limbs. We not unfrequently meet with palsied limbs in an œdematous state, more especially in old persons; we may also remark that the state of paralysis favours the formation of vesications on the affected parts,—an occurrence more commonly noticed in paraplegia.

Much has been written respecting the temperature of paralytic limbs. Does it differ from that of healthy ones? or are they, from the want of nervous power or any other cause, less able to resist the influence of cold? Mr. Earle, by actual thermometric examination of a considerable number of paralysed limbs, found that their temperature was some degrees lower than that of the sound ones, and observes that, wherever nervous energy is impaired, the part loses the power of maintaining a healthy standard temperature, because the integrity of the nervous power is essential to the complete performance of the calorific function.† Observation, however, has frequently shown that paralytic limbs may be of a higher temperature than others. Dr. Abererombie's views on this head place the question in so clear a point of view that we shall transcribe his remarks: "In regard to the temperature of paralytic limbs, I think it is generally supposed that they are colder than the healthy limbs; but this does not appear to be the case. The truth seems to be that they have lost in some degree that remarkable power possessed by the living body, in a healthy state, of preserving a medium temperature, and that, *according to the temperature to which they have been exposed*, paralytic parts become hotter or colder than sound parts which have been exposed to the same temperature. A case has been related to me by a friend, in which a medical man, paying a visit to a paralytic patient, found the paralytic arm so intensely hot that it was painful to touch it. This, upon inquiry, was found to be owing to the application of very hot brau, which the patient had made to the arm by the advice of a neighbour, though he was himself insensible of the change of temperature."*

The sensibility of paralysed limbs is generally more or less impaired; most frequently there is paralysis of sensation incomplete or complete, the latter, however, being very rare. Dr. Cooke states that he "never saw a case of palsy in which sensation was entirely lost; and an eminent physician of great experience asserts that a total loss of feeling in this disease is very rare." Sometimes the sensibility is exalted, and the patient can hardly endure the slightest touch upon the affected limb. Dr. Abercrombie refers to a case in which the sensibility of the arm was so increased that the least breath of cold air excited convulsion. The sensibility may likewise be so altered that the patient will draw erroneous inferences from his sense of touch; thus, cold bodies will feel hot to him, and as in the case related by Dr. Falconer,† the feeling of heat will subside as the body in contact gradually acquires the temperature of the limb.

In general there is but little pain in palsied limbs; Drs. Cooke and Abercrombie, however, speak of patients who suffered extreme pain. We have observed pain accompanying incomplete palsy, and we should say that it is in such cases that pain is to be expected, there being in general a more or less spasmodic condition of the muscles.

The vital and natural functions, says Cooke, are generally but little affected in palsy; sometimes those of respiration and circulation are somewhat impeded, but this is generally towards the close of the patient's life. The bowels are usually more torpid, and less easily brought under the influence of purgative medicines, but the excretions are not diminished. When the paralysis extends to the sphincter, and to the muscular coat of the bladder, the involuntary discharges are apt to lead one to imagine that the excretions are increased in quantity.

Paralytics are in general irritable and peevish, and, if the palsy be of long duration, sometimes become quite imbecile. Dr. Cooke relates a case, however, in which the attack of paralysis produced a remarkable change in the temper of the patient;—"from being of an irascible and irritable disposition, he became perfectly placid, and remained so until his death about two years after." The powers of the mind too are not unfrequently affected, as well antecedently as subsequently to the attack of paralysis. The memory is most frequently affected in these cases: the power of recollecting names, whether of persons or things, as well as the memory of languages, is often lost; the habit of substituting one name for another, and a predilection for particular names, which the patient will apply to all persons and on all occasions, are also among the deranged mental phenomena attendant on these cases. In some

* Andral's Pathol. Anat. by Townsend, vol. ii. p. 797.

† Med. Chir. Trans. vol. vii.

* Abercombie on the Brain, &c. p. 288.

† Mem. Med. Soc. Lond. vol. vii.

instances, paralytics even invent names which are unintelligible to all except those who are in daily attendance on them. The writer remembers the case of an old domestic, rather famous for loquaciousness when in health, in whom some curious defects of verbal memory preceded for a considerable period the paralytic attack which ended her days. She entirely forgot the names of persons, and first lost the recollection of the names of those with whom she was most familiar; yet for some she invented names, which seemed to please her better than the real names of the individuals, as she almost invariably rejected the real names when they were mentioned to her. She had nearly the same defect as to names of things; she often pronounced the first syllable of the name of any thing she wished to ask for, but could get no farther; nor would she be put right. She at length grew irritable and suspicious of even those who ministered to her wants; she husbanded her few articles of property with the greatest care and closest watchfulness; and ultimately she became amaurotic, and the subject of extensive palsy. Such instances are, we believe, by no means rare. Dr. Bright relates one in some respects similar.

Causes of paralysis.—It is to the effect of some alteration in the centres or ultimate ramifications of the cerebro-spinal system that observation has taught us to look for the true cause of most of the paralytic affections met with in practice. There are forms of palsy where no appreciable alteration can be detected in any part of the nervous system. Such are those in which the palsy arises from the impregnation with metallic particles—lead, mercury, and others, for which no satisfactory cause is assignable. Yet even in these cases we are scarcely warranted in denying the existence of organic lesions merely because they are not obvious to our senses. We would here observe that close and unbiassed observation is more called for to promote the elucidation of the class of affections we are now considering than of any other, and we may add that an accurate symptomatology is as essential to this important end as an exact and minute detection of the several morbid appearances of the cerebro-spinal system. It is mainly by a series of pathological facts, well arranged, that we can hope to unravel with certainty the many intricacies connected with that system in its healthy as well as its morbid state. To accumulated experimental and pathological investigations we owe in a great measure the advances made within latter years, and to such we look forward, and not without sanguine hope, for a still farther insight into a class of diseases at once dreadful to the afflicted and perplexing to the practitioner.

Paralysis is said to occur more frequently in men than in women, and generally in persons past the meridian of life; it is a common disorder of old age. Those of a sanguine and what has been called nervous diathesis are most liable to it.

Its exciting causes are such as dispose the brain, spinal marrow, or nerves to diseased action acute or chronic; accidents; and a variety of other causes, both moral and physical. (See Apoplexy and Inflammation of the Brain.) Exposure to the action of particles of mercury, lead, and arsenic, produces a peculiar form of paralysis, the paralysis *venenata* of Cullen.

Paralysis is often co-existent with various nervous diseases—hysteria, epilepsy, mania, hypochondriasis. It also sometimes appears after parturition, and occasionally with phlegmasia dolens.

The duration of paralysis depends so much on its cause, the constitution of the patient, and various other circumstances, that no general statement can be made regarding it.

With respect to the extent of parts affected, we find that paralysis has, to use the words of Heberden, innumerable degrees, from the torpor and debility of a single joint of a finger to a complete apoplexy, in which sense and motion vanish from the body. It may, therefore, be divided into, 1. general paralysis, 2. partial paralysis.

1. *General paralysis.*—When both sides of the body are paralysed, and when, in fact, the whole muscular system is deprived of the power of motion, so that the patient cannot move in any way by an effort of his own, the condition is that of general paralysis. If the four extremities be paralysed, the affection would likewise come under this head. It sometimes happens that one or more of the senses are impaired in addition to the motive power; and not unfrequently the general sensibility of the body is diminished or destroyed.

It is remarkable to what an extent paralysis of motion as well as sensation will affect the body without destroying life. Some interesting cases are recorded in which the palsy was so general as completely to deprive the patient of all means of communication with the surrounding world. One of the most remarkable of these is that related by M. Defermon, in the Bulletin des Sciences Médicales for January 1828. It is defective, however, inasmuch as the examination of the body was not permitted. M. C. L., of a nervous habit, and having lived a dissipated life, was suddenly seized with amaurosis; which being suspected to have had a syphilitic origin, was treated accordingly, without success. Immediately afterwards there came on a remarkable exaltation of all the other senses, but especially of that of touch. His intellect being perfect, he was enabled to continue in the duties of his office in an important financial department. Some years afterward his hearing became dull, and gradually advanced to total deafness; at length general paralysis of sense and motion, except in the tongue and muscles of deglutition and respiration, supervened; the whole body became insensible, and the limbs were successively paralysed, without the least trace of external lesion.

The patient was thus shut out from all means of communication with others; yet his speech and intellects were unimpaired. It

was accidentally discovered that a small patch on the right cheek retained its sensibility; and by tracing letters on this sensible spot, his wife and children were enabled to maintain an intercourse of ideas with him! After some time, however, his strength began to fail, the paralysis extended to the sphincters, and he sank.

Another somewhat similar but more complete case is recorded in the Edinburgh Medical and Surgical Journal for 1828, by Mr. Davies Gilbert, the late distinguished President of the Royal Society.

The young girl, the subject of it, had been born a little before her full time, and at birth was in a state of great weakness. She did not manifest in any way the instinct which usually directs other infants to seek their natural nourishment; she was consequently reared with much difficulty. One of her eyes was much smaller than the other, which seemed to be of the natural size. Some weeks after birth she was seized with violent convulsions, which lasted some time. She continued, however, to grow like other children, but a deficiency of sensation and motion became daily more obvious. She was destitute of the sense of sight and hearing, and a cataract was observed upon the eye, which was of natural dimensions. The sense of taste appeared to be tolerably perfect, as she afforded some feeble sign of satisfaction when sweetmeats were given to her. As to voluntary motions, they were totally defective, and she arrived at her seventeenth year without having ever raised her head, carried her hand to her mouth, or put a foot to the ground. She was quite dumb, and only occasionally uttered a feeble cry, which her attendants regarded as indicating a desire for food. Some time before death her feebleness seemed to increase, and on the day on which she completed her seventeenth year she expired so tranquilly that she was supposed to have fallen asleep. It is positively stated that this girl had shewn some appearances of menstruation, as well as other signs of puberty.

On dissection, the brain appeared perfectly healthy, but on raising it from the cranium it was found that the dura mater lining the basis cranii was deficient, and its place occupied by a thin and semi-transparent membrane, very loose and singularly arranged; the tentorium cerebelli was likewise deficient, so that the posterior lobe of the brain rested immediately upon the upper surface of the cerebellum. All the nerves were perfectly regular.

General paralysis is most commonly the result of apoplexy, and is then accompanied with stertor, coma, and the other symptoms usually attendant on that disease. The continuance of circulation and respiration are the only remaining signs of life, the power of swallowing is impaired or lost, and the excretions pass involuntarily. This condition either gradually increases, the paralysis extending to the muscles of respiration, and the vital powers becoming slowly exhausted; or the coma subsides, consciousness is restored, and the patient is found paralysed in sensation and motion to a greater or less extent; or the paralysis may totally disappear with returning consciousness.

Paralysis from apoplexy is easily detected by the suddenness of its invasion and other concomitant circumstances. (See Apoplexy.) In surgical practice this condition of general palsy is met with not infrequently as a consequence of a severe concussion or compression of the brain.

We observe other cases of general paralysis characterized by a development more or less slow. The tardy progress of these cases distinguishes them sufficiently from those which are the result of apoplexy. Most of them partake of the nature of that described above as *creeping palsy*; there is some variety as to the part first affected; sometimes the eyelid falls, or a hand, or foot, or even a finger or toe become paralysed; sometimes also the tongue: at other times an impaired condition or complete loss of sensibility precedes the paralytic attack; sometimes loss of sight or hearing is the first indication; or a series of cerebral symptoms, for which it is difficult to assign an adequate cause: and this is often succeeded by impaired memory, and deranged mental powers, such as we have already alluded to. These cases generally result from disease, acute or chronic, affecting the brain or its membranes, or from disease of the spinal cord. (See Brain, Inflammation of.)

Injuries of the spinal marrow in man and animals fully authorize the conclusion, that the higher in the spine the seat of injury is, the greater the extent of the consequent paralysis. Hence, then, we may reasonably expect, that in order to produce general paralysis, the spinal disease must be either of considerable extent, or situated at the upper part of the spinal marrow. This statement is confirmed by the cases (several of which are now on record) of rapid death following the separation of the atlas and axis, when a sudden compression is exerted upon the contained portion of the spinal marrow by the odontoid process.

The morbid conditions of the contents of the spinal canal which have been found coexistent with general paralysis, are pretty much the same as those of the brain and its membranes. They may be thus enumerated:— 1. Inflammation of a considerable portion of the cord towards its upper part, the existence of which is generally indicated by ramollissement, suppuration, or abscess. 2. Extensive hardening of the substance of the cord, in which the membranes are more or less implicated. 3. Tubercles, or circumscribed tumours, developed in the spinal marrow. 4. Extensive serous effusion, probably an increase of the natural spinal fluid as described by Majendie. 5. Thickening, or fungoid disease of the dura mater, and ossific growths, either in that membrane, or from the bony parietes of the vertebral canal.

In the present state of our knowledge of spinal diseases, it is not easy to assign any general symptoms which would point unequivocally to the spinal cord as the source of

evil in certain cases of general paralysis. From all that has been collected on the subject, however, we think we are justified in asserting that there are certain phenomena which more frequently, or in a more marked manner, accompany paralysis resulting from spinal, than that which depends on cerebral disease. There is in these cases, generally, a more excited state of muscular action, evinced by spasms, twitchings, or even convulsions, and sometimes a permanent contraction. The sensibility of the surface, too, is often more deranged: thus, formication, tingling, or numbness are very frequently found as the precursors of the form of palsy we are alluding to. We may further remark, that it is in cases of spinal disease that we sometimes see the line drawn with the greatest precision between the motive and sensorial powers; the latter being totally unimpaired, while the former is completely destroyed, —a fact which seems clearly to direct us to the two distinct sources whence experimental physiology would derive these powers. Ollivier seems to think that diminution of temperature is more obvious in palsied limbs from spinal disease; and it would appear from the reports of cases by him and others, that they are more liable to œdema, vesication, sloughing, &c. In fine, the mode of access of paralysis dependent on spinal disease, is for the most part such as has been described as characteristic of the *creeping palsy* of authors.

We occasionally meet with cases of general palsy, well calculated to perplex the pathologist, presenting many indications of spinal disease; and yet, when we come to examine them after death, no lesion whatever is discernible, or at least a very slight one, obviously insufficient to account for the phenomena. We quote such a case from Dr. Abercrombie as a specimen: and it is further worthy of notice, as another instance of palsy almost universal. "A woman, æt. 20, a servant, sprained her back in lifting some heavy article of furniture. Some time after she began to experience weakness of the legs, which gradually increased to perfect paraplegia. After some time the affection extended to the arms, and she then had not a vestige of motion of any of the parts below the head, except a very slight motion of some of the fingers; but the internal functions were all entire, and her speech was distinct, except that in speaking she was sometimes seized with spasmodic twitches of the lips and lower jaw. She lived in that state without any change in the symptoms, her general health continuing good, for about twenty years. In the morning she was taken out of bed and placed in a chair so contrived as to support her in a sitting posture. Her arms were supported on a cross board placed before her; and if by any accident one of them slipped from its support, she had no resource but to call the assistance of some other person to replace it. On one occasion the arm was allowed to hang for two hours, she having been left alone, and it became extensively œdematous. In the same manner, if her head fell forward upon the thorax, it remained in that position until raised by an attendant. Her mind was entire. She died of four days' illness with symptoms of typhous fever. I examined the body," adds Dr. A. "with the utmost care, along with Dr. Pitcairn, and *we could not discover any disease either in the brain or spinal cord.*"*

Cases nearly similar as to the extent of palsy are recorded by Bretonneau and Ollivier, but in which a very slight morbid alteration was discovered. In one, the palsy commenced by loss of motion of the little finger, and rapidly spread to the extremities, the tongue, and partly to the muscles of deglutition. The patient, however, strange to say, retained the power of moving the thumb and two fingers of the right hand. In this case the only obvious morbid change in the nervous centres was, a rust-coloured spot three lines in extent upon the tuber annulare.† In Ollivier's case, a strong sense of pricking in the points of the fingers of the left hand, and toes of the left foot, was the first symptom. This was followed in half an hour by a similar sensation in the same parts on the right side. On the following day there was general paralysis, but the sensibility was not impaired. Respiration and deglutition were considerably affected: the difficulty of respiration increased, and she died the third day. There was only a slight appearance of infiltration of blood in the cellular tissue on the outside of the dura mater of the cord, especially about the lower part.

Now and then cases of general paralysis, apparently dependent on the state of the spinal marrow, are observed to recover. Ollivier has recorded several examples of this kind. The palsy spreads from limb to trunk, commencing in the fingers and toes, and often preceded by tingling or formication, and more or less numbness of the cutaneous surface. The paralysis, although general in extent, is, however, rarely complete; the functions of the rectum and bladder are not at all or but slightly affected, and the intellectual powers are entire. In some cases the palsy is preceded by pains in the dorsal region of the spine, or a sense of fatigue and lassitude and weakness of the spine. It has been observed to follow the stoppage of an habitual evacuation, abuse of sexual intercourse, and the suppression of the lochia in women after parturition. Such cases are supposed by Ollivier, and with much reason, to be occasioned by a temporary congestion of the vascular system of the spine, especially the venous system, so remarkable for its numerous and intricate anastomoses.‡ He conceives that, though the anastomoses are large and numerous, yet the circulation is often deranged and retarded; for, first, these veins are destitute of valves; secondly, he has found in old persons fibrinous clots filling all the venous

* *Abercrombie*, p. 417.

† Revue Médicale, May 1826.

‡ If the reader can have access to the beautiful and accurate plates of Breschet, "Du Système Veineux," he may from them form an adequate conception of the extent and intricacy of the veins of the spine.

ramifications of the spinal marrow, as well as those which accompany its nerves; and, lastly, he considers that respiration exerts a direct influence on this portion of the circulating system, and causes obstacles in it during efforts of various kinds, or strong emotions, or those affections which in a greater or less degree excite the respiratory act.* As a venous congestion, such as we have been alluding to, is not likely to be a permanent morbid appearance, that is to say, might be dissipated under the influence of various causes, either immediately prior or subsequent to dissolution, it is not unreasonable to suppose that some of those cases in which no morbid change was discoverable, may have been attributable to a similar cause.

The general paralysis of lunatics, as described by Esquirol and Calmeil, has been already fully noticed in the articles INFLAMMATION OF THE BRAIN and INSANITY. We may here observe, however, that one of its earliest symptoms, viz. defective articulation, would alone serve to distinguish it from palsy dependent on spinal disease.

It is hardly necessary to advert to the propriety of observing great caution in forming a prognosis of any or all of the forms of general palsy now described. The difficulty of arriving at a certain diagnosis of the proximate cause must necessarily involve the practitioner in considerable doubt.

II. *Partial paralysis.*—Under this head are included those varieties of paralysis in which only a part of the body is engaged; it admits of a threefold division—1. local paralysis; 2. hemiplegia; 3. paraplegia.

1. *Local paralysis.*—This division comprises all those palsies which have their seat in parts of small extent. Local palsies are most frequently met with as precursors of a more extended condition; yet we sometimes find them localized as well in cause as in extent. In the former case they should be regarded with great suspicion, and should excite a vigilance on the part of the practitioner to counteract as far as possible the threatened danger; hence the importance of distinguishing accurately between local palsies under these different circumstances.

We shall notice local paralysis under the following heads: 1. paralysis of the eyelids; 2. paralysis of the face; 3. paralysis of a limb or part of a limb; 4. paralysis of particular sets of muscles, or of single muscles.

Paralysis of the eyelids.—Two forms of palsy are found to affect the eyelids, which, as engaging antagonist muscles, are totally opposite in their effects. In the one the eye remains totally or partially closed (*ptosis, blepharoptosis*); in the other the eyelids are permanently open, the patient having lost in a greater or less degree the power of closing them. (*Lagophthalmia.*)

Ptosis has been so named from its chief and most conspicuous phenomenon, viz., the drooping or fall of the upper eyelid; it occasionally comes under the care of the surgeon as arising from a relaxation and extension of the common integuments of the lid and consequent folds of the skin, by which the energy of the *levator palpebræ superioris* muscle is somewhat but not very considerably diminished.* But that form which we are about to notice is dependent essentially on palsy of the muscle above-named, owing to some affection of the nerve which supplies it. It has been named *blepharoplegia* by the Germans, the patient being unable by any voluntary effort to raise the upperlid, although the power of closing the lids remains entire. It is therefore the object of the practitioner to ascertain in the first place whether this condition of the eyelid be merely produced by the mechanical cause above alluded to, and, secondly, if it be connected with a deranged state of any of the muscles of the eyelid. To decide the first question we would adopt the proposal of Scarpa. "If," he observes, "the atony or complete paralysis of the elevator muscle of the eyelid have had any share in producing the relaxation of it, it may be known by making a transverse fold of the integuments with the fingers or forceps near the superior arch of the orbit. For if this muscle have not lost its power of contraction, when it is relieved as it were from the superincumbent weight of the integuments, the patient is able to raise the eyelid and open his eye sufficiently; if otherwise, the eye remains half closed."† Such a proceeding, it is obvious, must at once determine the state of the *levator palpebræ* muscle; but it should be remembered that a spasmodic state of the *orbicularis palpebrarum* muscle may likewise produce the appearance of fallen lid. The want of permanence of this affection, the occasional power of raising the lid, and the degree of resistance which is always made by the spasmodic state of the orbicular muscle to any attempt to open the lids, will in general be found sufficient to indicate the precise nature of the affection.

Secondly, the practitioner should direct his attention to the motions of the eye-ball. It rarely happens that the fallen lid is a solitary affection; in general, and when it does not depend on either of the causes above named, we find a paralysis of most of the muscles of the eye complicated with it. The patient, it will be observed, has no control over the voluntary motions of the eye-ball; when told to look to the ground he is unable so to do, and the same inability is manifested when directed to look upwards or inwards. If the eyelids be forcibly opened and held apart, and the patient be desired to endeavour to close them, the eye-ball is seen to turn upwards when he makes the effort. Sometimes the power of looking outwards is retained, and in some instances a strabismus in that direction is present.

A moment's reflection will shew that symp-

* *Ollivier*, De la Moelle Epinière, vol. ii.

* Weller's Manual of Diseases of the Eye, by Monteath, vol. ii. p. 97.

† *Scarpa*, by Briggs, p. 127.

oms such as we have now detailed can only be produced by a palsied state of the third nerve. The muscles supplied by the nerve are paralysed, and the eye-ball exhibits motion in only two directions. One of these is abduction, performed by the external rectus which is supplied by the sixth nerve; the other is to be regarded as an involuntary action, instinctively co-existent with the effort to close the eyelids: it is that by which the eye is turned upwards, and, according to Sir C. Bell, is caused by the combined action of the obliqui,* although in such a case as we are now considering, it is difficult to conceive how the inferior oblique muscle can be exempt from that paralysis into which all the other muscles supplied by the third nerve had fallen.

Ptosis, attended with such an imperfection of the motions of the eye-ball, is to be regarded in general as a formidable affection; it is very frequently indicative of cerebral disease, and therefore is often witnessed as a precursor or accompaniment to hemiplegia. Sometimes it is merely the result of local compression of the nerve by a tumour within the orbit. There are occasionally present symptoms indicating more extensive disease, the sensibility of the eye being destroyed, as well as of the integuments supplied by the ophthalmic portion of the fifth nerves, or even of the whole side of the face. Such a case was that related by Mr. Shaw in the twelfth volume of the Medico-Chirurgical Transactions.

If the affection which we have thus briefly noticed be dependent on cerebral disease, the treatment must be directed accordingly; it is obvious that when it is caused by a tumour in the orbit, it is almost completely beyond the control of medicine. Cases may occur in which the propriety of a surgical operation may become a question: we shall only remark on the necessity of observing due caution, lest by converting a closed state of the eyelids into a permanently open one, we thereby endanger the safety of the eye-ball, from its unavoidable exposure to irritating particles.

The second form of palsy of the eyelid is that in which the patient is unable to wink or close the lids. It has been denominated *lagophthalmia, vue de lièvre, oculus leporinus*, from the vulgar notion that the hare sleeps with its eyes open. In these cases the eye remains permanently open, even during sleep, the orbicularis palpebrarum muscle being paralysed. The eye-ball projects to an unusual degree from the socket, owing to the absence of the accustomed resistance from the lids, and if the patient be directed to attempt to close the lids, the eye-ball is instinctively turned up with the effort so as nearly to conceal the cornea; nor is he conscious of that action. As winking can only be performed by drawing down the lid with the hand, free access is allowed for particles of dust, &c. to the surface of the eye, which, being likewise constantly exposed to the air, is necessarily subjected to much irritation and consequent inflammation.

This form of local palsy is chiefly worthy of attention from the contrast afforded by it to that last described; it is unquestionably dependent on disease of the portio dura nerve, and therefore is for the most part only a symptom of a paralytic affection which comes under our next head.

Paralysis of the face.—The muscles of the face receive their nervous supply from the fifth, as well as from the portio dura of the seventh, pair of nerves. Of these, as is now pretty generally admitted, in conformity with Sir C. Bell's views, the former is a compound nerve, conveying sensibility as well as the power of voluntary motion; the latter directs the actions of the muscles in relation to the respiratory act. We have already alluded to the loss of sensibility of the face; it remains to notice these two distinct forms of partial palsy of the face, according as the motive portion of the fifth or the portio dura is the nerve affected.

Reasoning *à priori*, it is quite obvious that palsy of the fifth must produce a set of phenomena very distinct from those resulting from palsy of the portio dura. All voluntary power not only over the features, but also over the motions of the jaw, must be lost on the side affected; whilst, if the latter nerve be in a state of integrity, those motions of the facial muscles which are in accordance with the act of respiration are unimpaired. Mastication is impeded not only by the imperfection of the grinding motions of the jaw, but also from the loss of power in those muscles which place the morsel under the operation of the teeth; "in chewing the action is only on the *sound* side of the head; the masseter and temporal muscles of the *affected* side do not rise or bulge out as in their natural actions, while there remains a perfect command over the features through the operation of the portio dura."* The distortion of the countenance is not very great; the jaw hangs on the affected side, and the angle of the mouth is depressed, that of the other side appearing to be slightly raised; the distortion is moreover either removed or greatly diminished when the patient laughs or smiles, an effect which all excited states of the act of respiration tend to produce. The condition of the face now described is that most commonly seen in hemiplegia; it is rarely met with unconnected with a more extensive palsy, and when it does occur, the sensibility of the face and eye-ball, nostrils and tongue, is very generally impaired or destroyed. The disease of the fifth nerve may be seated either within the cranium immediately in connexion with its ganglion, or there may be cerebral disease.

In those cases where the portio dura is the seat of disease, there is no evidence of the existence of palsy till those actions are called for, to the performance of which the palsied muscles ought to contribute. So long as the patient

* See Appendix to Bell on the Nerves, p. xxxix. et seq.

* Bell on the Nerves, p. 106, 4to edition.

remains quiet, without speaking or smiling, nothing remarkable is observable in the countenance; but when any of the actions of excited respiration, laughing, sneezing, coughing, crying, &c. are produced by the sound muscles, the marked deformity of the countenance becomes apparent. The mouth is drawn to the sound side; and it may be observed in general that the disorder of the features is directly as the intensity of the respiratory act: thus laughing produces greater deformity than smiling. The affected cheek remains motionless, while, to use the expressive words of Mr. Shaw, the face on the other side "seems convulsed with laughter." The patient cannot snuff up with the nostril of the paralysed side; blowing or whistling is imperfectly performed, or failed in altogether. On further examination it will be found that voluntary motion still exists in the muscles of the face and jaw, varying, however, in degree in each, according as the voluntary action of the muscle is more or less connected with respiration. Thus mastication is perfect; here the buccinator performs its office fully as a muscle of mastication, and in one striking case related by Mr. Shaw the child even preferred chewing her food with the affected side. The voluntary action of the muscles influencing the motions of the mouth are not so distinct as those of the muscles of the jaws. Although, when an attempt is made to whistle, it proves completely ineffectual, yet the patient can "purse up" the mouth so as to hold a whistle or a pencil by the action of the orbicularis oris muscle. A slight power remains of elevating the angle of the mouth, and an analogous power can be exerted over the muscles of the forehead.

It is in the cases to which we are now alluding that we meet with that condition of the eyelids termed *lagophthalmia*, and it generally forms one of the most painful and distressing features of the case, in consequence of the constant irritation to which the eye is exposed. Articulation is sometimes affected in this form of local palsy; the patient learns from experience that by supporting the paralysed cheek with his hand the defect can be in some degree remedied. It is clearly important to distinguish between defective articulation arising from this cause, and that from palsy of the muscles, of the tongue, or larynx. The wasting of the paralysed muscles is equally conspicuous in this as in other forms of palsy, and in cases of old standing gives such a peculiar appearance to the countenance, as could hardly fail to direct an experienced observer to the true nature of the complaint. Mr. Shaw, in relating the particulars of a case, writes thus: "There is a remarkable wasting of all those muscles of the face which are subservient to respiration and expression. His cheek is so thin that when he speaks it flaps about as if it were only skin, and the corrugator supercilii and occipito-frontalis, which are principally muscles of expression, are so wasted that we might at first sight suppose they had been removed by operation, and that now the bones were only covered by skin."*

Several opportunities have now occurred of ascertaining the cause of the palsied state of the portio dura. In many instances it has been suddenly produced by the influence of cold; the affection, as resulting from that cause, was long known under the name of *blight*. An inflamed state of the parotid gland, a tumour in the neighbourhood of the stylo-mastoid foramen, or an ulcer over the course of the nerve, have been found severally to cut off the nervous supply. Wounds of the portio dura, whether from accident or the surgeon's knife; disease of the petrous bone, engaging the aqueduct of Fallopius; inflammation of the internal ear: or a tumour compressing the nerve at its entrance into the internal auditory foramen, may likewise be reckoned among the causes. In fine, this form of palsy may have its origin in disease of the brain.

The symptoms above detailed are such as arise from a palsied state of either the fifth or seventh nerve, the other being perfectly free from any disease. Symptoms, however, so exclusively denoting an affection of a particular nerve of the face, are not frequently to be met with, and then only at a short period after the invasion of the palsy; for if the disease be of any continuance, the palsy is apt to spread, as it were, to the unaffected nerves. This is more especially the case when the portio dura is primarily affected, the slight degree of voluntary power over the muscles of expression gradually disappearing, but not from those of mastication. When the fifth nerve is the primary seat of disease, the branches of the portio dura retain their integrity for a much longer period, and in some instances do not exhibit any mark of disease; but in many cases, where the palsy has been of long duration, the extent of the disorder of the countenance can hardly be accounted for, except on the supposition that the disease has extended to the filaments of the portio dura. We think that a careful observation of the countenances of individuals who have been hemiplegic for some time, will sufficiently confirm this statement.

It is rare to meet with palsy of both nerves at the same time.† When such is the case, there must obviously be a modification in the symptoms dependent on the complete resolution of the muscles of mastication as well as of expression. The characteristics of the countenance of the hemiplegic will be conjoined with the strangely disordered expression resulting from the diseased portio dura.

In the treatment of local palsies of the face, especial attention should be directed to ascertain the state of the brain. If there be reason to suspect that the origin of the complaint is there, of course the treatment will be directed to that quarter. If otitis, or

* Med. Chir. Trans. vol. xii.

† See a case by Dr. Abercrombie, in which the fifth nerve was paralysed on one side of the face, and the portio dura on the other, occasioned by a tubercle in the brain. On the Brain, p. 178.

ic pressure of a tumour externally, be the ause, then the proper remedies to subdue he inflammation in the one case, and to pro- iote the absorption of the tumour in the ther, must be had recourse to. External timulants, blistering, directing the steam of oiling water to the face, local bleeding, vill be found useful, but especially in the ases which have been caused by cold. The pplication of strychnine to a blistered surface as proved successful in some cases; the ighth, fourth, or half a grain may be applied n the dressings. We may here observe that he acetous preparation of cantharides, rubbed n to the part with a camel-hair pencil, will e found a very convenient and cleanly mode f producing vesication on the face in these ases. Electro-puncture has been practised with great success by Pichonniere in several ases of this kind; the needles having been sunk in the vicinity of the branches of the liseased nerve.*

Paralysis of a limb or part of a limb.—In children, palsy of a single limb (generally an upper limb) is not uncommon; sometimes dependent on a deranged and loaded state of the bowels, sometimes on disease of the brain, and occasionally from congenital deficiencies in that organ: in such cases, if the child grow up, we see, to use the expression of Sir C. Bell, the limb of a child as it were unnaturally joined to the body of an adult.†

A peculiar form of palsy of the upper extremity is described by Dr. Healy, in the third volume of the Dublin Hospital Reports. "The affection alluded to attacks persons of all ages, males and females being equally liable to it. Prior to the attack, the patient generally enjoyed good health; consequently he is not a little surprised, on awaking from a long and sound sleep, to discover total loss of power of one hand; and, what is remarkable, he generally describes the loss of power as extending to the middle of the fore-arm: in some few cases it extends to the elbow, and is accompanied with a great sense of numbness. The fingers are so completely paralysed that the patient is deprived of their use: great dejection of spirits attends the complaint." No cause could in general be assigned for these symptoms, unless the pressure upon the nerves occasioned by lying with the head resting on the arm; an opinion confirmed by the fact that in many the palsy succeeded to sleeping in a chair in that position. Dr. Healy further remarks, that "this affection has invariably yielded to electricity."

Dr. Darwall has described a species of paralysis affecting the upper extremity, most of the individuals attacked having been in the habit of lifting heavy weights. In some of the cases the palsy at first occupied the muscles connecting the humerus to the scapula, especially the deltoid, which was wasted; there was, therefore, inability to raise the arm, but the power of flexing the fore-arm remained. After some little time, total paralysis of the upper extremities gradually supervened. In one case of this kind, the patient continued for eight years without any use whatever of his upper extremities. In some of the cases the paralysis did not descend below the muscles of the shoulder. Considerable pain in the deltoid muscle generally preceded the paralysis, and one or two of the cases yielded readily to treatment in that stage. Dr. Darwall considers this affection as "one primarily engaging the nerves supplying the elevating muscles; and that they may have been injured by the straining necessary in raising or carrying heavy weights."*

A case in some degree analogous to those last alluded to is recorded by Dr. Abercrombie; it is that of a young lad aged 14, who had nearly lost the muscular power of the upper part of both his arms, accompanied by a most remarkable diminution of substance of the principal muscles. The deltoid and biceps were reduced to the appearance of mere membranes, and the muscles of the scapula were found nearly in the same state: the affection came on gradually, without any sign of spinal or cerebral disorder.

Local palsy seated in either extremity, or part of an extremity, is mostly, as all the other forms of local palsy, found as the first step or stage to a more extended affection. In such cases there is frequently some indication to direct the practitioner to the true source of the complaint. It is not uncommon to meet with instances where palsy affects only a few of the muscles of an extremity. The muscles affected are, as Sir C. Bell† observes, generally those which are naturally combined in action; although those muscles be in different parts of the extremity, and are supplied by different nerves as they are by different arteries; of which an obvious example may be taken from the case of paralysis of the short muscles of the ball of the thumb, in which the palsy also extends to those muscles of the thumb which lie on the fore-arm. Sometimes all the extensor muscles will lose their power, while the flexors preserve it. This seems to be the case in a patient alluded to by Dr. Bright. She had no power of extending her hands; they were precisely in the condition of the "drop hand" from the paralysis caused by lead. She could carry her child between her fore-arms and arms. Sir C. Bell has found the action necessary for writing gone, or the motions so irregular as to make the letters be written zigzag, whilst the power of strongly moving the arm or fencing remained.

It may be asked, what is the condition of the nerves in these cases of local palsy? Some

instances have presented symptoms in the commencement indicating an inflammatory state of the nerve or its neurilemma, which has been further confirmed by the success which has followed local depletion and other antiphlogistic remedies in such cases. It is not rare to see a palsied and atrophied state of the lower extremity succeed to inflammation of the sciatic nerve. In a case by Shaw, palsy of the extensors of the fingers and thumb succeeded to tight bandaging after a dislocation of the shoulder, and was evidently caused by inflammation of the musculo-spiral nerve.* Dr. Bright has given a case in which complete paralysis of the fore-arm resulted from the pressure on the nerves produced by a badly united fracture. Paralysis from pressure on a nerve in various ways is common. Dr. Abercrombie mentions a case of paralysis of the fore-arms and hands of both sides, induced by pressure in consequence of leaning for a long time upon a bar of wood, while the person was stooping forward in his anxiety to witness some public exhibition.

There are cases of local palsy affecting the extremities, or parts of them, in which the state of the circulation in the limb seems a more probable cause of the attack than any primary disorder of the nerves: such are those cases detailed by Dr. Storer, Dr. Abercrombie, and others. The sudden accession of considerable pain in the part is the first symptom; this is succeeded, after a variable interval, by paralysis. The cessation of pulsation in the principal arteries of the limb, with the coldness and numbness which attend the palsy, seem strongly to point to the arterial system as primarily diseased. In Dr. Abercrombie's case, post-mortem examination proved that the arterial system was extensively ossified; and in many places the arteries were obstructed by firm coagula. Drs. Graves and Stokes have also given a case of paralysis of one lower extremity from marked disease of the common iliac, femoral, and profunda arteries of the same side, those vessels being completely plugged up by a dark clot, which likewise extended into many of their ramifications.† There are paralytic states of the extremities connected with rheumatism and gout, for an account of which we refer to the articles on those diseases.

Paralysis of sets of muscles or single muscles.—The muscles concerned in the act of deglutition are sometimes affected with paralysis, but in general towards the close of an old paralytic affection of great extent. Some few cases, however, are recorded in which these muscles were alone paralysed. A well known case of this kind is that described by Mr. Hunter.‡ The patient had laboured under a train of nervous symptoms for some time; one morning he awoke with a sense of choking, a numbness of the right side, together with a paralysis of the muscles of deglutition, which deprived him of the power of swallowing. The palsy did not extend; and this patient owed his cure to the judicious employment of an elastic tube introduced into the œsophagus, by which food and medicines were administered, thus obviating the effects of the palsy. Hysterical palsy sometimes assumes this form, giving rise to dysphagia. The muscles of the larynx may be likewise palsied, giving rise to a species of aphonia: this likewise frequently takes place in hysterical cases. Palsy of the tongue, as a solitary affection, is of very rare occurrence. Sometimes one half of it is paralysed in consequence of pressure on the ninth nerve upon that side; as in a case related by Dupuytren in his Leçons Orales, in which a hydatid compressed this nerve, producing paralysis and atrophy of the same side of the tongue.

Single muscles are frequently the seat of paralysis, in general occasioned by pressure upon the nerve which supplies the muscle. The palsy of the deltoid from pressure on the circumflex nerve by the dislocated head of the humerus, is a case familiar to every surgeon. Palsy of the sterno-mastoid muscle may give rise to all the characters of wry neck. Paralysis of the serratus magnus anticus muscle from pressure on or injury of the posterior thoracic nerve (external respiratory of Bell) gives rise to a remarkable set of phenomena, with which, as liable to lead him to mistake the complaint for something more serious, the practitioner ought to be acquainted. Two cases of this affection are on record; one by Gendrin, the other by Velpeau. In Gendrin's case, there was a marked deformity produced by a tumour seated at the superior dorsal region of one side, and which was evidently formed by the posterior edge of the scapula pushed firmly backwards; it appeared without any assignable cause in the course of a few days. The power of drawing the scapula forwards, and elevating the prominence of the shoulder, was lost; and when both rhomboid muscles were made to act fully, and to approximate the scapulæ posteriorly, the tumour disappeared completely. This case had been mistaken by two medical men for distorted spine. The patient recovered after a few weeks, under the successive application of blisters.* In Velpeau's case the palsy was caused by violence inflicted on the nerve in its passage along the inner wall of the axilla.†

Many forms of strabismus are occasioned by a palsy of one or more of the muscles of the eye-ball; the sound muscles thus obtaining a predominance of action.

The internal muscles, those of organic life, are sometimes palsied. The circular coat of the intestines is no doubt frequently the seat of paralysis; an opinion which would seem to be confirmed by the frequent occurrence of paralysis of the sphincter ani.

Paralysis of the bladder, from prolonged

† *Velpeau*, Anat. Chirurg. vol. i. p. 303.

over-distention, frequently comes under the surgeon's care. In such cases, as well as in that connected with paraplegia, there is *retention* of urine. *Incontinence* of urine is in some cases, in old persons especially, to be regarded as dependent on a paralysed condition of the fibres which act as a sphincter to the neck of the bladder.*

Treatment.—The treatment of the last two classes of local palsy should be conducted on similar principles to those laid down in speaking of paralysis of the face. Of course the palsied states of the bladder will require a distinct plan of treatment, chiefly surgical. Paralytic limbs may be benefited by local treatment, to which we shall refer more at large in another part of this article.

2. *Hemiplegia*, (ἥμισυ, *dimidium*, and πλήσσω, *percutio*,) *semisideratio*. The term is applied to denote paralysis existing only on one side of the body, and affecting not less than the upper and lower extremities. Some have employed it in alluding to paralysis occupying the upper and lower extremities of opposite sides; but that form of palsy may, with less risk of confusion, be denominated *crossed or tranverse paralysis* (paralysie croisée).

Hemiplegia is by far the most frequent species of palsy met with in practice; and it has been stated, upon the authority of Sir Gilbert Blane's comparative observations, that it occurs more frequently on the left than on the right side; the proportion being as three to two.† In general the paralysis affects the side of the face as well as the extremities; the angle of the mouth is drawn to the sound side, and more or less upwards; the tongue is frequently half paralysed, as is rendered evident on its protrusion, when it presents a curve, the convexity of which is towards the affected side, sometimes it is only sluggish as it were, the patient not having the full power of protrusion. The muscles of deglutition are frequently more or less engaged. The mode of progression of a patient labouring under hemiplegia is remarkable. He is said to "drag the leg," the paralysed lower extremity being moved along, or perhaps propelled, by the inclination of the trunk to the sound side; the foot is generally pointed outwards, and when the limb is raised it falls as it were by its proper gravity, presenting that remarkable pointing of the foot which cannot fail to have attracted the attention of any who may have observed a hemiplegic patient walking. The arm of the affected side generally is adducted to the trunk, and the fore-arm appears slightly flexed upon the arm, the wrist and fingers being likewise in a slight state of flexion.

Considerable variation is observable in the manner in which hemiplegia appears. The symptoms which precede or accompany its invasion claim much attention from the practitioner, as being his chief guides in the formation of a correct prognosis, as well as in the application of a suitable treatment.

1. Hemiplegia is the most common form which paralysis assumes from effusion of blood within the cranium. When the coma of the apoplectic seizure is removed, and consciousness is restored, the patient is generally observed to be hemiplegic.

2. Hemiplegia sometimes appears suddenly without previous indication, and with or without stupor: in such cases it is most frequently a precursor of apoplexy.*

3. A third variety is that in which symptoms, more or less painful in their character, precede the paralytic attack: pain in the head, with fever of variable duration and intensity; more or less disorder of the intellectual powers; spasmodic twitchings of the muscles; muscular stiffness; convulsions, ending in hemiplegia, with considerable pain in the paralysed limbs.

4. Another form occurs chiefly in persons past the meridian of life. The patient is observed to be morose, heavy, and drowsy; his digestion is disordered; memory and intellect are impaired; there is loss of one or more senses, usually sight or hearing; then sudden loss of speech, difficulty of protruding the tongue, followed by paralysis of half of it; distortion of the face; complete hemiplegia.

5. A train of symptoms of an anomalous, and to the physician a perplexing character, sometimes precede the hemiplegia; viz. headach, nervous excitability, deranged functions, with a number of uneasy sensations referable to various causes. The patient continues to complain; nor is the obscurity of his condition removed till paralysis begins to develop itself either by suddenly attacking one half of the body, or by creeping on from some remote part. It is with such cases as these that we occasionally observe symptoms resembling chorea, or fits of an epileptic character. The writer has lately seen a child in whom there is an incomplete hemiplegia, the lower extremity being completely paralysed, the upper partially so: there is also a convulsive action of the flexor muscles in the fore-arm, and a convulsive protrusion of the tongue, taking place almost every two minutes; there is slight ptosis of the eyelid, but the features are regular. The case of the celebrated M. de Saussure is one somewhat in point.†

6. Hemiplegia is occasionally met with at some period after the receipt of an injury of the head. We remember such a case in the person of a gentleman about forty years of age, who about two years previously had been severely wounded on the head by highwaymen. The hemiplegia, which came on gradually, and was on the side opposite to that on which the injury had been inflicted, was complete, and resisted every kind of treatment. The case proved fatal, but the body was not examined after death.

* Abercrombie, p. 14.
† See Med. Chir. Trans. vol. vii.

The morbid states of the brain with which hemiplegia in the above-mentioned varieties is connected have already been sufficiently dwelt upon in the article INFLAMMATION OF THE BRAIN. In fact, there is no diseased condition of either the brain or its membranes with which this form of palsy has not been found co-existent. With a few exceptions, not altogether to be fully relied upon,* the disease has been found on that side of the brain opposite to the seat of the paralysis. That this should be the case, anatomy would lead us to expect; the interlacement or decussation of the fibres of the anterior columns of the spinal marrow *(corpora pyramidalia)* at their summits being now generally admitted, and easily demonstrated. According to the views of Foville and others, we should likewise expect to find the optic thalami and corpora striata, or some of the fibrous radiations which pass through these bodies, the seat of disease in hemiplegia. And in point of fact we must admit, that in the generality of cases of this description, those bodies, or some portion of the cerebral hemisphere, present a morbid alteration of structure variable in extent as well as in degree. Cases, however, it must likewise be admitted, do occur, in which only one of the bodies above-mentioned is the seat of disease, or in which no appreciable alteration can be detected in the hemisphere. Such occurrences can hardly be deemed as decidedly to militate against the theory of Foville, &c., inasmuch as our ignorance of the mechanism of cerebral action, whether healthy or morbid, is alone sufficient to render them anomalous to us. They should, however, increase our caution in receiving speculations upon the uses ascribed to the different portions of the brain, and should excite us to increased accuracy of detail and minuteness of enquiry upon these points of pathological anatomy.

Hemiplegia may be induced by disease of the upper part of the spinal marrow, the morbid alteration being on the same side with the paralysis. Such cases are rare, however; for it is seldom that disease would be exactly limited to a lateral half of the marrow. In general, when they do occur, the hemiplegia is only a precursor of the general paralysis above described. Dr. Bright,† Ollivier, and Velpeau‡ give cases of this description; and in the Edinburgh Medical and Surgical Journal for April 1825, a case is related where hemiplegia resulted from concussion of the spine, accompanied with complete anæsthesia of the other side of the body. The paralysis of motion did not extend.§

Cazauvieilh has published two interesting memoirs on *congenital* paralysis, by which he would signify that which appears at birth, or a short time after it. To the cerebral alteration on which the paralysis depends he has given the name "*agénésie cérébrale*," denoting a defect of development or of growth in the brain or any of its parts. In the majority of the cases detailed in these memoirs, the paralysis was in the form of hemiplegia, the limbs were greatly wasted, stunted in growth, and with many in a state of permanent flexion. The upper extremities were generally more altered than the lower; in many cases they were bent and contracted, the elbow, wrist, and fingers being flexed. Among the muscles of the lower limbs, those of the calf of the leg chiefly presented the phenomenon of contraction, and thereby kept the foot permanently extended. The paralysis was complete in only a small number of cases. The organic defects were as follow: a depression on one side of the cranium indicated a corresponding want of development of the subjacent cerebral hemisphere,—a deficiency further proved by the flattened, non-developed appearance of its convolutions, the difference of size from the hemisphere of the other side, the less capacity of the ventricle, as well as a slight diminution in the dimensions of the corpus striatum and optic thalamus. The cases observed by Cazauvieilh were mostly in persons who had arrived at an advanced age.*

Intermittent hemiplegia.—A form of hemiplegia, which may be denominated *intermittent*, has been alluded to by Sauvages, Morgagni, and Cullen. Sauvages, by whom the species has been particularly noticed, describes it as coming on every day, and after some hours receding, with an accession of quotidian fever; and he gives a minute account of a case of this kind. The case described by Morgagni was that of a woman aged forty, who, after severe and long-continued headach, became completely hemiplegic; when thus affected, she was likewise seized with the same kind of palsy *on the healthy side* every day towards the evening, which went entirely off as the morning came on. After this disorder had attacked her seven or eight times at nearly the same hour, she died of pneumonia. There was no examination of the body.†

A case of this description is recorded by Dr. Elliotson.‡ The patient, forty-eight years of age, had been in the East and West Indies, and had had fever at Bombay and at Batavia, and had suffered from dysentery and diarrhœa. For two years and a half previous to his admission into St. Thomas's Hospital he had been subject to paroxysms, which threw him into the condition of a perfect hemiplegic; totally losing the power of his arm, and "dragging his leg in a semicircular way, as patients

* See the cases of Bayle, Revue Médicale, 1825; one by Bright, (Reports on Diseases of the Brain,) which the author himself admits to be a "doubtful exception;" and Morgagni, lib. i. epist. ii. § 16. The most complete exception with which we are acquainted is one mentioned by Cazauvieilh, Archives Gén. de Médecine, May 1827, p. 15-16.

