THE medical profession should give a thorough trial to the merits of galyl as an antisyphilitic. Since reading the article on it by Dr. Johnston Abraham in the BRITISH MEDICAL JOURNAL (March 14th, p. 582) I have employed it extensively with excellent results. Nearly all my cases have given a negative Wassermann reaction after three injections (35, 40, and 45 cg.), and this, though not a positive proof of cure, is at least satisfactory. I do not think galyl as good a general tonic as neo-salvarsan, but it certainly produces a negative Wassermann reaction in shorter time. It is cheaper, and it is made in Paris.

JOHN HARTIGAN,
Medical Superintendent, Royal Hamadryad Seamen's Hospital, Cardiff.

MALARIAL FEVER WITH SEVERE CEREBRAL SYMPTOMS.

A. P., a negro boy aged 11 years, was admitted to the Public Hospital, Buff Bay, Jamaica, West Indies, on June 11th, in a comatose condition. Reflexes were absent, and soon after admission he passed urine and faeces involuntarily. He seemed in a dying condition. The thoracic

and abdominal organs were found to be normal, except that the spleen was slightly enlarged; the temperature was 104° F.

Malarial fever was diagnosed; a hypodermic injection of quinine hydrochloride was given, and an icebag applied to the head. Next day the boy had improved considerably, and he was in a semiconscious state.

On June 13th he was able to answer questions, but was dull and apathetic. He was then having a mixture containing quinine sulphate gr. iv in each dose.

On the morning of June 15th he had frequent epileptiform convulsions, and was in a semicomatose state; the temperature, which had fallen to normal, was again 104°. He was given another hypodermic injection of quinine hydrochloride gr. v, and this was repeated every four hours. A mixture containing sodium bromide and chloral hydrate was also prescribed. The convulsions soon ceased: the hypodermic injections of quinine were continued, and he gradually improved. He proved to be a bright, intelligent boy, and was discharged perfectly well on July 6th.

Unfortunately there was no examination of the blood made for parasites, but 95 per cent. of cases of malaria in the district are of the sub-tertian variety.

I have to thank Dr. George, senior medical officer of the hospital, for permission to publish this case.

Jamaica, W. I. R. F. RUSSELL, M.B., Ch.B.

ANAESTHETICS IN EYE-WORK.

IN a notice of a pocket-book of ophthalmology by Dr. Curt Adam your reviewer expresses the opinion that chloroform as an anaesthetic should be entirely banished from ophthalmology.

I venture to criticize this view because it is, I believe, contrary to the experience of most ophthalmic surgeons in this country. The duty of the anaesthetist in any particular case is to administer the anaesthetic so that the surgeon may carry out the operation under as favourable conditions as possible, and at the same time to keep in view the safety of the patient.

Now, what are the main conditions required in anaesthetics for eye operations?

1. Anaesthesia must be deeper than in most general operations, since the corneal reflex must be abolished.

2. The surgeon must have as much as possible of the patient's face clear of the anaesthetist's hands and apparatus.

3. Coughing, vomiting, or straining of any kind must not occur during an operation which involves opening the globe, and are highly undesirable in any eye operation.

These conditions are either satisfied with difficulty or not at all by ether anaesthesia, while they are, as a rule, easily met by the use of chloroform or chloroform and ether mixed. From the point of view of the surgeon, then, chloroform or chloroform and ether provide the most suitable anaesthesia.

Is the use of these agents compatible with the reasonable safety of the patient? By reference to the records of the Royal London Ophthalmic Hospital I find that out of 3,082 administrations of anaesthetics in the last five years, in all but 80 the anaesthetic was either chloroform or chloroform and ether. During that period there has been only one death, though the anaesthetics are there given by the house-surgeons, and not by a regular anaesthetist.

The following table has been kindly drawn up for me by Mr. Bland, the secretary of the hospital:

Operations Performed in the In-patient Theatre, Royal London Ophthalmic Hospital.
General Anaesthetics.

	1909.	1910.	1911.	1912.	1913.
Chloroform	790	526	321	50	—
Gas and ether	3	39	7	—	—
Chloroform and ether ...	5	11	266	566	467
Gas, chloroform, and ether ...	—	9	4	—	—
Gas	—	2	—	15	6
Ether...	5	—	—	—	—
Deaths under anaesthesia ...	—	—	—	—	1

My own experience at Moorfields included about 450 anaesthetics in sixteen months. A few of these (mainly other than eye cases) were gas, and the rest all chloroform and ether mixture. The method I adopted has no claim to originality, but as a matter of personal experience I found it answered well. I used a Schimmelbusch mask covered with a double layer of lint, and gave chloroform and ether from separate bottles. Starting with chloroform by the drop method, ether was soon added, and anaesthesia was maintained at the requisite depth, using as large a proportion of ether and as small a proportion of chloroform as possible. The series of over 400, though small from the point of view of anaesthetics for general operations, yet represents, I suppose, considerably more eye anaesthetics than the professional anaesthetist would give in a corresponding time. I did not feel any serious anxiety with regard to any of these cases—in fact, no more than it is desirable to feel with every administration until the patient's recovery.