‡ London Medical Gazette, vol. vii. p. 486.

sually do when labouring under hemiplegia." The paroxysm began at ten o'clock on every hird or fourth morning, and lasted in its full orce from three to four hours; "but although t lasted only that time, he was not perfectly lear from it the whole day." The man had a ickly aguish look, and very much the appearance of one who had suffered from a hot climate. Under the supposition that the patient's complaint arose from malaria, he was reated with large doses of sulphate of quinine, ive grains every sixth hour, afterwards increased o ten grains. The effect of the medicine was decided improvement in the general health, and a considerable increase in the intervals between the paroxysms. It does not appear that a perfect cure was effected.

Prognosis.—We believe it is quite consonant with the results of general experience to state, that hemiplegia connected with an apoplectic condition of the encephalon is that which is most likely to recover. That the effused blood may be absorbed and leave nothing to indicate the situation it occupied but a small cavity, is now abundantly proved. But in cases where there is no effused blood, it is obvious that less difficulty exists to restore the brain to its healthy condition, and in these cases accordingly we frequently find the paralysis yield readily and even quickly to treatment. When the effusion has taken place, we sometimes see the disappearance of the palsy and the absorption of the coagulum to proceed *pari passu*; but such an event does not occur so frequently as we might, *à priori*, be led to expect. It sometimes even happens that the coagulum has been completely absorbed, and yet the paralysis continues in no degree diminished. The writer has in his possession a portion of brain of a girl twenty-two years of age, who had been hemiplegic after apoplexy, and continued so, without any recurrence of apoplexy, till her death, one-half of the body being *completely* paralysed. The brain was healthy, with the exception of a small cavity not exceeding four or five lines in diameter, situated about the centre of the left hemisphere lined with a brownish-coloured membrane, and containing a serous fluid of a similar colour. In fact, it would seem as if, after a certain period, the cerebral lesion and the palsy lost their relation to each other as cause and effect, and the latter continues as it were independent of the condition which originally gave rise to it.

Treatment of hemiplegia.—The treatment of hemiplegia varies according to the time which has elapsed since its accession. If the patient be seen immediately after the appearance of paralysis, the practitioner must look accurately to the condition of the nervous system, directing his remedies to that which appears to be the seat of the disease. These remedies, though few, are, when appropriately applied, powerful, and in the diversity of lesions which give rise to the affection under consideration, require the exercise of much judgement and discrimination in order to their successful employment.

The principle of treatment, then, in this early stage of hemiplegia, will depend on the precise nature of its cause, on the general condition of the patient, his age, and previous state. Bleeding, purging, and other antiphlogistic remedies may be adopted where there is decided evidence of plethora, inflammatory or apoplectic. How far these measures may be carried with safety or advantage, the circumstances of each particular case can alone decide; in general, however, it will be found necessary to employ them to some extent, so as to produce a decided effect upon the system of the patient. When all inflammatory symptoms have been reduced, a mild mercurial treatment has often proved extremely useful. Does it in apoplexy promote the absorption of the coagulum? Dr. Prichard observes, respecting the use of mercury in hemiplegia, "that those patients in whom a slight degree of ptyalism has been produced, have almost uniformly appeared to him to derive material benefit from it, and their recovery has been more complete than that of others in whose cases the same remedy has either not been used or has not been administered to the same extent."

Due attention must of course be paid to regimen. Abstinence from all stimulating elements, solid or fluid, must be rigidly observed in the great majority of cases. In a more advanced stage of hemiplegia, where the urgency of the brain symptoms appears to be either diminished or removed, and where the palsy is the object chiefly worthy of attention, the physician has in view a twofold object,—to prevent a recurrence of head symptoms, and, secondly, to alleviate the condition of the limbs. The former end is to be attained more by avoiding what has a known injurious tendency than by adopting any particular plan of treatment; this, however, is not to be neglected, as a proper regimen does much towards maintaining a uniform state of the general system: we may add that in this stage especial benefit will be derived from allowing the patient to enjoy air and exercise as much as he is able to bear. Change of air and scene are unequivocally of decided advantage, and a visit to some watering-place is often made in this stage of the complaint with marked benefit. Mental serenity and a freedom from the cares of business are indispensable.

To alleviate the condition of the paralysed limbs, the treatment may be applied to the seat of the original disease as well as to the limbs themselves. Thus, with a view to act upon the seat of the primary disease, we have recourse to counter-irritation in the vicinity, or, as some prefer it, more remotely. For this end we employ setons, issues, blisters, tartar-emetic ointment, or tartar emetic in powder sprinkled on the dressings applied to a blistered surface; frictions with liniments containing various irritating substances, among which we may mention the croton oil as being an extremely severe irritant. Dr. Prichard highly extols the practice of inserting a large issue in the scalp in cases of this kind; he advises an incision to be made completely through the scalp for four or five inches over the sagittal suture, and the

edges of the wound to be separated by a row of peas.*

The treatment of the paralytic limbs consists in the application of stimulating applications, with the idea that a stimulus applied to the sentient extremities of the cutaneous nerves may have the effect of rousing from their state of torpor the more deeply-seated trunks. Of these external stimulants we may enumerate the following: dry friction with the hand or by the flesh-brush, a remedy much approved by Dr. Cooke; warm baths; stimulating liniments prepared of the concentrated acids or the caustic alkalies combined with oil or lard; brine, or a strong solution of sea-salt; terebinthinate applications; sinapisms; blisters. Dr. Cullen has found the use of liquid styrax, in the proportion of one part to two of the old black basilicon, remarkably serviceable in paralytic cases. The application of cold has been recommended, and we have known it beneficial when applied daily in the form of a shower-bath. Some more simple stimulants than those now enumerated have been employed, such as, tickling the parts with a feather, which, according to the statement of Mr. Wardrop, proved beneficial in a case of eighteen months standing, which recovered in two months. Stinging with nettles was employed by Celsus, and Graefe is said to use the *dolichos pruriens* as an external stimulant applied to the surface, and maintained in apposition with it by means of a bandage. It produces some degree of cutaneous inflammation, but requires frequent renewal.

Among the external stimuli we may mention electricity: the efficacy of this agent in many paralytic cases does not want proof. Lightning has been known to cure paralysis: we extract an anecdote exhibiting this effect of the electric fluid from one of the numbers of the Medico-Chirurgical Review: a vessel on the Atlantic was struck several times with lightning, insomuch that many of the crew were strongly electrified. Among the passengers was a man who had been paralysed in both his inferior limbs for three years. At the time of the electric discharge he lay on his bed, but soon after perceived the return of power to his limbs, and was enabled to rise with perfect use of them. The cure in this case was permanent. A case is related in the Haerlem Transactions, in which a hemiplegic patient recovered the use of his side after a hundred strokes from the *gymnotus electricus*, or electric eel.

Though it must be admitted that electricity is occasionally a successful remedy in palsy, still it has by no means equalled the anticipations at first entertained respecting it. Its failure may be very well ascribed to a cause which is equally calculated to impair the power of all stimulants over palsied nerves. "Applied in a certain manner," says Dr. Cooke, "electricity is a most powerful stimulant to the nervous system; but as it is also a stimulus to the sanguiferous system, it has often been hurtful in those palsies which depend upon a compression of the brain, and especially when it has been so employed as to act upon the vessels of the head." Great circumspection must be observed, lest in the use of electricity we excite the circulation to such a point as to increase the evil we seek to remedy. Applied as a topical remedy, it will be less apt to produce mischief, and for this purpose the method of *electro-puncture*, already alluded to under the head of Local Palsy, may be resorted to with advantage. The facility afforded of gradually increasing the force of the shock by the employment of the galvanic apparatus, renders galvanism a more safe and suitable agent than electricity; and according to the conclusions of Dr. Bardsley from comparative observations, its efficacy is superior to that of electricity.

But there is a class of internal stimulants which, having a tendency to excite the nervous system so as often to produce convulsive action, have been employed in paralytic cases. Among these we may mention rhus toxicodendron, strychnine, brucine.

The rhus toxicodendron *(poison sumach)* was first introduced by Dr. Alderson of Hull. A powder from the leaves is given in doses of half a grain three times a day, and its quantity increased to two, three, or four grains, carefully watching its effects. Its most common effect is a twitching or convulsive motion, or a sense of tingling or pricking in the paralytic part. The medicine, like all of this class, does not seem much to be relied upon.

Strychnine and brucine, the former the active principle of the nux vomica, the latter extracted from the bark of the false angustura, *(brucia anti-dysenterica,)* are both remedies of the same class, powerful excitants of the nervous system. Strychnine, however, is much more potent than brucine. Andral ascertained by comparative trials that six grains of brucine were equal in their effects to one grain of impure, or a quarter of a grain of the pure strychnine; he therefore considers the former a safer medicine than the latter. Both, however, are dangerous and uncertain; dangerous, from the risk of increasing cerebral irritation, an effect which we have frequently seen; and uncertain, inasmuch as some persons appear more susceptible of their effects than others. Thus, in one individual one-twelfth of a grain of strychnine produced severe symptoms; and in another the dose was raised to a grain without inconvenience. Andral comes to the conclusion that in cases where, as if from habit, the paralysis continues after the effusion has been absorbed, the limbs will be improved under the use of strychnine or brucine; that when the brain is still in a disordered state, these medicines have the effect of exciting inflammatory action; but that, in those forms of palsy not dependent on disease of the nervous centres, they are advantageous, as, for instance, in the lead palsy, or that from rheumatism.* Strychnine may be administered in doses of one-twelfth or one-eighth of a grain, gradually and cautiously increased. Brucine may be given in half-grain doses.

* Lond. Med. Gazette, vol. vii. p. 427.

* Journal de Physiologie, 1823.

The following observations, from Dr. Abercrombie, respecting the administration of stimulants, are well worthy of attention: "All the remedies of this class must be used with considerable degree of caution; and perhaps the use of them may be more safe, and may be carried on with a greater degree of activity, if the general system at the same time be kept in a very low state by spare living and occasional evacuations. This, I imagine, is always to be considered as an essential part of the treatment, and I cannot agree with some respectable writers, who hold that the diet in paralytic cases ought to be nourishing and restorative. With this precaution I think it probable that there are many cases of paralysis in which stimulants may be employed with much benefit."

Iodine, in various forms, has been of late years employed in the treatment of palsy. The result of Dr. Manson's* trials of this medicine are not very encouraging. In scrofulous constitutions, where the paralysis seems immediately dependent on some local development of scrofula, it may be tried with more hope of success than in any other form.

A sudden excitement of the nervous system has been known to carry off the palsy. Thus, a violent fit of mental emotion, anger, fright, have had this effect. The sudden supervention of a fever has likewise removed it: hence Dr. Good recommends as a remedy, in some instances of paralysis, a journey into the hundreds of Essex, or some other marshy district!

Several cases are on record of the spontaneous cure of hemiplegia as it were by the mere remedial energy of nature.†

3. *Paraplegia.* It is of importance, for reasons which will presently appear, to decide what is the established acceptation of this term among medical writers. The principal modern writers, as Sauvages, Cullen, Swediaur, Good,‡ Baillie, Cooke, and Rostan, employ the term paraplegia to denote that species of palsy in which the lower half of the body on both sides is paralysed. Much confusion existed among the older writers as to the sense in which they used this term; Hippocrates signifying by it any palsy which was the consequence of apoplexy; Aretæus denoted by it a partial palsy in any situation; Boerhaave and Van Swieten a palsy of all the parts below the neck. Mr. Earle has infringed upon the unanimity of modern writers by endeavouring to revive the definition of Boerhaave and his commentator; for what reason we are at a loss to understand, inasmuch as the etymology§ of the word affords us but little guidance.

We have preferred adhering to the definition of Cullen and others,‖ as that which is almost universally adopted, and, moreover, because that degree of palsy which Mr. Earle employs the term paraplegia to denote, appears to us to come more appropriately under our division of *general paralysis*. When paraplegia is perfect, there is complete loss of the power of motion in the lower limbs, with paralysis of the bladder, rectum, and sphincters; there is also in general a considerable degree of impaired sensation, more, as we have already had occasion to remark, than in any of the other forms of paralysis of motion. Very frequently we find paraplegics more or less affected with spasmodic action in some particular muscles of the lower limbs; sometimes this is confined to the flexor muscles, and we occasionally see a permanent state of flexion of the thighs on the trunk, and the legs on the thighs; sometimes, on the other hand, the extensors are thus spasmodically affected, as in the case of a young man which occurred to the writer, in which there was no power of flexing the lower limbs; but if at the request of the patient they were placed in the state of flexion, (for when in that condition they were more free from uneasiness,) after the lapse of a short interval they were, by short and successive twitchings of the extensor muscles, gradually brought back to the state of extension.

In general there is, along with the palsy of the limbs, paralysis of the bladder and of the sphincters; the former shews itself sometimes by incontinence of urine, but more frequently by retention. All ages are liable to paraplegia, but it occurs more frequently in adults and old persons, and, according to Dr. Baillie, in males than in females.

In the mode of access of paraplegia there is less variety than in that of hemiplegia. The first symptom is generally a derangement of sensation, a sense of numbness in the lower limbs, with impaired power of motion. The weakness of the limbs is further indicated by the patient evincing a tendency to trip when walking, being tired after but a little exertion in that way; complaining of a sense of weight and some degree of pain in the feet and extending up the legs. "The want of power of motion in the limbs, and the inability to preserve the due balance of the body very much increase, and the person cannot walk without the assistance of one or two sticks, or the aid of some other person, who more or less supports him."* The paralysis of the bladder and sphincter next appears, and now the patient is obliged to confine himself to his bed; there is a great tendency to sloughing of the nates, or of any part on which there is prolonged pressure; in some cases a communication has been produced between the rectum and bladder, thus affording the patient a relief from retention by converting it into incontinence of urine. The secretion of the kidneys seems a good deal affected in this complaint; the urine seems prone to calculous deposit, a remark which we believe originated with Dupuytren, who observed that catheters left in the bladders of paraplegics became more quickly

‖ "But there is another form of paralysis called paraplegia, in which the lower half of the body is more or less impaired in its nervous power."—*Baillie.*

* *Baillie*, Trans. Coll. Phys. vol. vi.

encrusted with calculous matter. Sometimes there is a remarkable degree of flatulency of the abdomen, amounting even to tympanitis. The uterus is likewise found to be incapable of its contractions in cases of paraplegia. This fact was observed by M. Brachet of Lyons, who had a patient who became pregnant during the existence of the paraplegia: it was necessary to effect delivery by the forceps. It may be stated that the same physician found, by experiments on animals, that injury to the lumbar portion of the spinal marrow destroyed the contractile power of the uterus.

This form of palsy may depend on disease of the brain or of its membranes, or of the spinal cord or its membranes, or disease of the vertebræ or the uniting ligaments. It was not very long ago supposed that paraplegia resulted only from spinal disease, and Dr. Baillie was the first to call the attention of the profession to its dependence on diseased brain, the spinal cord being perfectly healthy. If diseased brain can produce a palsy of one lower limb, as in hemiplegia, why should not a more extensive or differently situated disease produce palsy of both lower limbs? Were the views of Foville regarding the influence of the corpora striata over the lower extremities established, it is obvious that the effect of simultaneous disease in both would be the production of paraplegia. It must be confessed, however, that the general symptoms of paraplegic palsy chiefly resemble those resulting from spinal disease: the tendency to spasm, the frequent impairment of cutaneous sensibility, the absence, in many instances, of any of those symptoms which so often precede or accompany cerebral disease, are so many circumstances connected with paraplegia which favour the above opinion. Admitting, however, the possibility of the production of paraplegia by cerebral disease alone, we cannot but consider that, as a practical question, it is still *sub judice*, and that chiefly from the too frequent neglect of examining the spinal marrow. Thus we read reports of cases of this affection where post-mortem inspection discloses marked disease of the brain; but from no examination of the spinal marrow having taken place, we can arrive at no satisfactory conclusion. A case of this kind is reported in Dr. Abercrombie's work. The patient was a boy, seven years of age, and before death was blind, epileptic, and paraplegic. Examination after death discovered a firm white tumour, the size of a large bean, lying over the junction of the optic nerves. There was extensive effusion to the amount of twelve ounces in the ventricles, and both hemispheres of the cerebellum were diseased; the left being much indurated, the right reduced to a mass of unhealthy scrofulous suppuration. The spine was not examined.* Who could venture, in the true spirit of philosophy, to state to what cause the paraplegia was attributable in this case?

Perhaps the greatest difficulty which the practitioner has to encounter in the consideration of a case of paraplegia, is to determine the precise seat of the lesion which gives rise to it. In some cases there are unequivocal signs of spinal disease, such as great tenderness on percussion over a particular portion of the spine; alteration of the form of the spine; projection of one or more vertebræ. Mr. Copeland has adopted a very simple and obviously useful expedient in obscure cases to ascertain the locality of spinal irritation; he takes a sponge dipped in water as hot as can be borne, and passes it down the whole length of the spine; and if there be any irritation confined to a particular spot, the patient will evince it by expressing pain, and wincing as the sponge passes over that region.

The habit of the patient, his previous mode of life, as well as the symptoms immediately preceding the attack of paralysis, will assist the practitioner to discover whether any cerebral affection is complicated with the spinal disease; thus in some instances, as Mr. Earle remarks, there is an impaired state of some of the external senses, accompanied with vertigo, a sense of weight on the head, and a general disturbance of the cerebral functions; in some there is likewise derangement of one or more of the mental faculties. In such cases there can be little doubt of at least *the complication* of cerebral disorder. "But," as Mr. Earle adds, "it is in slighter and more chronic cases that it is often difficult to form a correct opinion; yet to establish a correct diagnosis in such cases is of the utmost importance, both with respect to the probable termination of the case and with reference to the proper treatment to be adopted, that we may not subject the individuals to useless suffering from the application of caustic issues and setons to the spine, and the disappointment which would follow." To obviate this difficulty, Mr. Earle has proposed an expedient which we shall give in his own words: "It is well known that when a nerve is stimulated or injured in any part of its course, the painful sensation is referred by the percipient mind to the sentient extremity of such nerve; the familiar instance of the pain referred to the extremity of an amputated limb may be adduced in proof of this. The exact reverse of this takes place when there is a partial paralysis arising from morbid affection of the cerebral organs. Here the centre of the sensorial functions being impaired, it appears to be incapable of transmitting its influence to the extreme parts of the body; in such cases, if the nerves supplying the limbs be irritated, *they will convey the impression of such injury only part of the distance down the limb, about as far as the*

* *Abercrombie*, p. 182. In a case by Mr. Earle the lower part of the spinal marrow was not examined, yet it is headed "Paraplegia from Disease of Brain."—Med. Chir. Trans. v. xiii. p. 530.

* See an interesting paper on paraplegia in the Med. and Phys. Journal for June 1827, by Dr. Burder, who considers that those cases of paraplegia which are coincident with cerebral lesion, are caused by the increased *spinal* effusion consequent on that lesion.

commencement of the paralytic affection. I have repeatedly examined cases of paraplegia from affection of the spine, and in no one instance have met with the same phenomenon, which I have therefore been induced to consider as diagnostic of the paralytic affection being dependent on disease of the brain or its membranes; which opinion has in several instances been confirmed by examinations after death, in which both brain and spinal marrow have been carefully investigated." It is hardly necessary to mention that paraplegia is a frequent result of concussion and other spinal injuries.

Treatment of paraplegia.—As topical remedies are chiefly applicable in this form of palsy, it must be obvious of what importance it is to ascertain to what region they may be most advantageously applied. Cupping and leeching are, in the generality of cases, primarily indicated. Counter-irritation by blisters, issues, setons, moxas, &c. may then be had recourse to. Purgatives are to be administered as they may appear necessary, and Dr. Baillie's mode of treatment is well calculated to be serviceable; he directed a grain of calomel, or five grains of the pilula hydrargyri, with one grain of dried squills, to be taken every night for many weeks; these were followed by purgatives.

The same treatment of the palsied limbs may be adopted here as that alluded to under the head of hemiplegia. The palsy of the bladder will require the introduction of the catheter, and we would merely allude to the necessity of using pressure above the pelvis to ensure the complete expulsion of the urine.

Certain mineral poisons, viz. mercury, lead, and arsenic, give rise, when received to a great extent into the system, to a form of palsy which Cullen has denominated *venenata*. The palsy resulting from mercury and lead has already been so fully treated of that we think it needless to allude further to it here. (See Diseases of Artisans and Colica Pictonum.)

Palsy has, in some cases, followed the use of arsenic, chiefly where it had been taken or administered as a poison. In some of the cases related by Orfila, the palsy was not extensive, and appeared a short time before death. In a young man whose case is related in the Medical and Physical Journal, there was paralysis of the four extremities, which continued for some time, and ultimately proved fatal.

Paralysis agitans.—The peculiar affection thus denominated by Mr. Parkinson is the *scelotyrbe festinans* of Sauvages, and from the peculiarity of the patient's gait has been called by Dr. Good synclonus ballismus, (*βαλλίζω, tripudio.*)

Mr. Parkinson's description of the disease is the best we possess; we therefore subjoin it. "So imperceptible is the approach of this malady, that the precise period of its commencement is seldom recollected by the patient. A slight sense of weakness with a proneness to trembling, sometimes in the head, but most commonly in the hands or arms, are the first symptoms noticed. These affections gradually increase, and at the period perhaps of twelve months from their first being observed, the patient, particularly while walking, bends himself forward. Soon after this his legs suffers similar agitations and loss of power with the hands and arms. As the disease advances, the limbs become less and less capable of executing the dictates of the will, while the unhappy sufferer seldom experiences even a few minutes' suspension of the tremulous agitation; and should it be stopped in one limb by a sudden change of posture, it soon makes its appearance in another. Walking, as it diverts his attention from unpleasant reflections, is a mode of exercise to which the patient is in general very partial. Of this temporary mitigation of suffering, however, he is now deprived. When he attempts to advance, he is thrown on the toes and forepart of his feet, and impelled unwillingly to adopt a running pace, being in danger of falling on his face at every step. In the more advanced stage of the disease, the tremulous motions of the limbs occur during sleep, and augment in violence till they awake the patient in much agitation and alarm. The power of conveying the food to the mouth is impeded, so that he must be fed by others. The torpid bowels require stimulating medicines to excite them into action. Mechanical aid is often necessary to remove the fæces from the rectum. The trunk is permanently bowed; muscular power diminished; mastication and deglutition are difficult, and the saliva constantly dribbles from the mouth. The agitation now becomes more vehement and constant; and when exhausted nature seizes a small portion of sleep, its violence is such as to shake the whole room. The chin is almost immoveably bent down upon the sternum; the power of articulation is lost; the urine and fæces are discharged involuntarily, and coma with slight delirium closes the scene."*

But few cases of this disease are recorded: it possesses many points of similarity to chorea, or to the palsy from mercury, which has been better termed *tremblement mercuriel.* It is therefore to be distingished from these diseases as well as from the trembling which succeeds the abuse of spirituous liquors; that which proceeds from the immoderate use of tea or coffee; or that which appears to be dependent on old age. In these cases the agitation ceases if the trembling limb be supported, and none of its muscles called into action; whereas, in the real shaking palsy, the reverse takes place; the agitation continues in full force whilst the limb is at rest and unemployed, and even is sometimes diminished by calling the muscles into employment. To this we may add the peculiarity of gait evinced here; "*the patient, when he attempts to walk, being impelled unwillingly to adopt a running pace*"—a symptom which we would be disposed to consider as pathognomonic.

All is conjecture respecting the anatomical condition of the nervous centres in this disease: the symptoms, however, seem strongly to fa-

* Parkinson's Essay on the Shaking Palsy. London, 1817.

vour the opinion of Mr. Parkinson, that there is spinal disease, and in the cervical portion of the spinal marrow.

The treatment consists in the adoption of the same measures which are applicable in all forms of palsy dependent on spinal diseases.

(R. B. Todd.)

PARAPLEGIA.—See Paralysis.

PAROTITIS, (from παρωτὶς, the parotid gland,) inflammation of the parotid gland, *mumps*. Inflammation of the parotid gland is an occurrence which may be the effect of the common causes of inflammation generally, in healthy persons, as of exposure to cold or local injury; or it may be secondary, and consequent to a cachectic state of the body or already existing disease, as in strumous subjects, and as it takes place occasionally in a subacute form at the termination of fevers, to which it has sometimes appeared to be critical. Parotitis is now and then observed to follow the inflammatory eruptive diseases, as measles, small-pox, and scarlatina; and occasionally to come on as if from the absorption of acrid matter from disease of the surrounding parts, as eruptions or excoriations. Lastly, parotitis presents itself as a peculiar and probably a specific disease, characterised by the duration of its inflammatory stage, and originating from no manifest exciting cause, except contagion. As it occurs under all but the last mentioned circumstances, the affection corresponds to the *parotis* of some of the ancient writers, and to the *phlegmone parotidæa* of Mason Good: the exception constitutes the *empresma parotitis* of the same nosologist, and the cynanche parotidæa of Cullen its more general nosological appellation at the present period.

Parotitis, from whatever cause it may arise, is characterised by tumefaction of the parotid gland, recognizable by the eye and hand of the examiner, together with local pain increased by and rendering difficult the natural movements of the lower jaw, and giving rise to febrile symptoms more or less severe. The modifications of it which seem to arise from various causes, and *not* from contagion, we shall refer to under the term simple parotitis; that which has the more peculiar character, commonly known by the name of cynanche parotidæa, we propose to treat of afterwards, under that name, as a distinct disease.

1. *Simple parotitis* presents, in most of its circumstances, phenomena similar to those of inflammation in other parts which have the same relative approximation to the surface of the body, namely, local pain, tumefaction, and increased heat, and, as it advances, redness of the superjacent integuments; added to these, there is occasionally a sense of throbbing about the parts, with headach and other cerebral disturbance, and occasionally even difficulty of respiration and deglutition. The degree of fever which accompanies it is proportionate to the extent of the local affection and the irritability of the subject. At an uncertain period, simple parotitis terminates in resolution, with subsidence of the febrile symptoms, or goes on to suppuration or abscess and ulceration, and may even end, although it very rarely does so, in gangrene and death.

Parotitis is often so transient and little distressing to the patient as to yield to the mere promotion of warmth of the part by covering it with flannel or any other additional wrapper; and it may be well to remark here that warm applications to the angle of the jaw, in all inflammatory swellings of the parotid gland, contribute much more to the mitigation of pain and other consequent symptoms than the cold epithems usually found to give relief in inflammation of other parts. When parotitis is more severe, detraction of blood from the region of the inflamed gland will be further necessary; to be followed up by constitutional treatment of the antiphlogistic kind, proportioned to the general effects of the local disease. If, nevertheless, suppuration should not be prevented, an early outlet should be made for the contents of the abscess, and the treatment of this and every other stage of the disease pursued on the principles laid down in the article Inflammation.

The subacute inflammation of the parotid gland, which is occasionally found in complication with scrofula and other diseases, is in fact a manifestation of them, and pertains to their discussion in other parts of this work. When consequent to acute or eruptive fevers, the primary inflammatory stage is rarely if ever to be recognised, and an abscess of the gland proclaims that it has existed. An early evacuation of the contained pus will be the direct medium of relief, and the treatment of debility consequent to such diseases, of which it is generally an indication, the method to be pursued for the further restoration of health.

When parotitis is a consequence of any particular state or disease of the adjacent parts, the removal of its cause must be the first object of attention. Leeches, however, applied to the region of the enlarged gland will give relief, and their repeated use may be necessary to counteract the continued operation of an irritant, the removal of which perhaps cannot be immediately effected.

2. *Cynanche parotidæa* is that species of parotitis commonly known in this country by the name of *mumps;* in Scotland called *branks;* and in France *oreillons* and *ourles*. It is almost universally admitted to be contagious; it is often endemic, and sometimes epidemic. It commences with the local symptoms already mentioned as common to parotitis in general, but the tumefaction, which is at first distinct, soon extends to the maxillary glands, (if the latter be not synchronously affected,) over a considerable part of the throat; the disease is frequently developed in the glands of both sides, but sometimes only of one; febrile symptoms, varying in degree, but usually slight, are also present, and increase as the swelling advances, until about the fourth day, when both the local and constitutional disorder begin to subside; and within as many, or sometimes a few more, they entirely disappear. As the

tumefaction diminishes, it not unfrequently happens that the testicles in the male sex, and the mammary glands in females, begin to increase in size, become hard and somewhat painful, but in this country soon again recover their former state. Experience has proved that this local determination is a favourable omen, for its non-occurrence as well as its expulsion have been frequently succeeded by inflammation of some other organ, generally the brain or its membranes, and even death has been the unfortunate issue.

In cynanche parotidæa the inflammation of the gland rarely if ever terminates in suppuration, but almost always manifests a tendency to resolution, on or about the fourth day of its progress.

When the inflammation has been confined to the glands on one side, the translation above noticed has generally also been evinced in the corresponding testis or breast.

A large majority of persons have passed through life without ever having suffered from this disease, and it is not common to find that it has been experienced a second time. We are not aware that its prevalence is peculiar to either sex, but children are generally the subjects of it, and more frequently those of a strumous diathesis: in such subjects, an occasional and apparently consequential occurrence is a more decided development of struma in the glands which have been the seat of vascular excitement. At sea, it has occasionally happened that cynanche parotidæa has attacked a number of sailors in the same vessel, when the cause of its first appearance has not been very evident; for although, besides contagion, exposure to cold and humidity have been commonly considered its exciting causes, it has occasionally arisen without any evident reason to suspect that it has been the effect of either.

Treatment.—Common observation has taught that cynanche parotidæa might in most instances be safely allowed to proceed without other care than that of guarding against exposure to cold of the general surface of the body, but particularly of the local swelling; by the abstinence from food and drink of a stimulating quality, with the occasional exhibition of gentle laxatives, purgatives having sometimes appeared to occasion a metastasis of the inflammation to another organ. To promote local warmth, the usual application of flannel round the neck and jaws is congenial alike to the feelings of the patient, and calculated to counteract the proneness to metastasis of the inflammatory action. When one or both of the mammary glands or testes are only slightly affected, a continuation of the same plan of treatment will generally be found adequate in aid of the natural actions of the body; but if the inflammation should be excessive, either in the original or consecutive stage of the disease, the antiphlogistic line of treatment must be more rigidly adhered to; topical detraction of blood by leeches, or, when the testis is the organ requiring relief, by several small punctures, with a lancet, of the superficial vessels of the scrotum, must be adopted, and even general bloodletting in further relief of the system. The depleting plan should be extended to the more active saline aperients, and to diaphoretic and diuretic medicines of the same class with antimonials, to be selected and varied on the general principles of therapeutics, according to the particular exigencies of the individual subject of the disease.

The well-established fact in pathology, of the tendency to metastasis of inflammation from its original seat to some other organ in cynanche parotidæa, renders it an important axiom that cold applications, whether to the parotid, maxillary, or mammary glands, or to the testes, should be carefully avoided, at least whilst the progressive steps evince the peculiar character of this disease. The secondary as well as original inflammation, when confined to these glands, will be soonest relieved by hot fomentations and the continued application of flannel: when leeches have been applied, as before advised, the same object will be further promoted by enveloping the part in a bread-and-water poultice, which should be renewed at intervals of six hours. Observance of the horizontal posture, the warmth of bed, and a suspending bandage, when the testis is enlarged and painful, will also be important auxiliaries. If, unfortunately, a metastasis should occur, and the brain or its membranes (which under such circumstances is most common), or any other structure become the seat of the vicarious inflammation, the new form of disease must be the immediate object of attention, requiring precisely the same treatment as if it were wholly unconnected with its precursor, whilst at the same time an attempt should be made to divert the inflammatory action to the organ from which it has receded, by the immediate application to the latter of hot fomentations, and subsequently by local irritants: blisters have been usually recommended for this purpose, but as the probabilities of success (at all events very slight), it is reasonable to suppose, would diminish in proportion to the length of time from which the inflammation had left the particular organ, a sinapism, we conceive, on account of its quicker action, would be preferable.

In advanced life, Dr. Mason Good observes, cynanche parotidæa is apt to run into a chronic form, accompanied with symptoms formidable in their nature. This is more especially apt to take place, he adds, in females when menstruation is on the point of ceasing, and the general action of the system labours under some disturbance. The tumour should, if possible, be carried off by leeches and cooling repellents, as he further advises, urging as a reason that if it proceed to suppuration, which it tends to, though very slowly, the ulcer rarely heals, usually degenerating into a foul offensive sore that sinks deeper and spreads wider, resisting all medical treatment, and at length destroying the patient. Vomits, frequently repeated, he continues, have in this case been found highly serviceable, and those of the antimonial preparations rather than ipecacuanha, from their maintaining a longer action, and determining more effectually to the surface, or rather to the excernents generally.

(*William Kerr.*)

PELLAGRA, or PELAGRA.—This is the name of a disease in which a morbid condition of the skin is a prominent symptom, very prevalent amongst, if not exclusively peculiar to, the peasantry of the northern states of Italy: the word pellagra is obviously a compound from the Latin *pellis*, the skin, and *agria*, "scabies fera," signifying an inveterate eruption.

The earliest account given of pellagra is from the pen of Francis Frapolli, a physician of Milan, and was published in the year 1771; since which period it has been the subject of a great deal of discussion and controversy amongst the Italian practitioners and medical writers. Of our own countrymen, Dr. Holland (so far as we have been able to ascertain) is the first whose description of the disease was founded on personal observation; and excepting a recent sketch of its prominent features by Dr. James Johnson, his paper is the only one in our literature to which the desirable distinction of originality can be attached: it has not, however, escaped the attention of Parr and Hooper,* and has been noticed by Good under the title of Elephantiasis Italica, and by Alibert under that of Ichthyosis Pellagra. Dr. Holland has expressed himself decidedly of opinion that it should be classed among the impetigines, but has remarked its resemblance to an inveterate degree of psoriasis or lepra vulgaris, admitting also that it has some affinity to ichthyosis.

General observation has determined that there is considerable variability in the symptoms of pellagra, and that they are often complicated with other forms of disease; a fact which, with the circumstances of the protracted period of its entire development as well as of its intermitting appearance and remissions, may in a great measure account for the conflicting opinions concerning its nature and history. The poor are almost exclusively its victims; and of these chiefly the peasantry and such as are occupied in agriculture. In the ordinary form of its occurrence, according to Dr. Holland,† it first appears as a local disease of the skin, preceded, however, occasionally by languor, debility, and other indications of a general cachectic state of the body. The local symptoms very generally show themselves, in the first instance, early in the spring, at the period when the mid-day heat is rapidly increasing, and when the peasants are most actively engaged in their labours in the fields. The patient perceives on the back of his hands, on his feet, and sometimes, but more rarely, on other parts of the body exposed to the sun, certain red spots or blotches, which gradually extend themselves, with a slight elevation of the cuticle, and a shining surface not unlike that of lepra in its early stage. The colour of this eruption is a somewhat more obscure and dusky red than that of erysipelas: it is attended with no other uneasy sensation than a slight pricking or itching, and some tension in the part. After a short continuance in this state, small tubercles are frequently observed to arise on the inflamed surface; the skin almost always becomes dry and scaly, forming rough patches, which are excoriated and divided by furrows and rhagades. Desquamation gradually takes place, which, though it leaves behind a shining unhealthy surface in the parts affected, yet in the first year of the disease is rarely followed by a repetition of the appearances just described. Towards the close of summer, or occasionally still earlier, the skin has resumed its natural appearance; and but that the further progress of the disease is familiar to every inhabitant of the country, the patient might be led to flatter himself that the evil was gone by, and that there was no particular reason to dread its recurrence.

With this local affection are connected, even in the first period of the disease, certain general symptoms, important inasmuch as they indicate the constitutional nature of the malady; namely, debility of the whole body; vague and irregular pains of the trunk and limbs, but especially following the track of the spine and dorsal muscles; headach, with occasional vertigo; irregular appetite, and general depression of spirits. The bowels are for the most part lax, and usually continue so in the further course of the disease. There are no febrile symptoms, and in females the menstruation is generally continued without irregularity.

The remission which the patient obtains during the autumn and winter of the first year is almost universally followed by a recurrence of his symptoms, in the ensuing spring, under a more severe form, and with much greater disorder of the constitution. The cutaneous disorder returns and spreads itself more extensively, but, as before, affecting chiefly the hands, neck, feet, and other exposed parts of the body. The skin becomes callous and deeply furrowed; and large rhagades show themselves, especially among the articulations of the fingers. The debility is greatly increased, frequently depriving the patient of all power of pursuing his active labours, and rendering him peculiarly susceptible of all changes of temperature. Partial sweats break out without any obvious cause. All the nervous symptoms of the first year are renewed in a more severe degree; there is a general tendency to cramp and spasmodic affections; the mind begins to suffer under the disorder, and the feeling of anxiety and despondence is very strongly marked. The *libido inexplebilis*, mentioned by some writers as one of the characteristic symptoms of pellagra, did not come under Dr. Holland's notice, and he is disposed to believe that it has been so considered from the credulity common upon this topic, or to a desire of associating the disease more closely with the leprosy as described by ancient writers. The other symptoms already noticed make progress as the heat of summer advances, and with greatest rapidity in those patients who are much exposed to the sun. As in the preceding year, they begin to decline towards the middle or end of autumn, but the remission, as well of the local affection as of the general

† See his valuable paper on the subject, published in the eighth volume of the London Medico-Chirurgical Transactions.

disorder, is much less complete than before, and the patient continues to suffer during the winter from the debility and other effects consequent upon the disease.

In the third year, every symptom is renewed at an earlier period, and in an aggravated degree. The constitutional malady shows itself under a variety of forms, some of the symptoms having a considerable analogy to those of scorbutus; all of them indicating a general cachexy, and more particularly a lesion of all the voluntary functions. The debility now becomes extreme; the patient is scarcely able to support himself; and the limbs, besides their feebleness, are affected with pains, which still further impede the power of motion. The diarrhœa continues, and tends of course to augment the patient's weakness. Frequently a dysenteric state comes on in the latter stages. The breath is generally fetid, and the odour of the perspiration often extremely offensive. The appetite and digestion are irregular, yet on the whole perhaps less affected than most of the other functions. Dropsical effusions are now apt to supervene,—occasionally ascites, but more commonly anasarca. Vertigo, *tinnitus aurium*, and double vision are almost universally concomitants of this stage of the disorder, and all the senses become exceedingly impaired. Some spasmodic affections are very general, and these not unfrequently of an epileptic character.

Connected with these latter symptoms is the effect which the pellagra produces upon the minds of the sufferers, which effect forms one of the most striking circumstances in the history of the disease. The anxiety, watchfulness, and moral depression of the patient are rapidly augmented. The unhappy objects seem under the influence of an invincible despondency; they seek to be alone; scarcely answer the questions put to them, and often shed tears without any obvious cause. Their intellectual faculties and senses become alike impaired, and the progress of the disease, where it does not carry them off from debility and exhaustion of the vital powers, generally leaves them incurable idiots, or produces maniacal affections, which terminate eventually in the same state. "In demonstration of this tendency of the disease, I may mention the fact," says Dr. Holland, "that at the time I visited the Lunatic Hospital at Milan, there were nearly five hundred patients of both sexes confined there, of which number more than one-third were pellagrosi, people brought thither by the termination of their disorder either in idiocy or mania. Even this statement gives little adequate idea of the nature of its ravages. The public hospitals of the country are far from sufficient to receive the vast number of persons affected with the pellagra; and the greater proportion perish in their own habitations, or linger, wretched spectacles of fatuity and decay. Where debility, as generally happens, is the cause of death, it manifests itself in the latter stage with the usual concomitants of colliquative diarrhœa, spasmodic affections, and coma, and produces a degree of emaciation scarcely to be surpassed in any other disease."

"Though, for the sake of brevity," continues Dr. Holland, "I have described this train of symptoms as going on from the third year, I may remark that the pellagra is generally of longer duration, and that other intermissions usually occur in its progress, giving the patient a certain relief in the degree of his sufferings, though little hope as to the issue of the disease. In some instances the cutaneous affection forms the principal indication of the complaint for several successive years, being renewed every spring, and disappearing again every autumn. In other cases, where it has been found possible to remove the patient to a new situation and mode of life, the disease is still further arrested in its progress. It rarely happens, however, that these means can be practically adopted, and the constitutional malady is generally so far established in the third or fourth year, that little hope remains of benefiting the patient either by medicine or change in the mode of life."

To enumerate all the symptoms which the Italian writers have attached to pellagra would in fact involve a description of several diseases with which it is complicated; it appears, however, that such complications are characteristic of this peculiar malady, and equally so their occurrence under several varieties of form. At different periods, in the same individuals, the morbid condition of the skin has exhibited the appearance of erysipelas, lepra, psoriasis, elephantiasis, and ichthyosis, and of such as are usually termed constitutional disorders, in which it appears to merge: scorbutus, tetanus in its varied forms, chorea, epilepsy, convulsions, dropsies, melancholia, mania, and marasmus, form a condensed list. "It is on this account," Dr. Johnson has observed, "that we see written over the beds in the Milan Hospital the various diseases to which pellagra forms the adjective, as atrophia pellagrina, phthisis pellagrina, hydrops pellagrinus, paralysis pellagrina, mania pellagrina, &c."* Jansen, one of the most esteemed authors on this subject, states that the cutaneous affection sometimes disappears, but without any mitigation in the other symptoms, and that a person accustomed to see this disease would at once recognize it by the peculiar odour of the perspiration the patients are often bedewed with, compared by him to the smell of mouldy bread. In the advanced stage the victim of pellagra (the *mal de misère*, as it has been emphatically called by Vaccari,) experiences in an extreme degree the effects of irritation in all the mucous surfaces, whilst at the same time the sensibility of the nervous system seems to be infinitely increased. The whole mouth becomes painful, tense, and phlogosed; the palate cleft: the gums swelled, fungous, and bloody; the tongue dry and blackish, and covered with a muddy coating; the teeth blacken and fall out; aphthous ulcer-

* Change of Air, or the Pursuit of Health, by James Johnson, M.D. p. 75.

ations are not uncommon, and the saliva, which is extremely salt, is frequently secreted in such a quantity, particularly in the morning, as to constitute complete ptyalism: the voice is sometimes so changed as not to be recognizable, and, as may readily be imagined, the thirst is excessive; the latter, however, is the only constant and invariable one of this group of symptoms. As the disease proceeds, diarrhœa becomes uncontrollable, and prior to the fatal issue the emaciation is excessive; but sometimes the patient is said to have the appearance of a mummy. Nervous sensations of a very distressing and peculiar kind also accompany the latter stage; they have been described as a sense of burning heat of the head and spine, radiating to the other parts of the body, and extending particularly to the palms of the hands and to the soles of the feet; occasionally as if an electric spark or flash of fire issued from the brain, and darted through the eyes, ears, and nostrils: all kinds of imagined noises distract the unhappy sufferer; saws, grindstones, mills, hammers, bells, the chirping of birds, and buzz of insects at one time or another appear to assail his ears; and thus deprived of sleep or rest, in the summit of despair, it not unfrequently happens that suicide is resorted to,—an act which (as if the means were indicated by some physical association) is often accomplished by drowning, so often as to have induced Strambio to distinguish this particular hallucination by the title of hydromania.*

The consideration of pellagra has been encumbered with a variety of discordant and trivial distinctions. Frapolli, for instance, has divided it into the incipient, the confirmed, and the mutable; Gherrardini into slight, severe, and desperate; Soler into the dry and moist, from some supposed difference in the disorder, according as it appears in dry and elevated situations, or on the flat and moist surface of the plains; and Titius into the latent and manifest, in conformity with the presence or absence of the eruption, the latter being a peculiarity in the manifestation of the disease, but attested by Italian authorities of respectability, amongst whom are Cevri and Zanetti.

It appears that the knowledge of the nature of pellagra has been as yet but little extended by pathological investigation. "In some patients," says Dr. Holland, "the liver, in others the spleen, has been found enlarged and indurated; marks of disease are also occasionally seen in the intestines and mesenteric glands, but these appearances are by no means constant, and may more reasonably be considered as effects than causes of the disease."

Dr. Johnson, in his notice of some cases of mania pellagrina, collected from the great hospital at Milan by M. Brierre de Boimont, who visited Italy in 1830, has included the following remarks on the pathology of the disease by that writer: "there is a collection of yellowish serum between the membranes and in the cavities of the brain; congestion of the vessels of the pia mater, plexus choroides, and of the cerebral substance; suppuration and hardening of the brain itself; inflammation of the spinal chord and of its membranes; accumulation of serum in the pleural cavities; inflammation and abscesses of the lungs; ulcers of the trachea; dropsy of the pericardium and of the abdomen; chronic peritonitis; ulceration of the stomach and intestines; hypertrophy, tubercles, and scirrhus of the liver, &c."*

The period at which pellagra first made its appearance is a point that has been much disputed by the Italian and German physicians, without any satisfactory conclusion. According to Moscati, a Milanese of great repute in science, and some other writers, it has not been known in Lombardy more than between sixty and seventy years. Alhoni, who has attempted to estimate the various opinions on the subject, dates its rise in the year 1715, though the attention of the Milanese physicians was not drawn to it until 1740. Strambi, who was appointed by Joseph II. the director of an hospital established at Lagnano, near Milan, for the reception of pellagrosi, had the best opportunities of gaining information on the subject. In his treatises on the pellagra published in three successive years, from 1784 to 1787, he mentions the fact of his having seen many pellagrosi in the hospital, who gave him distinct assurances of their fathers and grandfathers having had the disorder, and from some particular instances he thinks himself entitled to believe that the pellagra must have been known in Lombardy sixty or seventy years before the time when he wrote. Frapolli contends also for its antiquity, but it may be questioned whether his opinion does not rest on the mere analogy of a name, it having been formed from the circumstance of a minute in the journal of the Milan Hospital, dated the 6th of March, 1578, which provides for the reception of patients attacked with the disease known at that time under the name of *pellarella*.

The pellagra, as an endemic disease, prevails chiefly in the provinces of Lombardy, lying between the Alps and the Po. This country may be briefly described as a vast surface of alluvial plain, little elevated above the sea; but rising on its northern side into chains of hills, which intermediately connect it with the Swiss and Tyrolese Alps. From the long, narrow, and profound lakes among these hills the numerous rivers issue, which, flowing southwards to the Po, and giving their waters into a number of artificial channels for the purpose of irrigation, maintain that extraordinary fertility of soil for which the plains of Lombardy have long been celebrated. The principal objects of cultivation on these plains, besides the vineyards extensively spread over their surface, are maize, rice, and millet. In some districts, and particularly between the rivers Adda and Tireino, the pastures are extensive, and yield a considerable produce of milk, from which the Parmesan cheeses are made. The hilly country,

* Dict. des Sciences Méd. art. *Pellagra*.

* Medico-Chirurgical Review, Jan. 1833.

ust noticed, on the northern side of Lombardy, s less productive, and cultivated on a more imited scale. The valleys, however, intervening among these hills, are of great fertility, yield a considerable quantity of grain, and much wine rom the numerous vineyards to which they give shelter.

The district which appears to have suffered most from the ravages of the pellagra is that which formerly constituted the duchy of Milan, and particularly the Alta Milanese, or that portion of country lying up towards the hills between the Lago Maggiore and the Lago di Como. It was in this part of Lombardy that the disease first became an object of medical attention; and some time elapsed before it was described as appearing in the Venetian provinces, and near the shores of the Adriatic sea.*

The propagation of pellagra has by some been referred to contagion; facts and authority, however, preponderate greatly against this opinion. Its hereditary tendency is proved by its frequent appearance at the earliest period of life, as attested by Dr. Lacco of Milan, who, in the capacity of Director of the Vaccine Establishment, has had the best opportunities of observation. It has, moreover, been generally remarked that the disease is continued in succession through families. Conflicting accounts are given of the sex in which it most prevails, but there is ample reason to conclude that the discrepancy has arisen from the occupations of the men and women in different districts being reversed, and not from any physical peculiarities in the conformation of either.

In reference to the remote causes, the most important facts in evidence undoubtedly are, the limited period during which the disease appears to have existed in the country, its being confined almost exclusively to the lower classes, and its rare appearance in the towns or cities of Lombardy. The climate is obviously not the cause concerned; since this, as far as it is known, has been unchanged for a much longer period than that which includes the history of pellagra; or had it been changed, it would have affected alike both the higher and lower classes of the population. The same objection may be made to the opinion that any circumstances of mere locality are concerned in producing the disease. It may possibly be true that the plains of Lombardy are more frequently and irregularly flooded than formerly, and that the general surface is more marshy and unwholesome; but this does little to explain the causes of a disorder which is chiefly prevalent in the higher lands, where such changes have not equally taken place.

The point, then, to which we are almost necessarily conducted, is the mode of life and subsistence among the peasantry: this, it appears, is as wretched as the soil is productive; an evil which has been progressively increasing for more than the last half century, and is probably the result of devastation from repeated wars, political changes, and the consequent heavy taxes and imposts, combined with a decaying commerce, and bad arrangement between the landlords and cultivators of the soil.

The ordinary diet of these people consists chiefly of maize prepared in different ways, of rice, millet, beans, and some other articles of vegetable food. Their bread, which is principally made from maize, is for the most part of bad quality, ill fermented, and not unfrequently deficient in salt. Animal food rarely forms a part of their diet; and though living on a soil which produces wine, their poverty almost precludes the use of it, even when sickness and debility render it most needful. The same condition of poverty is evident in their clothing, in their habitations, and in the want of all the minor necessaries and comforts of life. By several of the Italian physicians the common use of maize has been considered a specific cause of this peculiar disorder. Dr. Holland controverts this opinion by the results of his personal observation with regard to the peasantry in the northern parts of Greece, who, though subsisting chiefly on the same kind of grain, are wholly free from the disease, as is also observed in the south-western parts of Europe, where the same diet is as generally in use among the lower classes; and, with the exception of a disease occurring in the Asturias, (the elephantiasis Asturiensis of Mason Good,) Dr. Holland further states that he does not know of its existence in Spain or Portugal, where the maize is very extensively used. Rice has also been supposed to be specifically productive of the disease, but it must be acknowledged that facts by no means warrant the supposition. One circumstance which seems to deserve a prominent place in the consideration of this part of the subject is the first appearance of the symptoms in the spring of the year, their partial disappearance in the autumn, their renewal in the ensuing spring, and the continuance of this alteration for successive years, whenever the disease is protracted thus long without reaching its latter stages. This chain of phenomena has led Albera, Frapolli, and other Italian writers, to refer the origin of the disease to the frequent exposure of various parts of the body to the action of the sun's heat, which, it seems probable, is an exciting cause of the cutaneous and some other of the symptoms; but that it is not the fons et origo mali is proved by the circumstance of the peasantry of other parts of Italy and of tropical countries being subjected to more intense exposure of the same kind without corresponding results. That such insolation, moreover, is not the only exciting cause, has been proved by the fact adduced by Strambi, that the cutaneous eruption may be prevented by avoiding exposure to the sun, whilst the other symptoms proceed in their usual course. There is also reason to expect that the incipient stage of the disease would, if induced by this cause, be common when the sun's heat was most intense, a circumstance contrary to common observation; and it may be presumed, as suggested by Dr. Holland, that the increased labours of the peasantry in the early part of the spring, being speedily followed by the develop-

* Medico-Chirurg. Transactions, vol. viii. p. 320.

ment of the symptoms, must have some influence on their production at this particular period. Perhaps, also, adds the same observer, the periodical returns of the pellagra, during its early stages, depend in part on the natural periodical changes of the body itself, independently of the external causes just alluded to.

It must be acknowledged that the chain of connection between the causes of pellagra and its specific symptoms has not hitherto been distinctly traced; but we know from universal experience that identity of disease has a common origin in a prevailing insufficiency of food, or in the use of such as is depraved or innutritious in its quality: we know, moreover, that the combined evils, already detailed, in the moral and physical condition of the people who become subjects of pellagra, have at all times been observed in connection with the prevalence of analogous disorders, which have been variously described under the comprehensive name of leprosy. It is further evident that the end of the several processes subservient to alimentation demands a sufficient and suitable supply of aliment, and in defect of either, the immediate wants of the system, as well as the imperfect actions of the various organs, become evident by the train of phenomena constituting the symptoms of disease. Added to and aggravating these in pellagra, we have the direct action of an irritant (the sun's heat), which, besides the local effect, and its direct consequences upon the nervous system, must, by impeding the important function of the cutaneous secernents, reflect their uneliminated material through the medium of the circulation over the whole body, and thereby help to generate its universal disorder. When we further consider the diversity of modifying influences, the mutability of their nature, and their relative operation, we cannot be surprised at the diversified appearances, nor at the endless discussions on the identity of diseases of this nature, arising no doubt from the unwarrantable habit of endeavouring always to limit to the arbitrary signification of a name circumstances confessedly Protean in their nature, and which have a very distant analogy to the distinct and circumscribed characters proper to objects of natural science, the classifications of which have been the models of nosological imitation.

The treatment of pellagra, like that of other endemic diseases which have their origin in the privation of the necessaries and comforts of life, has been infinitely diversified, and, according to general acknowledgement, unsuccessful. The patients on their admission into the hospital (we quote Dr. Holland,) are immediately allowed a nutritious diet, and, unless contra-indicated by some local affection, wine and tonic medicines are given with the same view. A decoction of the lichen Islandicus is in common use in the hospital of Milan, as a part of this plan of diet. The warm bath is very generally employed at the same time; a favourite remedy among the peasantry, probably in consequence of its comparative cheapness, but esteemed also by most of the medical practitioners who are concerned in treating the disease. Diaphoretics, and especially antimonials, are in considerable use, under the idea of correcting the state of the skin, and getting rid of the morbid humours through this channel. Depletion by bloodletting is very rarely employed except where some local inflammation happens to occur, or in the mania which sometimes supervenes upon the disease. Attention is of course paid to the bowels in correcting the diarrhœa, and bringing them as far as possible to a natural state.

Besides these means, a long list of medicines, commonly termed antiscorbutics, are in popular use; but having mentioned the various preparations of cinchona, sarsaparilla, guaiacum, sassafras, cantharides, terebinthina, and mercurials, it would be superfluous to enumerate the thousand remedies for this hitherto untractable and fatal disease.

From the preceding detail it is evident that the labour of physicians in the treatment of pellagra must continue in its result to resemble that of Sisyphus, until a decided amelioration can be effected in the moral and physical condition of that unfortunate class of persons in whom it is found to occur; and all former experience of diseases analogous in their nature justifies us in asserting that when, and not till when, it ceases to be the opprobrium patriæ, will it cease also to appear to be the opprobrium medicorum.

(William Kerr.)

PEMPHIGUS, from πέμφιξ, *a bleb*, or *blister*. This disease belongs to the order *Bullæ* of cutaneous diseases. Under the present heading we shall include both pemphigus and pompholyx, as we consider the latter as merely a variety of the former.

Previously to the time of Willan, nosologists made a distinction between these diseases, describing pemphigus as an idiopathic eruptive fever *(febris pemphigodes)*, running through a certain fixed course like measles or scarlatina, and pompholyx as differing from it, in not being accompanied by fever; and this view is still supported by some writers on skin diseases. An additional line of demarcation was supposed to be found in the local characters of the eruptions; pemphigus being supposed to present bullæ with inflamed edges, and pompholyx to consist of bullæ without inflammation or redness around them. These distinctions will not bear examination. The fever which sometimes precedes or accompanies the bullæ of pemphigus, makes no approach to the regularity of the fevers of measles or scarlatina, but is, on the contrary, very irregular in its nature and duration. It may be a short inflammatory fever, or of a low typhoid type, or it may assume the characters of an intermittent. The period of the fever at which the eruption of bullæ appears, is equally uncertain. The bullæ may appear almost simultaneously with the accession of febrile symptoms, or on the second day of fever, as in the case related by Seliger, and referred to by Dr. Willan; or on the second accession of an

attack of intermittent fever, as in the case related by Dr. Winterbottom; or on the fourth day of low typhoid fever, as in the case related by Dr. Dickson in the first volume of the Transactions of the Royal Irish Academy. The bullæ may be still more irregular in their eruption, coming out in successive crops at uncertain periods of a continued fever, and, lastly, may appear either as sympathetic with or as a crisis of internal visceral disease. These irregularities of the type of the fever, and of the coming out of the eruption, are sufficient to convince us that pemphigus has no claim to the title of an idiopathic eruptive fever. The further supposed distinction between it and pompholyx, of the bullæ of pemphigus having a red inflamed edge, and those of pompholyx not possessing this character, will prove equally invalid; for this character is merely accidental. The bullæ will possess or will be deficient in this character according to the time at which they are examined. In almost every instance a distinct circular erythematous patch upon the skin precedes the formation of each bulla. If the bullæ be examined before having attained a sufficient size to occupy the entire of the erythematous patch, there will then be seen around its circumference a red inflamed edge formed by the outer margin of the erythematous patch not yet occupied by the bullæ; but if not examined until a later period, or if even examined at a very early period, when (as in pemphigus solitarius) the growth of the bulla is very rapid, then the entire of the precursive erythematous patch will be covered by the bulla, and there will be no surrounding blush or tumefaction; or, in other words, the disease will be the pompholyx of some authors. These are our reasons for considering pompholyx as merely a variety of pemphigus.

Pemphigus may be defined "an affection of the skin, consisting of the eruption of one or more bullæ containing serous fluid, and terminating either in thin scales, in superficial excoriations, or in ulceration."

The immediate pathology of pemphigus is an effusion of serous fluid from the surface of the rete mucosum, which first detaches portions of the cuticle, and then distends them into bullæ. In most instances there are erythematous patches upon the skin preceding the appearance of the bullæ. Between these the skin preserves its natural appearance, or seems very slightly swollen. If the finger be passed over the surface, each erythematous patch gives a sensation, arising from the local congestion, of being a little firmer and more elevated than the surrounding surface; but there is no marked increase of thickness or hardness of cutaneous or cellular tissue, such as is found in the commencement of pustular diseases. The bullæ first appear on the centres of the erythematous patches; and around each bulla there may or may not be a red margin according as the bulla occupies only the central portion, or has spread over the whole of the inflamed base from which it has arisen. The skin between the bullæ continues to preserve its natural appearance and colour. The bullæ always commence as such, and never as papulæ or pustulæ; in the commencement they are translucid, either colourless or of a pale fawn or slightly bluish cast; and as they continue to grow, they assume a hemispherical shape, and present different sizes from that of a split pea to a size sufficient to contain a tea-cupful of fluid. The fluid contained in the bullæ consists principally of albumen; it readily coagulates by heat into an almost solid mass, and sometimes, although rarely, the albumen of a bulla is in such quantity as to coagulate spontaneously and form a layer lining the distended cuticle. The fluid of the bullæ is usually bland and devoid of smell, but, in some varieties of the disease to be afterwards noted, gives out a most disagreeable fetor, and seems to acquire acrid properties. When the bullæ are fully formed they become opaque, and sometimes, from a trifling admixture of purulent matter, present a yellowish, or greenish yellow shade. Arrived at this stage, they may terminate in various ways. In mild cases the smaller sized bullæ, after having reached their greatest degree of development and tension, begin to wither; the cuticle wrinkles; and the albuminous portion of the effused fluid, together with the detached cuticle, dries into a thin brownish scab, which, falling off, exposes a red patch formed of the inflamed true skin, with its thin new cuticle. The larger sized bullæ burst either spontaneously or through accident; and the broken cuticle, lying flat upon the inflamed surface, now dries away into a scale, which separating, exposes, as before, the red base on which the bulla arose. For a short time after the larger bullæ are opened, the inflamed excoriated surface continues to secrete a fluid similar to that originally effused. In weakly constitutions, after the bullæ have burst, the inflamed surface of the true skin, instead of furnishing a new cuticle, takes on the action of secreting pus; and if the pus or scab formed of it be removed, then presents the appearance of an indolent ulcer. In more severe forms of the disease, the fluid of the bullæ is thin and ichorous, forms no crust, and when discharged by the bursting of the cuticle, exposes an unhealthy-looking flabby ulcer; the tissue around softens, and the ulcer continues to spread as a gangrenous ulcer, engaging in its destructive progress all the surrounding tissues without distinction.

No portion of the cutaneous surface is exempt from the invasion of pemphigus. It may confine itself to a part, or may spread itself over the entire surface; but the parts on which the eruption most frequently appears are the limbs, particularly the lower limbs and the skin of the abdomen. The bullæ also make their appearance on the mucous membrane of the mouth and of the vagina. One variety of the disease (pemphigus gangrenosus) has a tendency to attack in preference the skin behind the ears and the folds of the thighs.

Pemphigus may make its appearance as an idiopathic disease, or as sympathetic of some internal visceral irritation; or its bullæ may occur during the course of other diseases, more

especially those of the skin, principally erysipelas, herpes, prurigo, scabies, and varicella. It is asserted by some writers that the bullæ of pemphigus are occasionally found on the mucous membrane of the stomach and intestines. Rayer admits the occasional existence of bullæ on the mucous membrane of the mouth, but denies their existence in the stomach and intestines. Of their occasional existence in the mouth there cannot be a doubt. In the case related by Dr. Dickson, and already referred to, the patient, a delicate woman, twenty-three years old, felt on the third day of low fever a tingling pain and smarting in the tongue and inside of the mouth. On the next, the fourth day, a pellucid bulla appeared on the tongue one inch long, and half an inch broad, turgid, with faintly yellowish serous fluid, and a smaller one on the inside of the left cheek. The sensation felt was as if these bullæ were full of scalding water. On the fifth day, bullæ appeared over the body; and on the ninth day the bullæ of the mouth left behind them an excoriated and acutely sensible surface.

In the abdominal viscera the changes observed most frequently in fatal cases of pemphigus are redness, softening, and ulcerations, the ordinary effects of gastro-enteritis. Biett states that the internal derangement which he has observed most constant in pemphigus is the fat liver.

Diagnosis.—Vesicles, or bullæ, are sometimes found in erysipelas which bear a close resemblance to pemphigus; but they are at once distinguished by the whole surface of the skin on which the vesications appear in erysipelas being tense, shining and red. The vesicles of herpes somewhat resemble the bullæ of pemphigus; but exclusively of being much smaller and irregular in form, they are always clustered upon a red inflamed surface; while the bullæ of pemphigus are scattered, the skin between them preserving its natural appearance. The extremely small size and immense numbers of the vesicles of miliary eruption furnish us with a well-marked line of distinction between it and pemphigus. Varicella, or chicken-pox, when fully developed, presents vesicles, which, however, are easily distinguished from the bullæ of pemphigus by being pretty equally diffused over the entire body, and by all being of nearly one size, and much smaller than the bullæ of pemphigus.

Rupia has some characters in common with pemphigus, and belongs to the same order; but in rupia the bullæ are generally fewer in number, smaller, less tense, and more flattened than in pemphigus, and the contained fluid quickly becomes sanious or purulent. The cutaneous tissue around the bullæ of rupia is more deeply inflamed; and the bullæ, after having reached their full growth, instead of forming thin crusts or excoriations as in pemphigus, are followed by thick prominent scales, which, when removed, expose deeply-eating ulcerations.

These are the only diseases which can be confounded with pemphigus. The characters distinguishing pemphigus from all other affections of the skin are so marked, that it is quite unnecessary to point them out.

Prognosis.—It may be laid down as a general rule that the more acutely pemphigus sets in, the less dangerous it is; and as it shews a tendency to become chronic or occur in weakly constitutions, or is accompanied by a fever of a low typhoid type, the more unfavourable is its prognosis.

Causes.—Whatever acts directly as a stimulant to the skin, or indirectly injures its function through the medium of the constitution, or of the mucous tissue of the digestive organs, may be an exciting cause of this disease, viz. exposure to the direct and burning rays of the sun, or the application of any irritating substances. Among mowers in Ireland, a local form of pemphigus attacks the skin over the ancles, and is a very troublesome complaint. It is by the men themselves attributed to the seeds of the cow parsnip (*heracleum sphondilium.*) The bites of some serpents, the prolonged impression of cold or damp upon the surface previously over-heated, excess in the use of spirituous liquors or heating spices, depression of mind, marsh residence, debility however induced, are also in the list of exciting or of predisposing causes. The disease has supervened on the suppression of the lochia, of the menstrual discharge, of hemorrhoids, and of diarrhœa.

The bullæ of pemphigus occasionally accompany epidemic diseases, such as scarlatina; and from this complication has arisen the description of pemphigus Helvetieus as an epidemic given by Laughans. There is, however, no authentic description of simple pemphigus prevailing as an epidemic.

Pemphigus is a disease of all climates and seasons; but one variety, pemphigus gangrenosus, is generally confined to certain districts as an endemic disease: we shall have occasion to speak more at large on this form of it. Cullen, in his "Synopsis," characterises pemphigus as a contagious disease; but at the same time observes that he has only followed Sauvages, and that he has no knowledge of the disease from personal observation. Experiment is unfavourable to the supposition of the disease being contagious. Husson inoculated five children with fluid taken from the bullæ of pemphigus, and the disease was not in any instance transmitted.* Martin confirmed these by similar experiments.†

The varieties of pemphigus may be considered with most practical advantage under the heads of *acute pemphigus*, *chronic pemphigus*, and *gangrenous pemphigus*.

1. *Acute pemphigus.*—This variety is preceded by febrile symptoms of very uncertain characters. There is generally a premonitory shivering fit very well marked, and in some cases there are two or more shivering fits so distinct, that the attack at first sight appears

* Recherches Historiques et Médicales sur la Vaccine.

† Journal de Médecine, Chirurgie, et Pharmacie, vol. ii. p. 225.

) be intermittent fever. In other cases, after fit of shivering, there are the symptoms of ontinued fever—thirst, loss of appetite, coated ongue, and dry hot skin; and after these have ontinued usually from one to four days, the urface about to become the seat of the erup- on, generally the skin of the abdomen and ower extremities, in a few cases of the whole ody, is affected by a sensation of tingling eat, and circular red patches of various sizes ome out, irregularly scattered over the surface; heir colour will not disappear under pressure, nd within twenty-four hours of their appear- nce bullæ arise on these patches and rapidly ncrease, until each bulla occupies the entire r nearly the entire of the inflamed plane on hich it has arisen. Some of the bullæ, al- hough rarely, become confluent. The bullæ aving arrived at their full size, usually within he period of two or three days from their first ppearance, become turgid, burst, and discharge heir contents, leaving the surface of the true kin now exposed, red, excoriated, and painful. The pain is like the sensation produced by burn or scald, and is not felt until the true kin is exposed by the bursting of the bullæ. The exposed cutis is, however, soon covered vy a thin crust formed by the old cuticle, the emnant of the contained fluid, and a secretion f similar fluid, which continues for a short me from the inflamed surface. The thin scab us formed, after a few days drops off, and xhibits the true skin covered with a new uticle, and of a dark red colour. This colour emains for an uncertain time. The febrile ymptoms which ushered in the disease usually bate on the appearance of the eruption, and ontinue in a mild degree until the healing of he broken bullæ. In a very great majority f cases the termination of the attack is a narked crisis, either by diarrhœa or a copious eposition from the urine.

The duration of acute pemphigus is very ncertain. It never runs its course in less than week, and is seldom prolonged beyond a nonth. When gastro-intestinal irritation is superadded, the symptoms are aggravated, and n such cases the mucous membrane of the nouth may present bullæ resembling those pon the surface, but, from being constantly athed in moisture, not forming scales. There s a form of acute pemphigus, in which, after eat, itching, and redness of a part, a single ulla arises, (pompholyx solitarius of Bate- an,) and after becoming enlarged to a size ufficient to hold a tea-cupful of fluid, bursts, nd is, perhaps, succeeded by another follow- ng the same course. In this variety, if a ulla burst before it has attained its full size, t may heal in the centre, and the circumference f the bulla continuing to increase will pro- luce the appearance of the whole cuticle of the art peeling off.

Treatment.—The treatment of acute pem- higus, when it exists as an idiopathic affection, s very simple; the febrile symptoms not ge- erally running so high as to demand very ctive treatment. Mild purgative and diuretic nedicine and cool drinks are generally all that are required. If the disease be complicated by gastro-intestinal irritation or inflammation, or be sympathetic with the disease of any im- portant internal organ, the cutaneous affection becomes of secondary importance; the internal disease demands all our care. Warm-baths or any heating application to the skin are im- proper in acute pemphigus. It is recom- mended in some works to open the bullæ as soon as they are formed. This is not judicious practice. The distress of the patient is com- paratively little before the bullæ have burst; but after this there is, as we have already noticed, a most painful sensation of burning produced by the exposure of the raw surface of the true skin. The febrile excitement is thus increased, and we shall both hurry and prolong the pain and fever if we unnecessarily puncture the bullæ. We can apply to the excoriated surface no dressing so mild as its own albuminous secretion, and can protect the excoriated skin from the irritation of exposure by no covering so effectually as by its own cuticle. When the bullæ have burst either spontaneously or by accident, and the exco- riated surface is scalding and painful, the de- nuded part should be covered with the mildest dressing, with slips of gold-beater's leaf or the delicate membrane which lines the interior of an egg-shell. When the bullæ are wither- ing, and cicatrization is taking place, and after the fever has subsided, it becomes necessary to support the strength of the system and aid it in its curative efforts by the exhibition of tonics, of which the best is cinchona or sul- phate of quinine. Sometimes the fever which ushers in acute pemphigus presents almost from its very onset a low typhoid type; and while intestinal irritation is allayed by the mildest purgatives, the patient's strength re- quires to be supported by light broths, and, according to the symptoms, by wine and bark.

2. *Chronic pemphigus.*—This variety of the disease is generally met with in old persons or in debilitated constitutions, is sometimes idiopathic, but more often sympathetic, with internal visceral disease; in the latter, of course, the more serious. It is the *pompholyx diutinus* of Bateman, *dartre phlycténoide confluente* of Alibert. This is a very obstinate and dis- tressing form of skin disease, and there is scarcely any limit to its duration. After pre- monitory symptoms of lassitude, headach, &c. bullæ appear on different parts of the body. These heal, and are succeeded by others, which, as the patient's strength becomes weaker, shew a disposition to ulcerate. There is intolerable pain and burning from the exposure of the denuded cutis, and irritative fever sets in. A crisis may now take place either by diarrhœa or by a copious deposition from the urine; the bullæ dry up and heal, the symptoms of irritative fever disappear, and the patient be- lieves there is a perfect cure; but after a short interval the disease again shews itself. There is less disposition in the bullæ of each suc- cessive eruption to heal; the constitutional irritation produced by the numerous excoriated

surfaces prevents rest, destroys appetite, and finally wears out the patient by exhaustion; or the constant irritation aggravates to such a degree some internal lesion, otherwise of little consequence, that a new train of symptoms sets in, the pemphigus disappears before some more formidable affection, and the patient dies of internal visceral disease. The bullæ of chronic are always larger than those of acute pemphigus, and, as already observed, are more generally sympathetic with some internal disease of function or of structure than an idiopathic affection of the skin. Persons advanced in life are most subject to chronic pemphigus, and whatever debilitates the constitution, as mental depression, or bad or insufficient food, or injures the functions of the skin, as a residence in cold damp situations, may tend to bring forth the disease; and in cases where the previous debility has been very great, the bullæ not only ulcerate, but the surface on which they have arisen sloughs around the bullæ to a considerable extent.

Treatment.—As this disease is so frequently a symptomatic affection, the treatment is in general complex, and must in such circumstances be directed as much to internal visceral disease as to the external skin affection. For the treatment of the rheumatic, gouty, or visceral derangements which may be combined with chronic pemphigus, we of course refer our reader to the various heads under which those derangements are considered. Internal irritation (if any) being allayed by appropriate means, the patient who is the subject of chronic pemphigus is then to be put upon a full and nourishing but not stimulating diet, and tonics combined with diuretics, as sulphate of quinine with compound infusion of juniper, or bitters with alkalies, are to be administered. Locality has often much influence over this disease, and hence, if the ordinary measures above recommended are not successful, change of air should be enjoined, and the change should always be to a dry air and a high situation. The bullæ should not be opened by art, for the same reasons as given for not opening the bullæ of acute pemphigus. If the bullæ burst and leave indolent ulcerations, these are to be stimulated with powdered bark or burnt alum, or touched, if necessary, with solid nitrate of silver. Warm-baths generally aggravate this disease when present, but are very useful as preventives by preserving the skin in the exercise of its healthy functions.

Before we proceed to the third variety, gangrenous pemphigus, it is necessary to mention a form of pemphigus which does not perhaps strictly come under any of the heads we have named. For practical utility we have described two forms of pemphigus, as acute and chronic; but here, as in most diseases, this line of distinction is more arbitrary than real, the two forms running into one another by imperceptible gradations: perhaps the term subacute, borrowed from the French, would be the best name for the variety of pemphigus to which we now allude, and which forms the connecting link between the acute and chronic forms. This variety of pemphigus corresponds with acute pemphigus in being accompanied with fever, but agrees with chronic pemphigus in presenting, not simultaneous, but successive eruptions of bullæ. It is called by French writers "pemphigus aigu successif." The accessions of febrile symptoms are irregular, and with each accession a new crop of bullæ appears on the skin, the whole attack usually running its course within a few weeks. The treatment is merely a modification of that recommended for acute pemphigus, with this addition, that as the fever which precedes the eruption takes on an intermittent form, the early exhibition of bark is called for.

3. *Gangrenous (or infantile) pemphigus.*—(Pemphigus infantilis of Willan, rupia escharotica of Bateman and Biett.) Bateman and Biett place this disease under the head *rupia*, but improperly, for the fluid of the bullæ in this disease is a thin sanious ichor, neither forming thick crusts, nor turning purulent, which are the distinguishing characters of rupia. This form of pemphigus is exclusively confined to children, and very rarely attacks them after the age of five years. In many parts of Ireland this singular disease prevails to a great extent, principally among the children of the poor, and appears to be in some situations an endemic disease, but from time to time breaking out as an epidemic, attended with great mortality. This latter circumstance has probably originated the belief in the contagious nature of the disease, very generally entertained by the people of the districts where the disease is prevalent. There are, however, no satisfactory proofs in support of this opinion. Dr. Macbride, in his "Methodical Introduction to the Theory and Practice of Medicine," notices an outbreak of this disease. "In the county of Wicklow, about twenty miles from Dublin, a disease of this kind (as the author has been informed) appeared in the year 1766, but attacked only children, many of whom were carried off until the cortex was thought of as a remedy, and found equally efficacious as in the malignant sore throat." It is singular that in the same county the disease is still prevalent. It is known in different parts of Ireland under the various popular names of "white blisters," "burnt holes," "eating hive," &c. No systematic work on diseases of the skin contains either full or accurate information on this singular form of pemphigus. To Dr. Whitley Stokes we are indebted for our knowledge of its symptoms and treatment, and we cannot give that information in better words than his own.

"The approach of this disorder is sometimes, though rarely, denoted by a livid suffusion like that of erysipelas slightly elevated. This was both observed by Dr. M'Donnel of Belfast, and by Dr. Spear, in the county of Monaghan, at a time when the disease prevailed there epidemically. It more frequently happens, however, that the complaint comes on in perfect health. One or more vesicles

appear mostly larger than the best distinct small pox; these increase for two or three days, burst and discharge a thin fluid having a disagrecable smell, limpid in most cases, sometimes whitish, and sometimes yellowish, the latter less dangerous; usually the weaker the child's constitution is, the thinner is the matter. Before or after breaking, the vesicles run together, the sores become painful, with loss of substance and a thin fetid ichorous discharge; the edges of the ulcer are undermined, and it spreads quickly. The more usual seats of the disease are behind the ears, sometimes on the hands or feet, on the private parts (seldom on the arm-pit), the breasts, folds of the thighs, lower belly, on the inside of the mouth or lips. The disease however, it is said, seldom passes from the inside to the outside of the mouth. In the progress of the disorder, the ulcers enlarge rapidly, with remarkable fetor, very great discharge, and livid edges. If the sores are behind the ears, they destroy the connexion of the posterior cartilage with the cranium; they spread to the meatus auditorius; to the eyes, the sight of which seemed in a few cases to have been destroyed one or two days before death; and they sometimes extend to the vertex. The constitutional disturbance that accompanies this disease seems principally the effect of irritation. When the vesicles burst, the child begins to grow peevish and fretful, pale, loses its appetite, and the flesh becomes remarkably flabby. The periods of this disorder are not very regular; but it often happens about the eighth day that the pulse sinks, the lividity spreads over the whole sore, the fetor and discharge increase greatly. The smell is so strong as often to be perceivable at a distance from the bed. The discharge in one case where the ulcers affected the arm-pits and breasts, was such that the linen was completely loaded several times a day. Death takes place about the tenth or twelfth day, often preceded by convulsions, sometimes by extreme debility. Patients are apt to relapse soon after the sores are skinned over. The causes of this malady are rather obscure. It seems exclusively confined to children. Dr. M'Donnel saw twenty cases before the year 1795; all the patients were under four years old. Dr. Spear observed that it was confined to children from the age of three months to that of five years; but it has been observed near Dublin in children of nine years old. It attacks the finest children in preference; the children of the poor more frequently than those of the affluent; and those who live in damp situations seem more peculiarly subject to it than others. The disease is more prevalent in summer than in winter. It appears to be infectious, though obscurely so in general; but in the year 1800, Dr. Spear observed it to spread epidemically. It has been said that the disease oftener affects the younger from the older than the reverse. It would be interesting to determine whether it attacks the same person twice; it certainly is apt to return after apparent recovery. Children, as is well known, are subject to excoriations behind the ears which sometimes produce formidable sores; these may possibly, in a few cases, resemble the disease we speak of, in its advanced stages; but in a great majority of cases these excoriations are far less rapid and dangerous than the complaint in question. On the other hand, the swine-pock (varicella) resembles this disease in its first stage; but the fever rarely precedes the eruption in white blisters, and pustules of varicella dry readily.

"This is a disorder of great danger, but of various progress in different individuals. It often happens that a fatal change takes place about the eleventh day. The unfavourable signs are, the rapidity with which the sores spread; the blackness, first at the edges, after some time spreading over the whole; the quantity and fetor of the discharge; its colour, the paler being the most dangerous.

"It has been alledged by empirical practitioners in this disease, that after the blackness had covered the whole sore, death was certain; but I have observed the blackness to go off, although it had spread over the whole surface of the sores. When this appearance abates, livid streaks generally remain for a day or two. When a favourable change is effected in bad cases, the diminution of the fetor and discharge were the first signs of the abatement of the malady; appetite was afterwards restored."*

Dr. M'Adam, in a paper on this disease in the same journal (vol. i. p. 307) states that the discharge from the vesicles is acrid, and that he has seen erosions produced on the breast by fluid which fell accidentally from the vesicles. This disease was very fatal and very unmanageable in all its stages. Dr. Willan says, speaking of pemphigus infantilis, that treatment was attended with little success. All ordinary modes of treating the disease having failed, Dr. Stokes was led to search after a traditionary empirical cure of which he had heard a favourable report. He carefully watched over some cases treated by a person who professed to possess the secret of curing the disease, and having satisfied himself that the treatment was successful, he made himself acquainted with its details. The principal application was a compound green ointment composed of a great number of herbs, some active and some inert. From one plant, "scrophularia nodosa" *(great figwort)* occurring in several receipts which Dr. Stokes procured, he was led to fix upon a simpler ointment made from this plant alone; the following are his directions for treatment. "When the parts adjoining the sores are swelled, and strongly suffused with a dusky redness, or if the sores have been previously dressed by any dry powder, I apply a poultice of porter and oatmeal. The carrot poultice in fermentation, if it can be procured without any delay, would perhaps be useful. After about eight hours, the poultice should be removed, and the parts affected

* Dublin Medical and Physical Essays, vol. i. p. 146. 1807. On an Eruptive Disease of Children, by Whitley Stokes, M.D. S.F.T.C.D., Professor of the Practice of Medicine.

very gently wiped with a roll of lint or soft rag; then the scrophularia ointment should be applied. It should be as highly saturated with green vegetable matter as possible. For this purpose the plant should be taken fresh, the smaller leaves selected, and stewed a considerable time with as small a quantity of unsalted butter as will be sufficient to prevent the leaves from being scorched. If well prepared, it is of a full grass-green colour; but after keeping it becomes the colour of box leaves, especially at the surface; yet I apprehend it preserves its efficacy, in a great degree, for many months. When applied, it should be melted and suffered to cool to the consistence of honey; it should be applied by a soft feather, with the utmost gentleness, to the whole surface of the sore. Through the whole of the treatment, the greatest gentleness should be used. If the ear is strongly drawn open, the parts affected are made to bleed, which produces many inconveniences, and retards the progress of the cure. After smearing the ulcer with the ointment, it should be dressed with the same ointment, with the addition of one-eighth part of wax. This last ointment should be spread on lint folded to the dry side, and cut so as to fit behind the ear; the whole should be secured by a broad bandage, drawn under the chin, and fastened over the top of the head. This dressing, in very severe cases, should be repeated every fourth or sixth hour; but as the fetor abates, larger intervals may be allowed. I do not pretend that this treatment will always succeed; but perhaps, of four such cases as may occur to any practitioner, not excluding the most hopeless, it will succeed in three on an average: and if we could accurately ascertain the mortality which takes place when other methods are used, we should consider this proportion of success as very satisfactory." This ointment is now introduced into the Dublin Pharmacopœia, and is found a most useful application, not alone in the disease here noticed, but in many other affections of the skin and scalp. Dr. M'Adam, in the paper already alluded to, speaks favourably of the internal exhibition of cinchona in this disease, and of the external application of strong ung. hydrargyri nitratis.

(D. J. Corrigan.)

PERCUSSION. See AUSCULTATION, and CHEST, EXPLORATION OF THE.

PERFORATION OF THE HOLLOW VISCERA.—This term is generally employed to designate a solution of continuity in consequence of disease of the walls of a hollow organ. The term *spontaneous perforation* has likewise been applied to those perforations which occur without having been preceded by any perceptible modification of function, local or general.

Perforation is far from being a rare occurrence in several organs of the body, and has been observed to take place under various circumstances in most of them. The relative order of its frequency may be stated as follows: the organs of respiration; digestive organs; organs of generation in the female; vascular system; urinary organs; hollow bones; the eye and the ear.

Perforation of the parietes of the three great cavities is occasionally observed, and perhaps more frequently in those of the abdomen and head than in those of the chest.

When perforation takes place in any of these parts, a preternatural communication is established between two or more natural cavities; between these and an accidental cavity formed in consequence of ulceration, mortification, or the accumulation of pus, blood, or other fluids in the solid viscera; and between one or both of these and the external surface of the body. Hence it follows that perforation may give rise to the effusion of a natural or accidental fluid into a serous or mucous cavity, or on the external surface of the body, and which, consequently, may be either retained or rejected.

Perforation may, however, occur without a communication being established between the perforated organ and a natural or accidental cavity. This is accomplished in two ways; 1st, by the union of a neighbouring organ with that which is perforated previous to the occurrence of this lesion; 2dly, by the formation of a false membrane between which and the surface of the perforated organ an organic union had previously been established.

Examples of these two modes in which a preternatural communication from perforation is prevented from taking place between two or more hollow organs, or between these and accidental cavities, are often met with in the abdominal and thoracic viscera. One, two, or more portions of the small intestine are found more or less firmly united over ulcerations of greater or less extent which occupy in depth the whole of the coats of these portions of intestine. A portion of the epiploon has been found adhering to the surface of the intestine or gall-bladder, and covering perforations of these organs; and the liver, spleen, pancreas, mesentery, transverse arch of the colon, and diaphragm, furnish striking examples of the means which nature employs to supply the loss of substance occasioned by several diseases, of all the coats of the stomach, and to prevent a communication from taking place between the cavity of this organ and that of the abdomen and thorax. Similar examples are met with in the lungs when these organs are the seat of tubercular excavations. The walls of these excavations, particularly when they occupy the upper lobes of the lungs, are often found to be formed in great part by those of the chest, the pleura pulmonalis and costalis over the excavation being intimately united by immediate contact, or by means of dense cellular or *cellulo-fibrous* tissue.

The second mode of prevention of a preternatural communication from perforation, viz. the formation of a cellular or serous membrane, is much less common than the former. The presence of this accidental serous or cellular membrane may be confined to that portion only of the walls of the organ in which the perforation exists, or it may extend over the

reater part or even the whole of the serous urface of the affected organ. It is almost lways of a limited extent on the peritoneum hen it forms a barrier to the escape of the ontents of the intestines into the cavity of the bdomen, and more or less extensive on the leura when it accomplishes a similar purpose, amely, when it prevents air, pus, or other uids contained in the lungs, from passing into ie cavity of the chest.

Perforation has been found to occur in consequence of ulceration, mortification, inflammatory softening, and chemical dissolution. Among these organic lesions, those which give se most frequently to perforation are ulceration and mortification, because of these diseases ccurring in almost every organ of the body. Inflammatory softening and chemical dissolution being, on the contrary, met with only in ertain organs, are much less frequently the auses of perforation.

We shall now take a general view of perfotion as it occurs in the different organs of the ody in consequence of one or more of the sions we have named, and shall confine ourelves to the description of its anatomical chacters, and such other circumstances as may ppear necessary to illustrate this part of its athology, as the symptoms and treatment will e given in the history of those diseases by hich perforation is preceded or followed, and which we shall occasionally refer.

I. *Perforation of the digestive organs.*— his lesion most frequently occurs in that porion of the digestive tube situated beneath the aphragm, and more frequently in the intesnes than in the stomach. In both it may cur either during life or after death. In the rmer case it is the consequence of ulceration mortification; in the latter it depends on the resence of an acid, formed most frequently in e stomach during the process of digestion. It curs besides in the stomach in consequence the introduction of irritant and acid poisons. We are not disposed to believe, and we think at facts are wanting to prove, that perforation the stomach or intestines takes place in conquence of inflammatory softening of the walls these organs; but as the facts on which we und this opinion will be given in detail in e article Softening, we shall not enter at esent upon the investigation of the numerous d important questions which this subject volves.

11. Perforation of the superior portion of the gestive tube is occasionally observed to take ace in consequence of several of the diseases which it is subject, as well as from some hers which occur in some of the neighbouring gans. In the œsophagus it is occasioned rhaps most frequently by cancer, formed ther in the walls of this tube or in the cellular sue external to it. In this case the walls of is muscular tube may be destroyed within a nited extent without any communication ing formed between it and any neighbouring vity; or, if the disease extends to the trachea pleura forming the mediastinum, a commucation may be formed between the cavities of both and that of the œsophagus, through which a portion of the food and drink of the patient may pass, and give rise to the most distressing symptoms. It is indeed owing to this circumstance alone that we are enabled to detect the existence of such a communication, at least between the trachea and œsophagus.

The upper part of the œsophagus behind the larynx is sometimes the seat of ulcers, which, extending to the cellular tissue situated between it and the latter, form collections of pus which impede mechanically, to a certain degree, respiration and deglutition. The inferior portion of the œsophagus has several times been found perforated, particularly in children, in consequence, we believe, of the chemical action of the gastric acid after death.

Aneurisms of the aorta occasionally produce perforation of the œsophagus, into which the blood is effused in greater or less quantity, so that the patient may live only a few hours, or several days, after the occurrence of the accident. In some cases there is no difficulty of swallowing from compression of the œsophagus, so that the progress of the aneurism in that direction is not suspected till the perforation takes place. In others, this termination of the disease may be predicted from the obstacle opposed to the passage of the food or drink.

Perforation of the velum and palate is generally observed to take place in consequence of ulceration or necrosis, and in those persons who have taken large quantities of mercury for the cure of venereal diseases.

Perforation of the stomach occurs in consequence of ulceration and mortification of a limited portion of its walls. The ulcer which is found to have produced the perforation generally bears the characters of having been produced by chronic inflammation, that is to say, its edges are hard and thickened, although sometimes neither of these states, particularly the latter, are present. The extent of the perforation compared with that of the ulcer is always small, and its border, which is formed by the peritoneum, is generally smooth. Perforation arising from this cause is met with in general at the small curvature or pyloric portion of the stomach, rarely at the great curvature, and perhaps never at the fundus.

Perforation of the stomach from cancer may be mentioned at present, as this disease gives rise to perforation not only from the softening of the tissue of which it is composed, but also from the ulcerative process which accompanies its latter stage. Perforation of the stomach from cancer occurs, however, most frequently on account of the softening or sloughing of the cancerous tissue when it occupies all the coats of the stomach, and on this account the solution of continuity produced by these changes is larger than that occasioned by any other cause during life, except when it follows the operation of corrosive poisons.

Perforation from cancer may occur in any portion of the stomach, but is most frequently met with at the pyloric portion and at the small curvature.

It is rare that perforation from this cause is

followed by a communication between the cavity of the stomach and that of the abdomen, on account, as we have before stated, of some of the neighbouring organs becoming united to the stomach before the perforation is completed. This very circumstance, however, which prevents the establishment of a preternatural communication between the stomach and the cavity of the abdomen, gives rise, at some future period, to those complicated cases of perforation in which a direct communication is formed between two or more of the abdominal organs, or between these and the contained viscera of a neighbouring cavity, or the external surface of the body. Examples of these three modes of communication are met with as the consequence of perforation of the stomach. Thus, it is not rare to find the walls of the transverse arch of the colon perforated where they had before occluded a perforation of the stomach, and a communication established between the respective cavities of these organs.

In the same manner is occlusion of a perforation of the stomach by the diaphragm followed by perforation of the latter, from which the ulcerative or sloughing process by which this lesion had been produced, extends to the inferior lobe of the lung, which had become united to the diaphragm. In this manner a portion of the lung is destroyed, several of the bronchi are laid open, and a communication formed between these tubes and the cavity of the stomach, and consequently between the latter and the external surface of the body. Lastly, it sometimes happens that the cavity of the stomach communicates with the external surface of the body, from the successive perforation of the walls of this organ and of those of the abdomen.

In all the examples of perforation of the stomach to which we have alluded, this lesion is represented as having taken place from within outwards. It may, however, occur in the opposite direction, or, as is said, from without inwards. Examples of this kind of perforation are rarely met with, except in cases of cancerous tumours situated in the left lobe of the liver, the mesentery, or mesenteric and lymphatic glands, and in scrofulous enlargement of the latter glands.

Mortification, so far as we are aware, has not been known to give rise to perforation of the stomach, unless when it has been produced by the presence of an accidental tissue, such as that of cancer, as in the cases to which we have alluded, or when it follows the violent operation of powerfully irritant or corrosive poisons, directly applied to the walls of this organ. In this latter case the vitality and, to a certain extent, the organization of that portion of the stomach to which the poison has been applied, are destroyed. The portion thus circumstanced sloughs, and the cavity of the stomach, if adhesion has not taken place between this organ and a neighbouring one, is laid open, and its contents pass into that of the abdomen. The solution of continuity thus produced may vary from the fourth of an inch to two or three inches in diameter, and has mostly a round form. Its edges are seldom irregular, and should they happen to be so, they are not thicker than the walls of the stomach, unless blood or serosity has been effused into the cellular tunic; the density of the tissues of which they are formed is seldom or only partially increased, and never so diminished that they assume a gelatinous consistence. The colour which they present is either that produced by an accumulation of blood in the capillaries, or by the effusion of this fluid into the cellular tissue which enters into their composition, or by the chemical action of the poison either on the blood or on the tissues which form the boundaries of the perforation. In the former case the edges are more or less red, or vascular, or both; in the latter they possess either a yellowish or orange tinge, or various shades of brown, amounting to black, as if they were painted with bistre, or dusted over with charcoal-powder or soot. Irritating poisons may produce the former appearances, but not the latter, which we believe are the effects of those poisons only which possess acid properties, as the nitric, muriatic, sulphuric, and oxalic.

The *post-mortem* appearances of perforation of the stomach from the introduction of acid poisons, in particular, into this organ, still require to be investigated with greater care than hitherto has been done, and particularly by means of a series of experiments on living animals, before we can affix to them that diagnostic importance of which they seem susceptible, or refer to them with confidence as medico-legal evidence in cases of poisoning. Perhaps even in the present state of our knowledge on this subject, may the toxicologist derive more assistance from the study of the *post-mortem* appearances of perforation of the stomach from acid poisons than is generally believed. But in order to do so, he must be intimately acquainted with those of all the other forms of perforation, particularly that produced by the gastric acid after death. We shall give a general sketch of the physical and chemical effects of this acid on the stomach, and endeavour to point out the means by which they may be distinguished from those produced during life by the acid or irritant poisons which have given rise to perforation.

Perforation of the stomach in consequence of the chemical action of the *gastric acid* takes place almost always in the most depending part of this organ, viz. the fundus. In those cases in which it has been met with in other parts of the stomach, accidental circumstances have concurred which afforded a satisfactory explanation of this difference as to its seat. The size of the perforation is generally large, often occupies the whole of the fundus, and sometimes a part of the body of the stomach. Its form is almost always irregular; its edges are thin, ragged, more frequently fringed or filamentous. The tissues of which it is composed are soft, pulpy, gelatinous, and more or less transparent; either perfectly pale, of a milky hue, or streaked with lines or stripes of

a pale yellow, orange, brown, or black colour. These colours are always most marked in, or limited to, the mucous and submucous tissues, the muscular and serous coats which form the fringed edges of the perforation being quite pale. It is of the greatest importance to observe that these colours are always accompanied with softening of the mucous and submucous coats to a greater or less extent beyond the perforation; or, if these coats have been destroyed, the muscular is found similarly altered. If the bloodvessels, whether the capillaries or larger branches, were filled with blood at death, this fluid, wherever the coats of the stomach are softened, presents either the brown or black colour of chocolate or soot, and assumes of course the form and distribution of the vessels in which it is contained. Such is always the chemical effect of the gastric acid on the blood after death, and therefore we arrive at the important conclusion that redness, whether arising from the effusion of blood or vascularity, is incompatible with perforation from this natural chemical agent.

From these, the most remarkable of the *post-mortem* appearances which accompany perforation of the stomach from the gastric acid and acid poisons, it appears to us that such evidence may be obtained as will enable us to distinguish perforation produced by the former from that produced by the latter.

The pulpy, thin, transparent, pale, fringed edges of the perforation from the gastric acid; its situation in the fundus of the stomach; the presence of softening of the coats of this organ beyond the perforation, accompanied with discoloration of the blood only where this softening exists, and the entire absence of redness under any form in the same situation, are characters which we do not believe belong to any other form of perforation. Were it necessary to seek for still stronger evidence in favour of this opinion, we would refer to the histories of the cases of the individuals in whom these appearances have been found after death, to the results of our own experience on this subject in animals, and in particular to that strong collateral evidence by which it is supported, viz., the entire absence of all the anatomical characters of peritonitis, such as redness, increased vascularity, coagulable lymph, or adhesions in the neighbourhood of the perforation, and in general of effusion of the contents of the stomach,—consequences which may be said to follow invariably, and to a greater or less extent, perforation of the stomach from the acid poisons, or indeed any other pathological agent.

If we are correct in our estimate of the distinctive characters of this kind of perforation, it follows that this lesion cannot be confounded with any other, however similar to it, but produced by a different agent. The analogy which exists between the former kind of perforation and that produced by acid poisons depends, as we have already said, on the acid property of these poisons, and because, therefore, of the same kind of discoloration being present in both cases. The difficulty thus created is, however, not such as it has been represented; nay, we believe that the embarrassment of the toxicologist has arisen from his not being acquainted with those *post-mortem* appearances which we have endeavoured to shew are so peculiarly characteristic of the chemical action of the gastric acid. We may observe besides, that the local characters of perforation from acid poisons are in several respects very different from those of perforation from the gastric acid, as will be seen by comparing the description which we have given of them with those which accompany perforation from the gastric acid, particularly as regards the situation of the former, the character of its edges, and the redness of the tissues surrounding it, to which we may add effusion of the contents of the stomach, and peritonitis.

Perforation from cancer or chronic ulceration never can be confounded with that from the gastric acid.

Perforation in consequence of an ulcer of the stomach from common inflammation, neither acute nor chronic, cannot, perhaps, be distinguished from perforation produced by irritant and even acid poisons. But as facts appear to be wanting on this part of the subject, we must leave it in its present state of uncertainty without any further comment.

2. *Perforation of the intestines* takes place most frequently in consequence of ulceration; and in the great majority of cases in the inferior portion of the ileum, in the situation of the *glandulæ agminatæ*, or glands of *Peyer*. It may occur also in the points of the small and large intestines occupied by the *glandulæ solitariæ*, as well as in those of both intestines in which no follicles exist. The ulceration which preceded the perforation may have been either acute or chronic, but is far more frequently of the latter kind, and may have given no signs whatever during life of its existence. The ulcerated portion of the intestine is found either pale or presenting various degrees of redness and vascularity, and is accompanied with similar states of the surrounding mucous membranes. The changes in the thickness and consistence of this portion of the intestine present considerable variety, and vary with the degree and duration of the inflammation by which they have been occasioned. The perforation is sometimes not larger than to admit a common-sized probe; at other times so large as to admit the point of the fore-finger, or even of the thumb. Its edges are generally smooth, and more frequently circular than of an irregular shape, and are formed by the peritoneal coat, except in some rare cases, in which the ulceration has destroyed to the same extent the other coats of the intestine. Perforation of the small intestines may occur in one, two, or three of the glands of Peyer in the same individual, and in either case it almost always gives rise to a communication between the cavity of the intestine and that of the abdomen, followed by an effusion of the contents of the intestine, and peritonitis.

Perforation from ulceration may take place in the rectum, caput cœcum coli, duodenum,

and indeed throughout the whole of the large and small intestines, where the mesentery separates to be reflected over them, without giving rise to much effusion or a communication with the cavity of the peritoneum. But this variety of perforation is chiefly met with in the rectum and caput cœcum, and is no doubt sometimes the cause of the abscesses which not unfrequently form in the cellular tissue in the situation of these portions of the intestinal tube.

In the intestines, as in all organs covered by a serous membrane, perforation from ulceration is always preceded by *sloughing* of this membrane. When the ulcerative process has destroyed the sub-serous cellular tissue, and consequently the vessels which supplied it with the materials of its nutrition, it soon dies, and is separated in the form of a pale or grey-coloured slough, or tinged with the colouring matter of the bile or fæces, and without the odour of gangrene.

Perforation from mortification of all the coats of the intestines, is, perhaps, never met with unless in some cases of intus-susception and strangulated hernia. In the former case, the fæcal matter passes into the cavity of the peritoneum; in the latter a similar consequence may follow, but much more frequently adhesion takes place between the intestine, before it perforates, and the walls of the abdomen, when the perforation of both takes place, and a communication is established between the cavity of the intestine and the external surface of the body, or what is called an *artificial anus* is formed.

We are not aware that there is a single example of recovery from peritonitis produced by perforation of the intestines. The patient may survive the accident only a few hours, and seldom survives more than two or three days, the length of time depending chiefly on the previous state of the patient and the quantity of the fæcal matter effused, although some cases have occurred in which the quantity of this matter was so small that it could hardly be detected either by its presence or odour, while the symptoms were violent, and the disease proved rapidly fatal. See Fever, and Peritonitis *from perforation of the serous membrane.*

Perforation of the intestine from poisons has not, so far as we know, been observed. There are, however, several examples of its having been produced by the gastric acid after death, but which have been regarded by some pathologists as the consequence of disease,—an opinion, the accuracy of which will be particularly examined in the article Softening.

Perforation of the intestines from without inwards is occasioned by the same diseases as those mentioned as giving rise to this variety of perforation of the stomach. Tubercles and abscesses, are, however, the most frequent causes of it in the intestines. We have seen the former perforate the intestine in a number of points, without any traces of inflammation of the mucous membrane around the perforation, and without a communication being formed between the cavity of the intestine and that of the peritoneum. The abscesses which perforate the intestines are retro-peritoneal, and most frequently those situated in the loose cellular tissue situated in the ilio-cæcal region. The coats of the intestines, generally the cœcum or commencement of the colon, are gradually destroyed by ulceration, and a quantity of pus in proportion to the size of the abscess is evacuated by the anus.

The preternatural communications which are found to take place between the intestines and neighbouring organs, in consequence of perforation of the former, we have already alluded to generally, and they are by no means so frequent as when they are occasioned by perforation of the latter. Sometimes portions of the small intestines are found united together, and communicating with each other by means of several perforations, through which the liquid fæces pass in greater or less quantity, and examples have been met with in which the passage thus formed was lined with an accidental mucous tissue. In the cases of preternatural communications of this kind which we have seen, the perforated intestines were included in a common accidental serous envelope, the evidence of peritonitis having existed at some remote period; and the coats of the intestine more or less destroyed by tubercular ulceration commencing in the glands of Peyer. We do not believe that the peritonitis in such cases was the consequence of the effusion of fæcal matter from perforation of the intestine. We believe, on the contrary, that it is produced before the perforation of the serous membrane is accomplished, so that the coagulable lymph which is thrown out becomes organized and united with a neighbouring portion of intestine. Afterwards the ulceration proceeds, and the preternatural communications we have described are effected.

Another variety of preternatural communication of the small intestines, and which takes place in a manner similar to the former, is that in which there exists cellular adhesions between the perforated portion of intestine and the walls of the abdomen. The effused fæcal matter is prevented by the presence of this tissue from passing into the cavity of the peritoneum. In this tissue it collects in greater or less quantity, and as the abdominal parietes with which it is in contact are more susceptible to its stimulating effects than the former, they become inflamed, ulcerate, and are perforated, and a communication is established between the intestine and the surface of the body, through which the fæcal matter escapes. Andral mentions a case of this kind. Besides the fæcal matter there escaped an ascaris lombricoides, and several of these worms were found, after the death of the patient, contained in the cavity formed in the accidental cellular tissue which united the perforated intestine with the perforated walls of the abdomen.

Although it is said that worms perforate the intestines, we have never seen a case of perforation which could in any way dispose us to attribute it to such a cause. Were such a case

o happen, it could only be in consequence of nflammation and ulceration excited by these nimals; and yet we have found them very umerous, in one instance amounting to thouands, without the slightest trace of inflammaon of the mucous membrane.

There are a few examples of the walls of the bdomen being perforated in consequence of rge collections of purulent fluid in its cavity; nd we may mention here that perforation of ne diaphragm may take place in cases in which similar collections are formed in the avity of the pleura.

3. Perforation of the walls of the liver, which orm the boundaries of an abscess situated in is organ, and of the gall-bladder, may with ropriety be noticed in this place. Perforation f the former, with effusion of the contents of ne abscess into the cavity of the abdomen, is y no means common, because of adhesion aking place, previous to the occurrence of this ccident, between the peritoneum covering ne abscess, and that of the stomach, colon, alls of the abdomen, or diaphragm. Under nese circumstances, however, the perforation ay afterwards extend to the hollow organs we ave named, and establish a communication etween them and the cavity of the abscess, by eans of which its contents are evacuated by omiting or by stool. A communication beween the abscess and the external surface of ne abdominal parietes where they cover the bscess, is more common than the former. When the diaphragm adheres to the abscess, nd is perforated, three consequences may follow:—the contents of the abscess may pass nto the cavity of the chest; into the bronchi, om a portion of the lung which had adhered o the diaphragm having been destroyed by lceration or sloughing; or into the cavity of the hest and bronchi at the same time. We have een only one case of the last variety of perforaion of abscess of the liver, or, more correctly peaking, of a purulent cyst containing a great umber of hydatids. Although these vesicular nimals have sometimes been expectorated in ases of this kind, such did not happen in the ase to which we allude. The communication etween the bronchi and cyst took place first, ollowed by a yellow-coloured expectoration, which, because of the existence of the cyst in he liver having previously been detected, was upposed to be owing to the passage of the bile nto the bronchi from perforation. Soon afterward, symptoms of pleurisy manifested themelves, accompanied with those of effusion and neumothorax, the real nature of which was not nderstood till after death. Only one opening vas found in the diaphragm, where it covered a yst from six to seven inches in diameter, conaining a yellow, puriform fluid and hydatids. This opening, sufficiently large to admit the ore-finger, communicated with an excavation ormed in the inferior lobe of the lung, which dhered but slightly to the diaphragm. In the ottom of this excavation there were several penings, some of them, which were small, communicating with the bronchi, others larger, eading into the cavity of the pleura. This cavity contained a quantity of air, yellow scropurulent fluid, and a great number of large and small hydatids. The lung was considerably compressed, and the pleura covered with recent coagulable lymph.

Perforation of the gall-bladder occurs rarely except when biliary concretions, of considerable size, are lodged within it. In such cases the preternatural communication generally takes place between this organ and the ascending or transverse portion of the colon, through which these concretions pass into this intestine, and are voided by stool. A similar mode of transmission is afforded them when they are enclosed in the ductus communis choledochus. Their transit from either of these situations into the intestine may be accompanied with violent paroxysms of pain, or no pain at all; a difference which is not easily explained. In one case, in which the pain was extremely severe, and which terminated fatally, we found the duodenum perforated in four or five points near the pylorus, and communicating with the gall-bladder, which contained two large concretions. In two other cases, on the contrary, from the history of which we could not learn that the patients had ever suffered from any of those symptoms attributed to the passage of gall-stones, and who died of diseases unconnected with any derangement of the hepatic organs, we found in one of them a communication existing between the gall-bladder and the colon, in which a concretion was lodged and projecting into the latter, the mucous membrane and other coats of this intestine being quite healthy. In the other case there existed a similar communication, presenting the character of a fistulous passage (for it was lined with a mucous membrane), about half an inch in length, into which a small probe only could be passed. The gall-bladder was empty and greatly atrophiated in both cases, the natural consequence of the cessation of its function. Perforation of the gall-bladder from ulceration is not common. The only case worth noticing which has come under our observation, was one in which double perforation took place from ulceration of the walls of this organ. One of the perforations was situated towards the free surface of the gall-bladder, and was prevented from communicating with the cavity of the abdomen by the adhesion of a portion of the epiploon: the other was formed where this organ is in contact with the liver, so that the bile was effused between them, and had formed for itself a cavity of considerable size, covered superiorly only by the peritoneum, which rose above the surface of the liver. On this account it could be felt through the parietes of the abdomen, accompanied with the sensation of fluctuation, circumstances which led the physician to diagnosticate the existence of an abscess of the liver. Caustic potash was applied preparatory to laying it open, but the patient died two days after, before this plan of treatment could be carried into effect.

II. *Perforation of the respiratory organs.*—As perforation of the bronchi and pleura will be described in the articles PLEURISY and

Pneumothorax, and as a description of it produced by mortification has already been given under that head, we shall only mention a few facts, with regard chiefly to the comparative frequency of its occurrence in the tubercular diseases to which the lungs and some of the neighbouring organs are subject.

The presence of tuberculous matter in the lungs is by far the most frequent cause of perforation of the pleura or bronchi, both of which it destroys within a limited extent, by means of the ulceration or mortification which its presence occasions. It is only when situated beneath the pleura that the tuberculous matter gives rise to a communication between the cavity of this membrane and the bronchi, or when a tubercular excavation occupies the same situation. The escape of the air into the cavity of the pleura is not always the consequence of perforation of this membrane and of the bronchi. We have already stated that the opening in the former is sometimes closed by adhesion of the pleura, and by accidental serous or cellular tissue, which consequently prevents the air or other fluids from passing into the cavity of the chest. It is in this way that perforation of the thorax takes place, and that a communication is established between the surface of the body and the bronchi, through which the air enters and escapes. But should the perforation take place in the mediastinum and bronchi, the inspired air is effused into the cellular tissue included within the former, whence it passes to that of the neck, face, and chest, and may produce extensive and distressing subcutaneous emphysema.

Perforation of the bronchi without perforation of the pleura is a much more frequent occurrence than the former, in whatever part of the lung the tuberculous matter may have been deposited. In this case the bronchi may be simply perforated, or perforated and communicating with a tubercular excavation. Perforation of the bronchi is not an unfrequent consequence of the accumulation of tuberculous matter in the bronchial glands, or the presence of cretaceous matter in these bodies. The former occurs in young persons, and especially in children: the latter sometimes in middle-aged persons, but most frequently in those advanced in life.

This kind of perforation may sometimes be detected during life, from the presence of considerable masses of tuberculous matter or concretions in the sputa. Perforation of the bronchi from the latter cause undergoes sometimes a cure, from obliteration or cicatrization, after the entire evacuation of the concretions.

The most fatal kind of perforation of the bronchi is that which is accompanied by perforation of a large branch of the pulmonary artery. This complication takes place in two ways:—first, a large bronchus, most frequently the first or second branch of the trachea, and a corresponding branch of the pulmonary artery, are perforated by a tuberculated bronchial gland situated between them. In this case a direct communication is formed between the blood-vessel and bronchus, and the hemorrhage which ensues is so great and rapid, that the blood is thrown forth as if vomited, sometimes by the nose as well as the mouth, and may terminate fatally in from ten to twenty minutes; secondly, a tubercular excavation with which several bronchi communicate, extends in the direction of the pulmonary artery or one of its principal branches to which it adheres. The corresponding portions of the walls of the artery and those of the excavation ulcerate or slough, and hemorrhage takes place, first into the excavation, and afterwards into the bronchi. It is on account of this indirect communication between the perforated vessel and bronchi that hemorrhage in cases of this kind is generally small at first, diminishes and increases at irregular intervals, and sometimes continues for several days.

Perforation of the pleura from abscess, and the effusion of blood under the pleura in pulmonary apoplexy, is not common. In the cases which we have seen of the latter kind, the pleura appeared to have sloughed because of its having been separated from the cellular tissue by the effused blood.

Chronic pleurisy with effusion sometimes terminates in perforation of the walls of the chest or diaphragm; and there are examples of fluid making its way into the bronchi, whence it was expectorated, and the disease terminating favourably.

For perforation of the bronchi and trachea from aneurism, see Aneurism of the Aorta.

III. *Perforation of the organs of generation.*—Perforation of these organs in the female, after the middle period of life, is very common, and, in the great majority of cases, in consequence of cancer. Cancer of the uterus and vagina may give rise to perforation of the walls of both, and a communication be established between them and the following organs: between them and the bladder, or rectum separately, or between them and both of these organs at the same time. Hence the urine, fæcal matter, or both, may be passed in greater or less quantity by the vagina, and sometimes the latter makes its way also into the bladder.

Perforation of the posterior walls of the neck of the uterus or upper portion of the vagina, is not unfrequently followed by perforation of the peritoneum, and as the progress of the disease upwards is generally accompanied with sloughing of the cellular tissue behind this membrane and the neck of the uterus, a putrid sanies is poured into the cavity of the former, which gives rise to peritonitis, rarely less violent than that which is occasioned by the presence of fæcal matter. Perforation of the peritoneum is sometimes arrested by the adhesion of a portion of small intestine, which may either remain entire, or afterwards become perforated. The latter is the more frequent occurrence.

Caries and necrosis of the bones of the sacrum may give rise to perforation of the upper part of the vagina, from the ulceration and sloughing of the cellular tissue situated between them extending to the latter organ. Such a case may readily be confounded with perforation from cancer.

Perforation of the ovaries and Fallopian tubes seldom occurs. We have met with it in one of the latter, between which and the rectum there existed a communication, through which a purulent fluid, the contents of the tube, escaped, and was passed by the anus. In another case, in which the left ovary was transformed into a purulent cyst, similar consequences followed. Both patients died of other and complicated disease of the uterus. In another case, a communication existed between the left Fallopian tube and ovary. The ovary formed a cyst as large as the two fists; the Fallopian tube was from an inch to two inches in diameter, and both were filled with a sero-purulent fluid, none of which, however, appeared to have passed into the cavity of the uterus. For further information on this subject, see Diseases of the Uterus and Ovaries.

IV. *Perforation of the urinary organs.*—1. Perforation of the bladder occurs most frequently in the female, and from the extension of cancer of the uterus, to which we have already alluded. It is also occasioned by ulceration or sloughing in consequence of pressure during pregnancy or delivery; chiefly in deformity of the bones of the pelvis, or from the improper use of instruments when employed to extract the fœtus.

In the male it is more often occasioned by the catheter left in the bladder in cases of paralysis of this organ, and in stricture of the urethra in old men, than by any other cause. The perforation is generally the consequence of sloughing of the walls of the bladder which were in contact with the point of the catheter.

2. Perforation of the walls of the kidneys seldom occurs. When it happens, the loose cellular tissue with which these organs are so abundantly surrounded, becomes the seat of abscess. In one case of this kind which we examined, a small abscess was situated between the kidney and descending colon, and communicated with the cavity of this intestine. In another, an abscess containing several pints of pus, and situated between the kidney, descending colon, and lateral walls of the abdomen, likewise communicated with this intestine. The quantity of pus passed by stool in the latter case was considerable. The substance of the kidney was almost entirely occupied with tuberculous matter, as well as the infundibula and pelvis. In the former, the pelvis of the kidney contained a large calculus, and its substance was converted into a firm uniformly grey tissue. Both cases terminated fatally. The patient, a female, in whom the former case occurred, was about twenty years of age; the other was a man above fifty.

V. *Perforation of the organs of circulation.*—Perforation of these organs may be considered as it occurs in the heart, arteries, and veins. The occurrence of this lesion in the arteries is infinitely more frequent than in the heart or veins, owing obviously to their being subject to diseases which rarely affect the latter, as well as to the impulse of the blood, and the distension occasioned by this fluid propelled into them by the heart: thus, perforation of the arteries, in the great majority of cases, takes place in consequence of the deposition of a substance resembling bone, chalk, or putty, which often destroys their walls, or deprives them of their elasticity. In the first case, the internal and middle coats may be perforated without their having undergone any previous change of capacity, so that the cellular coat, being brought in contact with the blood, is pushed outwards by this fluid, and forms what is termed *circumscribed false aneurism*. In the second case, the internal and middle coats being deprived of their elasticity by the presence of one or other of these substances we have named while yet in a fluid state, yield to the continued impulse of the blood, and ultimately form a sac or pouch of various dimensions, occupying either a portion or the whole of the circumference of the artery, and which, under these circumstances, constitutes what are commonly called *circumscribed* and *diffuse true aneurism*. Perforation of the dilated coats of the artery takes place at a subsequent period, first in the internal and middle, and afterwards in the cellular. In whichever of these ways the aneurism is produced, perforation of the cellular or outer coat of the sac may take place under the two following circumstances;—first, when the surface of the aneurism is free from adhesion with a neighbouring organ, as sometimes happens when it is lodged in the thorax or abdomen, when the blood is poured into the serous cavity of either of these parts of the body; secondly, after the aneurism has become united with a neighbouring hollow organ, or the walls of the cavity in which it is contained, when, after the perforation of either of these, the blood is effused either directly on the surface of the body, or escapes by one of the natural passages, for example, the œsophagus or trachea.

Perforation of the arteries (we speak of the larger branches or trunks) is not unfrequently the consequence of ulceration proceeding from without inwards. When this happens, the ulceration may take place originally in the walls of the artery which becomes perforated; or in a portion of an organ in the immediate vicinity of an artery, to which it afterwards extends, producing a solution of continuity of its walls. We have already given examples of perforation of the former kind in the case of tuberculated bronchial glands; and examples of the latter are met with in several organs, and particularly in the stomach in some cases of chronic ulcers, in which one of the coronary arteries or a large branch happens to traverse the bottom of such an ulcer, and becomes perforated by the ulcerative process.

When cancer produces perforation of an artery, it is, in general, owing to the walls of the vessel having been destroyed by the extension of this disease to them than by ulceration. The same is the case in perforation of veins from a similar cause. These vessels are not so often perforated by ulceration as the arteries, and the hemorrhage is seldom great unless they are considerably dilated, as in hemorrhoids; or their walls much thickened and united with

indurated cellular tissue, which prevents them from collapsing, as sometimes happens in the case of chronic ulcers of the inferior extremities, accompanied with varicose dilatation of the veins. In a case of this kind which we had occasion to examine, the hemorrhage which followed the perforation of the vein was so great that the patient, a man about forty years of age, expired in little more than ten minutes.

There are a considerable number of examples of perforation, more commonly termed *rupture*, of the heart. The portion of this organ the most subject to this lesion is the inferior and middle portion of the left ventricle. Sometimes softening or ulceration, at other times atrophy of the muscular substance in the situation of the perforation, are the lesions which are found to precede the occurrence of this accident; at the same time, the walls of the ventricle are, in general, more or less hypertrophiated.

There may be one, two, or three perforations which traverse the walls of the ventricle either perpendicularly or obliquely. In the latter case the hemorrhage which ensues does not, it is said, prove so suddenly fatal as in the former case. It does not appear that the *quantity* of blood effused bears a necessary relation to the length of time that supervenes before death takes place.

We have no certain evidence to show that perforation of the heart is curable, although Rostan relates a case in which he conceived he saw the cicatrix of a perforation of the left ventricle in a patient, who was supposed to have presented the symptoms of this lesion some time before her death, which was occasioned by a second perforation.

Perforation of the valves of the heart is seldom observed except in those of the aorta, and in the cases which we have seen, it appeared to be the consequence of the presence of osseous or cretaceous matter deposited in their substance or between their laminæ.

VI. *Perforation of hollow bones* occurs in cancerous affections of their walls, and when pus or hydatids are contained within them. The latter generally produce perforation by exciting inflammation and caries of the bone; the former, by the gradual transformation of a portion or the whole circumference of the bone into a lardaceous or cerebriform substance. In this case, fracture more frequently takes place than perforation of the bone.

VII. *Perforation of the eye.*—The cornea is that part of the eye which is most frequently perforated. It may be in consequence of ulceration or sloughing, accompanied or not by similar diseased states of the other tunics of the eye; by an accumulation of pus, or the presence of malignant tumours proceeding from within outwards. (See Ophthalmia.)

VIII. *Perforation of the ear.*—Perforation of the membrane of the tympanum is not very rare in severe cases of inflammation of the internal ear terminating in suppuration. The solution of continuity of the membrane, which follows the accumulation of the pus in the cavity of the tympanum, may be the consequence of ulceration or sloughing, favoured by the mechanical distention to which it is at the same time subjected. So soon as the perforation is completed, a sudden and copious discharge of puriform fluid makes its appearance, and which, if there has been no discharge before from the external orifice of the ear, may be regarded as a certain sign of its coming from the cavity of the tympanum in consequence of perforation of its membrane.

The effects of perforation of the tympanum on the function of hearing depend on the size and situation of the artificial opening, and the degree of integrity of the *ossicula* with which this membrane is connected. Suppurative inflammation of the bony structures of the internal ear may produce in a similar manner perforation of the *membrana tympani*, as well as accidental products developed in the same situation.

(R. Carswell.)

PERICARDITIS and CARDITIS.—I. Or Pericarditis.—The anatomical characters of acute inflammation of the pericardium are, 1, preternatural redness of the membrane; 2, coagulable lymph adhering to its surface; and 3, fluid effused within its cavity. These characters we shall treat of in succession, and at some length; for as the anatomical characters are the key to the symptoms, the latter cannot be understood, and, consequently, so rapid and fatal a malady cannot be treated with the promptitude and decision essential to the safety of the patient, unless the nature of the former and their intimate connexion with the symptoms are thoroughly known to the practitioner.

1. *Preternatural redness of the pericardium.*—The redness very seldom pervades the whole of the inflamed portion. It presents itself sometimes in numerous small scarlet specks, with a natural colour of the intervening membrane, sometimes in spots of greater or less magnitude formed by the agglomeration of the specks, and sometimes in patches of considerable extent. Even these, however, have, almost without exception, a dotted or mottled character. In some cases, according to Laennec, though the inflammation, judging of it by the thickness of the false membranes, had been very severe, scarcely any redness exists. Vascular injection of an arborescent and sometimes stellated appearance, accompanies redness, and is generally proportionate to it in degree. Occasionally, however, the redness is uniform, like a stain.

The pericardium is very rarely, if ever, thickened; that which is often regarded as thickening being nothing more than superimposed and intimately adherent false membrane.

When acute pericarditis degenerates into chronic, the redness loses its brilliancy, sometimes becoming very deep and of a brownish colour, and sometimes acquiring a cinnamon hue. Beneath a layer of lymph of this colour, we have seen the surface of the heart of a bluish-white appearance, like the spots so frequently found on this organ.

Redness alone does not afford conclusive

vidence of pericarditis, as all serous as well as mucous membranes are liable to vascular injection from various causes independent of inflammation. To afford such evidence, therefore, the redness must be conjoined with an effusion of lymph or sero-purulent fluid.

2. *Coagulable lymph adhering to the surface of the pericardium.*—The inflamed pericardium secretes serum and lymph conjointly, and in a fluid state, from the same vessels. Soon after the secretion has taken place, the lymph concretes, while the serum remains fluid. The former, when recent, is of a pale straw-colour, and of a soft tender consistence, becoming firmer and more tenacious as it grows older. Though occasionally deposited in detached lumps and specks, it generally forms continuous layers, sometimes covering a portion only, but more commonly the whole, or nearly the whole, of the pericardium. The thickness of the deposition may vary from a line to an inch; but from a line and a half to three lines is its ordinary mean. Its adherent surface is smooth; the opposite or free is rough and singularly figured. It is sometimes pitted with small depressions at tolerably regular intervals, presenting the aspect of a fine reticulation, or of the section of a sponge. This occurs principally where the layer is thin: where it is thick, the surface is distributed into more spacious cells, often as large as a pea, and separated by coarser partitions. The partitions are sometimes irregular, being higher and thicker in one part than another, in which case the effect is exactly that produced by separating two flat plates between the surfaces of which a layer of soft butter has been spread. At other times the partitions are very regular; in which case the appearance, as Corvisart observes, is analogous to that of the second stomach of a calf. Occasionally they are very thick and rounded, and then they have an appearance somewhat similar to that of a congeries of small earth-worms. Not unfrequently they are shaggy and flocculent, hanging in shreds like tow. Sometimes no cells are apparent, but the lymph is arranged in transverse, and, as it were, plaited wrinkles, like undulations of sand on the sea-shore. When lymph becomes old, and not adherent, it acquires a deeper hue, varying from cinnamon to an intense brown-red or mahogany colour. When of the latter colour, it usually secretes bloody fluid.

Now, what is the object which nature proposed to herself in the effusion of lymph? Unquestionably to effect reparation—the object for which the effusion is designed in whatever part of the system it takes place. But how, it may be inquired, can it effect reparation in the pericardium? By causing adhesion. Supposing that the inflammatory process does not terminate by resolution—by the complete absorption of both lymph and serum, the most desirable termination which remains is adhesion; for should this not take place, the lymph becomes a secreting surface, which effuses more and more lymph and serum, until in a short time the cavity is completely distended, and the action of the heart so embarrassed that a fatal termination speedily ensues. But, should adhesion of the opposite surfaces take place, by which further effusion is prevented, life may be prolonged for a considerable period, even for years; though, as will presently be explained, the adhesion, so far from being a perfect reparation, gives rise to another form of organic disease, which eventually proves destructive to the patient.

Adhesion takes place in some cases and not in others,—a circumstance which has been attributed to a difference in the quality of the lymph, dependent on the greater or less energy of the inflammation, in consequence of which it possesses different degrees of aptitude for adhesion. This explanation, though perhaps not unsound, is scarcely applicable to the pericardium; for here the union or non-union depends mainly on the absence or presence of fluid in the cavity: the best lymph, equally with the worst, being incapable of uniting when interposed fluid prevents the apposition of the opposite surface. Hence it is that the upper part of the pericardium, where it is reflected from the great vessels, often adheres when the lower part does not: and for the same reason it is that, when the whole of the peritoneum is covered with lymph, the intestines adhere to each other, but their adhesion with the walls of the abdomen is prevented by the interposition of fluid.

Hence the immense importance in pericarditis, of prompt and energetic treatment in the first instance, in order, if resolution cannot be effected, to cause absorption of the fluid, and thus afford the opportunity for adhesion. Temporising indecision is inadmissible; for unless one or other of these terminations be induced, the patient inevitably dies.

Such is the object of adhesion: we have now to describe the process. When the fluid has been sufficiently absorbed, the depositions of lymph on the opposite surfaces of the pericardium come in contact, thicken, blend, and gradually become organized by vessels presenting themselves under the successive appearances of blood-stains, straggling lines, and, lastly, of uniform pinkish vascularity, susceptible of injection from the pericardium. The depositions are thus converted into perfect cellular tissue, by which the contiguous parts are more or less firmly, closely, and extensively agglutinated. When adhesion is of recent standing, the lymph is generally thick, and separable by mere tearing into two layers, one adhering to each fold of the pericardium. In proportion as the disease is older, the false membrane is thinner and firmer, consisting, in cases that date several years back, of the finest layer of dense cellular tissue. In some, even this is not perceptible, the folds of the pericardium having become amalgamated—apparently without the intervention of any membrane,—so as with difficulty to be separable, even by the scalpel. It is in such cases that pathologists have sometimes erroneously supposed the heart to be destitute of a pericardium.

In some rather protracted cases, generally of at least two or three months' duration, where,

though adhesion has been established, inflammation has either recurred or never been completely subdued, an additional interstitial deposition of lymph takes place, which has been known to thicken the adventitious mass to the extent of an inch and upwards. In this case it sometimes possesses a laminated texture, the layers of which are progressively redder in proportion as they are nearer the heart; and sometimes it exhibits different degrees of consistence in different parts, one being almost liquid and purulent, while another has the density of tubercular induration.* Such cases are ordinarily fatal at no very remote period.

But adhesions are not always universal; in cases of partial pericarditis they are restricted to the portions inflamed; and when these portions are limited, the adhesions are not close or intimate; for as the gliding motion of the heart within the pericardium is not prevented, it stretches the adherent lymph, and converts it into long loose bands of cellular tissue. But when the portions inflamed are extensive, partial adhesions are sometimes close and firm, and the intervening parts of the pericardium may be healthy and in contact. Instances occasionally occur of adhesions being partial though the inflammation had been universal; and the parts not united are overspread with lymph and separated by purulent fluid, thus constituting a series of small, detached abscesses around the heart.

Cases of partial pericarditis (exclusive of white spots, of which we shall presently speak) are very rare in proportion to those of general, scarcely amounting, according to Laennec, to one in ten.† They almost always terminate in recovery, and the adhesions, if loose and long, seldom lead to enlargement of the heart.

Partial pericarditis sometimes leaves no other vestiges than opake white or milky spots, which are a well-known appearance on the surface of the heart. They vary in extent from a few lines to two or three inches in diameter; their thickness is about that of the nail: they consist of condensed cellular tissue, and with a little care they may generally be detached without injury to the pericardium beneath. This membrane is commonly somewhat injected, though not thickened.

Sometimes lymph is converted into small, roundish, soft granulations, like concrete albumen, with which the pericardium is more or less extensively studded.

3. *Fluid effused within the cavity of the pericardium.*—It has been stated that serum is effused conjointly with lymph, from the vessels of the inflamed pericardium. This fluid is sometimes transparent, and either of a faint yellow more or less tinged with green, like that of the interior of a lemon, or of a pale fawn colour; at other times it is less transparent, but very seldom milky or opake from containing particles, filaments, or flakes of imperfectly concrete albumen. Its quantity, though variable, is in general considerable at the commencement, that is, within the first two, three, or four days of the disease,—not unfrequently amounting to more than a pint. Corvisart once found four. It is speedily diminished, however, by absorption, when the first violence of the inflammation begins to subside; and after the lapse of a few days it is, in the majority of cases, not more abundant than the concomitant exudation of lymph. Sometimes, indeed, even in very acute inflammation, the absorption is so complete that no serum whatever is found, while a copious exudation of thick concrete lymph fills and agglutinates the whole cavity.

Should complete absorption of both the fluid and lymph not take place, nor yet adhesion of the pericardium be established, the fluid presently assumes a very different character. For it is no longer secreted by the pericardium, but by the lymph itself, which, when organized, becomes a secreting surface; and its secretion, though at first consisting of clear serum, gradually becomes more and more turbid, milky, and opake, until it eventually assumes the character of pus. Rarely, however, is perfect pus found in the pericardium; probably because the patient dies from irritation before the suppurative process is fully established. Not unfrequently the fluid is bloody, and the lymph of a red colour. This is attributable to the tenderness of all newly organized structures, in consequence of which they are apt to become congested and to effuse blood when subjected to any unusual irritation or excitement. The excitement in the present instance most probably consists in inflammation of the adventitious membrane, either renewed, or never wholly suspended.

Compression exercised by fluid, and even by great accumulations of lymph, sometimes reduces the volume of the heart, and renders it atrophous.

Such are the anatomical characters of acute pericarditis, both in its early and its advanced stages. It remains to make a few remarks on that form of pericarditis which appears, from the mildness of the inflammatory symptoms, to have been chronic from the first. Its anatomical characters do not differ very materially from those exhibited by the advanced stages of the acute form. The inflammation always pervades the whole of the cavity; the redness is deeper and duller than in the acute affection; the albuminous false membranes are, in many cases, totally deficient, and when present, they are thin, soft, and fragile, as if wasted by suppuration: finally, there is always a more or less abundant effusion of turbid, milky, and sometimes completely puriform fluid. *Intimate* adhesions of the pericardium to the heart may follow the absorption of this fluid; but M. Laennec does not appear to be borne out either by facts or by analogy, when he supposes that chronic pericarditis alone is the cause of intimate adhesion, and that the acute affection only gives rise to loose adhesion by more or less elongated bands. According to our experience, the latter is the more frequent cause of intimate adhesion.

† De l'Auscult. Med. tom. iii. p. 655.

The muscular substance of the heart is, in general, not affected by pericarditis; but sometimes it is rendered redder or paler, browner or yellower, harder, softer, or more lacerable, than natural. These changes result from inflammation propagated from the pericardium to the muscular substance. They will be more fully considered in the article CARDITIS.

In scrofulous and phthisical individuals, tubercles are sometimes developed in the false membranes of pericarditis, and according to Laennec, they may cause the acute to pass into the chronic state, as frequently happens in the case of pleuritic and peritoneal false membranes.

Signs and diagnosis of pericarditis.

General signs.—There is no inflammatory affection of which the diagnosis has been considered more difficult than pericarditis. Laennec states that he has often, on dissection, discovered the disease in a severe form, when nothing had afforded a suspicion of its existence; and, on the other hand, that he has frequently witnessed all its signs without finding a vestige of the malady. Dr. Latham mentions two cases of what appeared to be and was treated as marked inflammation of the brain; yet this organ was found perfectly sound, and the heart affected with intense pericarditis.* Andral relates a similar case.† It is proper to keep these difficulties prominently in view, in order that practitioners may be better prepared to contend with them. But it must be added that such cases as those of Latham and Andral are extremely rare; and that, with the improvements in diagnosis introduced by modern research, the disease may, we feel assured from numerous post-mortem examinations, be nearly always detected. We shall first enumerate the symptoms, and then endeavour to point out the causes of their obscurity, the means of rendering them available, and the diagnosis from other inflammatory affections.

The symptoms are as follow: acute inflammatory fever; a pungent, burning, lancinating pain in the region of the heart, shooting to the left scapula, shoulder, and upper arm, but rarely descending below the elbow, or even quite to it. The pain is increased by full inspiration, by stretching the left side, and especially by pressure between the præcordial ribs, and by forcing the epigastrium upwards underneath the left hypochondrium. When the inflammation is only subacute, the pain is more or less dull, and does not lancinate. The next symptoms are, inability of lying on the left side, and sometimes in any position but one, which is most commonly on the back; dry cough; hurried respiration; palpitation of the heart, the impulse of which is sometimes violent, bounding and regular, though its beats may at the same time be unequal in strength; at other times it is feeble, fluttering, and irregular; pulse always frequent, and generally, at the onset, full, hard, jerking, and often with a thrill. Sometimes it maintains these characters throughout, but more commonly it becomes, after a few days, weaker than accords with the strength of the heart's action, and in the worst cases, small, feeble, intermittent, irregular, and unequal. Occasionally it possesses the latter characters from the commencement; whenever they exist, they are accompanied by dyspnœa; a constrained position, deviation from which induces a feeling of suffocation; extreme anxiety; a peculiar drawn or contracted appearance of the features, occasionally with the sardonic grin; faintness, constant jactitation, insupportable distress and alarm, cold perspiration, and, finally, from obstruction of the circulation, by intumescence and lividity of the face and extremities.*

One cause of the obscurity of the above symptoms would, at first sight, appear to consist in their diversified, incongruous, and variable nature. The pulse, for instance, displays, at one time or other, almost every kind of character; the disease, though the inflammation be equally intense, is sometimes very supportable, —at others, agonizing; in one case it terminates fatally in two or three days, in another it lasts as many weeks.

Now, in reality, these diversities, while they do not render the symptoms less pathognomonic of the disease in general, as will presently be shown, are invaluable indications in another point of view—they denote the nature and progress of the anatomical changes of structure, and, in correspondence, the progress and exact state of the malady. For it is ascertained by experience that a difference in the quality and quantity of the effusion imparts a totally different aspect to the symptoms. Thus, when, either from the effusion consisting principally of concrete lymph, or from the simultaneously secreted serum being absorbed, universal adhesion of the pericardium promptly takes place, preventing all further fluid effusion, the action of the heart maintains throughout much the same vigour and regularity as it manifested at the onset of the malady, and the pulse exhibits corresponding characters of strength, hardness, and regularity. Under these circumstances also, the position is less constrained, and less pain is produced by an unfavourable one; in consequence, perhaps, of the heart being curbed by the adhesion, and thus prevented from impinging with the same degree of violence against the thoracic walls. Finally, as the force and rhythm of the heart's action, and consequently the circulation, are adequately maintained, the life of the patient will be prolonged probably for weeks, even though the inflammation remain unsubdued, and he will sink at last apparently from mere exhaustion by the effects of protracted irritation.

But should there be a copious serous effusion, the heart's action is mechanically embarrassed by the compression that the fluid occasions,—a compression which is the more considerable because the pericardium, deprived

* Lond. Med. Gaz. vol. iii. p. 209.

† Clinique Médicale, vol. iii. p. 444.

* We have seen extensive œdema of the feet supervene during the last twelve hours of life.

of its distensibility by inflammation, is incapable of yielding as the fluid accumulates. Hence the organ, unable to transmit its contents, becomes congested: it flutters, intermits, beats feebly, irregularly, and unequally. The pulse has corresponding characters, and is sometimes scarcely perceptible. Hence supervene faintness, dyspnœa, anxiety, coldness, lividity, a sense of suffocation on the slightest deviation from a certain position, with all the other symptoms indicative of an obstructed circulation. If this state be not expeditiously relieved by remedies, the patient dies in the space of a few days or even hours.

Should the fluid be copious from the first, this series of symptoms will make its appearance equally early; but, in general, two or three days elapse before the accumulation becomes considerable; in which case the former series will exist during this period, and will then be suddenly replaced by the latter. In a few instances we have found the latter exist when the quantity of fluid was inconsiderable, but that of lymph enormous. We conceive, therefore, that an enormous accumulation of lymph has the same effect as fluid in embarrassing the action of the heart. We have also found the worst class of symptoms occasioned by a less quantity of fluid in some cases than in others,—a difference which probably depends in some instances on diversities in the nervous irritability; but in others we suspect that it is connected with the co-existence of carditis; for when the affection has been thus complicated, we have known the feeble, fluttering action of the heart and all its concomitant train of unfavourable symptoms, occur, though the effusion within the pericardium was inconsiderable. The peculiar expression of the features is occasioned by the sympathy subsisting between the respiratory nerves of the face and those of the heart.

Such are the causes of the symptoms. It will now be apparent that their variability is calculated to enlighten rather than to perplex the practitioner; and that, whatever aspect they assume, they would still be abundantly sufficient, did no other difficulties interfere, to render the disease one of easy diagnosis. But unfortunately there are other difficulties. Some of these consist in the absence or mildness of certain of the most important symptoms.

When pain in the immediate situation of the heart, increased by pressure in the interspaces between the ribs, or upwards under the left hypochondrium, is accompanied by increased action of the organ and by fever, there can scarcely be a doubt of the existence of pericarditis. But sometimes, though rarely, pain is totally absent; in which case the practitioner must carefully employ pressure, as above directed; and if, notwithstanding, no pain be felt by the patient, he must carefully turn his attention to the remaining symptoms. Should the pulse be feeble, faltering, intermittent, unequal, &c., without any apparent adequate cause, (and it is well known to practical men that such a pulse rarely if ever exists in ordinary cases without a discoverable cause,) this sign,* especially if attended with the usually concomitant signs of an obstructed circulation, affords evidence of the strongest description.

But there may be neither pain nor an unsteady pulse. In this case, should the action of the heart be violent, and of a remarkably bounding or jerking nature, without any manifest cause,—especially organic disease of the organ; and should it be accompanied by a greater degree of fever and anxiety than can be accounted for by any other existing complaint; finally, should it be attended with the stethoscopic signs presently to be described, the physician will seldom be wrong in diagnosticating pericarditis. The presumption is still stronger if, when the symptoms supervene, the patient is affected with acute or subacute rheumatism,—an affection which, whether severe or mild, whether in its early or its latter stages, is beyond comparison the most frequent cause of pericarditis.

It was an opinion of Corvisart that the most acute cases were the most obscure, because, says he, "the attack is abrupt, the progress rapid, and the termination always sudden." This obscurity was felt by that acute observer because he was not acquainted with any signs of the disease on which he could depend but the feeble, unsteady pulse, the anxiety, dyspnœa, lividity, and other symptoms dependent on obstruction of the circulation,—symptoms which did not always show themselves early enough to afford him data for the diagnosis before the case was hopeless. At present, however, when we are in possession of so many signs, the same obscurity does not exist. We have seldom experienced, nor have we seen other physicians experience, much difficulty in recognising the acute pericarditis to which Corvisart refers. The most obscure cases are those mentioned by Latham and Andral, in which an inflammation of the brain or any other organ diverts the attention from the heart, and the delirium of the patient renders it impossible to obtain information from himself. Still, when apprised that such cases exist, we should think it perhaps not impossible to provide against them. If, for instance, it were the general practice (one which we invariably pursue) to place the hand on the præcordial region as well as on the pulse in every severe inflammatory or febrile affection, in the same way that we daily feel the abdomen in cases of fever, even though the patient make no complaint of it, we should seldom fail to find an inordinately increased impulse or some other anomaly in the action of the heart, which would lead us to make a regular and probably successful investigation for pericarditis. For there can be little doubt that the symptoms, in the cases alluded to, are in reality not absent, but merely masked by others of predominant severity. Such an investigation is especially necessary in young children, who cannot explain their sensations, and seldom give indications of the existence even of acute pain.

* On it alone we have seen M. Chomel found a successful diagnosis in the last stage of a typhous fever, when the symptoms were extremely complex.

The only remaining cause of obscurity is, flammation of some of the thoracic viscera, rticularly the pleura, the pain of which may seated over the heart. Pleurisy may be tected by ægophony, extensive dulness on rcussion, and diminished or absent respiratory murmur. Peripneumony may, in addition its ordinary symptoms, be recognised by the epitous rhonchus, deficient respiratory murur, and dulness on percussion; finally, bronitis may be known by the mucous, sibilous, d sonorous rhonchi. Should none of these gns be present, the negative evidence thus obined fixes the disease on the heart; but should ey be present, the diagnosis of the pericarditis ust be made by a general comparison and utious consideration of all the symptoms. this case, should the affection of the heart be verlooked, the error is not one of the most erious kind, as the treatment for pleuritis or eripneumony is well adapted for pericarditis.

In a disease the treatment of which requires much decision and promptitude in the practioner as pericarditis, it is necessary for him to e thoroughly conversant, not only with the ymptoms of deterioration, but also with those of melioration. To these, therefore, we shall advert before proceeding to the physical signs.

If the worst symptoms decline, namely, the eeble, fluttering, unsteady pulse, the feeling of intness and suffocation, and the constrained osition to which that feeling confines the atient, we may be tolerably sure that the fluid, n which these symptoms commonly depend, is ecreasing by absorption. But, notwithstanding, should pain, violent impulse, fever, and nxiety continue, the inflammation is in progress, and is adding to the accumulation of ymph, if not also of fluid. Should, however, ne pain, instead of being fixed and pungent, become a diffuse uneasiness; should the anxiety decrease, and the peculiar vehemence of the eart's action gradually degenerate into the beat f a merely accelerated circulation, the inflamnation may be presumed to be on the decline; ut it is not until all these symptoms have ompletely ceased that it can safely be said o have terminated.

Still, lymph and adhesion of the pericarlium may remain, rendering the reparation imerfect; and such we may consider to be the ase so long as, with every advantage of perfect ranquillity and abstinence, the motions and sounds of the heart do not completely regain heir natural standard. Even though this be egained, nothing is more common than a recurrence of palpitation and other symptoms of liscased heart when the patient resumes his ccustomed avocations. It is not, therefore, until, very gradually returning to corporeal exercise, he finds himself, after an adequate trial, perfectly capable of his wonted exertions, that he cure can be pronounced complete.*

Physical signs.—The impulse of the heart is greatly increased,—not only heaving the thoracic walls vigorously, but being remarkable for its abrupt or jerking character; whence it often shakes the whole anterior chest Some beats are generally stronger than others, even when the action is regular. The pulse or rather throb of the arteries, often perceptible over the whole body, is of a corresponding nature, each undulation of the blood shooting with instantaneous velocity under the finger, as if through a lax or imperfectly filled tube, and constituting what is called a bounding, or, more expressively, a jerking pulse,—the pulse that we feel during reaction after uterine or other excessive hemorrhage. Very frequently it is accompanied with a distinct thrill. Sometimes it is stronger and more voluminous, at others smaller and weaker; yet in the latter case it still retains the same jerking character.

When the action of the heart becomes feeble and faltering, the impulse of the organ of course sustains a corresponding change; but, notwithstanding, the jerk accompanies any isolated contraction that happens to be strong.

An impulse and pulse of the jerking description denote an inordinately abrupt, and as it were spasmodic contraction of the heart, probably attributable to an increase of irritability resulting from the inflammation. It is this peculiarity in the beat which distinguishes it from the beat of a merely accelerated circulation, a distinction perfectly familiar to practical men. The peculiarity subsists not only during the continuance of inflammation, but so long as the action of the heart remains quick after the inflammation has apparently subsided,—a period which generally occupies several weeks, and, if adhesion of the pericardium has taken place, frequently as many months. We have known it exceed half a year. In very protracted cases it is probable that the irritability of the heart is kept up either by an occasional recurrence of inflammatory action, or by the unnatural circumstances in which the organ is placed by adhesion, or, finally, by a softened state of the muscular substance, the result of carditis.

The sounds.—The sound of the ventricular systole is not only unusually sonorous, but is accompanied with a bellows murmur. This sign was first noticed by Dr. Latham, who pointed it out to us at St. Bartholomew's Hospital in 1826. Since that time we have never found it absent *when the heart presented the increased jerking impulse* above described. Dr. Latham restricts his observation to rheumatic pericarditis: to ourselves the phenomenon has appeared to exist equally in every form of the disease. When the action of the heart has been feeble and faltering, we have found the murmur absent; but when, in the same case, the action has, either previously or subsequently, been strong and jerking, the murmur has existed. The reason of this will be obvious from the explanation which will presently be offered. The murmur sometimes continues after the heart appears to have resumed its natural action and the patient to be well; but so long as it

* See an excellent paper by Dr. Latham, Lond. Med. Gaz. vol. iii. p. 213, to whom the profession in general, and ourselves in particular, are greatly indebted for his researches on this subject.

remains, as remarked by Dr. Latham,* "his return to the habits and exertions of health will bring back palpitation and other symptoms, which bespeak the certainty of mischief still abiding in the heart."

Not the ventricular systole only, but occasionally, though by no means always, its diastole likewise is attended with the bellows murmur; and we have found this supersede and as it were annihilate the natural second sound more completely in pericarditis, than, we think, in any other affection of the heart. Sometimes, in short, it is a pure whizzing, as prolonged as, and almost continued into, the first sound. Three cases at present under our care present this character.

What is the proximate cause and what the mechanism of these preternatural murmurs? That of the ventricular systole we are inclined to attribute, mainly at least, to the increased velocity with which the blood is propelled in consequence of the morbidly abrupt contraction of the heart,—an explanation which appears to us to be rendered probable by the following considerations: 1. by repeated abstractions of blood, in animals, at intervals of a day or two, we have produced at pleasure the rapid, throbbing, jerking, and thrilling action of the heart and arteries, and, in strict concomitance with it, the bellows murmur; 2. the murmur takes place in nervous palpitation when the action of the heart and arteries is of the nature described; 3. the loudness of the murmur observes a very accurate ratio to the violence of the throbbing, and it subsides when the throbbing ceases, unless there remain an organic lesion, presently to be described, which generates it on a different principle.

But though we attribute the murmur of the ventricular systole *mainly* to the cause described, we believe that it may, in some instances, originate partly in another cause: namely, constriction of the arterial orifices consequent on inflammation of the lining membrane. For, as this membrane is more liable to inflammation where it constitutes the valves than elsewhere, it is consistent with analogy to suppose that, by its intumescence and loss of elasticity, the orifices will undergo the constriction alluded to.

The murmur accompanying the second sound we are inclined to attribute perhaps entirely to the same constriction, affecting the auriculo-ventricular orifices. This we infer, because we have not found it produced in any appreciable degree by abrupt, jerking action of the heart in reaction from loss of blood, and in nervous palpitation; and because, when we have noticed it in pericarditis, we have invariably found it connected with a more or less thickened and opaque state of the valves—a state which, though perhaps scarcely amounting in every instance to an obstruction when it was examined in the dead subject, gives sufficient reason to believe that it might have constituted one during the period of acute inflammation. Should this be found true, the bellows murmur of the second sound renders the prognosis more gloomy; as it bespeaks a more extensive inflammation and the probability of subsequent valvular disease.

Percussion.—When the pericardium contains much fluid, the resonance of the præcordial region becomes dull over a greater extent than natural. The impulse, also, it may be added, is undulatory, and not exactly coincident with the first sound, in consequence of the heart having to displace the fluid interposed between it and the thoracic walls, before it can impinge against the latter. (See HYDROPERICARDIUM.) M. Louis states that he has found a temporary effusion of fluid cause a prominence of the cardiac region. We do not happen to have noticed this, but we think it very probable, especially in young subjects in whom the cartilages are soft.

Signs and diagnosis of chronic pericarditis.

General signs.—The signs of chronic pericarditis are much the same as those of acute, but in a very inferior degree. The fever is more that of hectic or marcor, with occasional exacerbation, when perhaps the inflammation becomes subacute. The anxiety and restlessness, though sometimes great, are comparatively supportable. The position is less constrained, and we have observed that the patient often prefers the sitting posture with the body inclined forwards. The circulation is less embarrassed, and the action of the heart, though often abrupt and jerking, is usually somewhat feeble, except during any temporary exacerbation of inflammatory action. The pulse, also, is sometimes not very unsteady though the pericardium be full of fluid; which we attribute to the elasticity of the membrane not being so far destroyed by the inflammation as to prevent it from gradually undergoing extension, and accommodating itself to its contents, whence compression of the heart by the fluid is in some degree obviated. The patient, we have thought, more frequently complains of a load and fulness, "something which he cannot get down," in the scrobiculus cordis, in chronic than in acute pericarditis.

Chronic pericarditis, especially if such from its commencement, is more obscure than acute. We have, in former years, seen it overlooked more than once. But these cases, when we now revert to them, appear to us to have presented sufficiently characteristic symptoms. The history affords the greatest light. If the patient, previously exempt from disease of the heart, has suddenly become affected with its symptoms, attended by marcor and some degree of fever, within a period seldom extending beyond a few months, and which he often dates from a blow or fall on the breast, a rheumatic fever, or an inflammation with pain in the præcordial region, chronic pericarditis may be strongly presumed; and if these symptoms coincide with the physical signs of fluid in the pericardium, the existence of the malady may be regarded as almost certain.

Physical signs.—The impulse and pulse have much the same general characters as in

* Lond. Med. Gaz. vol. iii. p. 214.

ute pericarditis, except that, as the heart's tion is less vigorous, they are not so strong.* ne signs of fluid in the pericardium are the me; namely, the extensive dulness on rcussion and the undulatory impulse.

auses, prognosis, and treatment of pericarditis.

Causes of pericarditis.—The most frequent uses are blows or excessive pressure on the præcordial region, inflammation propagated om the lungs or pleura, and, far above all, eumatism. From this cause, children and oung persons suffer much oftener than others. he remaining causes are those of inflammation general, viz. cold, febrile excitement, &c.

Prognosis.—This disease, supposed by Corsart to be necessarily fatal, has, by subsequent xperience, been proved curable,—and completely curable; but as the possibility of effectng a complete cure is limited to a very brief eriod, and as, unless it be complete, the atient almost inevitably dies sooner or later om the consequences, the disease must be egarded as one of the most formidable inident to the human race. Some of these onsequences we shall describe in the next ection under the head of *adhesion of the ericardium.*

Treatment of acute pericarditis.—The antihlogistic treatment, in as energetic a form as ircumstances will allow, should be employed vith the utmost promptitude. The loss of a ew hours at first may be irretrievable; and ence hesitation and indecision may seal the ate of the patient. If the attack be recent, nd the patient's strength will admit, blood hould in the first place be drawn freely and y a large incision from the arm, so as to ring him to the verge of syncope. From ive-and-twenty to forty leeches, according to he strength, should then be applied to the præcordial region, so soon as the faintness rom the venesection disappears, and reaction ommences, which generally happens in the ourse of from ten minutes to an hour or two. Unless the pain be completely subdued by hese measures, the leeching may be repeated wo, three, or more times, according to the strength, at intervals of from eight to twelve hours; or, what is a better rule, so soon as the pulse and action of the heart denote a recommencement of reaction.

It is not, however, in every case that so active a treatment is required: we have seen a single prompt and abundant application of leeches, or a cupping, at once subdue every formidable symptom. When the patient, either from age, a feeble constitution, or the advanced state of the malady, cannot bear extensive depletion, local bleeding is, according to our observation, decidedly preferable to general; but it should be practised effectually, by cupping to twenty ounces or more, or by the application of from twenty-five to thirty or forty leeches. When, from depletion having already been carried to a great extent, or from the advanced stage of the disease, it is not safe to draw much more blood, yet it appears expedient, from the persistence of pain, &c. to draw some, we have generally found that a smaller quantity drawn by cupping, produced more effect than a larger by leeching. The cause of this probably is, that by cupping it is drawn more expeditiously.

While the bleeding is in progress, other means should not be neglected. The intestinal canal, if at all confined, should immediately be evacuated by a purgative enema. Three drachms of senna leaves, and an ounce of sulphate of soda infused in a pint of boiling water and strained, answers the purpose. At the same time, five grains of calomel with five or ten of comp. extr. of colocynth, and two or three of extr. of hyoscyamus, should be given, and, in two hours, be followed by a senna draught.

The strength of the remedies employed must in each case be apportioned to the vigour of the patient's constitution; but the object is the same in all—expeditiously to prostrate the action of the heart, and for a time to keep it prostrate by preventing the re-establishment of reaction. If this object can be accomplished for the first twenty, thirty, or forty hours, the disease frequently does not rally, but remains perfectly under the control of remedies. We feel satisfied that a degree of activity in the first instance, which to some may appear excessive, is an ultimate source of economy to the strength of the patient; for the disease is subdued at once, and the protracted continuance of depletory measures, the most exhausting to the constitution, is rendered unnecessary.

In addition to the above measures, diluent, cooling drinks, as four scruples of supertartrate, or two of nitrate of potass in a quart of water, and flavoured at pleasure, should be allowed in unlimited quantity, in order, by diluting the blood, to render it less stimulant to the heart. Nauseating doses of tartrate of antimony, as one-sixth to one-eighth of a grain, every two hours, may be employed with advantage. The diet should consist wholly of the weakest slops, as barley-water, gruel, weak tea, arrow-root, &c.

But the antiphlogistic treatment alone is not to be relied upon: rarely, if ever, does it, in a severe case, effect a complete cure. The practitioner sees all his resources gradually exhausted, while the disease proceeds with an even, uncontrolled tenor to its fatal termination. Sometimes, indeed, all the other symptoms disappear, but the action of the heart remains stronger than natural; at other times the heart even regains its healthy action, and the cure appears complete: yet in both these cases the palpitation, accompanied with symptoms of organic disease of the heart, recurs when the patient resumes his accustomed oc-

* The sounds will vary according to circumstances. When the action of the heart is jerking, and not wholly devoid of force, the first sound will be attended with a murmur, which, however, is generally very slight. When there is inflammatory constriction of the orifices, a murmur will attend both sounds. Should the heart be dilated, as is frequently the case, the sounds will be increased; and should hypertrophy be conjoined with the dilatation, the impulse will sustain a corresponding augmentation of force.

cupations. The reason of this is very intelligible. Unless the effused lymph, as well as the serum, be absorbed, it causes an adhesion of the pericardium, and thus establishes destructive disease. Now antiphlogistic measures can neither prevent the effusion of lymph, nor with any degree of certainty cause its absorption. Mercury *can* do this, as is visibly displayed in iritis; mercury, therefore, is the sheet-anchor of the practitioner. Dr. Latham is of opinion that its success is restricted to the condition of its producing salivation rapidly. From many observations we are satisfied of the general truth of this remark, and would therefore give the remedy on this principle; but we have seen cases in which cures, not falsified after many months, were effected, though salivation was not produced. The mineral, however, was freely administered, and probably produced its specific effect, though not in an apparent manner. From five to eight grains of calomel, or from ten to fifteen of blue pill, prevented from purging by a grain or a grain and a half of opium, three times a day, commencing after the first bleeding and a purgative, generally produce the effect with sufficient expedition. Inunction may be superadded or partially substituted, if mercury, taken internally, disagree. A manifest abatement of the symptoms generally takes place immediately on the effect of the remedy becoming apparent in the mouth, especially if a free salivation is established within the first thirty or forty hours. It should be maintained for a week or ten days, or even longer, unless the symptoms completely yield before the expiration of this period.

Should pain continue in the advanced stages of the malady, and after the period for applying leeches has passed, blisters may be resorted to, and repeated in quick succession, with great advantage. I have occasionally found a third or a fourth necessary before the pain has been completely removed. In the repetition of blisters, as well as of leeches, cupping, and venesection; and in the selection of one of these remedies in preference to another, much must necessarily be left to the judgment of the practitioner. It is only experience which can teach the exact adaptation of remedies to the circumstances. It must also be left to his discretion whether to give sedatives or not. When the restlessness and nervous irritability was great, we have seen much benefit derived from tinct. hyoscyami, *m*xv. ad xx. with the same quantity of tinct. digitalis, in a draught three or four times a day. Sedative remedies, however, should not be given until the first severity of the inflammation has subsided; nor should they ever be allowed, by producing their poisonous effects, to confuse the symptoms, already sufficiently complex, in the latter stages.

During convalescence it is sufficient to say that a very spare unstimulating diet and extreme tranquillity must be imperatively enjoined until the action of the heart has become perfectly and *permanently* natural.

An individual who has recently been affected with pericarditis is peculiarly liable to a recurrence of it, especially if it has resulted from rheumatism, and if the reparation has been incomplete. In this case, should rheumatism return, it rarely fails to be accompanied with a renovation of the pericarditic symptoms.

This cannot be a subject of surprise; for it is consistent with general analogy that a part recently injured by inflammation is more susceptible than a healthy tissue of inflammatory action; the reason of which probably is, that the vessels of newly organized adventitious structures are more tender and irritable than others. Secondary inflammation, however, has not the same energy and intensity as that of a healthy structure, it yields more promptly to curative measures, and is more completely within the powers of medicine. Hence a first attack of pericarditis is more dangerous than any subsequent one. It is comparatively rare for a patient to die from the direct effect of a recurrent attack; and, what is still more remarkable, he may sustain several without being left in a materially worse condition than after the first.

Much discretion, however, is requisite on the part of the practitioner to bring such recurrent attacks to a favourable termination; and the danger of doing too much is, perhaps, greater than that of doing too little. He must, in particular, be cautious of bleeding too extensively, with the object of reducing the excessive energy of the heart's action; for this energy, he must recollect, is a consequence not of the inflammation only, but partly also of an organic affection of the organ left by the primary attack. Nor is there the same motive for a vigorous employment of mercury; for the heart being already irreparably disorganized, it would be chimerical to entertain the expectation of effecting a *perfect* cure. The object, therefore, should be simply to prevent deterioration by combating the inflammation as it presents itself.

For the accomplishment of this object, a moderate use of bloodletting and mercury suffices; and leeching or cupping on the præcordial region is more efficacious and less exhausting than venesection. Blisters are, in these cases, peculiarly beneficial; and they may be repeated in quick succession as often as they are required and can be borne. When there still remains a little lingering pain, which scarcely authorises vigorous measures, but cannot prudently be left, the most valuable and convenient remedy has appeared to us to be, a plaster composed of a scruple of tartrate of antimony, five scruples of the emplast. picis comp. and one scruple of wax to diminish the tenacity of the adhesion.

In these cases, also, where the sufferings of the patient, though perhaps not severe, are very protracted, and accompanied with much loss of rest, great advantage is derived from a pill of from three to six grains of extr. of hyoscyamus at bed-time, and moderate doses of tincture of digitalis during the day, the specific poisonous effect of the latter remedy

eing obviated by omitting it for a couple of ays after every three or four.

Chronic pericarditis.—When pericarditis is ssentially chronic, and the cavity appears to ontain fluid, counter-irritant remedies are the ost suitable. After what has already been id, it will be sufficient merely to mention listers, either in succession or kept open with avine cerate, the tartrate of antimony and itch plaster, and likewise issues and setons. he last remedy, however, generally creates so uch irritation as to do more injury by deriorating the general health, than good by s local effect. Mercury to a moderate extent ay, if discreetly employed, be advantageous y promoting absorption; but in general the atient is too much reduced by constitutional ritation to admit of more than the mildest tion of this remedy.

The diet may in chronic cases be more utritious, comprising light animal food and oths.

II. Carditis.—Inflammation of the muscur substance of the heart may be, 1. universal, . partial.

1. Of universal carditis with effusion of pus enerally throughout the muscular tissue, there not to our knowledge more than a single stance on record, and that occurred to Dr. atham. "The whole heart," says he, "was eeply tinged with dark-coloured blood, and s substance softened; and here and there, pon the section of both ventricles, innuerable small points of pus oozed from among e muscular fibres. This was the result of a ost rapid and acute inflammation, in which eath took place after an illness of only two ays."* Laennec, never having met with or eard of a case of this kind, and considering a effusion of pus the only unquestionable gn of carditis, says, "there does not perhaps xist a single incontestible and well described xample of *general* inflammation of the heart ther acute or chronic."† Independent of the bove instance, however, there are probably any others, which, though not attended with ffusion of pus, will come under the denomiation of universal carditis; for few will concur ith this distinguished writer in excluding om the proofs of carditis softening and indu ation, with increased or diminished colour of e organ. These are results of inflammation other muscles, and analogy points out at they have the same origin in the heart, urther evidence is derived from the fact that, cases of pericarditis, the characters in ques on sometimes occupy only a certain depth of e exterior surface of the organ, whence the rsumption is almost positive that they originate in an extension of the inflammation from e pericardium. The cases of this description at are on record are too numerous to be uoted. Several have fallen under our own bservation. In this point of view, then, eneral carditis is not very rare.

As softening and induration are of sufficient importance to demand separate articles, we refer the reader to them for all that remains to be said on general carditis.

We have already stated, when treating of pericarditis, that this affection is greatly aggravated by the coexistence of carditis. As the treatment of the two is the same, it is unnecessary here to enlarge on it.

2. Partial carditis, characterized by the existence of an abscess or ulceration in the walls of the heart, is not very uncommon. Bonetus, in his Sepulchretum, has described a considerable number of cases. Abscesses are more rare than ulcers. The latter occur both on the external and the internal surface of the heart, and are consequent sometimes on inflammation of the membranes of those surfaces, and sometimes on steatomatous deposition in the cellular tissue beneath the lining membrane. The external ulcer is uncommon, but Olaüs Borrichius, Peyer, and Graetz have left perfect descriptions of it. The first says, "Cordis exterior caro, profundè exesa, in lacinias et villos carneos putrescentes abierat." The internal ulcer is more common. Bonetus, Morgagni, and Senac present many cases. We have met with two or three.

An ulcer, whether external or internal, may perforate the heart.

The signs of abscesses and ulcers vary in different subjects, and are not distinguishable from those of other affections. "I know not," says Laennec, "if auscultation will afford any more sure signs, and I avow that I think not."*

Ulceration is the most frequent cause of rupture of the heart,—fortunately a very rare occurrence.

The existence of gangrene of the heart has never been distinctly proved, and the following reasons lead to the belief that its occurrence is perhaps impossible: first, the muscular tissue is one of those least susceptible of it; and, secondly, inflammation of the heart sufficiently intense to occasion it is fatal to the patient before gangrene can take place. The cases on record of reputed gangrene appear to have been nothing more than softening, which incipient putrefaction had rendered more analogous to gangrene

Adhesion of the pericardium.—Pericarditis, both acute and chronic, and especially that originating in rheumatism, frequently terminates in adhesion of the pericardium. Lancisi, Vieussens, Meckel, Senac, and Corvisart are of opinion that, with a complete and intimate adhesion, the patient cannot live in a state of health. We know not how it is that Laennec and Bertin have formed an opposite opinion. The former states that he had opened a great number of subjects so affected who had never *complained* of any derangement in the circulation or respiration; whence he infers that adhesion often does not in any respect interfere with the exercise of those functions. Our experience is entirely opposed to this doctrine.

* Lond. Med. Gaz. vol. iii. p. 118.
† De l'Auscult. t. ii. p. 554.

* De l'Auscult. t. ii. p. 664.

The *complaints* of the patient are, perhaps, not a just criterion, for we have often found the working classes disclaim dyspnœa when labouring under enormous hypertrophy and dilatation, and when that symptom obviously existed in a great degree. Many others, also, especially children, are naturally inattentive to their own sensations, and close interrogation is the only mode of ascertaining that after the attack of pericarditis they became incapable of some exercises, habits, or efforts which they previously accomplished with facility.

We have never examined a case of complete adhesion of the pericardium without finding enlargement of the heart,—generally hypertrophy with dilatation. We have observed that cases of adhesion terminating in enlargement often hurry to their fatal conclusion with more rapidity than almost any other organic affection of the heart; and we have, on the other hand, repeatedly seen patients die from the consequences of an adhesion, the history of which we could trace back eight, ten, or more years; yet such individuals would not unfrequently represent their health to have been perfect during the greater part of that period, and would not admit, until closely interrogated, that they had been more or less "short-winded." Hence we infer that, though adhesion may not for a time create much inconvenience, its effects are ultimately fatal. This refers, of course, to intimate, not to loose adhesion. It appears to us that a tranquil, abstemious life, by which in other forms of organic diseases of the heart existence may sometimes be prolonged to its natural period, cannot be equally availing here; for as the action of the organ itself is a constant struggle, repose is impossible.

How adhesion occasions hypertrophy is easily understood; for the organ must increase its contractile energy, in order to contend against the obstacle which the adhesion, by shackling its movements, presents to the due discharge of its function, and, as explained in the article Hypertrophy, increased action leads to increase of nutrition. The cause of the co-existent dilatation is not less manifest; as the shackled organ transmits its contents with difficulty, in a state of greater congestion than natural, and, as is more fully explained in the article on dilatation, permanent distention is the most effective cause of this affection. When the muscular substance is softened, as frequently happens, dilatation takes place much more readily, in consequence of the deficient elasticity or tone of the heart's parietes.

When adhesion of the pericardium has produced hypertrophy with dilatation, its history identifies itself with that of the latter maladies, of which it renders the symptoms more severe and the progress more rapid. To avoid repetition, therefore, we refer the reader to the article Hypertrophy, and shall, here, only describe the signs which are pathognomonic of adhesion.

These signs have generally been considered very obscure. Dr. Sanders believed that he had discovered one of a positive nature in a dimple or retraction taking place, as he states, during the ventricular systole, in the epigastrium immediately below the left false ribs. We have searched for this attentively in several cases of adhesion, but have not been able to detect it in any degree which could constitute a sign. Laennec, who was equally unsuccessful, thinks that it could not take place unless the stomach, by adhering both to the diaphragm and the abdominal parietes, formed the medium of retraction.

In five or six cases we have remarked one sign, which has not, to our knowledge, been hitherto noticed; namely, the heart, though enlarged, beats as high in the chest as natural, and sometimes occasions a prominence of the cartilages of the left præcordial ribs. We should, indeed, naturally expect that the adhesion would brace up the organ, and that, when enlarged and not able to descend, it must, being bounded behind by the spine, force the walls of the præcordial region forward.

Another sign, and perhaps the most characteristic of all, is an abrupt, jogging, or tumbling motion of the heart, very perceptible in the præcordial region with the cylinder. It is more distinct when the heart is hypertrophous and dilated; and under these circumstances we have found the jogs correspond with the ventricular systole and diastole respectively, that of the diastole being sometimes nearly as strong as the other, and having the character of a receding motion. This jogging motion is distinguished from the undulatory movement of fluid in the pericardium, both by its nature, by the synchronism of the jogs with the sounds, and by the feeling that the heart at each systole comes in immediate contact with the thoracic walls.

A third sign consists in a bellows murmur with the first sound, which we have always found present when the heart is enlarged and acting vigorously. Nor is it, in every case, confined to the heart: we have often heard it in the aorta, and formerly experienced difficulty in discriminating it from the murmur of dilatation of this vessel.* Although, when the heart is dilated, the murmur in question may be occasioned partly by the relative smallness of the orifices, and the greater angles at which the currents meet in them in consequence of the unusually rounded form of the ventricles, as elsewhere explained, it is also, we believe, occasioned in a great measure by the sudden velocity with which the fluid is propelled, as it would not otherwise exist in the aorta.

(J. Hope.)

PERICARDIUM, DROPSY OF. See Hydropericardium.

PERITONITIS, from *περιτονέον*, *peritonæum*.—This is the term now universally used to express an inflammatory state of the serous membrane which lines the interior of the abdo-

* Vide Treatise, by Dr. Hope, p. 63.

inal eavity, and invests all the viseera conined therein.

l Pain, tumefaetion, and tenderness of the bdomen on pressure, are the most prominent mptoms whieh characterize this affection uring life; and increased vaseularity, thickeng, effusions of coagulable lymph, of serum, of is, or blood, are the principal loeal effects oduced by it. These elementary features, companied in general with more or less of rexia, will exist in different degrees and comnations, in every variety of age, sex, or conitution, modified, however, by circumstances rived partly from the nature of the cause, d partly from the eondition of the patient at e time of the attack.

Peritonitis may assume either the aeute or ronic form. It may exist as a sporadie sease, or prevail as an epidemie. It may ther present itself openly, with a numerous oup of well-marked symptoms, or creep on in latent state, with searcely one of its characristic features. It may be limited in its exnt to a small portion of membrane, or spread ver a large surfaee. It may run its eourse neombined with any other affeetion, or be omplicated with various diseases. There is o period of life exempt from its attacks. It ay affect the infant, the adult, and the puereral female: pursuing the same course, and xhibiting similar effects in all, it yet presents vast variety of symptoms in individual cases, rincipally according to the organ whose perioneal covering is the chief seat of the inflamnation.

Pure peritonitis is exclusively confined to he peritoneum, without involving the muscular r mueous tissues of the intestines, and can in nost cases be distinguished by peculiar symoms from inflammatory affections of those issues. Not uncommonly, however, inflammation commencing in one tissue extends to hose contiguous; but this is by no means niformly the case; frequently the very oppoite effeet is induced in this disease, and the ntestinal mucous membranc becomes remarkbly palc, while the peritoneum is aeutely nflame.l.

We shall proeeed, in the first place, to notice the disease as it exists in the acute form in the different periods of life.

I. *Acute peritonitis in the infant.*—This disease may attack the infant during its intrauterine life. Its exciting eauses during this period of existenee are obscure: they may possibly be transmitted from the mother to the infant, or originate from an internal strangulation of the intestines, of which M. Legoues and M. Ducis have seen examples. However difficult it may be to assign a satisfactory eause for its origin, its existence has been unequivocally demonstrated by the post-mortem appearances which infants who have died a few hours after birth have exhibited. In some eases of this kind the usual effects of peritoneal inflammation, adhesions between the intestines, false membranes, and sero-purulent effusions into the abdomen, have been detected—effects which must have been produced during the abode of the infant in utero. Five cases of infants who died a few hours after birth have been detailed by M. Billard, in which the above appearances were found. In one instance the child was emaciated and pale; and old, solid adhesions were discovered in the abdomen, apparently indicating that the disease had existed for some time previous to birth, and had probably become chronie before it terminated fatally. In the other four cases the infants presented nothing unusual in their external appearance.

The eauses which may excite peritonitis during the period of laetation are not very evident. They probably are essentially the same as may operate during adult years. Infants are exposed, to a eertain extent, to similar injurious impressio s from external agents, and their organs are at least equally susceptible of morbid aetions.

Symptoms.—The abdomen of the child presents a tumefied and tense appearance, and is elevated in a point towards the umbilicus. This distention is caused in the early period of the disease by flatus in the intestines: it is accompanied by some dyspnœa, which does not, however, always indicate a pulmonic affection, but is produced by the obstruction whieh the diaphragm suffers in its deseent from the distended abdomen, and the pain which its movements occasion by the friction of the inflamed peritoneal surfaces against each other. There is eonstant abdominal pain, which is much aggravated by pressure. The eountenance exhibits an expression of suffering: the features are contracted, and the little patient cries almost without intermission. Vomiting usually is present, and the bowels are in most eases constipated. There is restlessness, with general debility; hot, dry skin, and frequent, weak pulse; and, if prolonged into the chronic state, the child beeomes emaciated, and dies exhausted.

It is difficult to distinguish this disease from infantile enteritis, with which it is occasionally complicated. In its simple form it is usually attended with more abdominal tenderness on pressure. Constipation generally exists in peritonitis, while diarrhœa is frequently an attendant on inflammation of the mucous membrane. The appearance of the tongue may assist in the diagnosis, being, in the latter affection, generally furred, with red tip and edges and red papillæ, while in simple peritonitis this redness is not generally present. Peritonitis is a mueh less frequent disease during infancy, not being so likely to be indueed by irregularities of diet and the other injurious agents to which children are particularly exposed, and whieh are common exciting causes of enteritis. M. Billard observes that it may be distinguished from pleuritis by the sonorousness of the chest, and from flatulent colic by the pains being remittent in the latter affection, and ceasing on the expulsion of gas.* The prognosis in this disease is generally unfavourable. The post-mortem appearanees do

* Maladies des Enfans, Paris, 1828, p. 449.

not differ from those which the disease presents in adults, and which will be hereafter described.

Children of a scrofulous habit are subject to a form of chronic peritonitis, which deserves distinct notice: it is characterized during life by great tenderness of the abdomen on pressure, with occasional paroxysms of acute pain, at first coming on only once or twice a day, but afterwards becoming more frequent, after which the child appears quite lively, and free from indisposition. At first the pain is limited, but afterwards extends over the whole abdomen, which in the early stages becomes swollen and tense, but afterwards subsides: the pulse is generally about 100, with some strength and fulness, the tongue clean, appetite irregular, but generally good, and frequently voracious; some thirst, the bowels free, the evacuations unusually large in quantity, and peculiar in appearance, consisting generally of a whitish-brown matter, of the consistence of a thin pudding. This state of the bowels may continue for six weeks or two months with progressive emaciation, until diarrhœa, attended with petechiæ, puts a period to the child's life. The head seldom suffers, but cough and dyspnœa occasionally attend. The usual duration of the disease is four or five months, but often the child is not confined to his bed till the last month. Dissection exhibits the mesentery, bowels, and peritoneum lining the parietes, united together into one mass; the peritoneum thickened, and containing large masses of scrofulous matter; the intestinal mucous membrane perforated by ulcerations, which form numerous communications between the different coils of intestine; and the intestines and abdominal cavity containing matter resembling that which was passed during life by stone. The causes of this disease are unknown, and it in general terminates fatally. Dr. Gregory recommends leeches and fomentations during the early stages, afterwards purgatives, mercurial alteratives, tonics, chalybeates, and absorbents. Laudanum affords the only relief from the pain. This disease appears to be a frequent cause of infantile marasmus.*

II. *Acute peritonitis in the adult.*—The causes which predispose to peritonitis in mature years are involved in some obscurity. They probably do not differ essentially from those which predispose to other inflammations. It is observed to be more common during adult years than at other periods of life; in women than in men; and in sanguine and plethoric individuals than in the opposite constitutions. A disposition to local determinations of blood, proved by previous inflammatory attacks and repeated discharges of fluids, is, according to Broussais, a common predisposing cause, and to this may be added cold seasons of the year, residence in damp situations, the abuse of intoxicating liquors, and over-excitement of the passions.

* Medico-Chirurg. Trans. vol. xi. p. 262. Dr. Gregory on Scrofulous Inflammation of the Peritoneum.

The exciting causes may be arranged in three classes—the *mechanical*, the *chemical*, and the *vital*.

The *mechanical* causes include all injuries inflicted on the abdomen by blows, falls, or compression, pressure of the gravid uterus, extra-uterine conceptions, enlarged ovaries, or other morbid growths within the abdomen. Under this class may also be included all wounds of the peritoneum, whether the result of accident, surgical operations, or strangulation arising from hernial protrusions, or invagination of a portion of intestine. M. Broussais considers violent and long-continued corporeal exertions, violent and repeated contractions of the abdominal muscles in vomiting, strictures of the colon or rectum producing unnatural contortions, and friction of the intestines on one another, as causes of peritoneal inflammation.

The *chemical* causes include all extravasations into the peritoneal cavity not quickly absorbed, whether of blood, urine, bile, chyle, or fæces, and perhaps the morbid serous secretions of the membrane itself.

The *vital* causes comprehend all aberrations of healthy actions, transmission of morbid action from a part previously affected to the peritoneum, or extension of inflammation from a contiguous organ or tissue to this membrane.

An aberration of action takes place when certain functions of the system are interrupted, as when the perspiration, the catamenia, or the lochia are suppressed, and peritonitis is induced as a consequence. The remote cause in these cases arises from the operation of cold, moisture, or both combined, applied to the surface, or the drinking of cold liquids when the body is overheated. Transmission of morbid action or metastasis may be ranked among the exciting causes. We see examples of this when the retrocession of rheumatic, arthritic, erysipelatous, or other inflammations, is quickly followed by an inflammation of this membrane. According to M. Broussais, the chill of an intermittent, when the abdominal viscera, and especially the spleen, are suddenly swelled by the centripetal motions of the fluids, may prove an exciting cause of peritonitis, examples of which he has frequently seen during the course of these diseases.

Extension of inflammation from a contiguous texture or organ to the peritoneum, is a very frequent cause of this affection. Thus, when the gastro-intestinal mucous membrane is inflamed, the inflammation may extend itself to the serous envelope of the intestines; or when the uterus or any other of the abdominal viscera are similarly affected, the inflammatory action may be propagated to their peritoneal coverings, and the two diseases may either co-exist, or a revulsion of the phlogosis takes place, the primary affection subsides, and simple peritonitis is established. This subject, however, will be more fully considered when we come to treat of the complications of this disease.

Symptoms of acute peritonitis.—This affection frequently commences by a shivering more or less prolonged, accompanied by a feeling of general indisposition and weariness in the

mbs: at an uncertain period re-action takes lace, and heat of skin more or less pungent, ith headach, constriction at the epigastric egion, and frequent, hard, concentrated pulse, ucceed, attended with a sensation of heat and ain in the abdomen, and tenderness on ressure. This pain soon becomes the prinipal symptom of the disease, and is not unfreuently the first which appears, not being preeded by any general febrile symptoms: it is sually of an acute, tensive, pungent character, nd has been compared by some patients to ne sensation which a cutting instrument or a crew introduced into the affected parts would roduce. It varies much in its permanency, eat, and degree: in some cases the pain comes n in paroxysms, which continue for a short me, and then pass off, leaving in the intervals nly an acute tenderness. "These accessions," ays Abercrombie, "seem to be excited chiefly y flatus moving through the bowels and disending the inflamed part, and the action of a urgative is often followed by a violent aggraation of all the symptoms."* In other intances the pain is permanent, and is confined o a single spot of small extent, in which it ontinues to preserve its intensity during the whole course of the disease: in other cases, gain, the pain shifts from one part of the abomen to another, and sometimes extends early over the whole membrane. The pain iffers much in its degree, and may even ometimes be altogether absent, or only felt on ressure: in other instances it is very severe, nd much increased by the erect posture, or ny motion of the body; hence the patient lies onstantly on the back, and cannot, without an ncrease of suffering, lean to either side, finding ost relief from remaining motionless, with the nees in a slight degree elevated. This position, while it throws the weight of the intestines on ne spine, and therefore removes pressure from ne inflamed membrane, at the same time reaxes the abdominal muscles, and prevents ny stricture on the anterior surface of the inamed parts. The respiration is frequent, mall, and interrupted, and chiefly performed y the thoracic muscles, the depression of the iaphragm producing on the affected parts the ame effect that pressure does on the abdomen; onsequently, full inspiration, coughing, sneezng, vomiting, or the evacuation of the urine or eces, aggravate the pain.

The increased sensibility of the abdomen is ometimes not perceived unless when pressure s made; but in other cases the soreness is so xquisite that the slightest weight on the abdoinal parietes aggravates it to an intolerable egree. The pressure of the bed coverings beomes insupportable, so that it is found neessary to keep them from being in contact with the abdomen by artificial means. This ensibility to pressure is the grand criterion by which we are to judge of the existence and legree of the disease; "and this," it has been bserved, "we are not to estimate solely by the complaint, but by the countenance also of the patient. Even gentle pressure causes a sudden retraction of the lips and expression of pain, as if he were pierced by a sharp instrument. On the other hand, we are not to overrate the tenderness (though it is the surest diagnostic) by the wincing of the patient, especially if very irritable or young, or afraid of being hurt, or if the bowels happen to be uneasy and distended with flatus at the time."*

In addition to pain and tenderness on pressure, tension and tumefaction of the abdomen are constant and characteristic symptoms of peritonitis: those in the early stages arise from a tympanitic distention of the intestines, though at a later period of the affection they may be caused by effusion of fluid into the peritoneal cavity. This swelling, which is equal and regular in general peritonitis, exists in different degrees in different individuals, depending partly on the intensity of the inflammation, and partly on the degree of resistance which is offered by the abdominal parietes. It is considerable with those whose belly is naturally flabby, or when the abdomen has been recently distended, as in females after parturition, and in both sexes after the operation of paracentesis. In individuals, on the contrary, with strong abdominal muscles, and particularly in thin robust men, the abdomen is scarcely at all swelled, sometimes it is evidently retracted, especially in the first days of the attack; in such cases it is very hard, and in general the hardness and tumefaction are in the inverse ratio of each other.†

Along with these symptoms there are frequently present singultus, nausea, and vomiting, the matter ejected being at first the contents of the stomach at the time of the attack, afterwards mucus or bile. The bowels are in general obstinately costive, though occasionally relaxed. The pulse, as the disease advances, is in general very frequent, ranging from 120 to 130 in the minute; it is also very small, as if not only the heart but the artery at the wrist had contracted upon itself; yet if it be accurately examined, it will be found, during the stage of excitement, firmer than natural, almost

* Abercrombie on Diseases of the Stomach, &c. . 151.

* *Dr. Dickson:* see Lond. Med. Chirurg. Rev. Sept. 1820. In order to form an accurate idea of the sensibility of the abdomen, the hand should be laid flat on its centre, and then pressed successively on every part of it, the physician observing at the same time the patient's countenance, which will at once indicate pain if the abdomen be sensible. Care should be taken not to make pressure with the ends of the fingers; for then, by being applied to one point, it becomes considerable, and will excite pain where there may be no disease. Martinet's Pathology, translated by Quain, third edition, p. 68.

In some subjects the thickness of the muscles and parietes of the abdomen renders the pain on pressure scarce perceptible. In such cases M. Broussais directs us to make lateral pressure towards the centre of the abdomen. "Elle (douleur) était plus difficile à supporter quand on la faisait (pression) latéralement en la dirigeant vers le centre. Ce signe est un des meilleurs pour faire découvrir les péritonites obscures." Histoire des Phlegmasies, vol. ii. p. 492.

† *Chomel,* Dict. de Médecine.

feeling like a small whip-cord or harp-string. The tongue is covered with a whitish fur, the urine is scanty and high-coloured, and there is excessive thirst, which the patient fears to gratify in consequence of the vomiting which the introduction of fluids into the stomach often induces.*

The course of acute peritonitis is in general rapid, and marked by a progressive increase of all the above symptoms: the abdominal pain, tenderness, and tumefaction become aggravated, the face more pale, the features contracted, and often covered with a cold sweat,† the pulse more frequent, and the anxiety augmented. The malady may remain stationary for some days with nocturnal paroxysms, either marked by a febrile exacerbation or an aggravation of the local symptoms, and may not terminate fatally till after thirty or forty days; but in most instances it runs a much more rapid course, and in some cases the patient sinks in sixteen to twenty-four hours from the commencement of the attack.

The approach of death is marked by cessation of the pain, by the pulse becoming quicker, smaller, and very weak, feeling like a soft undulating line; by coldness of the extremities, and ultimately of the entire surface of the body. The abdomen becomes more tumid and tense, but in some instances soft and relaxed; the face is sunk, and especially hollow round the orbits; the vomiting is succeeded by regurgitation of the liquid contents of the stomach without any apparent effort; and although the intellectual faculties are often preserved unimpaired to the last moment, sometimes delirium, a comatose state, or in other instances convulsive movements of the head or limbs, precede the fatal termination.

Such is the assemblage of symptoms which acute peritonitis, in its simple and open form, presents: they are not, of course, all present in every individual case, but the greater number of them will be generally found to co-exist in well-marked instances of the disease. Cases, however, occasionally occur in which nearly all the above symptoms are absent. This variety of the affection will be considered under a distinct head.

Acute peritonitis may terminate by resolution; by effusion; by gangrene; or it may assume the chronic form.

Resolution may take place between the fifth and twentieth day. It is indicated by a cessation of pain, fever, and other inflammatory symptoms, a re-establishment of the functions of the neighbouring organs, the capability of turning on the side, and of bearing pressure on the abdomen, disappearance of the nausea and vomiting, and sometimes by the appearance of a critical evacuation, such as diarrhœa, abundant urine, and copious perspiration; by the pulse becoming slow and soft, and by the return of quiet and refreshing sleep.

Effusion is a frequent termination in fatal cases. The fluid effused may be serum, pus, or in some rare instances blood. These fluids may either exist singly or in combination with each other, or with coagulable lymph. The symptoms which denote effusion are diminution of the abdominal pain, with sense of weight and oppression in the affected part, irregular chills, softness of the pulse, paleness of the countenance, and coldness of the extremities.* Effusion may be ascertained to exist in many instances by percussion, which, when made on the abdomen in the early stages of peritonitis, generally elicits a sonorous sound derived from the tympanitic state of the intestines; but, as the effusion increases, this sound becomes progressively more limited and obscure. Fluctuation can also occasionally be felt,† but in general only after the disease has existed some time; for, as Andral observes, during the early periods of the disease, the abdominal effusion, small in quantity, is rather to be discovered by the tension, resistance, and modification of form of the belly, than by the great increase of its volume or the existence of fluctuation.‡ Fluctuation may also be absent, if the effused fluid is contained in a number of distinct abscesses, separated from each other by partitions of false membrane, of which the same pathologist relates an instance.§

It is doubtful, when pus and lymph are effused in any great quantity, if they are ever absorbed, and such cases generally terminate fatally, or pass into the chronic form of the disease. However, M. Gasc asserts that he has known patients recover in whom the purulent matter escaped by the umbilicus;‖ and we have seen cases of ascites consequent on peritonitis cured by the aid of medicine.

Gangrene is a much rarer termination; but M. Gasc observes that, of all serous inflammations, peritonitis, when intense, is most disposed to pass into a state of gangrene. The symptoms indicative of this termination are, sudden cessation of the abdominal pain, smallness of the pulse, which becomes concentrated and intermitting, extreme prostration of strength, Hippocratic countenance, and speedy death. Dr. Abercombie considers this termination rare, and that it is not often found in *post-mortem* examination as a prominent appearance, but when met with is slight and partial, and always accompanied with extensive deposition of false membrane. It more frequently occurs when enteritis co-exists with inflammation of the peritoneum.

* *Armstrong*, Morbid Anatomy of the Bowels, p. 92.

† The French pathologists have given a peculiar term to the expression of the countenance in this disease, "face grippée." Slight contractions of the muscles of the face and principally of the forehead are caused by the force of the abdominal pains, by which the features are discomposed and appear drawn up towards the forehead, which is wrinkled and the nose pointed. See *M. Gasc*, Dict. des Sciences Médicales, article Péritonite. *Roche et Sanson*, Elemens de Pathologie, tom. i. p. 585.

‖ Dict. des Sciences Médicales, p. 508.

When acute peritonitis does not prove fatal the course of fifteen or twenty days, it generally subsides into the chronic form. It sometimes, however, continues acute for a much longer period, and has even been protracted, as already mentioned, to thirty or forty days, and proved fatal at the end of that period. The symptoms which indicate this form of the disease will be considered in a separate section.

Diagnosis.—This is frequently attended with considerable difficulty, as the inflammatory affections of the viscera and other parts which the peritoneum covers frequently present nearly similar symptoms as inflammation of this membrane. Neuralgia and rheumatic pains of the adjacent muscles and nerves may also occasionally be mistaken for peritonitis; and colic, the passage of calculi along the biliary ducts or ureters, have been considered by some writers as liable to be confounded with inflammation of the peritoneum.

In gastritis the pain and tenderness on pressure are confined to the region of the stomach; the vomiting in general is more urgent, and is more easily excited by food or drink, and the thirst, with desire of cold liquids, is more intense. The state of the tongue varies in gastritis; but when it does present the thick coat in the centre, and intense redness of tip and edges, it will assist us in the diagnosis, as this appearance is not observed in simple peritonitis. When the peritoneal coat of the stomach is inflamed, the diagnosis will be more difficult, and can only be established by an attentive consideration of the general history and characters of the two diseases which have been already detailed.—See Gastritis.

We have frequent occasion to discriminate between enteritis and peritonitis in practice, and the symptoms are often so very similar that some physicians have thought a diagnosis between them impracticable. Dr. Cullen, after having given peritonitis a distinct place in his nosology, tells us, in his First Lines, that it is difficult to say by what symptoms it may be known, and that when known it does not require any remedies beside those of inflammation in general, and gives this as a reason for passing it over without further description. Dr. Philip Wilson, in his work on Febrile Diseases, asserts, "that peritonitis seldom exists without the inflammation spreading in a greater or less degree to the stomach and intestines, nor does inflammation of the latter frequently exist without extending to the peritoneum. There is hardly room, therefore, for regarding peritonitis as a distinct complaint." Nevertheless, the two diseases are essentially different, as well in the texture affected as in several of their symptoms, and in the *post-mortem* appearances which they present; and they can in many, perhaps in most, instances be discriminated. The treatment of peritonitis ought also, in some degree, to vary from that of enteritis.

John Hunter was fully aware of the distinct nature of these two affections, for he observes, "If the peritoneum which lines the cavity of the abdomen inflames, its inflammation does not affect the parietes of the abdomen; or if the peritoneum covering any of the viscera is inflamed, it does not affect the viscera. Thus the peritoneum shall be universally inflamed, as in the puerperal fever, yet the parietes of the abdomen and the proper coats of the intestines shall not be affected; on the other hand, if the parietes of the abdomen or the proper coats of the intestines are inflamed, the peritoneum shall not be affected."*

The most important diagnostic symptom between peritonitis and enteritis is the sensibility of the abdomen to pressure; in the former, pain is excited by a very slight degree of pressure, which would produce little or no inconvenience in the latter. The action of the diaphragm in full inspiration or coughing does not produce so much suffering in enteritis, nor is it so much aggravated by motion of the body or abdominal muscles. The pain appears much more superficial in peritonitis, and in many instances is not accompanied with sickness or any other disturbance of the intestinal canal. The pain in peritonitis in general is of a more acute character, and is more frequently accompanied with constipation. Enteritis presents some peculiarities according as it affects different portions of intestine, and the presence or absence of which will assist our diagnosis: these have been already fully considered. (See Enteritis.) When the duodenum is inflamed, pain in the situation of that viscus, and occasionally jaundice, are present. In inflammation of the large intestines, there are generally diarrhœa or symptoms of dysentery, neither of which affections are common in simple peritonitis; but when the jejunum or ileum are inflamed, it is more difficult to discriminate; the pain in such cases is in general not so severe as in peritonitis, and is principally in the regions which those intestines occupy.

Rheumatism sometimes, though rarely, affects the abdominal muscles, and may be mistaken for peritonitis, as it presents the same pain on pressure or motion; but the pain in such cases is principally felt at the origin or insertion of the muscles, shooting to the false ribs and the spine of the ileum.† In such cases the skin may be greatly distended, and if the muscles are swelled, the figure of each is often preserved. The existence of these peculiar symptoms, conjoined with the absence of uniform tumefaction, vomiting, or constipation, will probably in most cases enable us to form a correct diagnosis. Neuralgic pains of the abdominal viscera or parietes may simulate peritonitis. Andral observes‡ that rheumatic patients are sometimes attacked with severe acute pains in the abdomen, which vanish more or less suddenly without leaving any trace of a severe affection; and M. Chomel states that in several cases acute pains suddenly occur in the abdomen, often without any appreciable

* On the Blood, &c. p. 244.

‡ Clinique Médicale, tom. iv. p. 539.

cause, and last for ten or twelve hours, with frequent pulse, nausea, and vomiting, and yield to the use of opium.* There is some reason to suspect that these pains may in certain cases originate from irritation of some portion of the spinal cord, or of the ganglionic nerves that are distributed to the different viscera.† Their fugitive characters, the absence of pyrexia or tumefaction, and the general history of the case, may enable us to ascertain their real nature. In doubtful cases we should examine attentively the spinal column, and if any tenderness or pain is evident in a particular spot, it will give an additional probability to our suspicions.

Hysteria frequently simulates peritonitis, and nothing but a careful consideration of the history of the case and watching closely its progress, can enable us to discriminate between them. In hysteric cases, as Dr. Bright well observes, in general some great incongruity of symptoms will be detected: a tenderness of the abdomen, indicating inflammatory action beyond any thing which the pulse or the condition of the tongue would authorize us to infer; a hurry and even labour of respiration, more marked than in the embarrassed breathing of peritoneal inflammation; a sudden subsidence of the symptoms, and their sudden return; a shifting and changing of the tender or painful part, and sometimes the decided intervention of hysteric symptoms and the very frequent accompaniment of some evidence of mental causes, or of irritation and deranged function in the uterus itself,—all these, together with the general aspect of the individual, will frequently be guides and indications to assist us.‡

Colic may be distinguished from peritonitis by the absence of fever, the pain being relieved by pressure, the state of the pulse, and the suddenness of the attack. (See Colic.) There are several other affections which occasionally may present some of the symptoms of peritonitis which would lead us into too long a detail to consider. We have endeavoured to select those only which either occur most frequently or present the greatest difficulty in diagnosis. Inflammation of any of the abdominal viscera, or the passage of calculi through the biliary ducts or ureters, may occasionally resemble peritonitis, though they in general possess sufficiently distinctive characters. (See the different articles that treat of these affections.)

Prognosis.—Peritonitis is always attended with considerable danger, but if subjected to active treatment at an early period there is a fair chance of effecting a cure, especially if the patient is not advanced in years, is of a good unimpaired constitution, and capable of bearing depletion to a considerable degree; or if the inflammation be limited in its extent and uncomplicated in its form, and the symptoms much mitigated by the evacuations employed. A favourable termination is indicated by the gradual diminution of abdominal pain, tension, and tenderness, the pulse becoming fuller, softer, and less frequent; the skin less parched, soft, and moist; the respiration less laborious, and the countenance more open and expressive of ease. An unfavourable result is to be expected when the patient is of advanced age, and of a debilitated or broken-down constitution; when the disease originates from perforation of the stomach or intestines, or rupture of any of the abdominal viscera, or when it succeeds to a wound, a surgical operation, or to parturition; or extends over a large portion of peritoneal surface, or is complicated with an affection of any important organ. The danger is also greater when the inflammation has existed some time before the employment of remedies, and when the symptoms exhibit considerable intensity, and do not yield to the depletions employed.

Complications. — The fever which accompanies peritonitis may present either an inflammatory, typhoid, or gastric character. The former is met with most frequently in robust and vigorous patients; typhoid symptoms for the most part prevail in old persons of debilitated constitutions; and gastric fever will coexist when the gastro-intestinal mucous membrane is in a state of inflammatory excitement. The symptomatic fever may be so modified by the state of the patient at the time of the attack, by the co-existence of other morbid actions, and the prevailing epidemics of the season, as to present a variety of intermediate grades. In some instances peritonitis has been complicated with an intermittent fever, disappearing during the intervals, and re-appearing on the accession of each paroxysm.* In some instances it has assumed a tertian or quartan type;† but such cases are rare. Andral relates an instance of peritonitis supervening on the disappearance of rheumatism; but it is most frequently complicated with affections of the abdominal viscera, especially of the stomach or intestines; the inflammation spreading from the peritoneum to the other contiguous tissues which form their parietes, or pursuing an opposite course, attacking primarily their mucous membrane, and afterwards penetrating to and affecting the peritoneum. It appears sometimes to co-exist with an hepatic affection, and Chomel mentions a form of peritonitis called *bilious*, in which the peculiar symptoms of peritonitis were accompanied with a yellow coating of the tongue, discharges of bile from the stomach and intestines, with a yellowish tinge and pungent heat of skin.‡ M. Broussais observes that the excess of pain is capable of disorganizing the brain by a too impetuous afflux of

ood into its capillaries, and that after much ffering, the delirium, convulsions, and coma : frequently the effect of the disease of the ain itself.*

The lungs and pleura may also be affected nultaneously with the peritoneum, in which se thoracic pain, cough, dyspnœa, and other etoral symptoms will be present. This mplication is not very uncommon. M. ages found traces of inflammation of the eura in forty cases out of two hundred and ty subjects who died of puerperal peritonitis, d whose bodies he examined after death.† e parenchyma of the lungs, or the pericar- um may be also affected, but such cases are e. Other complications may exist which uld lead us into too long a detail to include : trust sufficient has been said to impress on mind of the medical practitioner the im- rtance of directing his attention to the state other organs and textures in cases of inflam- ation of the peritoneum.

III. *Puerperal peritonitis.* — The perito- um is very liable to become inflamed in the erperal state, those portions especially con- ected with the uterine organs. The uterus or appendages are generally the first parts that come affected, and the morbid action spreads contiguity or continuity to the general rface of the peritoneum : it consequently ually exists complicated with an inflamma- y affection of one or more of the textures or gans belonging to the uterine system. This bject has been already fully considered in the ticle Puerperal Fever, to which we refer r details; but puerperal females may be fected with peritonitis in its simple form, hen it presents some peculiarities deserving tention. Its predisposing causes are the gh degree of irritability of the system which ists subsequent to parturition, and more pecially in the peritoneum, from the sudden straction of distention which it undergoes by e contraction of the uterus after the expul- on of the fœtus. M. Chomel observes that e repeated friction to which the peritoneum subjected during labour may account for the imitive development of peritonitis in those ses where it appears without inflammation of e uterus.‡ Dr. Burns remarks that those ho have suffered from uterine hemorrhage ter delivery are most liable to this disease.§ he affection may also be excited by violence ring parturition, by the application of cold, the injudicious use of stimuli. When it curs during the prevalence of puerperal ver, it appears evidently to owe its origin to epidemic cause, and in some instances to be mmunicated by contagion. It may there- re be considered as occurring under two rms, 1. as a sporadic disease, and, 2. as an idemic.‖

1. *Sporadic puerperal peritonitis* sometimes becomes developed a few days after parturition, but occasionally two or three weeks intervene, and in some cases the pulse continues frequent from the time of delivery till the accession of the inflammation. The first symptom that manifests itself is generally pain in the abdomen, which is usually preceded or accompanied by rigors; and Dr. Denman* observes that from the violence and duration of the shivering, we may generally estimate the danger of the succeeding disease.

The abdomen becomes exquisitely painful on pressure, and this symptom is usually accompanied by vomiting, thirst, sharp, small, frequent pulse, and white dry tongue. The symptoms are in fact, generally speaking, the same as those which ordinary peritonitis presents, with some modifications, however, derived from the peculiar state of the affected parts induced by parturition. The pain more especially occupies the hypogastric region, and when it extends to other parts of the abdomen, it still continues most intensely in this situation, indicating that the peritoneal covering of the uterus is principally affected. The abdomen becomes distended more rapidly and to a greater extent than in the other forms of the disease, owing to its not offering so much resistance in consequence of its relaxed state subsequent to delivery; but it does not present quite so much hardness and tension as in ordinary cases. The lochia are diminished or suppressed. The lacteal secretion is either not established or is arrested, and the breasts consequently either do not swell, or collapse after having been swollen. The disease generally runs a short course, and rarely terminates in the chronic state. When it terminates favourably, the abdominal tumefaction subsides as rapidly as it had before augmented; the lochial and lacteal secretions are re-established; the pain abates, and the vomiting ceases; the pulse becomes fuller and slower, and the other signs, indicative of termination by resolution, which have been already described, are exhibited.

The fatal termination is characterized by the increase of abdominal tumefaction, pain, and tenderness, quick irregular pulse, Hippocratic countenance, cold extremities, and sometimes by the sudden cessation of pain, while the other unfavourable symptoms continue. Dr. Gordon has related some cases which terminated by suppuration; in two instances the matter escaped externally by the umbilicus, and in a third by the urethra.

2. *Epidemic puerperal peritonitis* may be considered as a variety of puerperal fever, which has by some been thought to depend in every instance on inflammation of the peritoneum; but it has been already demonstrated that various forms of uterine inflammation may occur in this fever, and give rise to a variety of symptoms, and that these local inflammations may exist independently of each other though they are frequently combined. (See Fever, Puerperal.)

‖ See Fever, Puerperal, p. 252.

* Denman's Midwifery, p. 433, 6th edition.

When this fever excites peritoneal inflammation, it is not, according to Dr. Gooch, "one uniform disease, but may occur under different forms; it is sometimes so mild as to be curable by the gentlest aperients, and at other times is very obstinate and fatal. In this latter form it sometimes consists of acute inflammation of the peritoneum with inflammatory fever, which bears and is curable only by early and active depletion; sometimes of inflammation and fever of a low type, in which depletion is useless and even pernicious."* He observes "that in the leading circumstances of the disease there is certainly a great uniformity: it almost always commences a few days after delivery, is marked by pain and tenderness of the belly, and a rapid pulse; and if not cured, terminates fatally within a week, and after death commonly leaves the depositions and effusions of inflammation: thus far it is very uniform, but no further."† He describes the leading symptoms of the epidemic of 1812 (which he witnessed) to be "diffused pain and tenderness, with some swelling of the abdomen, a quick pulse, which was generally at first full and vibrating. Sometimes it was small, but still it was hard and incompressible; the skin was hot, though not so hot as in other fevers; the tongue was white and moist; the milk was suppressed. As the disease advanced, the belly became less painful, but more swelled, and the breathing short; towards the end, the pulse was very frequent and tremulous, and the skin covered with a clammy sweat; even in this state the tongue continued moist and the mind clear, and death took place generally about the fifth day. On opening the abdomen, which was often as large as before delivery, the intestines were found distended with air; the peritoneum was red in various parts, its surface was covered with a coat of lymph; the intestines adhered to one another, and the omentum to the intestines; coagulable lymph was deposited on various surfaces, especially in the depressions between the convolutions of the bowels and on the omentum, on both which parts it often lay in large masses; the cavity of the peritoneum contained several pints of a turbid fluid, apparently serum mixed with lymph. In the uterus the morbid appearances were generally confined to its peritoneal covering, which was coated with lymph, on removing which the membrane itself was found unnaturally red; but in some cases the disease had penetrated deeper into the uterus, the substance of which was sometimes infiltrated with pus, and sometimes contained small abscesses about the size of a nut; the inner surface of the uterus, especially at the fundus, often appeared black and ragged as if gangrenous. The enlargement of the abdomen depended entirely on air in the intestines; when there was no air there was no enlargement, even though the peritoneum contained several pints of fluid."‡ He describes several gradations of this affection, which have been already considered in the article PUERPERAL FEVER.

We have been induced to make this long quotation, in order to demonstrate that puerperal peritonitis, when epidemic, is nearly identical in its symptoms and post-mortem appearance with the common form of the disease. The peculiarities which it presents it possesses in common with the sporadic form, occurring after parturition, from which it only differs in its epidemic and occasionally contagious origin, in its frequent complication with uterine affections, and in being attended in some instances with a fever of a typhoid character. It appears to us that the epidemic form is primarily a fever that excites peritoneal inflammation, which is to be considered as symptomatic of a constitutional affection; and that the sporadic form is an idiopathic inflammation modified by the peculiarities of the puerperal state.

This view accords with Dr. Armstrong's ideas on the nature of this disease. He states that puerperal fever "is a common or specific fever, occurring in the puerperal state, and modified, like almost every other affection, by the condition of the patient at the time of the attack. In general," he further observes, "it is a common fever combined with inflammation of the abdominal and pelvic viscera, but it is sometimes genuine typhous fever occurring in the same state, and then, superadded to the symptoms of peritonitis, are developed, rapidly for the most part, those symptoms by which a fully formed typhus can be recognized."* Dr. S. Cusack, of Dublin, in his paper on puerperal fever,† observes that the low form of puerperal fever which exhibits a typhoid character was sometimes epidemic, and that the seasons which appeared to favour its occurrence are such as give rise to typhous fever, erysipelas, and diseases of a low type." It appears, therefore, to originate from the same causes as epidemic fevers, to exhibit the same constitutional symptoms, with only this peculiarity, that the uterine organs or peritoneum are in every case inflamed, an effect which we might, *a priori*, expect in the event of fever attacking a puerperal female.

IV. *Varieties of peritonitis.*—This disease presents several modifications in addition to those above described, which being attended with some peculiarities with respect to their causes, symptoms, and progress, are deserving of separate consideration. The principal of these are: 1. hemorrhagic peritonitis; 2. erysipelatous peritonitis; 3. peritonitis from intestinal strangulation; 4. latent peritonitis; 5. partial peritonitis; 6. peritonitis from perforation of the intestines; 7. peritonitis from paracentesis of the abdomen.

1. *Hemorrhagic peritonitis.*—This form of the disease is very rare: its predisposing causes appear to be a sanguine temperament, and a constitution liable to hemorrhagies and inflam-

* On Diseases of Females, p. 14, 15.

† Edin. Med. and Surg. Journ. January 1829.

tory affections. If in such persons any itation acts peculiarly on the abdominal se- is membrane, an hemorrhagic action may determined to its vessels, and a sanguineous usion thus take place into the peritoneal vity without any rupture of vessels. The mptoms of this variety are similar to those acute peritonitis. The pain, however, ap- ars to be much more violent, and to be cha- eterised by marked intermissions: the an- ety is greater; it is accompanied with pyrexia, pulse at first strong and inflammatory, which erwards becomes expanded and soft, and ally, at the approach of death, quick and nall. The disease runs a very rapid course, d convulsions with coldness of the extre- ities precede the fatal termination.*

2. *Erysipelatous peritonitis.*—This variety pears to owe its cause to the transference of ysipelatous inflammation from the skin or ucous lining of the throat and fauces to the ritoneum: its symptoms, as described by r. Abercrombie, are "sometimes slight and sidious, but sometimes very severe, and they e chiefly distinguished by the rapidity with hich they run their course, and by a remark- le sinking of the vital powers, which occurs m an early period, and often prevents the loption of any active treatment: a remark- le circumstance in the history of the affection its connection with erysipelas and other dis- ses of an erysipelatous character."†

In one case which he relates, the day after e disappearance of erysipelas from one of e lower extremities, acute pain attacked the gion of the stomach, which, in a short time, oved to the lower part of the abdomen, and ound the umbilicus, with little tenderness on ressure, but accompanied with great anxiety d restlessness: the patient sunk rapidly, and ied twenty-four hours after the attack. Dis- ection discovered a considerable quantity of loody sanies in the abdomen, part of the nall intestines of a dark red and part of a ull leaden colour, and the whole were con- derably distended.

The form in which the throat is primarily ffected seems occasionally to owe its origin to n epidemic cause. Dr. Abercrombie relates at in the spring of 1824 it prevailed as an pidemic in the Merchants' Hospital in Edin- urgh. Its leading features were a slight ery- ipelatous affection of the throat, beginning ith vomiting and slight fever: in some cases e internal fauces were covered with aphthous rusts or swelling of the uvula, and in some cases here were angry ulcerations about the lips, with ponginess of the gums; the larynx was un- ffected in every case, and, excepting in two nstances, which proved fatal by the superven- ion of abdominal inflammation, the symptoms vere mild, and little treatment was necessary. n the two cases referred, to the patients were ttacked with the above symptoms, and, when ecovering, pain and tenderness in the abdomen and serious constitutional disturbance super- vened, and proved rapidly fatal. The two fatal cases render it probable that the erysipelatous action may invade the peritoneum as well as the membrane of the mouth, and that its symptoms and history sufficiently distinguish it from common peritoneal inflammation. The post-mortem appearances were peculiar, consisting of a bloody serum or pus mixed with shreds of flaky matter, but without much or any of that inflammatory or adhesive exudation which forms so prominent a character of peritonitis in its common forms.

3. *Peritonitis from intestinal strangulation.* This form may arise from internal or external strangulation of a portion of intestine. It presents for some time obscure symptoms, the inflammation being at first limited to a small space, and it extends itself gradually from that portion of peritoneum which is strangulated to the rest of the membrane. When the whole peritoneum becomes affected, this variety presents the same general appearance as ordinary peritonitis: it differs, however, not only in the exciting cause, but also in the succession of the phenomena which it presents; in exhibiting some symptoms which accompany it in its whole course; by its termination, and by the mode of treatment which it requires.

In this variety constipation and vomiting are frequently the first symptoms which appear, to which pain succeeds; febrile paroxysms do not, however, develope themselves till after this last symptom, or even later. In the whole course of the malady, the constipation and vomiting, the irregular form of the belly, the parietes of which are elevated in several points above the obstacle, give a peculiar aspect to this variety of peritonitis. It is much more dangerous than ordinary peritonitis, and in treating it we ought to have more in view the removal of the exciting cause which still continues to operate than the management of the inflammation itself.*

4. *Latent peritonitis.*—Nearly all the characteristic symptoms of peritonitis may be absent, and yet the disease exist and be productive of serious effects, and even terminate fatally. This will be most apt to occur in patients of feeble powers and advanced age, in maniacal persons, or in those affected with some severe malady, which may either absorb the attention of the physician, or mask, by its greater intensity, the peculiar symptoms of peritonitis. In such cases it may steal on without pain or any accompanying pyrexia, and the only criteria by which we can judge of its existence, are perhaps the expression of the countenance, and, on a close examination, some degree of tumefaction and tension of the abdomen, and, occasionally, an obscure sensation of pain excited by pressure.

5. *Partial peritonitis.*—This affection may be confined to a small portion of the peritoneum during its whole course. This variety may be caused by a contusion or wound penetrating into the abdomen, or it may succeed to

* Broussais' History of Chronic Phlegmasiæ, y Hays and Griffith, vol. ii. p. 304.

† On the Abdominal Viscera, p. 182.

* *Chomel*, Dict. De Médecine, tom. xvi. p. 326.

a surgical operation, in which the abdominal parietes or viscera are concerned; while in some instances it may arise without any apparent cause. It often commences, without rigors, by a pain in a limited point of the abdomen, augmented by pressure, often accompanied with some tumefaction or hardness in the affected part, and occasionally with febrile symptoms of some intensity; but in general the vomiting and alteration of the countenance, which so frequently attend general peritonitis, are absent. It may, however, become general, and then it will present the same phenomena as the common form of the disease. When it remains circumscribed, it commonly terminates favourably in a short time, the effusion, then small in quantity, being absorbed. In some instances, the inflamed portion becomes the seat of a collection of pus circumscribed by adhesions, which may escape into the stomach or intestines by erosion of their parietes where they have formed an adhesion to those of the abscess. M. Chomel supposes that in most of those cases where, after signs of local peritoneal inflammation, pus is discharged from the stomach or intestines, it owed its origin to this source. Several forms of local peritonitis have been described by authors. Dr. Cullen mentions two, neither of which, however, he ventures to discriminate by any characteristic symptoms.

The peritonitis *omentalis* he tells us affects the omentum, and the peritonitis *mesenterica* the mesentery.* Dr. Mason Good informs us that the omental peritonitis is characterized by a more sensible swelling in the region of the omentum.† The same author describes mesenteric peritonitis as being attended with a pain deeper-seated, and more immediately in the mesenteric region, the external tenderness being less than in the other forms. Frank states that it is accompanied with deep pain in the back and in the umbilical region, that it often terminates in abscess, which may obstruct the bowels by mechanical pressure, or open into the cavity of the abdomen, or into the intestines.‡ Frank also mentions a variety of local peritonitis confined to the lining of the abdominal muscles, which, when limited to the covering of the rectus, sometimes causes the shape of that muscle to be developed, and effusion of lymph or blood into its sheath, with tension, distention, and occasionally speedy gangrene. When, also, the general peritoneal lining of the abdominal muscles is inflamed, the sensibility to pressure will be very great, and if it terminates in suppuration, an immense collection of purulent matter may form between the peritoneum and muscles, simulating ascites. The same author also states, that when the peritoneum covering the bodies of the vertebræ is inflamed, it will give rise to pain in the back, in the situation of the lumbar vertebræ, much increased by the erect position of the body, and resembling in some respects disease of the kidney. When the peritoneal covering of the psoas and iliacus internus is inflamed, pain is felt in the region of those muscles, extending through the groin to the thigh, which cannot be extended without an increase of suffering, but is unattended by any difficulty in passing the urine or fæces. Dr. Abercrombie describes several symptoms of peritonitis which seem to arise from the inflammation having its seat more peculiarly in the serous envelope of certain organs. When the covering of the liver is affected, the case can scarcely be distinguished from acute hepatitis. When it occurs in the neighbourhood of the kidney, Dr. Abercrombie thinks it may give rise to true ischuria renalis, proving fatal by coma and effusion in the brain.

These varieties of peritonitis are interesting in one point of view, as they enable us to explain the predominance of certain symptoms in individual cases, and an attention to them may, in some instances at least, prevent our mistaking affections of the peritoneum for diseases of the organs which it covers, and may also be a useful guide as to the local treatment.

6. *Peritonitis from perforation.*—For an account of this variety, we refer to *Peritonitis from perforation of the serous membrane.*

7. *Peritonitis from paracentesis.*—In this variety the pain is generally first perceived in the point where the puncture was made. The flaccidity of the abdominal parietes, and the rapid tumefaction of the belly which occurs when peritonitis arises from this cause, bear some resemblance to the phenomena which puerperal peritonitis exhibits. This form has almost invariably a fatal termination; in most cases that we have seen, it ran its course in a few days, and was attended with greater prostration of strength, and less of febrile excitement than the common form of the disease.

V. *Chronic peritonitis.*—When acute inflammation of the peritoneum continues beyond the fifteenth or twentieth day, it generally becomes chronic: this species of the disease may, however, arise primarily from the exciting causes we have before enumerated operating on a patient of advanced age or debilitated constitution. Particular occupations which cause pressure on the abdomen, may predispose to or excite this disease, to which may be added cold and moisture, prolonged residence in hospitals, fatigue, unwholesome food, protracted intermittents, and any kind of slow effusion into the cavity of the abdomen.

We shall consider chronic peritonitis under two heads: 1st, *primitive*, without being preceded by symptoms of acute inflammation; 2d, *consecutive*, following as a consequence of acute peritonitis.

1. The primitive form may commence in a slow and almost insensible manner, without presenting any very obvious symptom. There may not be any abdominal pain at its commencement or during its course, and it may

* Synopsis Nosologiæ Methodicæ, tom. ii. p. 109.

† Study of Medicine, 1st edition, vol. ii. p. 371.

‡ *Frank*, De Curandis Hominum Morbis, lib. ii. ord. iv. gen. i.

ly exhibit the appearance of simple ascites: many cases we cannot ascertain with any tainty its presence during life, but when it more open in its characters, they are identical ch the consecutive form, the symptoms of ich vary considerably in the early stages. is in general attended with some abdominal n, which is mostly deep, not very acute, and ely permanent; in many cases the patient ly complains of pain when his abdomen is ssed either by the hand or the action of the rounding muscles, or on a sudden shock of body. There is occasional vomiting and re or less distention of the abdomen, which netimes becomes tympanitic; and in some es indurated spots can be felt, which are der to the touch. Emaciation, irregular wels, either constipation or diarrhœa, or the alternating with the other; increasing dis- tion of the abdomen, and inability to bear n the pressure of the ordinary dress if at tight; various dyspeptic symptoms, and neral debility, mark the progress of the ease. The alvine evacuations are sometimes a pale colour and peculiar fœtor, in other tances of a dark appearance, and sometimes rly natural.*

Dr. Pemberton observes that there is no ssion of the skin of the abdomen as in the ute species; on the contrary, that the skin l abdominal muscles sit loosely upon the itoneum, which gives a sensation to the ch as of a tight bandage underneath, over ich the skin and muscles may be said as it re to slide.†

In some patients the appetite is often pre- ved, and the digestion is but little deranged, which cases we may conclude that the itoneum reflected over the stomach is not y deeply involved in the disease. Broussais ntions the sensation of a ball rolling about the abdomen, and sometimes approaching throat, which he attributes to the agglutination of the intestines, these forming with the ged mesenteric glands a round and mobile ss in the belly, often without any effused id.‡

The general phenomena are very obscure: pulse is often natural except towards eve- ng, when it becomes quick, with increased t of skin, and slight flush on the cheeks, l occasionally some dyspnœa and cough. . Pemberton, however, observes that though pulse is somewhat accelerated, and the ngue, particularly in the morning, slightly vered with a white fur, with considerable rst, he never observed any exacerbation of er in the evening, or any hectic flushes on cheeks: on the contrary, the countenance full of languor, and the face is pale and ughy.

In some forms of the disease, the abdomen comes augmented in volume, yields a dull nd on percussion on a part or the whole of surface, and occasionally presents the sense of fluctuation more or less obscure, with an œdematous swelling limited to the inferior extremities or parietes of the abdomen.* In other forms, the abdomen rather diminishes than augments in volume, and offers an unnatural resistance on pressure, with, occasionally, some degree of projection near the umbilicus, occasioned by the intestines matted together in a mass before the bodies of the vertebræ.

With more or less of these symptoms the disease advances slowly, and sometimes remains stationary for several months, and even may in some cases present some temporary amendment; but it generally terminates fatally, either by the supervention of acute peritonitis or enteritis; or the patient sinks from exhaustion, the result of long-continued irritation or diarrhœa. In some instances ascites precedes the fatal termination, or purulent effusion into the abdominal cavity takes place, which may escape outwardly by the umbilicus or inguinal ring: or the tubercles which have been developed on the peritoneal surface may ulcerate, and form a communication between the intestines and cavity of the peritoneum, with escape of the contents of the former into the sac of the peritoneum, inducing acute peritonitis, which proves rapidly fatal; or disease of the mesenteric glands may be induced, and the patient die in a state of marasmus with hectic symptoms.

The *diagnosis* in this disease is extremely obscure, and is rather to be deduced from a close consideration of the history of each case, the predisposing and exciting causes, and the assemblage of local symptoms, than from any definite rules.

Its *prognosis* in general is unfavourable. M. Broussais, in an early edition of his work, considered it as incurable; afterwards, however, he met with several cases which terminated favourably. Dr. Abercrombie succeeded in curing some cases in individuals whose families had formerly suffered from this affection. Dr. Pemberton states that the symptoms which indicate recovery are an abatement of the pricking pains in the abdomen, and a diminution of the frequency of the pulse to eighty in a minute; but that under these favourable appearances a relapse is always to be dreaded.

Morbid anatomy of peritonitis.—The alterations which the peritoneum presents after death from this disease are essentially the same as are found in cases of inflammation of other serous membranes. The morbid effects are greater or less, according to the intensity and duration of the disease. They are sometimes confined exclusively to the peritoneum, evidencing that this membrane may be partially or generally inflamed, without the subjacent tissues being affected: however, in some of the complicated forms of this disease, morbid lesions of the other intestinal tunics will be occasionally discovered to co-exist with those characteristic of peritonitis.

The following are the effects of inflammation of the peritoneum, as far as they are revealed

* *Abercrombie*, p. 192.

by dissection:—1. increased vascularity and thickening of the peritoneum; 2. effusion of coagulable lymph, either in the form of flocculi, membranes, bands, or masses; 3. effusion, into the peritoneal cavity, of various fluids, serum, pus, or blood, mixed or separate; 4. gangrene; 5. tuberculous formations; 6. granulations on the peritoneal surface; 7. ulceration.

1. *Morbid appearances in acute peritonitis.*—The first effects of a low degree of inflammatory action upon serous membranes appear to be simply an increased deposition of the serous fluid; and in this manner it is probable that a certain state of these membranes, which, if not actually inflammatory, closely borders upon it, is sometimes relieved; the increased quantity of fluid being afterwards absorbed, and the parts recovering their healthy relations.*

When inflammation is fully established, its earliest effect is increased vascularity, which produces at first a slight degree of opacity of the membrane, and red points begin to appear on its surface, which may either occupy a small portion, or cover nearly the whole extent of the peritoneum; the surface of which at this time appears dry and shining, but on touching it an unctuous coating will be detected. Sometimes, instead of the red points, blood-vessels are developed, forming red striæ more or less numerous. As the inflammation advances, the small points become multiplied, coalesce, and form patches of variable extent, and the blood-vessels become more evident and numerous. In a more advanced stage, the redness is rendered more intense, and occupies a larger portion of the membrane; sometimes forming broad surfaces of inflammation, which run like bands along the course of the intestines, and are bounded by the adhesions which different portions of the bowels contract with each other. This redness is frequently arborescent, sometimes intermixed like network. The vascular injection has been supposed by some to exist in the arterial capillaries; but Dr. Armstrong observes, that whatever may be the case during life, it is after death chiefly seated in the venous capillaries; for on a minute inspection the small ramifications of the arteries may be seen empty, traversing the intermediate portion of intestine, like so many transparent lines. The degree of redness is ultimately influenced by the quantity of secretion being greater in those cases where there is least serum and lymph.†

Along with this redness we observe more or less thickening and opacity of the peritoneum; an effect produced not only by the hyperæmia of the inflamed part, but also by the effusion of serum, lymph, or both, into the subserous cellular tissue, which causes some degree of pulpiness, and a facility in separating the serous coat from the subjacent parts. The serous membrane itself is also thickened by the effused fluid penetrating between its laminæ, and separating them more or less from each other, and in some instances a slight degree of emphysema exists, from the disengagement of air in the connecting cellular tissue; but when the inflammation is slight, this thickening is not apparent.

The intestines are much thicker and more massy, as well as the mesentery and the mesocolon; and the omentum sometimes is rendered as thick as a person's hand; effects which arise from the extravasation of coagulable lymph into the cellular substance between the laminæ of peritoneum which forms them.*

Redness and thickening may be considered as the first effect of peritoneal inflammation; but it is accompanied or quickly followed by effusion of serum and lymph, which have been supposed to be separated simultaneously. Dr. Armstrong, however, seems to think that the lymph is first effused; but it would appear that the degree of intensity of the inflammation determines the nature of the effusion. When the inflammation is not very violent, serum seems to be the earliest product of the vessels of the affected part; but if the inflammatory action is very acute, lymph is often thrown out in the first instance. This effusion of lymph may take place a very short time after the commencement of inflammation; it is at first soft and gelatinous, afterwards becomes more consistent, and finally assumes the texture of a membrane of considerable tenacity. It generally soon becomes organized: Andral† observes that in some cases, twenty hours after the commencement of peritonitis, vessels can be traced and injected in this fibrous concretion, which has become a living texture; in other cases, after several months, no trace of organization can be found in these membranous layers. This coagulable lymph may assume various forms; it may either be deposited in a lamina of variable thickness, lining the peritoneal surfaces, agglutinating the intestines to each other, to the abdominal parietes, or to the omentum; or narrow bands of membrane, of variable length, may connect two or more coils of intestine together; or a mass of lymph of a prismatic form may lie between the intestinal convolutions, filling up their interstices, the

* *Abercrombie*, p. 3.

† M. Scoutetten asserts that this redness, when intense, is not owing to the distention of the blood-vessels, but to a sanguine exudation which is formed on the surface of the peritoneum, and which adheres strongly to it; and that the surface is uniformly red, and appears villous. Both causes probably concur to produce the effect.

Bichat, M. Gasc, and others, have asserted that the absence of redness on the peritoneal surface after death may occur in cases where the membrane was inflamed during life. M. Scoutetten, (Archives Générales, tom. iii. p. 501,) however, from some experiments he has performed on living animals, has come to a contrary conclusion: he asserts that the disappearance of redness from an inflamed *external* surface after death is owing to the pressure of the atmosphere, which has but a very modified influence on an *internal* tissue; and that, consequently, the characters of inflammation are very nearly the same in those tissues during life and after death: his experiments are highly ingenious, and would seem to justify the conclusion he has deduced from them, viz. *that an inflammation of an internal membrane will in every case leave increased redness after death.*

* Baillie's Morbid Anatomy.

† Clinique Médicale.

anterior flat surface of which mass corresponds to the parietes of the abdomen, and the two other surfaces, slightly concave, are applied on the two contiguous intestines, and terminate in their interval by a rounded angle. The lymph may also be in the form of flocculi, or small shreds of membrane, floating in a serous fluid, or deposited on the free surface of the peritoneum when little or no fluid is found.

These false membranes are either of a white colour, grey, or sometimes a little reddish; they vary in their thickness from a quarter to two or three lines. When the inflammation has lasted twenty or thirty days, these adhesions acquire a considerable degree of firmness; they are often productive of no inconvenience, but if very numerous, and uniting the coils of intestine very closely together, they may give rise to a modification of the form of the belly, an habitual tension in the abdomen, and more or less disturbance in the digestive functions. Dr. Abercrombie relates some cases where fatal ileus seemed to be induced by the operation of such causes, which appeared to act by deranging the muscular power of the intestinal canal, or by inducing a strangulation of a portion of intestine.

Serous effusion, as we have before observed, may take place very early in this disease;* but in general it is not considerable in quantity until the affection has existed for some time. This, however, is not always the case: in some instances, after thirty-six or forty hours, there is a large quantity of fluid effused; it is generally accumulated in the inferior parts, unless retained in distinct cavities by adhesions. Its colour varies very much: it is sometimes limpid; and that is principally the case when the peritonitis has been partial:† at other times it is whitish, greyish, milky, or yellowish, and occasionally has all the sensible properties of pus. Dr. Abercrombie observes that the opaque milky deposition is commonly connected with alteration of the structure of the membrane, which in such instances presents a soft thickened appearance, resembling a part that had been boiled. The more common appearance of the peritoneum consists of a deposition of false membrane, co-existing either with the milky flocculent fluid, or with pus, or a fluid entirely limpid. In the latter case, the deposition on the surface of the membrane will prevent the re-absorption of the fluid; so that the accumulation which might otherwise have disappeared will thus become a permanent cause of ascites, provided the disease does not prove speedily fatal.‡

* In some cases of peritoneal inflammation the secretion of this membrane is suspended, and it appears dry.

† Bichat observes that, when serous effusions are the consequence of an affection of a viscus, the serosity is limpid, transparent, and probably of the same nature with that which is exhaled in its natural state; but that, on the contrary, when the effusion depends on inflammation of serous membranes, the fluid is almost always altered. (*Roche et Sanson*, Elemens de Pathologie, tom. i. p. 552.)

‡ *Abercrombie*, p. 3.

This effusion is sometimes reddish, evidently from a mixture of the colouring matter of the blood; and in the hemorrhagic variety of peritonitis, large quantities of blood in a coagulated state have been found by M. Broussais in the peritoneal cavity, without any rupture of vessels being detected, accompanied with extensive ecchymoses of the cellular tissue which unites the peritoneum to the contiguous parts.

The quantity of fluid effused in peritonitis varies from a few ounces to several pounds; its consistence is sometimes that of water, without containing any albuminous clots; at other times it equals that of milk or the pus of the cellular tissue, and often contains the flocculi before mentioned.

The peritoneum is seldom found in a state of gangrene in its whole extent; but eschars of variable size, and of a greyish slate-colour or blueish, are formed, which are easily lacerated, and exhale a fetid odour. The surface of these eschars is often covered with a greyish soft matter, little adherent, which appears to be the commencement of decomposition: these eschars sometimes pervade the entire thickness of the intestinal tunics, or the great epiploon, or extend deeply into the abdominal parietes.

There are certain brownish, black, or violet degenerations of the peritoneum which have been mistaken for gangrene, but are only the results of chronic irritation; they are easily distinguished by not being readily torn, by being destitute of the gangrenous odour, and by the great extent to which the peritoneum is discoloured, the entire membrane being sometimes affected. These appearances are a common consequence of chronic peritonitis.

Ulceration very rarely occurs as a consequence of peritonitis; though not unfrequently the peritoneum is perforated in cases where the ulcerative process, commencing in the mucous membrane, erodes the other coats of the intestines: this naturally leads us to consider peritoneal ulcers as of two kinds:—1. *primitive ulcers*, or those which occur primarily in the peritoneum as a direct consequence of inflammation; 2. *consecutive ulcers*, or those which originate in the intestinal mucous membrane.

There are not many cases on record of primitive ulceration of this membrane. M. Scoutetten observes, that if the patient is not exhausted, and continues to live for some time, erosions of the peritoneum, at first slight, become by degrees more and more deep, and are converted into true ulcers, which may extend and destroy all the membrane, and even the subjacent tissues.* In a patient who had suffered from a venereal affection, and had experienced pains in the lumbar region, most severe at night, M. Portal found, on examination of the abdomen after death, several ulcers covered with pus in the peritoneum situated on the anterior of the lumbar vertebræ and of the kidneys. The same author cites Bouet and Paw as having seen subjects in whom the

* Archives Générales, tom. iv. p. 392.

peritoneum appeared eroded to a great extent.* M. Scoutetten observed the diaphragmatic portion of the peritoneum ulcerated in one case to the extent of two inches; and there is a case also mentioned by the same author, in which, after symptoms of peritonitis, the abdominal parietes were perforated at the umbilicus, and a whitish fluid of the consistence of pus escaped from the abdomen. We have before mentioned, in treating of partial peritonitis, that purulent effusions in this form of the disease occasionally escape by an opening into the stomach or intestines; from this we would infer that ulceration of this membrane may occur more frequently than is generally supposed, but there are not many cases of this description on record.

Consecutive ulceration is much more frequent, and will be fully considered in the article *Peritonitis from perforation of the serous membrane.*

2. *Morbid appearances in chronic peritonitis.*—The organic changes which are the consequence of chronic peritonitis are very nearly the same as those which result from the acute form. There are some peculiarities, however, belonging to the chronic species which deserve attention. In chronic peritonitis, the redness, the result of increased vascularity, is of a darker hue, and the larger branches of veins are more considerably dilated.† The peritoneum has acquired a greater thickness, and the inflammation appears to have penetrated to the subjacent membranes and organs. The false membranes are very numerous and firm, and unite many coils of intestine; sometimes they form a kind of envelope which surrounds the great epiploon and the intestines, and sometimes partial pouches are formed by false membrane which contain a quantity of fluid: when these membranes are detached, we find the subjacent peritoneum less red than in acute peritonitis. In some subjects scarcely any liquid is found: in these cases the false membranes are less abundant and less thick; and the intestines are united to each other by the adhesions which the inflammation has caused them to contract, and not by intermediate albuminous layers.‡

In some subjects, on the other hand, a considerable quantity of effusion is found without any false membrane on the peritoneum, which is thickened, reddish, and exhibits a multitude of dilated bloodvessels. The epiploon is red, thick, and fleshy, and sometimes contains between its laminæ transparent vesicles like hydatids, and substances resembling granulations are occasionally seen on its surface.

When the peritonitis has been of several months' duration, it sometimes occurs that the abdominal parietes are not distended by effusion, but are pressed close to the intestines. The epiploon is covered with a crowd of whitish tubercles of variable size, surrounded with bloodvessels more or less developed. These tubercles may also exist on any part of the peritoneal surface: Dr. Armstrong has found them under three modifications, 1. as small miliary points semitransparent and firm; 2. as uniformly opaque bodies of a larger size, and nearly of the colour and consistence of the kernel of the ripe horse-chesnut; and, lastly, as soft white substances, not unlike cut portions of the medullary matter of the brain. The first and second modifications are seated in the subserous cellular tissue, and likewise between the mucous and muscular intestinal coats; but the soft medullary variety appears to be formed in general on the free surface of the serous membrane itself.* Tubercles at first are extremely minute, but they gradually increase in size and number, and sometimes coalesce: they occasionally exceed the size of a large pea. When small, they are of considerable consistence, and adhere with such tenacity to the peritoneum, that they can only be separated by tearing this membrane; but as they increase in magnitude, they become softer, and approach in their appearance to pus, when they can be easily detached. After being softened, they may again become indurated, and are sometimes converted into a calcareous matter. Occasionally, when they have existed for a considerable time, the peritoneum in the intervals between the tubercles becomes of an obscure red colour, or bluish or black, and presents a strong contrast with the white appearance of the tubercles. These bodies may ulcerate and give rise to perforation of the intestines; when tubercles exist, there is generally only a small quantity of fluid in the abdomen, which may be of different shades of colour from a grey to a black. In most instances, where they have been found on the peritoneum, they existed simultaneously in other organs, especially the lungs. If the symptoms which characterize a tuberculous diathesis co-exist with signs of chronic inflammation or irritation of the peritoneum, we may have some reason to suspect a tuberculous state of this membrane.

M. Bayle has described certain bodies which he calls *granulations*, presenting a pisiform white appearance, and being of a hard consistence, not unlike miliary eruptions of the skin; but M. Broussais supposes they are nothing more than a transformation of the exuded matter which passed from a liquid to an organized state.†

Chronic irritation may produce several other morbid changes on the peritoneum or the subserous tissue, the detail of which would include nearly the whole of the morbid anatomy of this membrane. It may become cartilaginous, bony, or scirrhous. The mesenteric glands may become diseased and tuberculous. Broussais has found vesicles resembling hydatids, and extensive lardaceous depositions, in the subserous cellular tissue. This fatty matter

* Anatomie Pathologique, tom. v. p. 126.
† *Armstrong*, p. 76.

* Morbid Anatomy, &c.
† History of the Chronic Phlegmasiæ of Broussais, by Hays and Griffith, vol. ii. p. 294.

was not only deposited under the peritoneum, but also between the laminæ of the mesentery and omentum; it was of a white or yellow appearance like tallow, and mixed with a gelatino-albuminous fluid of thinner consistence and darker colour, which gave the whole mass a mottled appearance. He supposes this the result of chronic inflammation of the subserous tissue, but whether those productions are always to be considered the effects of inflammatory action is doubtful. They at all events are not the usual results of this state; and it appears necessary that a peculiar disposition to such formations must pre-exist in the constitution, which may be called into action, and determined to any particular structure or organ by the existence of chronic inflammation or irritation there.

M. Scoutetten* has described a morbid appearance which he considers as peculiar to primitive chronic peritonitis. It consists of a number of greyish spots formed by little points, the number and close propinquity of which determine the intensity of the colour of the spots, which are sometimes brown or even of a black hue. These spots vary in number, and are sometimes only a line, and in other instances an inch, in extent. They are occasionally accompanied with an increased development of vessels. Minute yellowish vesicles are also sometimes seen, and an abundant serous effusion almost constantly co-exists, in general transparent, because the inflammation has not been sufficiently active to change entirely the mode of secretion.

Treatment.—The general principles of treatment which are applicable to other internal inflammations are equally so to this; with some modifications however, arising from the nature of the texture affected, and from its relations to the organs which it covers. We shall first consider the treatment of this disease in the infant, and afterwards in the adult, and lastly speak of the management of chronic peritonitis.

1. *Treatment of infantile peritonitis.*—Our principal remedy in infantile peritonitis is the abstraction of blood, either general or local. In an infant under six months, though general bloodletting may often be required, yet a sufficient quantity can usually be obtained by the application of three or four leeches to the hand or foot, where we can easily controul the hemorrhage, which cannot be done so effectively if the leeches be applied to the abdomen. Applied to the extremities they are nearly as efficacious in removing local inflammation in infants as when applied to the vicinity of the part affected. They seem to produce the same result as a general bloodletting, as the face and lips become pale, the pulse falters, and syncope followed by vomiting occasionally takes place. These effects are apt to be produced when general bloodletting is carried to a considerable extent; and sometimes a state of nervous agitation and general commotion is induced, which, if not speedily removed, may terminate in death. The best remedies in a case of this kind are the horizontal position, cool air, and a drop or two of the tincture of opium.*

Where general bloodletting is practised, from two to three ounces may be abstracted from an infant between six and twenty months old; at two years from three to four ounces; and when the age is above four, about five, six, or eight ounces may be drawn according to circumstances. After the inflammatory action is lowered by the abstraction of blood, advantage will be derived by establishing and keeping up an open state of the bowels, but we should avoid effecting this by irritating medicine. Small doses of calomel alone, or combined with a little of the pulv. corn. ust. cum opio, if the stomach is irritable, followed at intervals by castor-oil or emollient enemata, will in general be found to answer sufficiently well. Fomentations to the abdomen will tend much to relieve the pain, and should be often repeated, and continued for some time; or we may put our little patient for a few minutes in the warm bath. If it is judged necessary to apply counter-irritation to the abdominal surface, warm flannel sprinkled with turpentine appears to us much preferable to blistering, as it produces a sufficient rubefacient effect, without the injurious consequences which blisters often produce on infants. The recommendation of M. Billard, to remove the child from the breast, appears to us questionable. The sudden alteration in diet would be very apt to produce derangement of the stomach or bowels, a complication which would add to the danger of the patient. If the acute symptoms subside, and it seems probable from the continuance of abdominal tumefaction, slight dyspnœa, quick weak pulse, dry tongue, and hot skin, that the affection has passed into the chronic state, we should suspend or be sparing of evacuations: a leech or two to the abdomen may occasionally be necessary. The strength is to be supported by animal broths, arrow-root, &c.; the bowels regulated by calomel in the combinations above recommended, according to circumstances. The warm bath may be occasionally useful; also counter-irritation to the abdominal surface, and in some cases mercurial inunction.

Treatment of peritonitis in the adult.—Acute peritonitis, though generally attended with considerable danger, yet in the greater number of cases admits of a cure by active and early treatment. The following are the indications which we should have in view: 1. to reduce the action of the heart and vascular system; 2. to diminish the hyperæmia of the affected part; 3. to allay local and general nervous irritation; 4. to restore the secretions to a

* Archives Générales, tom. iv. p. 398. We have been much indebted to this author for information on the morbid anatomy of the peritoneum. This essay contains more information on this point than any author we have consulted.

* *Dr. Cuming*, Transactions of the King's and Queen's College of Physicians in Ireland, vol. v. p. 49.

natural state, and to excite the peristaltic action of the bowels; 5. to relieve urgent symptoms. Copious and early bloodletting are the most efficient means we can employ for the reduction of vascular action. This is indeed the principal therapeutic agent in this disease, in which it can be employed to a greater extent than in inflammation of mucous surfaces. Its efficacy is greater according as it is used early, and carried to such an extent as to make a decided impression on the system. The quantity abstracted is to be regulated by our estimate of the capability of the patient's constitution to bear depletion, and not by any arbitrary rule of quantity. We have seen five or six ounces produce as decided an effect on a delicate female as thirty ounces on a robust patient. We should take the blood from a large orifice, and allow the stream to flow either until the pain is relieved, or weakness of the pulse, paleness, and tendency to syncope is induced: the apparent debility which the patient exhibits in the onset of the disease is not to deter us from active depletion. The pulse commonly rises after venesection, and becomes fuller and softer, and the patient feels relieved and lightened, rather than exhausted, by its employment. The advice which Dr. Abercrombie gives on the employment of bloodletting in this disease we have experienced the value of in many cases: viz. "to follow up the first bleeding by small bleedings at short intervals, when the effect of the first begins to subside: in this manner we prolong, as it were, the impression which is made by the first bleeding, and a twofold advantage arises from the practice— namely, that the disease is checked at an early period, and that the quantity of blood lost is, in the end, much smaller than probably would be required under other circumstances: if we allow the patient to lie after the first bleeding ten or twelve hours, or even a shorter period, the effect of it is entirely lost, and a repetition of it, to the extent of twenty ounces, may be required for producing that effect upon the disease, which by a former method might be produced by five. And, besides, the disease has been in the interval gaining ground, its duration is protracted, and the result consequently rendered more uncertain. The inflammation of a vital organ should not be lost sight of for above an hour or two at a time, until the force of it be decidedly broken; and unless this takes place within twenty-four hours, the termination must be considered as doubtful."

The efficacy of bloodletting will depend in a great measure on its early employment, but we are not to abstain from it altogether at even an advanced period of the disease. If we have not been so fortunate as to see our patient in the commencement of the attack, still if the stage of collapse has not been formed, if there is still some pulse and heat of surface, with abdominal pain and tenderness, we may abstract a moderate quantity of blood from the system with a chance of producing a good effect; or in debilitated patients apply leeches: but when the symptoms indicative of sinking are present, it would be obviously improper to take blood either generally or locally, as it would only hasten the fatal termination, and bring undeserved reproach on a valuable remedy.

Having reduced the general vascular action by the lancet, our next object should be to diminish the quantity of blood in the affected part by local bleeding, which will also assist in keeping up the constitutional effect produced by venesection. Gooch* has well observed, "that as long as the pulse is quick, full, and hard, it is in vain to take blood from the affected part; if we could completely empty its gorged capillary vessels, they would be instantly gorged again, whilst the heart and large arteries are injecting them with so much violence. On the other hand, after having reduced the force of the general circulation, the capillary vessels of the part often remain preternaturally injected. This I conclude from the fact that the patient is often not relieved till local bloodletting has been used, and then is relieved immediately."

Having allowed the patient to recover from the faintness produced by the general bleeding, the abdomen should be slightly fomented with warm water, wiped frequently dry, and leeches should be applied in numbers proportioned to the urgency of the symptoms and strength of the patient. They should be especially concentrated over the parts where most pain and tenderness on pressure exists, and after they have fallen off, fomentations with cloths dipped in warm water should be assiduously applied and repeated for some time, which will both encourage the bleeding and soothe the irritation of the inflamed parts. The application of leeches may be repeated several times, as long as any considerable soreness remains.

Either before or during the application of the leeches, and as soon as possible after the vascular action has been reduced by venesection, from five to ten grains of calomel combined with one or two of opium should be administered, which may be repeated in diminished doses every three or four hours. By this combination, the constitutional and local irritation consequent on the inflammation, and which has a tendency to aggravate it, will be allayed by the narcotic, and the secretions, which have been more or less suspended or deranged, will be restored by the mercury, which modifies its action, and determines it to the skin, and is also supposed to equalize the circulation. After the second or third dose of this medicine, the bowels may be opened by mild aperients, aided by enemata: castor oil, in doses of from half an ounce to an ounce in some aromatic water, may be given if the stomach is not irritable. If vomiting is urgent, the Rochelle salts with the supercarbonate of soda, in a state of effervescence with lemon-juice, may be used in repeated doses, so as to produce a moderately laxative effect. Strong purgatives are highly injurious, and even a small dose of castor-oil may exasperate the dis-

* Diseases of Females, p. 45.

case, if used previously to depletion. Having evacuated the bowels, the use of the calomel and opium should be resumed, and continued till the mercury has affected the system. As soon as salivation is established, we have generally found the symptoms become much mitigated, and our experience accords with that of Dr. Gooch, who remarks that whenever the gums were affected in this disease, the patients invariably recovered. The establishment of mercurial action not only assists in subduing the inflammation, but may prevent or remove those effusions of lymph which afterwards form adhesions that are often the source of future mischief.

In addition to these means, the warm bath may occasionally be useful, or repeated fomentations to the abdomen will tend much to relieve the pain and soreness. Counter-irritation, by means of blisters, after local and general bleeding, is generally recommended; but we have not been much in the habit of employing them. While much inflammatory excitement prevails, they would prove injurious, and at any period of the disease their application would deprive us of the most important means we possess of ascertaining the degree of tenderness by pressure. The application of warm flannel dipped in turpentine we conceive a good substitute, and it will generally produce a rubefacient effect.

Oil of turpentine, which was first recommended by Dr. Brennan of Dublin in puerperal peritonitis, may be useful internally in certain forms of the disease, but we conceive it requires to be used with caution: it acts as a powerful cathartic, and at the same time excites the general system; hence it would obviously prove injurious while much heat of skin, frequent pulse, and indications of active local inflammation were present; but in a debilitated patient, after the acute symptoms have been subdued, or in cases of puerperal peritonitis accompanied with typhoid symptoms, or where general and local bleeding cannot, from the delicacy of the patient's constitution, be carried to the requisite extent, it may be employed with advantage.

During the whole course of our treatment, the strictest antiphlogistic regimen should be observed. Light farinaceous diet, in small quantities, and rice or barley-water for drink, are most suitable for the patient; but if symptoms indicative of a sinking of the vital powers should appear, wine and other tonics may be necessary. Dr. Abercrombie used injections of beef-tea and cinchona with advantage.

When we have carried venesection to a considerable extent, and have reduced the vascular action to such a degree as renders the abstraction of more blood inadmissible, if we still find pain and tenderness present, the exhibition of a full opiate, followed by fomentations or a warm poultice to the abdomen, will sometimes remove the symptoms. If vomiting is urgent, it may sometimes be checked by saline draughts with tincture of opium, or by leeching and blistering the epigastrium. When the pulse continues very frequent after the inflammation appears to be subdued, Dr. Abercrombie recommends the use of digitalis.

A tympanitic state of the abdomen at an advanced period of the disease may occur from mere loss of tone, after the inflammation has been subdued. Small quantities of wine or brandy may be given at short intervals. Frictions of the abdomen, and injections of beef-tea, bark, or sulphate of quinine, turpentine, or tincture of assafœtida, with a moderate quantity of laudanum, may be repeated every two or three hours. The bowels may be moved with mild laxatives, such as aloetic wine, or aloes and hyoscyamus, but laxatives require to be given with the utmost caution. The authorities for the tobacco injection in inflammation of the bowels are numerous: among others, De Haen, Fowler, Abercrombie, and Howship, have recommended this remedy; the latter author relates three cases in which, having tried bleeding, the warm bath, and stimulating injections without effect, the fume of tobacco cautiously injected caused a general commotion and rumbling noise in the bowels, which was soon followed by copious evacuations of fæcal matter. The patients were all saved.*

During convalescence the greatest care is necessary in order to prevent a relapse. The patient should observe the strictest temperance in his diet, and return with great caution to the use of animal food or wine. The bowels should be kept regular, the feet warm, and flannel worn next the skin for a long time after every symptom has disappeared.

Treatment of chronic peritonitis.—Chronic inflammation of the peritoneum, when far advanced, is in most cases incurable, especially when the false membranes and other morbid productions are considerable in quantity, or when it co-exists with a tuberculated state of the peritoneum or subjacent cellular texture, such substances being for the most part incapable of absorption; but where the effusion consists of serum, with but little or no solid productions, our chance of success is greater. Much will depend on arresting the disease at an early stage, at which time a degree of subacute inflammation often exists which will require, with some modifications, the same treatment as the acute form. At every period in this disease, when the abdominal pain and tenderness are present, and the constitution of the patient is not very much debilitated, blood may be abstracted from the system to the extent of six or eight ounces at a time, which may be repeated twice a week until those symptoms have disappeared. The application of leeches also may be frequently adopted; this will be found the most effectual mode of relieving the abdominal soreness. All fæcal accumulations should be prevented, and the bowels kept regular by the gentlest aperients or enemata, but active purgatives should be avoided, as they may be productive of serious evil. The

* Practical Observations, p. 19.

warm bath or fomentations to the abdomen may be frequently employed, and will assist much in allaying irritation and pain, and in determining to the surface. Blisters may also occasionally be applied to the abdomen, or the external application of turpentine, as recommended in the acute form, will be found useful in relieving the abdominal tenderness.

The antiphlogistic regimen is to be observed to a certain extent, and light nutritious diet, composed principally of the farinaceæ and milk, in limited quantities at a time, appears the most suitable. Muscular exertion, or pressure on the abdomen, will be found to aggravate the symptoms, and are of course to be avoided; but in some cases gentle exercise in a carriage will promote the general health. A sea voyage has been recommended, and may be useful.

During the whole course of the disease we are to guard against the supervention of acute inflammation, which may be induced by a very slight exciting cause, and is especially to be dreaded, as the patient, from his debilitated state, could not bear the evacuation which would be necessary for its removal. When the pain and soreness are mitigated, if serous effusion exists, its absorption will be promoted by diuretics. Digitalis, either in the form of infusion or tincture, may be given conjoined with the alkalis and the spirit of nitric ether; but care should be taken to excite as little irritation of the stomach or intestines as possible. We have found the iodureted ointment of Lugol, mixed with equal parts of mercurial ointment, applied by friction to the abdomen, a powerful means of exciting absorption in cases of ascites consequent on peritonitis. In some instances it surpassed our expectation in producing the complete removal of considerable ascites in a few weeks. We have also in some cases exhibited at the same time internally the aqua mineralis iodinæ of the same author, and found it a valuable auxiliary. Broussais strongly recommends the introduction of diuretic medicines, such as the tincture of cantharides or squill, by means of friction on the skin, and it may be proper to try this mode of exciting diuresis, when, from irritability of the stomach, we cannot give diuretics internally. Anodynes may occasionally be necessary, and we should select those which do not produce constipation, such as hyoscyamus or conium. Rigid abstinence has been recommended as a means of producing absorption,* and in some cases perhaps it may be tried, but it will be improper where the patient is much debilitated by a protracted disease. Where all inflammatory symptoms have subsided, and a state of exhaustion remains while the effusion continues, tonics combined with diuretics may be cautiously tried. We have in such cases derived considerable advantage from the exhibition of the ferrum tartarizatum in solution, combined with the spiritus junip. comp.: it appeared to improve the patient's general health, and excite the action of the kidneys at this period of the disease. The antiphlogistic regimen will require to be relaxed a little, and more nutritious diet in small quantities may be allowed.

(D. H. Mac Adam.)

VI. *Peritonitis from perforation of the serous membrane.*—This most severe and generally fatal form of peritonitis is the result of a solution of continuity of the peritoneum, which may arise from various causes and occur in various portions of the sac. In most cases the result of this accident is the introduction into the sac of the peritoneum of some solid or fluid substance which produces a sudden, and generally universal, inflammation, so that the principal characters of this form of disease are, the suddenness of the attack, the terrible rapidity and violence with which the disease runs to its fatal termination, and its resistance to ordinary medical treatment. It will be found that in some of the cases, the particulars of which will be detailed, all these peculiarities were not observed, but we shall find, notwithstanding, that the above characteristics will apply to the disease in general. The following are the most common causes of the accident:—1st, external injuries, either of the solid or hollow viscera of the abdomen, or of the parietal peritoneum merely; 2dly, rupture of the bladder from distention, and of the uterus during parturition; 3dly, rupture of some portion of the digestive tube, from the gelatinous softening of its coats; 4thly, ulcerative perforation of the serous membrane, arising either from disease in any part of the subdiaphragmatic portion of the digestive tube, from suppurations of the solid viscera opening into the peritoneum; from ulceration of the bladder or ovaries; or from perforation of the diaphragm by purulent collections on its thoracic surface.

If we examine these different causes with respect to their frequency, it is plain that from the first order arise most cases of the disease. In this order,—which includes surgical operations on the peritoneum,—the introduction of irritating substances into the peritoneal cavity is by no means a necessary occurrence, although, in the case of rupture from external violence, we see the worst examples of this formidable occurrence; for, as will appear presently, the opening in such cases is generally much more extensive, whereby the quantity of matter introduced comes to be greater, and the closure of the orifice much more difficult.

In the present article we shall principally consider that form of peritonitis which results from perforation of the tunics of some portion of the digestive tube,—an occurrence, in the great majority of cases, the result of circumscribed ulceration of the mucous membrane and glands. The study of this form of the disease tends to elucidate those cases which arise from other causes.

It is necessary to remark, in the first place, that ulcerative perforation of the intestinal tunics does not necessarily imply a consequent effusion of the contents of the tube into the peritoneal cavity; for it may happen in many chronic and even in some acute cases, that in

* Med. Chirurg. Rev. Sept. 1820, p. 187.

consequence of adhesions being formed between the two surfaces of the peritoneum, at a point corresponding to the situation of the ulcer, the contents of the tube are prevented from escaping into the general cavity. Thus, the serous membrane covering the opposite fold of intestine, or some of the solid viscera, may come to form the base of an ulcer which originally was wholly unconnected with it. Again, it may happen that this new base to the ulcer may in its turn give way, and an unnatural communication be thus formed between two essentially different portions of the tube, and the fæcal contents pass across the serous membrane, but not enter its cavity. A remarkable case of this description is described by Dr. Abererombie. The patient, who was fifty-six years of age, had laboured for two or three weeks under impaired appetite, languor, and occasional pain in the abdomen, when he was suddenly seized, while walking, with vomiting of fæcal matter, but felt no other inconvenience until about a week after, when a similar attack recurred; he was then seen by Dr. Combe, who found him looking unwell, but with a natural pulse and good appetite. The bowels were easily regulated, and no sign of organic disease could be detected. After this time the vomiting returned at various intervals, sometimes three or four times a day, and sometimes he was free from it a week at a time. The matter ejected always consisted of pure fæces, sometimes so consistent that it was brought up with difficulty until he diluted it by swallowing hot water. During the course of this affection, the body continued regular or easily regulated, and the matter vomited completely resembled that which was passed from the bowels. No tumour could be detected by examination; his appetite continued good, and he never was observed to vomit food or other matters taken into the stomach. In this state he lived for three months, and died gradually exhausted, without any particular change in the symptoms, except that a week before his death he vomited a considerable quantity of blood. On dissection, the stomach was found contracted and adhering to the parietes of the abdomen on the left side, and to the arch of the colon. At the place of the adhesion a soft tubercular mass was formed, which seemed in general to be about two inches in thickness. The stomach appeared externally healthy; internally it showed a mass of ulceration which occupied the whole of the great curvature, and covered about one-half of its inner surface. The pylorus and whole pyloric extremity were healthy. In the centre of the ulcerated part there was a ragged irregular opening fully two inches in diameter, which made a free communication with the arch of the colon; and around the opening there was also some ulceration of the mucous membrane of the colon. The intestines in all other respects were healthy. The small intestines were empty; the caput coli was distended with feculent matter, and the colon throughout contained healthy well-formed fæces.* Chomel has described a case in which the duodenum communicated with the colon through the medium of the gall-bladder.* In another case on record a communication existed between two loops of intestine formed by a little canal about two lines in length and eight in width, which was lined by a mucous membrane continuous with that of the intestinal tube.

Many cases are recorded of perforating ulcers of the digestive tube communicating with the solid viscera. Thus the base of an ulcer of the colon has been found constituted by the tissue of the kidney; ulcers of the stomach have been found resting on the spleen; Rayer has described an ulceration of the duodenum, the basis of which was a portion of the liver. The effusion of the contents of the stomach from ulceration is commonly prevented by the pancreas, the substance or the peritoneal coat of which forms the base of the ulcer. In this way a perfect cicatrix may be formed, and the health of the individual be preserved.

In most of these cases of perforation without effusion, a partial and very circumscribed peritonitis ensues, which, by its adhesions, prevents the escape of the contents of the intestine. It is further to be remarked that this occurrence is commonly the result of a chronic disease, so that time is afforded for the exudation and organization of lymph. But we are not to conclude that this adhesion always takes place in chronic ulcerations; the contrary is the fact, as will be shown presently. In recent ulcerative perforations, effusion of the intestinal contents is, as might be expected, the almost constant result; but we have seen a case where not only one but several perforations, the result of recent ulcerations, occurred, and yet where no effusion of fæcal matter took place. The following are the particulars of this remarkable case.

A young woman was admitted into the Meath Hospital in the beginning of the year 1829. She had enjoyed good health, until thirteen days previous to her admission, when she was attacked with cough, followed on the next day by symptoms of fever. She complained of cough and dyspnœa; there was great prostration of strength, the skin was hot, and the tongue covered with a white paste. She took saline purgatives and effervescing draughts without relief. Headach and deafness supervened.

Two days before admission she complained of pain in the epigastric origin, which was removed by leeching. On the 24th of January, the day of her admission, she had intense bronchitis. Respirations 40, and pulse 130 in the minute. There was great restlessness, and the belly was tympanitic. For the next nine days all her sufferings seemed referable to the chest; but on the 2d of February she had a certain degree of tenderness in the epigastric region. This was again removed by the use of leeches, and for eleven days there was no prominent abdominal symptom; but the distress of respiration and the signs of bronchitis continued without alleviation. The exhibition of tartar emetic was now resorted to; and

* On Diseases of the Stomach, &c.

* *Andral*, Précis d'Anatomie Pathologique.

cough produced vomiting, yet the thoracic symptoms improved so much, and without any sign of abdominal disorder, that great hopes were entertained of her recovery. The skin became cool, the pulse fell to 100, and the deafness gradually disappeared. On the 12th of February, however, there was a severe relapse. The thoracic symptoms became again violent, *with some epigastric* tenderness. She sank on the following day.

On dissection, the lungs were found filled with miliary and granular tubercles; in some places hepatized, and presenting signs of intense inflammation in the bronchial mucous membrane. A small quantity of sero-purulent matter was found in the cavity of the pelvis. The small intestines were glued together by flakes of unorganized lymph; and on separating their folds, we discovered four perforations, each sufficiently large to admit a quill. These corresponded to recent ulcers in the muciparous glands, which had perforated all the coats of the intestine, and, in fact, rested on the serous membrane of the opposite fold. No faecal matter whatever was discovered in the cavity of the peritoneum.

We here see a case where, from recent disease, no less than four large perforations occurred without any faecal effusion; a circumstance explicable by the formation of lymph around each of the orifices, which we must suppose to have taken place prior to the giving way of the serous membrane at the base of the ulcers. Accordingly, the usual symptoms of peritonitis from effusion of the contents of the intestine did not occur. The gluing together of the small intestines, and the fluid in the pelvic cavity, must be then considered as resulting from the extension of the different (at first local) inflammations of the serous membrane; a circumstance not to be wondered at when we consider that the disease was acute, the fever high, and the points of irritation of the serous membrane numerous. How far the latency of the abdominal inflammation is to be explained by the co-existence of intense thoracic disease, we shall not now enquire.

Peritonitis from perforation of the intestinal tube, and effusion of its contents, is, as might be expected, almost always a violent and fatal disease. It is violent, because it arises from the introduction of a highly irritating fluid into the sac, and dangerous in the highest degree from the seat of the inflammation; it is, moreover, kept up by the continued ingress of faecal matter through the perforation, and derives further malignancy, from having supervened in a subject already attacked by another disease. In fact, although in a few cases the patients have shewn some power of resistance to the disease, and have lived for several days from the occurrence of the accident, yet these cases may well be considered as exceptions.

But are we to believe that the effusion of the intestinal contents is inevitably followed by a violent and acute peritonitis? A case recorded by Andral is in opposition to this opinion. It was that of a young person labouring under phthisis, through whose umbilicus a round worm *(ascaris lumbricoides)* was discharged. He lived for several weeks after this occurrence, and during each day a small quantity of faecal matter escaped through the umbilical fistula. On dissection a chronic peritonitis was discovered, and the serous cavity contained a fetid fluid quite similar to that which had passed through the umbilicus, and in which were several lumbrici.

It is obvious that such a case as this, though of great rarity, is not without its analogies in other systems. We know that the occurrence of a pulmonary fistula is not necessarily followed by violent symptoms; that the pleuritis may be so latent as that the period when the fistula was formed shall be quite uncertain. As a general proposition, then, it may be stated that in both the peritoneum and pleura a fistula, through which foreign substances pass into the sac, may form without violent symptoms or acute inflammation. These cases, however, are exceptions to the general rule; and the cause of the absence of acute inflammation in such instances is still to be sought for. Perhaps the anaemic state of the body, as in phthisis, may have some influence.

When we examine the different diseases in which, at some period, a sudden change in the physical relations of parts takes place, we observe, in most cases, that this sudden change is accompanied by striking symptoms, the suddenness of which leads to the diagnosis. For example, the paralysis, which is the result of an apoplectic effusion, comes on suddenly; and by this is distinguished from that from softening of the brain, which comes on gradually. Again, a patient has a recognized aneurism of the aorta: if he drops down dead, the great probability is that an internal rupture of the tumour has occurred. If the signs of an abscess of the liver suddenly disappear, with copious expectoration, or with a diarrhœa, a vomiting, or a peritonitis, we diagnosticate a solution of continuity, an opening into the lungs, the digestive tube, or the peritoneum. When a tuberculous or other abscess opens into the pleura, the empyema and pneumothorax are ushered in by new and violent symptoms. The same observations apply to the diagnosis of rupture of the uterus and bladder.

Now, although cases of exception may be met with in every one of these diseases, yet they are so rare that the general applicability of the diagnosis—as drawn from the suddenness of new symptoms—is not much infringed on. Apoplexy may occur with gradual symptoms. We have already stated that a tuberculous abscess may perforate the pleura without violent symptoms, and so on. On the other hand, suddenness of invasion of new symptoms may be observed without any solution of continuity. Yet both the want of suddenness and violence of symptoms in cases of rupture, and their occurrence where no solution of continuity exists, are to be looked on as exceptions to a general rule.

We shall now detail some examples of peritonitis from perforation of different portions of the digestive tube. "A young woman, aged

eighteen, had been affected for about six months with variable appetite and occasional pain in the stomach, which made her frequently sit with her body bent forward, and her hand pressed upon the epigastric region. Little notice was taken of the attacks, as she was going about, and otherwise in good health; and for some weeks previous to the attack now to be described, her appetite had greatly improved. On the 26th of November, 1824, while in a room by herself, she was heard to scream violently; and when a person went into the room, she was found unable to express her feelings, except by violently pressing her hand against the pit of the stomach. When she was soon after seen by Mr. M'Culloch, she was moaning as if in extreme agony, but was unable to speak. The pulse was 86, and very weak. She could scarcely swallow; but soon after vomited the contents of the stomach, which seemed to be merely food which she had recently taken. Various remedies were employed without relief. She continued with every appearance of extreme suffering till seven o'clock in the morning of the 27th, when she said the pain was considerably easier, but was still very severe in the pit of the stomach, and was extending downwards over the abdomen. The abdomen was now becoming distended; and when we saw her, about three o'clock in the afternoon, it was distended to the greatest degree, and very tense. The pulse was extremely feeble; she was scarcely able to speak, but her countenance was expressive of extreme suffering. Nothing afforded the smallest relief; and she died about two in the morning—twenty-nine hours from the attack. *Inspection.*—The cavity of the peritoneum was distended with air, and likewise contained upwards of eight pounds of fluid of a whitish colour and fetid smell. There was slight but extensive inflammatory deposition on the surface of the intestines, producing adhesions to each other and to the parietes of the abdomen. On the upper part of the small curvature of the stomach near the cardia, there was a small perforation of a size which admitted the point of the little finger. Internally, this opening communicated with an ulcerated space on the mucous membrane about the size of a shilling, with slightly thickened and hardened edges, and a considerable perpendicular loss of substance. The stomach in all other respects was entirely healthy."*

We have given this case at full length, as it may be considered as an example of the mode of inflammation of the serous membrane in these cases, both as to invasion and termination. In this case, and in some to which we shall just now allude, the perforation was the result of a chronic but circumscribed irritation. In another case described by Dr. Abercrombie, the peritonitis suddenly supervened in a subject apparently affected with chronic dyspepsia, in which the prominent symptoms were severe pyrosis and occasional vomiting. In consequence of a careful regulation of regimen, the stomach had recovered its healthy functions, and the patient's general health had become excellent; but he was obliged to observe great caution in regimen, from the occasional recurrence of slight attacks of his former symptoms. During one of these slight attacks, he was suddenly seized with excruciating pain in the pit of the stomach, some vomiting, coldness of the body, and a small frequent pulse. No relief was afforded by treatment, and death took place in thirty hours from the attack. On dissection, extensive recent peritonitis was shewn, and a perforating ulcer of the stomach near to the pyloric portion. The stomach, with the exception of the perforating ulcer, and another, the base of which was formed by the surface of the liver, was perfectly healthy.*

In this case there can be little doubt of the connexion between the primary symptoms and the ulcer, the base of which was formed by the surface of the liver; and in all probability there would have been a permanent cure had not the second ulceration occurred.

In almost all the cases of this form of peritonitis resulting from a perforation of the stomach, symptoms of a chronic disease of this organ had preceded the accident for a greater or less space of time. Of these, local pain and vomiting were the most frequent, but the degree of severity of these symptoms and their effect on the general health were exceedingly various. In some of these cases a cancerous ulceration existed; in others the affection of the stomach was a simple circumscribed ulcer; while in a third class the disease was the gelatinous softening (*ramollissement gelatiniforme*) of the French authors.†

The immediate cause of the accident in by far the greater number of these cases was the progress of the destructive process; but in two the effort of vomiting seemed to be the cause of the solution of continuity. Andral describes a case of an individual who laboured under the symptoms of a cancerous disease of the stomach, and who was suddenly seized with peritonitis during the act of vomiting, which had been brought on by an emetic. On dissection a perforation of the stomach was found in the centre of an old ulceration of the stomach.‡

In another case on record an old ulcer had existed and had formed adhesions with the pancreas. The perforation took place during the efforts at stool, and was found to have occurred at one of the extremities of the above-mentioned ulceration.§

It is admitted that in some cases a perforation of the stomach takes place in individuals who were in the enjoyment of the best health; and that on dissection no evidence of a pre-

viously existing *ulceration* of the organ could be found. Here the absence of gastric symptoms, previous to the fatal attack of peritonitis, is not extraordinary. But even a fatal ulceration of the stomach may occur with singular latency, as in a case recorded by Dr. Abercrombie, where, in a strong and healthy-looking girl, sudden and rapidly fatal peritonitis supervened. On dissection, a perforating ulcer was found in the smaller curvature, all around which the coats of the stomach were found greatly and extensively thickened. *This girl had been residing in the house in which she died for four months, during which she was never known to complain of her stomach, or to show the smallest deviation from the most robust health.** It appeared, however, that she had had fever some months before this; and in all probability this fever was symptomatic of or connected with a gastritis.

We shall now proceed to examine what appears to be the most common case of this disease, namely, that in which it supervenes on a perforating ulcer of the lower portion of the ileum. In the great majority of these cases the ulcerations were recent and the disease acute. In many of them, symptoms of a previous excitement of the muciparous glands were observed.

As Louis is the author who has drawn the attention of pathologists more especially to this disease, we cannot do better than quote from his memoir† the results of his observation of the first eight cases which he describes. "The patients who have been the victims of this disease were young and vigorous, with the exception of the first, who was weak and of a lymphatic temperament; they had a good constitution, were rarely ill, not addicted to excess, and presenting a sanguine, a bilious, or a lymphatico-sanguine temperament. Almost all had been but a short time in Paris. The causes of their disease were unknown. If we except a single case, it commenced as a slight continued fever, and presented no severe symptom before the period of the perforation; in but one patient was there a severe diarrhœa, which was, however, of short continuance; in another it had been moderate; still less in the subjects of the second and sixth case, and not occurring in the remainder. Those with whom the diarrhœa was for a short time severe had slight pains in the epigastrium and more severe pain in other portions of the abdomen, while in the remainder they were very slight, or not at all present before the period of perforation. Three of them believed themselves convalescent, and were considered so for some days, when the symptoms of this lesion occurred. A fourth seemed to have been cured rapidly of a slight enteritis; so that not only in these four subjects nothing occurred which could lead to the anticipation of the disease under which they sank, but it would have been absurd, from the mildness of their symptoms, to have apprehended any serious consequences. And at this moment we have before us the history of many patients who have died from an acute perforation of the intestine, and who, with this exception, presented no symptom which could distinguish them from analogous cases where there was a rapid return to health.

"If the period of the formation of these ulcerations cannot be accurately determined, we shall be scarcely far from the truth in supposing that it coincides with the first symptoms of the disease, from which it would result that the progress of these ulcerations has been very rapid, and that they have arrived at their last period in from twelve to twenty-five days, rarely later.

"At a certain period of the disease, on account of which the patients had entered hospital, they experienced suddenly an exquisite and tearing pain of the abdomen, rapidly followed by alteration of the features, nausea and vomitings, &c. &c. These symptoms continued with greater or less violence from twenty to fifty-four hours, presenting remissions which were more or less well marked, and indicating a most intense peritonitis, produced by a violent cause acting in a sudden manner, just as occurs when an irritating substance is applied to the surface of the peritoneum. It is by the reunion of these signs that the lesion that now occupies us has been recognised by MM. Lerminier, Chomel, and Martin Solon, under whose care the patients were. From these circumstances it appears that we may regard the following as characteristic signs of perforation of the intestine: *if in an acute disease and in an unexpected manner a violent pain of the abdomen suddenly supervenes, if this pain is exasperated by pressure accompanied by rapid alteration of the features, and more or less promptly followed by nausea and vomiting, we may believe and announce that there is a perforation of the intestine.*"

This author further remarks that the most intense pain of the belly suddenly supervening, and accompanied by alteration of the countenance, nausea, and vomiting, will be insufficient to allow us to make this diagnosis with certainty, unless the pain is exasperated by pressure. It is not only necessary that this character should exist, but also that the pain shall extend rapidly to the whole abdomen, so that, if it remains confined to the point where it has first occurred, we cannot, notwithstanding the coincidence of other symptoms, declare that the intestine is perforated, or that any other viscus has opened into the cavity of the abdomen. In illustration of this he states the case of a man who had laboured under symptoms of chronic gastritis, when he was suddenly attacked with violent pain in the epigastrium, soon followed by nausea, vomiting, and alteration of the countenance. This pain, which was exasperated by pressure, was confined to a very small space, where it first occurred. It continued along with the other symptoms for four days, when the patient died, and on dissection was found to proceed from an aneurism of the cœliac artery, which had

* Op. cit. p. 41.

† Recherches Anatomico-Pathologiques. Paris, 1826.

ruptured and caused an effusion of blood behind the peritoneum.

It is not always that the pain, though occurring under the above circumstances, continues until death. In one of the cases of this lesion, which occurred at the Meath Hospital, there was complete cessation of pain and even of tenderness for many hours before death. The patient declared himself much better, yet the other symptoms of peritonitis continued, such as the coldness of the extremities, the rapidity of the pulse, the swelling of the belly, and the Hippocratic expression. In three of Louis's cases the same circumstance was observed; the countenance continued altered, the nausea and vomiting persisted, the surface was pale and of a violet hue, and the patients were perpetually shivering and covering themselves carefully up in the bed-clothes. They resembled persons who, having taken a cold bath, cannot again regain warmth.

We may be further assisted in the diagnosis of perforation of the small intestine by the seat of the pain as it first occurs. This is generally in the ileo-cœcal region; but it may no doubt be felt in other situations, according to the place of the perforation and the disposition of the intestine.

We have now witnessed a considerable number of these cases, which occurred under our observation in the wards of the Meath Hospital. In nine of these cases the diagnosis of perforation of the intestine was made, and proved to be accurate by dissection. It is scarcely necessary to remark that the general features of these cases were the same, namely, *the sudden supervention of the symptoms of peritonitis, and the rapid sinking of the vital powers.*

In three cases, the serous inflammation supervened during the existence of gastro-enteric fever more or less well marked.

In one case, the symptoms came on on the seventh day of a catarrhal fever.

In two cases, the disease occurred after symptoms of acute enteritis, which in one of the cases followed a severe debauch.

In one case (which we have before mentioned), the perforations, though numerous, yet did not produce any well-marked symptoms, the patient dying apparently of acute phthisis.

In one case, the symptoms occurred after an hypercatharsis induced by an over-dose of salts. The same cause appeared to produce the disease in another patient, who recovered under the use of large doses of opium, and to which we shall hereafter allude.

In several of these cases there had been previous diarrhœa, which was suddenly checked at the time when the perforation appeared to take place; but in one of them in which this had occurred, a copious purging of natural coloured fæces came on twelve hours before death. This patient had used calomel freely the day before.

Another remarkable symptom was the irritation of the bladder, shewing itself by sudden inability to pass urine, and constant efforts at micturition. This irritation of the urinary organs occurred in several cases, and in two was the very first symptom observed. The bladder was found inflamed in one case; while in another it was merely contracted and empty, with its mucous membrane pale. This was remarkably the case in a patient who was admitted in December 1830. This man had enjoyed uninterrupted good health until three days previous to admission, when, on getting up in the morning to gratify the extreme desire to pass water, he found himself unable to do so, the attempt putting him to intolerable torture; he had pain in the region of the bladder, not so severe when he was not attempting to pass urine. The pain continued during that day, but towards night became more easy, and he passed about ten ounces of urine; still all the attempts at micturition were attended with considerable suffering. On admission he presented the general appearance of a person affected with peritonitis: he had acute pain in the right lumbar region, and great tenderness in the umbilical, right iliac, and hypogastric regions. What he complained of principally was retention of urine; yet the catheter shewed that the bladder contained but a few drops of turbid high-coloured urine, and that the urethra was unobstructed. Towards evening, after the use of an injection and venesection, he passed a small quantity of urine, the countenance was Hippocratic, and the patient died at three o'clock on the following morning. On dissection, the usual appearances of peritonitis from perforation were seen. The perforating ulcer existed about eighteen inches from the ileo-cœcal valve. Three other ulcers existed lower down, which had not made their way into the serous cavity. The peritoneal surface of the bladder was highly inflamed.

In another case where the symptoms succeeded a bilious diarrhœa, the sudden supervention of the pain was also accompanied by inability to pass urine. On dissection, the perforation was found large and corresponding to the fundus of the bladder. And in a third case, in which the disease appeared on the seventh day of a catarrhal fever, the first symptom of the perforation was sudden inability to pass urine. In this case a turpentine enema opened the bowels, and enabled the patient to empty his bladder. Here the opening existed about three inches above the ileo-cœcal valve, and the mucous membrane of the bladder was found highly inflamed.

In all our cases, evidences of a previously diseased condition of the mucous glands of the intestine existed to a greater or less degree; in some instances accompanied by functional disturbance, in others occurring in a perfectly latent manner. Of this last remarkable fact many other instances have been observed by authors.

The peritonitis thus supervening, as might be expected, almost always runs its course in a very short time. In the first nine cases recorded by Louis, death took place in from twenty to fifty-four hours, while in one case the patient lived seven days from the first appearance of the symptoms of peritonitis. In

this instance the symptoms, which had been violent at first, became moderated at the commencement of the fourth day, and during the remaining three days the pain of the belly was very slight, and if the first symptoms had not been so well marked, doubts would have been entertained of the truth of the diagnosis. "In confirming," says Louis, "those diagnostic symptoms which we have established, this observation is of great importance as connected with prognosis, since it shews that when once the signs of perforation have occurred, we must not depart from our diagnosis, and admit of hope even after an arrest of symptoms, and an apparent amelioration even of some days standing. This reserve is furthermore necessary from the fact that the lesion that brought about the perforation is not so soon arrested, and that the first perforation may be followed by a second, and even by a third. (Obs. vi. and vii.) This prolongation of life after so severe an accident is in accordance with the variations which we so constantly observe in the march of diseases, and points out the analogy between perforations of the intestines and those of the lung."

In our cases the length of time the patients lived after the occurrence of the perforation, varied from twelve to one hundred and twenty hours. We find, on examining the results of nineteen cases observed by ourselves, or recorded in the works of different authors, in which the period of the perforation could be accurately ascertained, that the average length of time that the patients lived after this accident was about twenty-nine hours. In one of our cases, however, which we have brought into this calculation, the patient lived about one hundred and twenty hours; and in a case recorded by Louis, the perforation took place on the 18th of May, and the patient lived until the 25th of the same month. The shortest period in which the fatal termination took place seems to be in six hours. We may observe that in some of the cases which have entered into the above calculation, the perforation occurred in the stomach, and in one in the duodenum.

We have hitherto been principally occupied with those cases of peritonitis from perforation in which the symptoms were well marked, and in which the intestinal contents passed into the cavity of the peritoneum. It is a fact, however, that in a very few cases this accident may supervene without the ordinary sudden and violent symptoms: thus, in the ninth observation of Louis, we read of a patient who was labouring under fever with diarrhœa, in whom the symptoms which appeared to correspond with the perforation were delirium and shivering, which occurred in the morning and continued till the evening of the next day, when the patient sank; there was also increased meteorism, and the patient winced only after a strong pressure of the belly. In this case the perforation was not suspected, yet Louis inquires whether we might not, under similar circumstances, suspect a perforation of the intestine, particularly when it is considered that peritonitis without perforation is rare as occurring in the course of acute diseases. He thinks that if, in the course of a continued fever with diarrhœa, the patient is seized with delirium, shiverings, and a slight tenderness of the belly, which until then had not been painful, we might be authorised to suspect a perforation of the small intestine.

In the case of the young phthisical patient recorded by Andral, through whose umbilicus a round worm (ascaris lumbricoides) was discharged, the individual lived for some weeks after this occurrence.

It must be always borne in mind that the diagnosis of peritonitis from perforation of the intestine in ordinary cases, is founded on the greater probability that the peritonitis thus suddenly supervening proceeds from the introduction of irritating matters from the intestine than from any other cause. It is plain also, that as far as the peritonitis is concerned, we shall observe the same general symptoms in cases of the rupture of abscesses into the peritoneal cavity, or the effusion of urine from rupture of the bladder; but still a few cases may occur where a sudden and fatal peritonitis may supervene without solution of continuity of the serous membrane of the peritoneum. We need scarcely allude to strangulated hernia further than to observe that, where the strangulated portion is exceedingly small, so as not to be capable of detection by external examination, the case may closely resemble one from sudden perforation of the intestine. Of this we witnessed a very remarkable case, where a portion of the intestine not larger than a small hazel-nut had become strangulated. The symptoms supervened with sudden pain, constipation, swelling, tenderness of the belly, and the other signs of peritonitis.

In the article HEPATITIS we have described a case of peritonitis from the opening of an hepatic abscess into the serous membrane; in this case the patient lived for eight days after the occurrence of the perforation; and on dissection we found the false membrane of the peritoneum in progress of organization, as shown by the existence of large bloodvessels of a deep blue colour passing through its substance, which had assumed a laminar structure.

It is scarcely necessary to remark that the prognosis in peritonitis from the introduction of irritating substances into the cavity must be unfavourable in the highest possible degree, for two reasons;—first, from the nature of the exciting cause, which produces a rapid and universal inflammation; and, secondly, from the previous existence of some other disease which was the cause of the perforation. Yet we believe that even under these almost desperate circumstances, we are not justified in abandoning the patient to his fate without an attempt to save life by medical treatment. We know that the peritoneum may recover from inflammation after solutions of continuity in various portions of its extent, and hence this circumstance merely, though dangerous in a great degree, is not necessarily to lead us to

despair. It would seem that it is from the introduction of irritating matters into the cavity that the greatest danger is to be apprehended, and hence to prevent or diminish the extent of such an accident should be the principal object of the physician. In cases of this description the principles of treatment are, then, essentially different from those of ordinary cases of peritoneal inflammation.

In the second number of the Dublin Journal of Medical and Chemical Science, the writer of this article has shewn the inapplicability of the ordinary mode of treatment of peritonitis in those cases. In most of them the powers of life sink so rapidly that bleeding, either general or local, cannot be attempted; neither can we use mercury internally, from the danger of exciting the peristaltic action of the intestine, which of course tends to keep open the communication, and cause a fresh ingress of fæcal matter into the sac; nor can we hope much from the external application of mercury, from its slow action, and the improbability of its affecting the system under these circumstances.

Yet, in a few cases, we find that the patients may live for several days, and that a process of organization of the effused false membrane may be found to have commenced; and hence the two great indications are, to support the strength of the patient so as to gain time, and to diminish, as far as possible, the peristaltic action of the intestine. In the paper above alluded to, we have proposed the use of opium in large doses for the treatment of this form of the disease, to which we were led from having witnessed the admirable effects of that remedy in low cases of peritonitis in the hands of Dr. Graves, who, eleven years ago, treated successfully two cases of peritonitis after paracentesis, and occurring in patients of a bad habit, by means of opium in free doses, and without abstracting a drop of blood. The same physician employed a similar treatment in a case of abscess of the liver opening into the peritoneal sac, and with success, as far as the cure of the peritonitis was concerned.*

In the paper above alluded to, we have detailed two cases in which decided evidence of the utility of this mode of treatment was obtained. In the first, in which the symptoms of perforation had existed for two days, and the patient was in almost complete collapse, the use of sixty drops of the black drop in the twenty-four hours was followed by the most singular improvement: the pulse had become full and soft, the extremities warm, and the countenance had lost the Hippocratic expression. The patient could bear pressure on the abdomen, which the day before was exquisitely painful. The same treatment being continued for twenty-four hours longer, *every symptom of abdominal inflammation had subsided*: the belly was natural, and the pulse good. At this period, the mildest possible saline laxative was exhibited, which produced four evacuations, followed by an immediate return of the symptoms of peritonitis, under which the patient rapidly sank. On dissection we found universal peritonitis, but the intestines were every where agglutinated together except in the left iliac fossa. The perforation existed in the cœcum, and was small; and the mucous membrane of the ileum and colon was but little affected.

The interest of this case consists, first, in the decided advantage derived from the use of the opium; secondly, in the danger it shews to result from any thing that excites the peristaltic action of the intestine; and thirdly, in the verification of the diagnosis of perforation, and the evidence of a process of cure having commenced.

In the next case the disease was of three days' standing, and it supervened suddenly from a hypercatharsis produced by an over-dose of Glauber's salts. The patient was apparently in the last stage when the opium treatment was commenced. He was ordered a grain of opium every hour. Next day the symptoms were decidedly improved, and though he had taken twenty-four grains, he had not experienced the slightest coma, headach, or delirium. The same plan of treatment was persevered in, the daily doses of opium being gradually diminished until the tenth day, when, the convalescence being completely established, the remedy was omitted. During this time diarrhœa set in for three or four days severely; this was treated by the application of a few leeches to the anus, and the use of anodyne enemata. The patient took in all one hundred and five grains of opium, exclusive of that in the injections, without experiencing any of the usual effects of this remedy in large doses.

When we connect these facts, and recollect that, in bad forms of peritonitis, such as that occurring after paracentesis in debilitated subjects, it has been found successful, and also that its efficacy has been proved in a case where the peritonitis supervened on the introduction of the matter of an hepatic abscess into the peritoneum, it seems justifiable to recommend the exhibition of opium in free doses in cases of peritonitis from the introduction of irritating matters into its cavity. Of these cases, that from ulcerative perforation of the intestine seems to be the one most likely to be benefited by such a treatment, as in these cases the solution of continuity is but of small extent, the disease from which it has originated much more often acute than chronic, and generally confined to a small extent.

It is necessary to remark that in the treatment of these cases the strength of the patients must be supported, and the greatest caution observed, even for some time after the symptoms of peritonitis have subsided, in the use of any thing that can excite the peristaltic action of the intestine.

(William Stokes.)

PERSONS FOUND DEAD.—Under this head we propose to treat of those causes by which life is suddenly or quickly extinguished in persons previously in the apparent enjoyment of good health. Cases of this kind are peculiarly the objects of legal investigation by

* See Dublin Hos. Reports, vol. 5. Dublin Journal of Medical and Chemical Science, vol. 2.

the coroner; and as all medical men are liable to be called on to assist him with their professional information and opinion, it is of the utmost importance that clear notions of the true nature of the phenomena that present themselves should be entertained. The object of such enquiry being to ascertain whether death was natural or owing to some accidental cause, the whole subject of sudden death may be conveniently arranged under two heads,—namely, 1. sudden death from natural causes; 2. sudden death from violent causes; comprehending under the latter every variety, whether the result of accident or of criminal intention.

Our first duty on the discovery of a supposed dead body is to ascertain whether any spark of life still remain, by rekindling which animation may be restored; and this leads us, before entering on the causes and phenomena of sudden death, to consider the states of body that may resemble death, and to point out the means of discrimination between those cases in which life is really extinct, and those in which the exercise of the vital power is only suspended. Nothing is more certain than death; nothing is at times more uncertain than its reality: and numerous instances are recorded of persons prematurely buried, or actually at the verge of the grave, before it was discovered that life still remained; and even of some who were resuscitated by the knife of the anatomist. Pliny, who devotes an entire chapter to this subject, entitled "De his qui elati revixerunt," amongst other instances gives that of the Roman consul Avicula, who, being supposed dead, was conveyed to his funeral pile, where he was reanimated by the flames, and loudly called for succour; but before he could be saved, he was enveloped by the fire and suffocated. Bruhier,* a French physician, who wrote on the uncertainty of the signs of death in 1742, relates an instance of a young woman upon whose supposed corpse an anatomical examination was about to be made, when the first stroke of the scalpel revealed the truth: she recovered, and lived many years afterwards. The case related by Philippe Peu is somewhat similar. He proceeded to perform the Cæsarean section upon a woman who had to all appearance died undelivered, when the first incision betrayed the awful fallacy under which he acted. A remarkable instance of resuscitation after apparent death occurred in France, in the neighbourhood of Douai, in the year 1745, and is related by Rigaudeaux,† to whom the case was confided. He was summoned in the morning to attend a woman in labour, at a distance of about a league. On his arrival, he was informed that she had died in a convulsive fit two hours previously. The body was already prepared for interment, and on examination he could discover no indications of life. The os uteri was sufficiently dilated to enable him to turn the child, and deliver by the feet. The child appeared dead also; but by persevering in the means of resuscitation for three hours, they excited some signs of vitality, which encouraged them to proceed; and their endeavours were ultimately crowned with complete success. Rigaudeaux again carefully examined the mother, and was confirmed in his belief of her death; but he found that, although she had been in that state for seven hours, her limbs retained their flexibility. Stimulants were applied in vain; and he took his leave, recommending that the interment should be deferred until the flexibility was lost. At five P.M. a messenger came to inform him that she had revived at half past three. The mother and child were both alive three years after. There is scarcely a dissecting room that has not some traditional story handed down of subjects restored to life after being deposited within its walls. Many of these are mere inventions to catch the ever-greedy ear of curiosity; but some of them are, we fear, too well founded to admit of much doubt. To this class belongs the circumstance related by Louis, the celebrated French writer on medical jurisprudence. A patient who was supposed to have died in the Hôpital Salpêtrière, was removed to his dissecting room. Next morning Louis was informed that moans had been heard in the theatre; and on proceeding thither he found, to his horror, that the supposed corpse had revived during the night, and had actually died in the struggles to disengage herself from the winding-sheet in which she was enveloped. This was evident from the distorted attitude in which the body was found. Allowing for much of fiction with which such a subject must ever be mixed, there is still sufficient evidence to warrant a diligent examination of the means of discriminating between real and apparent death: indeed, the horror with which we contemplate a mistake of the living for the dead should excite us in the pursuit of knowledge by which an event so repugnant to our feelings may be avoided.

Life consists (at least as far as we can perceive) in the presence of a preserving principle proper to all organized beings, and peculiar to each species, which opposes itself continually to the influence of the physical and chemical agents that surround us. The effects of these agents in altering the forms and nature of inorganic substances we daily witness, while our frames resist them in every latitude. This power, in conjunction with sensation and motion, constitutes the state of life; a state which subsists as long as this power remains. But we do not see this power; it only renders itself sensible by the motions given to the heart, lungs, and other organs; and it is by the existence of these motions that we generally judge of the existence of life. This isolated abstract principle cannot subsist, as far as we know, without the instruments by which it makes itself visible; it is for this reason that

* "Dissertation sur l'incertitude des signes de la mort, et l'abus des interremens et embaumens précipites." Bruhier mentions 180 cases in which persons still living were treated as dead; of these, 52 were buried alive, 4 were opened before death, 53 revived spontaneously after being placed in their coffins, and 72 were supposed to have died when they really had not.

† Journal des Sçavans, 1749.

these are to be particularly considered on the present occasion, without in the least, however, diverting us from the consideration of a great first cause. If life depends upon the presence of a force or power continually opposed to the action of physical and chemical laws, real death will be the loss of this force, and the abandonment of organized bodies to these agents; while apparent death will be only the suspension of the exercise of life caused by some derangement of the functions which serve as the instruments of vital action. This suspension may last for a considerable time, if we may judge by the cases collected by credible authors, to some of which we have alluded, and by the numerous instances of drowned persons restored to life after long submersion. From this definition of life and death, it would follow that putrefaction is the only evidence of real death; but in many instances it would be attended with much inconvenience, and often with danger, to wait for this confirmation of the extinction of life. In malignant diseases, and during times of severe general sickness, the keeping of bodies disinterred until putrefaction announced the reality of death, would be a measure fraught with considerable risk to the lives of the survivors. It then becomes desirable that we should be acquainted with those signs by which we may judge that life is extinguished by the interruption of its functions.

As respiration is a function most essential to life, and at the same time the most apparent, the cessation of it may be considered as an indication of death. But as in certain diseases and states of great exhaustion it becomes very slow and feeble, so as to the casual observer to appear quite extinct, various methods have been adopted for ascertaining its existence. Thus, placing down or other light substance near the mouth or nose; laying a vessel of water on the chest, as an index of motion in that cavity; holding a mirror before the mouth in order to condense the watery vapour of the breath; have all been proposed and employed, but they are all liable to fallacy. Down, or whatever substance is employed, may be moved by some agitation of the surrounding air; and the surface of a mirror may be apparently covered by the condensed vapour of the breath, when it is only the fluid of some exhalation from the surface of the body. We, therefore, agree fully with the judicious observations of Dr. Paris* on this subject. "We feel no hesitation in asserting that it is physiologically impossible for a human being to remain more than a few minutes in such a state of asphyxia as not to betray some sign by which a medical observer can at once recognise the existence of vitality; for if the respiration be only suspended for a short interval, we may conclude that life has fled for ever. Of all the acts of animal life this is by far the most essential and indispensable. Breath and life are very properly considered in the scriptures as convertible terms; and the same synonym, as far as we know, prevails in every language. However slow and feeble respiration may become by disease, yet it must always be perceptible, provided the naked breast and belly be exposed; for when the intercostal muscles act, the ribs are elevated, and the sternum is pushed forward: when the diaphragm acts, the abdomen swells. Now this can never escape the attentive eye; and by looking at the chest and belly, we shall form a safer conclusion than by the popular methods which have been usually adopted."

The absence of the circulation of the blood has been looked on as a certain indication of death; but this is a test not much to be depended on, for it is well known that persons may live even for hours in whom no trace of the action of the heart and arteries can be perceived. In applying this test, it is necessary to remember that it often occurs that the pulse at the wrist cannot be felt if the limb be extended or everted; but if it is bent, and the hand turned inwards, it becomes perceptible. We should, therefore, perform this movement, by which the artery is relaxed, and the passage of the blood is facilitated when only feebly propelled. Sometimes, also, the artery can be felt between the thumb and first metacarpal bone when it is not to be found at the wrist. It is well to seek for the artery at the bend of the arm, as the pulse can often be felt there after it has left the wrist. In these examinations it is necessary to press very lightly, lest we should obliterate the pulsation altogether; and care should be taken to guard against mistaking the beating of the arteries in one's own fingers for that of the artery under examination. The trial should be made at every part where large arteries pass; and sometimes the proceeding of laying the body on the left side, and placing the hand under the region of the heart, may be adopted. The stethoscope may be used with great advantage in these cases, as any motion of the heart will be sure to become sensible through the aid of this instrument.

The temperature of the body has also been proposed as a guide, but this is very fallacious, as it is well known that the cooling of a body after death is influenced by many circumstances, such as age, habit of body, and the disease of which the person died. With respect to age, it has been observed that the bodies of young persons retain their heat longer than those of old. In fact, in old age, the winter of life as it has been termed, death is scarcely any thing more than to become cold; and in those cases the temperature of the body is rapidly reduced to that of the surrounding medium. Hence we derive a caution in judging of priority of death among a number of bodies overwhelmed by the same accident; for the body of a young person found warm, and that of an old one found cold, would not indicate that the former had survived the latter. This will be more fully treated of in another article. (See SURVIVORSHIP.)

The habit of body has also been observed to exert an influence over the rate of cooling after death, and it is found, *cæteris paribus*,

* *Paris and Fonblanque*, Med. Jur. vol. ii. p. 10.

that fat bodies lose their heat sooner than lean, but putrefy sooner. The disease which has destroyed life is a powerful controlling agent in the loss of temperature after death. Thus it has been long known that in apoplexy the body retains its heat for a considerable time. This has been particularly noticed by Portal. Again, in that disease or accident frequently witnessed in tropical climates, the "coup de soleil," we are informed by Badenoch that the bodies of the sufferers remain warm much longer than in other forms of death. In most kinds of asphyxia except that by drowning, but especially in asphyxia by noxious gases, the dissipation of the animal heat is greatly delayed. In cases of the latter description, Orfila found the heat preserved for twelve hours after death; and we are informed by Samoelowitz, that during the great plague at Moscow, the bodies of those who were speedy victims to that disease preserved their temperature much longer than the bodies of those who die by ordinary diseases. Besides these cases in which the animal heat is preserved to an unusual length of time after death, there are others in which it is rapidly lost during life, and even when there is no danger of death, as in some forms of hysteria, and in syncope. It is also an effect of submersion in water, and is usually observed in the bodies of those restored to life after drowning. Flexibility of the limbs succeeding their rigidity is one of the most characteristic signs of death: we say succeeding their rigidity, because so long as the limbs are flexible, if the flexibility has not succeeded stiffness, we may presume that there are some remains of life. We are indebted to Nysten and Louis for some valuable observations on the occurrence and duration of the cadaverous stiffness. The rigidity of the muscles commences in the trunk and neck; it then spreads to the thoracic extremities, and finally reaches the legs and feet, and in subsiding it follows the same course. Its duration is in proportion to the lateness of its occurrence, it being found to continue longer in those cases in which it commences latest. Its energy and duration are always in a direct ratio with the degree of development and energy of the muscular system at the moment of death: thus it is extremely strong in the bodies of athletic individuals, in those who die of tetanus, or who are asphyxiated by noxious gases whose delcterious action does not affect the contractility of the muscles. In all animals, the moment when stiffness commences is that in which the vital heat appears to be nearly extinct. Professor Louis, from observations made upon more than five hundred subjects after death, found that at the moment of the absolute cessation of the vital movements, the articulations began to become stiff even before the loss of animal heat. Foderé has verified the justness of this observation several times in hospitals, and concludes that the flexibility of the limbs is one of the principal signs by which we may judge that a person is not dead, although there is no other sign of life. During the whole time this contraction of the muscles continues, they resist the action of chemical forces, and it is only when suppleness is restored that putrefaction commences. Nysten regards this stiffness as a measure of the resistance opposed by organic to chemical forces. Life on the point of extinction seems to take refuge in the muscles, and there causes the spasms we speak of, and during their continuance is able to resist the operation of chemical forces.

The occurrence of the cadaverous stiffness is subordinate to the same causes that influence the loss of temperature. We have seen that old age favours the dissipation of animal heat, and in like manner it is observed that the muscular rigidity comes on soonest in the bodies of old persons. The habit of body in which the temperature is longest preserved is that in which stiffness of the limbs is slowest in its invasion; thus the bodies of full and fat persons remain longer flexible than those of meagre and lean. And again, those diseases which are followed by a long continuance of warmth are also remarkable for leaving a corpse in an equal degree flexible; while those in which the body is rapidly cooled, as hemorrhage for example, favour the approach of the muscular spasm; and after death from these, the body becomes soonest and sometimes suddenly stiff. From this concurrence between the spontaneous cooling of the dead body, and the supervention of the cadaverous stiffness, it might be presumed that accidental cooling would be followed by a similar effect; and this is precisely what takes place; for bodies left exposed in cold situations, as on a field of battle, are found to become rapidly stiff.

The rigidity of the body is a criterion of great value, as it points out the general contraction of the muscular fibre that occurs shortly after dissolution; but in regarding it as a test of death, it is necessary to guard against mistaking the stiffness that arises from other causes for the cadaverous stiffness. In persons frozen but not yet dead, or, in other words, susceptible of reanimation, the rigidity of the body is very great, but on close examination it is found not to be confined to the muscular system, but to pervade all parts of the body. The breasts, belly, and skin, are all equally hard with the muscles, to which alone the stiffness is confined in that from death. This, coupled with the crackling noise caused by forcible flexure of a joint, will be sufficient mark of discrimination between the two. Moreover, it can scarcely be a source of error, because it is an effect of the accident to which the person has been exposed, and if it does not yield to the appropriate remedy (the gradual application of heat), it will be an indication that the subject is really dead.

The stiffness that occurs in certain forms of syncope and convulsive diseases can never be confounded with cadaverous rigidity if proper attention be paid to the facts connected with it; for in the former case it takes place immediately after the invasion of the disease, and always precedes apparent death, while the body still preserves a considerable degree of warmth; whereas the cadaverous stiffness is

not observed until some time after death, and when the heat of the body is scarcely sensible. In all stiffness of this kind there is much difficulty in moving a limb; so far it resembles that from death; but after having bent the limb, on ceasing to apply the force, it immediately flies back to its former position; while the dead limb, on the contrary, remains in the position in which it is placed. If death really takes place in any of these convulsive diseases, the muscular contraction ceases with the extinction of the nervous influence to which it was owing, and the true cadaverous stiffness succeeds at the proper time, and runs its usual course. But above all, the termination of the cadaverous rigidity in flexibility serves to distinguish it from every other, and is a certain indication of dissolution.

That peculiar cast of countenance termed from its first describer the *Hippocratic*, has been regarded by some as another sign upon which reliance may be placed in judging of the reality of death. It is thus described by Hippocrates: "The forehead wrinkled and dry; the eye sunken; the nose pointed, and bordered with a violet or black circle; the temples sunken, hollow, and retired; the ears sticking up; the lips hanging down; the cheeks sunken; the chin wrinkled and hard; the colour of the skin leaden or violet, the hairs of the nose and eye-lashes sprinkled with a yellowish white dust." Such is the alteration in the human physiognomy that usually takes place after death. But it is also produced by the near approach of death; often by the sight of imminent danger; and is also commonly observed in criminals at execution, whatever may be the degree of tranquillity assumed. Moreover, those who perish by sudden death, or of short diseases in which dissolution is not expected, preserve their usual physiognomy; while, on the other hand, the countenance may be pale, ghastly, and contracted in nervous and hysterical affections without extinction of life. Finally, there are some individuals whose integuments during life have a leaden and cadaverous aspect, and whose countenance during natural sleep puts on an appearance little removed from the Hippocratic. From these causes we think that little reliance can be placed on the countenance as a test of death.

The changes that take place in the eye after dissolution are remarkable, and have been regarded by some authors as satisfactory indications of death. These are, the cornea becoming opaque, and covered with a thin slimy membrane, which breaks in pieces when touched, and is easily removed by wiping; and general flaccidity of the eye-ball, which may be perceived by placing the finger on the upper eye-lid and moving it gently over the surface of the eye; when the point of the finger will sink on coming over the cornea, and a distinct ring will be felt, marking the attachment of this membrane to the sclerotic coat. Certainly these signs are valid in many forms of death, but they do not exist in all, and are therefore not infallible. The reason why they are sometimes present and at others wanting, is evident when we consider the causes upon which these changes depend. The cornea owes its brightness mainly to the tension of the eye-ball, produced by a full secretion of the humours. This is proved by evacuating a portion of the humours of a recent eye, when the cornea will become flaccid and opaque; or by taking an eye some time dead, and with the cornea already opaque, and compressing the humours towards the anterior part, when the cornea will reassume its brightness. We find the appearance of the living eye influenced by the same cause, and hence we see the dim cornea in very aged and meagre persons produced by a deficiency in the ocular in common with every other secretion. We do not speak of the arcus senilis, but of the general opacity of the cornea observed in such individuals. Hence we can understand why in death after long illness, when the powers of reparation have been for a length of time impaired, the eye should exhibit its want of fulness by a flaccid and dim cornea. On the other hand, we are led to expect, when death takes place suddenly in a healthy person, that the eye will preserve its lustre for a much longer period; and this experience confirms; for it has been observed that after death by apoplexy, asphyxia, prussic acid, &c. the eyes preserve their integrity for a considerable time, owing to their being at the time of death in a state of tension by the due secretion of the vitreous and aqueous humours. Moreover, it has been observed that in severe diseases of long continuance, and even in some affections of the mind, the eyes have become dim and shrunken although death may not happen, and thus another source of fallacy arises.

Different physical tests have been proposed for doubtful cases, such as incisions, burns, blisters, cupping, flagellation, &c.; but of these it may be said that there are so many instances of disease affecting the nervous system, in which their application causes no sensation in the sufferer, that they will be still less likely to produce any effect on the sensorium in a body nearly deprived of life. The influence possessed by galvanism in the production of muscular contraction in the living body has led to its adoption as a test of death; and with certain limitation it is one of considerable value; for although the muscles retain their contractility for some time after absolute death, yet if the death be real, they soon lose it, and become insensible to this stimulus. On the other hand, if the least spark of life remain, the contractility will be also present, and on the application of the galvanic fluid it will be evidenced by contraction. Galvanism thus becomes a test not of life, but of the reality of death, for if the muscular fibre does not obey it, there can be no doubt that vitality is extinguished. It should be recollected, however, that different parts of the muscular system retain their contractility, and consequently their obedience to the galvanic stimulus, for different periods after death.* Nysten found, in the body of a guillotined

* Dict. des Sciences Méd. art. *Mort.*

criminal which was given to him immediately after execution, that the contractility of the left ventricle was extinguished in forty-nine minutes after decapitation; that of the stomach, intestines, and urinary bladder continued for fifty-six minutes; while that of the right ventricle and diaphragm remained for two hours. He found the locomotive muscles lose their contractility in proportion to their free exposure to the atmosphere, and those that were not at all exposed continued excitable during four hours; but the auricles of the heart, although in contact with the air during the whole time, did not cease to contract, when stimulated, for four hours and forty minutes. From many similar opportunities of observation possessed by Nysten, he concludes that the muscles cease to be influenced by galvanism after death in the following order: 1. left ventricle; 2. intestines and stomach; 3. urinary bladder; 4. right ventricle—this retains its contractility under galvanism for one hour; 5. œsophagus, for half an hour longer; 6. iris; 7. muscles of animal life; 8. auricles.

We have now alluded to the chief criteria of real death; and we may conclude this part of our subject by stating that those most entitled to consideration are flexibility subsequent to rigidity of the joints; loss of contractility of the muscles under galvanism; and incipient putrefaction. These are not liable to any important fallacies: the rest are, for the reasons already mentioned, more or less equivocal.

It now remains, before we proceed to consider the causes of sudden death, to make a few observations on the changes which the human body undergoes after dissolution; and we prefer doing so in this place, because the subject naturally follows that which we have just discussed, and also because a knowledge of the attendant phenomena and their causes is often of the highest importance to the medical jurist in enabling him to determine the length of time a body submitted to his inspection may have been dead; or the period at which dissection may be attempted with a prospect of useful results. It is sometimes of the utmost moment to the surviving relatives of an individual found dead that it shall be determined at what time death took place; of this a case mentioned by Dr. Male* serves as a good illustration. At the Lent assizes, held at Warwick in the year 1805, a cause was tried in which a gentleman, who was insolvent, left his own house with the intention (as it was presumed from his preceding conduct and conversation) of destroying himself. Five weeks and four days after that period his body was found floating down a river. A commission of bankruptcy having been taken out against the deceased a few days after he had left his home, it became a question of great importance to the interests of his family to ascertain whether he was living at that period; for if it could be proved that he was not, his property would remain untouched by the legal proceedings. From the changes which the body had undergone, it was presumed that he had drowned himself the day he left home; and to corroborate this presumption, the evidence of Sir George Gibbes of Bath was required, as he had lately been engaged in experiments on the changes produced in animal substances by immersion in water. He stated on the trial that it required five or six weeks to effect changes similar to those observed in the body of this individual; and upon this evidence the jury were of opinion that the deceased was not alive at the time the commission was taken out, and the bankruptcy was accordingly superseded.

A few weeks back the writer of this article, in passing along the canal on the south side of Dublin, on a Saturday, observed a crowd collected on the bank; on approaching, he discovered the object of their attention to be the body of a man recently withdrawn from the water. None of the bystanders knew anything of the individual, or of the time at which he had been drowned; but, from the fresh appearance of the body, the general belief was that he had fallen in the preceding evening. From certain appearances (to be more fully treated of hereafter) the writer was induced to doubt the truth of this supposition, and to assert that the man had lain in the water for at least five days. An accidental circumstance served to corroborate this opinion. Seeing the individual well dressed, and not observing any hat, the writer inquired whether one had been found with him, to which he received a negative answer; when a boy, who lived in the neighbourhood, came forward and mentioned that a hat and handkerchief were found in the water, at that place, on the previous Tuesday morning, just five days from the time of finding the body. These articles were afterwards proved to have belonged to the deceased. This was a case in which, from the appearances presented by the body, very positive testimony could have been given as to the length of time that had elapsed since death; and in case any question similar to that in the preceding instance was pending, such testimony must have been of the highest importance.

The changes that take place in the body after death may be divided into those that occur before, and those that follow the invasion of putrefaction.

To the first stage belong diminution of temperature, contraction of the muscles constituting cadaverous stiffness, and lividity of certain portions of the surface. We have already taken notice of the causes by which the loss of heat and muscular rigidity are influenced, and therefore it is unnecessary to allude to these phenomena at present. The extensive lividities usually observed on the back parts of the body shortly after death, are entirely owing to gravitation; the blood, still fluid, and no longer kept in its proper course by an impelling power, obeys the physical law by which it is inclined to seek the most depending situations, and this takes place in the interior as well as on the exterior of the body; of which we have examples

* Elements of Juridical Medicine, p. 101.

in the gorged state of the posterior portion of the lungs, and in the vascular turgescence exhibited by the gastro-intestinal mucous membrane in the lowest part of depending convolutions.* That all these appearances are the result of gravitation is proved by the fact that we can produce them in other situations by altering the position of the body; thus, if it be turned on the face, instead of remaining as it usually does on the back, the skin of the face, breast, belly, and anterior parts of the limbs will be found livid, while the back will retain its natural colour, and the congestions in the interior of the body will all be found in the anterior part of the organs. Nay, the lividity, having formed on the back, can be made to disappear, if the body is turned before it becomes cold, and the blood coagulates. Of this the writer has convinced himself by experiment. As it has happened that these lividities have been mistaken for the effects of violence, and suspicions of murder having arisen therefrom, it is necessary, in judging of such appearances, to take into consideration the attitude in which the body may have lain during the first few hours after death, the great extent of surface occupied by them, and the absence of any effusion or infiltration of blood into the cellular tissue. We shall have to recur to this subject when we come to treat of the effects of blows on the dead body, and their resemblance to the consequences of injuries inflicted during life.

The second stage is marked by the occurrence of putrefaction. This is a process peculiar to organized substances, and it seems to follow as a consequence of the manner in which their ultimate elements are combined during life. These elements are few in number—oxygen, hydrogen, carbon, and nitrogen constitute the great bulk of organized substances. Other elements, as phosphorus, sulphur, iron, lime, potassa, and silica, are occasionally present, but in quantities so small as not to invalidate the statement just made. But we find these elements combined in various proportions, and thus constituting the different proximate principles of which our bodies are made up, such as fibrin, albumen, gelatine, urea, stearine, elaïne, cholesterine, &c., which in composition differ from each other chiefly in the proportion of their component elements. Now these combinations are not such as the ultimate elements have the greatest disposition to form; in other words, their natural affinities lead them to different combinations and to the production of more permanent compounds, namely, water, carbonic acid, ammonia, &c. This disposition is controlled by vitality, and as long as it continues, the operation of chemical laws seems suspended; but as soon as life is extinguished, the elements abandon their former combinations, and enter into new ones, and this constitutes putrefaction. The presence of nitrogen expedites this process, and hence vegetable substances, which with few exceptions are deficient in this element, undergo the change more tardily and imperfectly; and some animal substances, as fats, oils, cholesterine, in which nitrogen is absent, are little disposed to the putrefactive fermentation.

The human body, in common with other animal substances, suffers this dissipation of its principles after death; but, as the phenomena attending this change are not constant as to time, order, and results, it is necessary to inquire into those causes that influence its course.

The conditions necessary to the speedy putrefaction of a dead body are the exposure to air, moisture, and a moderate degree of heat. The presence of air, however, does not appear to be essential, although its exclusion retards the process. Putrefaction in vacuo was denied by Gay-Lussac, but some experiments by Guntz of Leipsic have proved the possibility of its occurrence. He took some pieces of human flesh, and having freed them from any air that might be lodged among the fibres by plunging them into mercury, he passed them into jars inverted over and filled with the same fluid. The flesh rose to the top of the jar, and the apparatus was kept in a moderate temperature. Putrefaction went on, but at a slower rate than if the air had been admitted. In a few days the flesh became soft and pulpy, and of a grey colour. Gas was generated, which was found to be carbonic acid gas, and some highly fetid fluid covered the surface of the mercury: the flesh had lost one-third of its weight. He also ascertained that blood alone will putrefy in vacuo. For this purpose he placed the fore-finger of his left hand under an inverted jar filled with mercury, and then made an incision into the integuments. The blood rose to the top, and in five days it was found to be undergoing putrefaction; an accident by which the apparatus was upset prevented an analysis of the product. These experiments shew that though the presence of air expedites the process, it is not essential.

A moderate temperature is a most important condition. If the heat be too high, it prevents the occurrence of putrefaction by rapidly dissipating moisture; and if too low, the process is equally arrested, and, it would appear, from the same cause,—for the fluids being converted into solids by congelation, are as efficiently deprived of the power of assisting putrefaction (so long as they continue in that state) as if they were altogether removed. The practice of packing salmon in ice for the purpose of preserving it fresh during long voyages is a familiar illustration of this point. But the most extraordinary instance on record is the preservation of the mammoth discovered some years ago in Siberia enclosed in a block of ice, on breaking into which the animal was found entire and fresh. This being a specimen of an extinct species of animal, it is of course impossible to calculate the number of centuries it must have been enveloped in its icy tomb. Below 50° Fahrenheit, the process is slowly performed, and at 32° it is altogether suspended. The temperature most favourable

* *Trousseau*, Dissertation inaugurale. Paris 1825.

to its perfection is from 60° to 80° or 90°. This is the range of the thermometer during our summer, and hence at this time putrefaction most readily goes forward.

Moisture is an indispensable condition. This is shewn by the readiness with which substances otherwise disposed to putrefy are preserved by drying, as smoked meats, fish, &c.; and still more strikingly by the preservation of animals buried in sand. Caravans in crossing deserts have been overwhelmed by the shifting sands, and the bodies of men and camels have lain for centuries until exposed by the same cause, when they were found dry, shrunken, but without any sign of having undergone putrefaction. Instances of this kind have occurred in Egypt, Arabia, and Persia. Chardin* mentions the preservation of certain bodies in the sands of Corassan (Persia), where they had been buried 2000 years.

It is supposed that the preserving power possessed by some burying places, as the vaults of the Cordeliers at Toulouse, and those of St. Michan's, Dublin, is owing to the dry and absorbent nature of the surrounding soil. In these situations bodies rarely putrefy, but they undergo a process of natural mummification. The products of putrefaction, when conducted under favourable circumstances, are—water, ammonia, carbonic acid, carburetted hydrogen, sulphuretted hydrogen, phosphuretted hydrogen, nitrogen, and hydrogen gases, and there remains a friable matter of a deep brown colour containing the salts of the body and some carbon.

From these cursory observations it must appear that the transformation of a dead body will be influenced by the medium in which it is placed. The media existing naturally, and to which all others may be referred, are the earth, air, and water. But as these do not exist in a purely separate state, being found mixed together,—as air impregnated with water, water with air, and earth with both,—the term *group* may be given to these combinations. Thus we have earthy group, watery group, and aerial group, by which are meant the combinations usually existing between these media. A group is called cold when the temperature is below 32°; cool between 32° and 60°; warm between 60° and 100°; and hot when it is above 100°.

The metallic oxydes and salts which enter into the composition of the earth exercise but a small influence in the transformation of a dead body. The action of this medium depends upon the greater or less exactness with which it excludes the access of air and water. Thus sandy soils, which quickly absorb water, and argillaceous soils which collect water round a dead body, differ materially in their effects; in the former decomposition goes on slowly, and is sometimes, as we have seen, altogether prevented; in the latter putrefaction readily takes place, and sometimes the transformation into adipocire is effected. Fresh ground or gardens which are rich in mould, and the soil of church-yards, appear to act as a sort of ferment which assists putrefaction; for it is found that flesh enters sooner into the putrefactive process when surrounded by substances already undergoing that change.

We have alluded to the formation of adipocire, and it is necessary, before we leave this part of our subject, to make a few observations on this curious phenomenon. Adipocire, so termed from its resemblance to fat and wax, is a peculiar substance of a soft ductile nature and whitish colour, produced by dead animal substances undergoing decomposition under particular circumstances. We are indebted to Fourcroy for the first scientific account of this peculiar transformation. His attention was directed to it on the occasion of the celebrated exhumations practised at the ancient burying place *Des Innocens* at Paris, in the years 1785, 86, 87, when from fifteen to twenty thousand bodies were removed for the purpose of eradicating this cemetery. This spot differed from common burying grounds, where each individual body is surrounded by a portion of the soil. It was the burying ground of a large district, wherein successive generations of the inhabitants had been deposited for upwards of three centuries. The remains of the human bodies immersed in this mass of putrescence were found in three different states, according to the time they had been buried, the place they occupied, and their relative situations with regard to each other. The most ancient were simply portions of bones irregularly dispersed in the soil, which had been frequently disturbed. A second state, in certain bodies which had always been insulated, exhibited the skin, the muscles, tendons, and aponeuroses, dry, brittle, hard, more or less grey, and similar to what are called mummies in certain caverns. The third and most singular state of these soft parts was observed in the bodies which filled the common graves or repositories. These were cavities thirty feet in depth, and twenty on each side appropriated to contain the bodies of the poor. Each cavity contained between 1000 and 1500, packed side by side in rows, without any intervening earth; so that it might be considered, when filled, as an entire mass of human bodies separated only by two planks of about half an inch thick. The first of these receptacles opened in the presence of Fourcroy had been closed for fifteen years, the coffins were in good preservation, but a little settled, and the wood had a yellow tinge. When the covers of several were taken off, the bodies were observed at the bottom, leaving a considerable distance between their surface and the cover, and flattened as if they had suffered a strong compression. The linen which had covered them was slightly adherent to the bodies, and with the form of the different regions, exhibited, on removing the linen, nothing but irregular masses of a soft ductile matter of a grey-white colour. These masses environed the bones on all sides,

* Traité des Exhumations Juridiques, par MM. Orfila et Leseur, vol. i. p. 382.

which had no solidity, but broke by any sudden pressure. The appearance of this matter, its obvious composition and its softness, resembled common white cheese; and the resemblance was more striking from the prints which the threads of the linen had made upon its surface. The grave-diggers asserted that they never found this matter in bodies interred alone; but that the accumulated bodies of the common graves only were subject to this change. Fourcroy remarked that the conversion appeared in different stages of advancement, so that in various bodies the fibrous texture and colour, more or less red, were discernible within the fatty matter; that the masses covering the bones were entirely of the same nature, offering indistinctly in all the regions a grey substance, for the most part soft and ductile, sometimes dry, always easily separated in porous fragments, penetrated with cavities, and no longer exhibiting any traces of membranes, muscles, tendons, vessels, or nerves. By examining this substance in the different regions of the body, it was found that the skin is particularly disposed to this remarkable alteration. It was afterwards perceived that the ligaments and tendons no longer existed, or at least had lost their tenacity, so that the bones were entirely unsupported, and left to the action of their own weight. In all the bodies so changed the abdominal cavity had disappeared. The integuments and muscles of this region being converted into the white matter, like the other soft parts, had subsided upon the vertebral column, and were so flattened as to leave no place for the viscera; and accordingly there was scarcely ever any trace of them observed in the almost obliterated cavity. The thorax was also flattened, and its viscera were no longer discernible. Sometimes an irregularly rounded mass was found, which appeared to have arisen from the fat and fibrous substance of the heart. The features of the face were converted into adipocire, and no longer distinguishable, and some of the same matter occupied the cavities of the mouth and orbits. The cranium constantly contained the brain, changed into a similar substance. From various observations, it was found that this fatty matter was capable of enduring in these burying places for thirty or forty years, and is at length corroded, and carried off by the aqueous putrid humidity which there abounds.

Adipocire, according to M. Chevreul, consists of margaric acid, oleic acid, a little bitter substance, of an orange coloured principle which tinges the acid, of a trace of odorous principle, of ammonia, very small quantities of lime and potass, and some salts. The alkalies we have mentioned partly saturate the margaric and oleic acids. The latter exists in a very small proportion relatively to the margaric, which abounds in this substance. It is easy to perceive from this analysis that adipocire is a soap with double acid and ammoniacal base. Sometimes, however, the acids are found combined with lime. This has been observed when bodies undergo the change in water containing carbonate or sulphate of lime; and also in earth permitting the infiltration of water which has dissolved these salts in its progress through it. In both cases the ammoniacal soap is first formed, and is then decomposed by the calcareous solution; margarate and oleate of lime, and carbonate or sulphate of ammonia being the result. To prove that such is the case the following experiments were made by Orfila and Leseur.

On the 4th of December, 1828, they interred a stomach, a portion of skin with the subjacent cellular tissue, two testicles, and an omentum, all belonging to the human subject. Each of them was enveloped in linen, and placed in a small deal box, which was buried at a depth of two feet and a half. They were disinterred on the 30th of July, 1829, seven months and twenty-seven days after having been deposited in the ground. In place of the stomach they found about half a drachm of adipocire not in the least ammoniacal, but composed of margaric and oleic acids and lime. The skin presented here and there the appearance of adipocire, and furnished on analysis a calcareous soap; the testicles were similarly transformed. The omentum had preserved its aspect and structure in several places, whilst in others it was changed into a yellowish fatty mass, having the odour of Roquefort cheese, and composed of lime and the acids mentioned above. These distinguished experimenters, although pretty certain that the presence of the calcareous soap at the expense of the ammoniacal, in these substances, was owing to the rain-water in filtering through the ground having dissolved some of the calcareous salts, which having thus got access to the interior of the wooden box decomposed the ammoniacal soap, and changed it into calcareous, nevertheless thought it necessary to prove by direct experiment that it really was so. Accordingly they prepared an ammoniacal soap with pure stearic acid and caustic ammonia, and plunged it into a solution of sulphate of lime. At the end of three weeks, on examining the soap, it was found entirely changed into stearate of lime, and sulphate of ammonia was formed. They made also another experiment: two human stomachs were buried, one in a leaden box enclosed in a wooden one, the other in wood alone: seven months afterwards they were taken up. The stomach contained in the wooden box was transformed into a soap partly ammoniacal but chiefly calcareous, whilst that inclosed in the lead offered no trace of saponification, and was but little altered.

"It is manifest," say they, "that, in this last experiment, the progress of the putrefactive process had been greatly retarded in consequence of the double envelope, and particularly of the leaden cases; and every thing leads to the conclusion, that if the apparatus had remained underground as long as was requisite for converting the stomach into soap, this soap would have been of the ammoniacal and not of the calcareous kind."*

* Traité des Exhumations Juridiques, tom. i. p. 366.

Adipocire is only formed when fat and some azotised substance are found together. The fatty matter furnishes the margaric and oleic acids, and the other the ammonia. This is proved by the following circumstances. Entire dead bodies, or entire parts of a dead body, such as a head, one of the limbs, or the thorax, parts in which are found skin, fat, muscles, &c. are changed into adipocire in stagnant or gently moving water, but isolated muscle furnishes but a small portion of this substance, and that only when it is rich in fat. Fat washed, freed from blood, and separated from parts which contain azote, is not transformed into adipocire. Neither does the fibrine of the blood, when perfectly washed and free from fat, undergo the change. Orfila found that portions of skin previously deprived of the subjacent cellular tissue, were not saponified after eight months of inhumation; while similar portions of the skin of the same individual, to which the cellular substance was left adhering, and buried during the same time, were converted into adipocire. It appears that a sojourn of about three years in the ground is necessary for the complete transformation of a body, and that the change goes forward more quickly in water; and it is only when a number of bodies are buried in the same grave, that the process is perfect, those at the bottom being the first to undergo it. A thick stratum of earth over the grave is necessary, in order to confine the gases given out in the first stages of putrefaction.

The chief object of the medical jurist to whom a dead body is submitted for inspection, is to ascertain the cause of dissolution. In order to assist in this investigation, we will follow the arrangement already proposed.

1. Death from Natural Causes.—Death is the inevitable condition to which all bodies that possess life must, sooner or later, be reduced. This termination of their existence forms a grand distinction between organized and unorganized matter. The gradual termination of life, or natural death strictly so called, is very different in its phenomena from the more common or accidental death. In natural death man expires, as it were, in detail; the external functions and those of the animal life being almost annihilated, whilst those of organic life still remain in vigour. The active powers gradually desert each organ; digestion languishes; secretion, absorption, and capillary circulation are arrested; the general circulation is then suspended in the large vessels; and lastly, the contractions of the heart cease. In accidental death, the general circulation and respiration are first arrested, while the other functions are successively and slowly extinguished. So that it has been said that in the former life is first extinguished in the parts, and then ceases in the heart, the influence of death being exerted, as it were, from the circumference to the centre; while in the latter it ceases first in the heart, and then in all the parts, death proceeding from the centre to the circumference. The termination of life termed natural death is a very rare occurrence in the human species in a civilized state: animals often reach it; but the cessation of existence from mere old age has become with us a rare phenomenon. Haller estimates the average probability of human life, and deduces the conclusion that only one individual in fifteen thousand reaches the hundredth year. Accidental death, in contradistinction to natural death, becomes, therefore, an object particularly worthy of attention. This may take place in two ways—either as the slow and gradual termination of a lingering disease; or as the sudden result of some great disturbance of the animal economy, and then called sudden death, as in apoplexy, hemorrhage, concussion, asphyxia, &c.

We now come to consider the natural causes of sudden death, and our observations upon them must be necessarily brief, as it would not be possible to enter into detail upon them in this place; a circumstance not of much consequence, as they are most of them treated of in separate articles through this work. However, we may notice some of the most frequent and remarkable. These are apoplexy, rupture of an aneurism or of a large vessel into one of the cavities; bursting of purulent cysts or other collections of fluid, or of blood-vessels into the air-passages; ossification of the valves of the heart; rupture of this organ; asphyxia idiopathica.

Apoplexy may attack at any age, but in the great majority of cases the age is above fifty years: certainly it may be said to be a disease rather of the decline of life. It is a disease which in some instances may be mistaken in its early symptoms, and may terminate fatally in situations which preclude any observation of the event. Those most predisposed are of a full plethoric system, with large head and short neck. Diseases of the bloodvessels of the brain, such as ossification of the arteries, aneurism, and obstruction of the sinuses, lead to rupture of their coats; and it is well known that hypertrophy of the heart sometimes produces apoplexy. In ordinary cases an examination of the brain sufficiently develops the complaint. Blood is usually found in some part of this organ, rarely on the surface, more commonly in or about the corpora striata or optic thalami, or effused into the ventricles. In old apoplectics who have had many shocks, cysts enclosing clots of blood are found; and the brain surrounding them is often observed in different stages of inflammation or ramollissement. (See Apoplexy.) It should be borne in mind that persons seized with apoplexy may fall from a height, and thus bear marks of external injury which might mislead a superficial enquirer as to the cause of death. In cases of rupture of internal aneurisms, or purulent cysts, or of ossification of the valves of the heart, an examination of the body will exhibit the true nature of the disease. The last of the natural causes of sudden death which we have mentioned is that peculiar disease termed by Mr. Chevallier "asphyxia idiopathica." A case of this rare and remarkable affection came under the observation

of the writer a few years ago. The subject of it was a healthy woman, forty years of age, in the ninth month of pregnancy. She complained suddenly one evening of weakness and sickness of stomach, and on making an effort to vomit, she fell back and expired without any struggle. The writer examined the body the following day, and enquired diligently after every cause of death in each of the cavities; but he never saw more healthy organs, and, taken altogether, certainly never a sounder body. But the state in which the heart was found led to a discovery of the nature of the case. The parietes of this organ were entire, but quite flaccid, and all its cavities were empty; while its proper veins were much distended with blood. This so exactly resembled the appearances described by Mr. Chevallier, and the manner of death corresponded so fully with that of the cases he mentions, that it was thought justifiable to refer the cause of death to the disease just alluded to. Mr. Chevallier accounts for death in these cases by supposing a sudden loss of power in the vessels, chiefly in the minute ones, to return the blood to the heart; in consequence of which this organ, after having contracted so as to empty itself, and then relaxing, continues in that state for want of its accustomed stimulus, and so dies. We mention this in order to shew that such cases are sometimes to be met with, and that it is necessary to be prepared to detect them. For further information we must refer to the paper alluded to.

II. Death from violent causes.—The wide extent of this division, and the great importance of the topics included in it, render it of the deepest interest to the medical jurist. The violent causes of sudden death may be reduced to seven heads, viz. *asphyxia*, *poisoning*, *wounds*, *burning*, *cold*, *starvation*, and *lightning*. From the very able manner in which the subject of asphyxia has been handled in a former part of this work, little remains to be said upon its general phenomena and theory. (See Asphyxia.) Asphyxia may be defined the suspension of the function of respiration, and consequently of the circulatory and cerebral functions. The interruption may affect primarily either the mechanical or chemical phenomena of expiration. The mechanical are the motions of the parietes of the chest, producing inspiration and expiration; the chemical are the disappearance of oxygen from the air taken into the lungs, the disengagement of carbonic acid gas, and the conversion of the venous into arterial blood. Asphyxia may commence by the cessation of either of these classes of phenomena; but in whichever it first begins, it speedily involves the other, and both are soon equally suspended. A violent compression of the thorax, such as is produced by the falling of heavy beams of timber, portions of buildings, roofs of mines, &c. a double wound giving entrance to the air into both cavities of the chest, rupture of the diaphragm by which the abdominal viscera gain admission to the chest, the effusion of large quantities of fluid into the pleura,—all these put an end to the mechanical phenomena of respiration by interrupting the motions of the thorax. In other cases these motions cease, but from a different cause; we allude to paralysis of the muscles that move the parietes, which happens when the spinal marrow is cut across, or is pressed on above the origins of the phrenic nerve, or above the third cervical vertebra, or when the whole nervous energy is destroyed, as by lightning. Most commonly, however, it is the second class, or the chemical phenomena of respiration, that cease first; and the motions of the chest are only interrupted because the black blood, which is then driven into all the organs, and especially into the muscles and brain, does not carry along with it the power of excitation necessary to carry on the functions of these parts. This interruption of the chemical phenomena may be produced in various ways: thus, sometimes there is total intercception of the passage of air into the lungs, as when an animal is placed in vacuo, or is smothered, drowned, or strangled; at other times, an aeriform fluid does enter these organs, but is not possessed of the principle necessary to act on the blood contained in them, such as azote and hydrogen gases. It may be that the gas inhaled is endowed with deleterious properties; either that it irritates the lungs, as the sulphurous acid gas, muriatic acid, and ammoniacal gases; or that it acts upon the whole animal economy as a poison, such as carbonic acid gas, nitrous acid, carburetted hydrogen and hydro-sulphuretted gases. Thus we find that, by the total interception of all air, or by the inhalation of noxious gases, the chemical phenomena of respiration may be arrested. It is to this we shall direct our attention at present, as the cases in which the mechanical phenomena are first affected are more rare, and will be afterwards considered in treating of death from wounds or bruises, (see Wounds, Death from,) and from lightning.

The causes that produce death by asphyxia are drowning, hanging and strangulation, smothering, and the inhalation of noxious gases or air deprived of oxygen.

The physiology of *drowning* having been already fully discussed in the article Asphyxia, we shall proceed to consider the medico-legal questions that may arise in the case of a body found in water. These may be arranged under the following heads:—1. whether the body was immersed before or after death; 2. whether the individual has fallen in by accident, has drowned himself, or has been thrown in by others.

1. The inference that the person was living at the time of immersion is drawn from an attentive examination of the external state of the body, and from a careful anatomical investigation. The body of a drowned person usually presents the following appearances. It is commonly very cold, apparently even colder than the actual temperature; the limbs are more or less stiff according to the time that has elapsed since death; the visage is

swollen, often dark-coloured, but sometimes pale; the eyes are half open, and the pupils dilated; the mouth is filled with froth; the tongue is advanced beyond the teeth; and the chest and belly are elevated, the latter being often much distended. This state of the body is common to those who perish in cold clear water, as the sea, rivers, &c.; but the body is sometimes drawn out warm, although death is so complete that animation cannot be restored, the countenance violet-coloured, and the veins of the neck turgid. This happens in drowning in warm fluids or in alcoholic liquids, or in marshes where deleterious gases are disengaged, or when the person has fallen into the water in a state of intoxication. The ends of the fingers are often found rubbed or scraped, and dirt or sand, of a nature similar to that of the bottom of the water, is perceived under the nails. Coupled with these is the negative sign furnished by the absence of any lesion that could have caused death previous to submersion. The internal appearances disclosed on opening a drowned body are generally the following. The epiglottis is found elevated, and a quantity of froth fills the trachea and bronchi; the lungs are dilated and gorged with blood; black and fluid blood is found in the right cavities of the heart in a much greater quantity than in the left. The diaphragm is depressed, and water of a nature similar to that in which death took place is discovered in the stomach. In the head there is turgescence of the bloodvessels, more or less intense as the death has been more or less speedy, and in proportion to the amount of struggling made by the individual. Orfila,* in a memoir read at the Academy of Medicine, has reviewed all the signs given by authors for determining whether immersion took place before or after death; and the conclusion he draws is, that there is no certain sign of submersion during life but the presence of water, similar to that in which it is found, in the stomach and air-passages; provided that, with reference to the stomach, the water has not been swallowed before submersion, and has not been injected after death: and with respect to the lungs, that the water shall have penetrated to the last bronchial ramifications, and has not been injected before death; and that the body shall not have remained long in a vertical position in the water, so that the water might have entered after death. It would appear from this that we possess two certain signs of submersion during life; but the restrictions imposed on them are such, that, taken apart from others, they are almost useless in the great majority of cases. In speaking of water in the air-passages, Orfila must have meant the froth formed by this fluid with the air; for it is very seldom found in substance in this situation. Devergie† states that in a great number of cases he could find but very slight traces of water in the trachea; and in two only did he observe it in any quantity. Indeed, from the observations of Cullen,* Goodwyn,† and Meyer,‡ it is plain that a very small quantity of water enters the air-passages in drowning; and this is speedily converted into froth by the motion given to it in the attempt at respiration. On the subject of this froth, Devergie makes some interesting observations, the substance of which is as follows:—It is commonly white, consisting of numerous and very small bubbles, constituting a lather rather than a froth properly so called. It never adheres to the trachea by mucus, but is in immediate contact with that tube. All the bubbles that form it have a watery envelope, easily broken, and often in opening the trachea the greater part disappear like soap-bubbles. The froth of drowned persons, then, has but little analogy with the expectoration of pneumonia or catarrh; and it is sufficient to have attentively observed it to avoid confounding them. Its formation necessarily brings with it the idea of vitality, for it cannot take place without motion; an impulse communicated to a fluid and a gas in mutual contact. In order to appreciate its mode of formation, and the value that it may possess as a sign of submersion during life, it appears necessary to enquire how it is produced in other cases than asphyxia by submersion. In pneumonia, for example, the individual is induced to expectorate because the extreme bronchial ramifications are filled with mucus, and the air can no longer reach them, and come into contact with the blood to effect the necessary changes. The invalid expels a frothy matter, because the mucus secreted under the influence of bronchial irritation is beaten and mixed up with the air by the alternate and quick efforts of inspiration and expiration, which constitute coughing. The formation of the froth takes place more easily as the irritation is nearer to the last bronchial ramifications, when the tubes, being of a smaller diameter, are more easily obstructed. It is, on the contrary, produced with great difficulty in the trachea, on account of the great dimension of this canal. In drowned persons similar phenomena take place, after they have expelled a part of the air contained in their lungs. They are soon solicited by the desire to respire; a small quantity of water enters the trachea, and causes a most distressing stimulus, of which we have a proof in the great suffering experienced by persons into whose larynx a drop of fluid has accidentally fallen while swallowing; a brisk and sudden expulsion of the water is effected, but it is rarely complete: the portion which remains dissolves a little mucus, and becomes viscid, whilst, at the same time, new inspiratory efforts draw in a new quantity of water; from that time the air, agitated with this fluid, rendered more viscid, constitutes the froth. This is formed with more difficulty in the trachea than in the last ramifications of the bronchi; and

consequently we esteem its existence in the superior part of the trachea as a more certain sign of the life of the individual at the moment of submersion, than when it is met in the extreme branches. This phenomenon does not leave very durable traces of its existence, for it is sensibly diminished, and even often disappears under the influence of putrefaction. The portion of the air-passages where it is preserved during the longest period is at the bifurcation of the trachea. In winter it may be discovered in most cases after eight or ten days, but later it completely disappears. It is true that if we except the water contained in the stomach, the other signs of submersion have not a more extended duration. It should be understood that the water thus taken into the lungs is not, as it was formerly supposed, the true cause of death; an opinion to which Baron Larrey seems to incline in his Mémoires. The experiments of Goodwyn have shewn that a much larger quantity of water than that which is found in the lungs of drowned animals may be introduced into the air-passages without causing death. Thus, he passed into the lungs of a cat, through an opening in the trachea, two ounces of water; a large quantity when compared with the size of the animal. It had, immediately, difficulty of breathing and a feeble pulse; but these symptoms soon abated, and it lived several hours afterwards without much apparent inconvenience: after this he strangled it, and found two ounces and a half of fluid in the air-tubes and cells.

The presence of water, then, in the lungs of drowned persons in the form of froth is to be considered as an accidental and not essential circumstance, although it is one of very constant occurrence. If this fluid is found in large quantity, and in substance, that is, not beaten into froth, the inference would be that it had passed in after death. With respect to the presence of water in the stomach, it has been proved by many authors to be a constant occurrence; and when it is discovered in this organ, and is identical with that in which the body is found, it furnishes a strong indication of submersion during life, being a necessary consequence of the act of deglutition. For it has been proved by Fine, Orfila, and Mare, that it is never found in bodies plunged into water after death, and cannot be made to enter the stomach without the assistance of a tube passed into the œsophagus.

From the above-mentioned circumstances the following conclusions are drawn by Devergie: 1, that almost all the signs, taken singly, do not prove that the individual was living at the moment of immersion; 2, that the one which furnishes the strongest presumption is the existence of froth placed in immediate contact with the lining membrane of a sound trachea; 3, that this sign acquires a value greater as its situation is nearer to the mouth; 4, that water in the air-passages is a sign of little value, for if it can penetrate the trachea after death, and extend even to the last bronchial ramifications, as Orfila has shewn, it becomes almost useless; 5, that water in the stomach is one of the most constant signs, but its value is greatly diminished by the difficulty of proving its identity with the fluid in which the body has been immersed; 6, that if each sign taken singly gives no certainty, the assemblage of all in the same individual may enable a positive conclusion to be drawn.

The proofs that death occurred before immersion are drawn from the absence of all those signs just enumerated; thus the thorax and abdomen will be found flat,—no excoriation of the ends of the fingers,—no dirt or sand under the nails,—no turgescence of the cerebral vessels,—and no froth in the air-passages. The lungs will be collapsed, and the diaphragm will not have passed the natural line. The stomach will be found not to contain any of the fluid in which the body is found, and in addition to these negative proofs, marks of violence may be discovered on the body quite sufficient to account for death. These marks are divided by Foderè* into three classes: 1st, those which are totally independent of any connexion with the circumstance of drowning. Of this nature are the usual signs of poisoning; a regularly formed ecchymosis round the neck, indicative of strangulation, or wounds inflicted by fire-arms or cutting instruments. All these lesions have an essentially distinct character which cannot be mistaken, and hence the evident importance of examining carefully the external appearance of all bodies found in water. It was by pursuing such an investigation that Deveaux discovered, in the body of a woman found in water, a penetrating wound under the left breast, made by a very small instrument which had reached her heart. 2dly. Marks of violence which may have resulted from accidents attending submersion, or may be caused by previous homicide, such as unequal irregular wounds which do not penetrate far into the body, contusions, fractures, and luxations. In all such cases we should ascertain, if possible, the height from which the individual may have fallen, and the resistance he may have encountered in the fall. The rapidity of the current, and the roughness of the banks of a river, may also cause extensive wounds. Dr. Fine remarks that the rapidity of the Rhone, and the numerous mills erected on its side, often produce most shocking wounds in the bodies which are driven against the stakes in the stream, or are drawn into the machinery. 3dly. There may be lesions received after death. These are to be distinguished from those inflicted during life by the lividity and flaccidity of their edges, the absence of tumefaction and redness, and want of hemorrhage, or, if the latter be present, by the fluidity of the blood.

2. It being ascertained that the subject was immersed while living, it is often of importance to be able to say whether the drowning was the result of accident, of suicide, or of homicide. The solution of these questions is to be

* Méd. Lég. tom. iii. p. 112.

obtained by an examination of what may be termed the external circumstances of the case. The locality of the water may be such as to account for the deceased having accidentally fallen into it, or its situation may at once preclude the possibility of such an event. Indications of struggling on the brink, such as tearing of the ground, and many footsteps, together with ecchymoses on the person of the deceased, may lead to the supposition of homicide. Thus, in the case of Mr. Taylor, who was murdered at Hornsey in December 1818, marks of footsteps deep in the ground were discovered near the New River; and on taking out the body, the hands were found clenched, and contained grass which he had torn from the bank.*

However conclusive the existence of ligatures on the hands and feet of the deceased may appear,—as to the question of the forcible interference of others, it should be recollected that suicides have sometimes adopted such precautions in order to insure their death. There are some instances on record in which the individuals seem to have pursued this course.† In June 1816, the body of a gauging instrument-maker, who had been found missing for some days from his home, was discovered floating down the Thames. On being taken out, the wrists were found tied together and made fast to his knees, which were in like manner secured to each other. He had been in a state of mental derangement for two years. The cord with which he had tied himself was recognised as one that had hung from the ceiling over his bed, by which he used to raise himself up, as he had been confined to bed for some weeks. He was a good swimmer, and it was presumed he had taken this precaution to prevent himself from employing that power. The verdict returned was, "found drowned." The other instance was that of a man, aged twenty-eight, who with a wife and child was reduced to great distress. On a certain day he took an affectionate leave of his family, declaring he would not return until he had procured some employment by which he should be able to buy bread for them. The following day his body was taken out of the New River with his hands and legs tied. A card with his address was found in his pocket, and also three-pence; when he left home he had five-pence, and it was supposed he had purchased the cord with the deficient sum; the verdict brought in was "insanity." Another case of a similar nature has been lately published. It was that of a gentleman who was found in the Seine at Paris, having his feet, wrists, and neck tied with a cord. After detailing the appearances on the body, the reporter concludes with the following note: "Mr. X—— had bound his neck, limbs, and hands by means of a rope with slip knots, in order to put it out of his power to aid himself when in the water, and thereby to render certain the execution of his suicide."* We mention these cases to shew how cautious a medical man should be in forming an opinion in similar instances, and how necessary it is to weigh well every circumstance before he expresses that opinion before a legal tribunal.

It is often, as has been already mentioned, of the highest importance to the survivors, that an approximation to the time that has elapsed since death should be arrived at. For assistance in such an investigation, the medical jurist will turn in vain to the systematic works on legal medicine, it being only within the last few years that any accurate information on the subject was possessed by the profession. We are indebted to M. Devergie for the first essay on this interesting subject, one concerning which the most vague notions were entertained previously to the publication of the memoir alluded to, in the year 1829. The observations of M. Devergie are entitled to much consideration, from the unrivalled opportunity afforded for their formation. He was authorized to carry on his investigations at the establishment called "La Morgue" in Paris, a building on the banks of the Seine, to which are transported all bodies found dead in the city and its environs, and where they are exposed during three days for the purpose of recognition by their friends. The number thus exhibited exceeds three hundred annually, and includes all manner of violent deaths. In case of the sudden disappearance of an individual, his friends repair to the Morgue, and leave with the porter an accurate description of his person, his clothes, and the period at which he was last seen; and when a body is brought in, it is carefully examined, and if it corresponds with any of the descriptions that have been left, notice to that effect is sent to the persons interested, who come and claim it. The number of persons recognised is very considerable; in the first six months of the year 1829, out of 148 bodies 116 were claimed. Of this number 62 were drowned, of whom 45 were recognised. Being thus furnished with positive information as to the time of immersion and that of finding the body, Devergie was enabled to prosecute his enquiries with great accuracy. He found that in general no change takes place on the exterior before the fourth or fifth day, and the cadaverous rigidity frequently continues two, three, or even four days after immersion. This is probably owing to the coldness of the medium in which the body is placed. About the fourth or fifth day, the skin on the palms of the hands begins to whiten, and this change of colour takes place particularly on the ball of the thumb, and the fleshy eminence on the inner side of the palm over the metacarpal bone of the little finger, together with the lateral surfaces of the fingers. The back of the hand does not partake of this colouring, and the rest of the body presents nothing particular. On the sixth or eighth day, the skin at the back of the hand begins to whiten; at the

* *Paris and Fonblanque*, Med. Jur. v. iii. p. 41.

† Op. cit.

* Ann. de Hygiène et de Méd. Lég. t. ix. p. 207.

same time that the sole of the foot has acquired a similar tinge: the skin of the face is softened, and of a more faded white than the rest of the body. On the fifteenth day, the face is slightly swollen and red; a greenish spot begins to form on the skin over the middle of the sternum; the hands and feet, with the exception of the dorsum of the latter, are quite white, and the skin of the palm of the hand is wrinkled. The subcutaneous cellular tissue of the thorax is reddish, and the cortical substance of the brain takes on a green colour in the upper part of that organ. At one month, the face is reddish brown, the eyelids and lips are green and swollen, the neck is slightly green, and a spot of about six inches in diameter, brown in colour and with a green areola, occupies the superior and middle part of the sternum. The scrotum and penis are enormously distended by gas, the latter being sometimes in a state of erection from that cause. The skin of the hands and feet is quite white and very much wrinkled, presenting the appearance of having been long enveloped in a poultice. The hair and nails are still very adherent. The lungs are emphysematous, and fill the cavity of the chest, overlapping the heart,—a condition different from that which these organs present at a more advanced period. At a month and a half, besides the appearances first mentioned, the neck and thorax are found very green, and the cuticle begins to detach itself round the base of the hand where it joins the wrist. At two months, the body is covered with slime, which penetrates through the clothes. The face is enormously swelled and of a brown colour, the lips are tumefied and separated so as to expose the teeth. The skin on the middle of the abdomen, as well as that of the arms, forearms, thighs, and legs, is still in a natural state. This is a most remarkable fact, and establishes a striking difference between the progress of putrefaction in water, and when the body is exposed to the atmosphere; in the latter case the abdomen being the first part to manifest any change. At this period the skin has become detached from the hands and feet, and having the nails attached to it, forms as it were a glove. The skin and nails of the feet are longer in separating than those of the hand. The hair begins to fall off, and is easily removed by pulling. The veins are almost completely empty of blood, and commonly distended with gas. The inner surface of the arteries is red, and that of the trachea between the cartilages presents the same colour. If at the moment of death the right cavities of the heart were gorged with blood, the internal surface of the ventricle is of a jet black colour; and in contrary cases an analogous appearance is presented on the opposite side. Devergie considers this a most important diagnostic mark of death by asphyxia. At two months and a half, the green colour of the skin extends to the arms, forearms, and legs; the nails are completely detached from the hands and feet; some adipocire is formed on the cheeks, chin, breasts, arm-pits, and anterior part of the thighs; the abdomen is greatly swollen by putrefaction within: the muscles at this period preserve their natural colour, and do not appear altered in texture. At three months and a half, there is observed destruction of the scalp, eye-lids, and nose, to such an extent as to make it difficult to tell the age of the individual. The skin of the breast is generally of a greenish brown; the centre of the abdomen is of an opaline colour, and scattered with small ulcerations caused by the water. Larger corrosions are found in different parts of the body. The hands and feet are completely naked of skin. The lungs no longer fill the thorax, but leave between them and the pleura costalis a space filled with reddish serum. At four months and a half, occurs complete destruction of the face and scalp, leaving the skull bare; the remains of face, the neck, and anterior part of the thighs is entirely converted into adipocire; and small eminences, indicating the commencement of calcareous incrustation, are observed on the prominent parts. The brain presents traces of adipocire in its anterior part. Devergie has not classified the changes that take place at more advanced periods. The paper from which we have extracted the foregoing account has been severely criticised by Orfila,* who endeavours to overturn the facts and doctrine contained in it. But we think he has been satisfactorily and triumphantly replied to by Devergie,† who adduces as the best proof of the validity of his conclusions, four cases, in which the periods of immersion, varying from fifteen days to one, two, and eight months, were ascertained with the help of his table.