From the Moorfields figures it would appear that anaesthesia by chloroform or chloroform and ether mixture may lay claim to a reasonable degree of safety.

I should like to ask those who are better fitted to judge than myself whether the abandonment of the "corneal reflex" test of anaesthesia would seriously inconvenience the anaesthetist or seriously imperil the patient's safety. This ritual appears often to distract the attention of the less experienced anaesthetist from more important observations, and certainly adds to the discomfort of patients after operation. It is not tolerated in eye-work. The patient has to suffer many things after operations; surely it is unnecessary to add the pain of extensive corneal abrasions.

London, W. MAURICE H. WHITING, M.B., B.C.Cantab.

Reports
ON
MEDICAL AND SURGICAL PRACTICE IN HOSPITALS AND ASYLUMS.

TUBERCULOSIS SANATORIUM, KILLINGBECK, LEEDS.

ACCUMULATION OF TARTAR RESEMBLING ODONTOMA.

(By ALLAN B. HAMILTON, M.B.)

MRS. G., aged 41 years, was admitted to this sanatorium suffering from pulmonary tuberculosis fairly advanced. Her mouth showed well marked marginal gingivitis; the gums were swollen and tender, and the dental margins oozing pus. Some teeth were missing, chiefly molars, and, excepting the incisors and canines, the rest were carious. On the right side of the upper jaw, and surrounding the first and second molars, the ends of which were visible, was a large mass, the size of half a walnut, firm and hard, and resembling bone, except that it was dull and slightly brownish. Pain was not present on admission, but developed soon afterwards. On closer examination slight movement was made out, and a fine steel probe was passed under its anterior edge, the point disappearing apparently into a cavity. On endeavouring to estimate the firmness of attachment more accurately with the fingers, the "tumour" collapsed like an egg-shell, exposing a large cavity within, filled with foul-smelling greenish débris. The shell was about $\frac{1}{16}$ in. thick, and was detached piecemeal. The two molars which it surrounded were carious and were extracted, along with some other stumps. The gum underneath was very red and swollen, but improved rapidly, as did the general condition of the mouth.

The interest of the case lies in the fact that the mass had been present for nearly ten years and had not given rise to any symptoms or pain. The patient had not been in the habit of cleaning her teeth in any way. In appearance the mass resembled a true bony tumour, and to be of such a size and composed of tartar must, I think, be unusual in medical practice.

DURING the week ending August 29th there were five cases of plague in Hong Kong, and the same number of deaths; in the following week there were three cases and three deaths.

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

BOMBAY BRANCH.

AN ordinary meeting of the Bombay Branch was held in the University Library on July 16th, when Lieutenant-Colonel ASHTON STREET, I.M.S., presided. Besides the Honorary Secretary, Dr. D. R. Bardi, there were about twenty-five members present.

Surgery in the Mofussil.—Professor Y. G. NADGIR, M.S. Bombay), read a paper on the surgery in the Mofussil, which created great interest and was much appreciated by members.

Wassermann Reaction.—Dr. F. D. BANA described his modification of Wassermann's reaction and gave notes and tables of cases in which it had been used.

Clinical Case.—Dr. F. D. BANA showed an interesting case of syphilis with symmetrical eruptions on palms and soles, cured by a single injection (intravenous) of salvarsan.

Serum Reactions in Kala-azar.—Dr. R. Row gave a brief account of a case of kala-azar now under his care, from whose peripheral blood (finger) he had succeeded in obtaining a pure and rich culture of flagellates, although in smears form of this blood no parasites could be detected even after a careful and prolonged search. The photograph of the patient and also the photomicrograph of the flagellates were shown. In this connexion Dr. Row also showed a series of coloured plates, drawn from nature by his brother Dr. N. Row, illustrating two or three remarkable serum phenomena of the patient. These were briefly described and summarized under four heads—(*a*) complement fixation; (*b*) cytolytic action; (*c*) agglutination; and (*d*) a precipitation phenomenon. The antigen used in all these experiments was an emulsion of flagellates of *Leishmania donovani* killed at 50°.

Parasite in Simple Continued Fever.—Dr. R. Row also showed a coloured plate illustrating a curious protozoan-like parasite found by him in two blood films (stained by Giemsa's method) from a patient who came under his care towards the end of an attack of simple continued fever which lasted fifteen days. The parasite looked like an amœba with a well marked nucleus like that of a mature malarial parasite but more condensed, and a pale blue vacuolated body protoplasm. The parasites were found outside the red blood cells, except in one instance when a parasite was detected inside a leucocyte which looked like a macrophage. Some of the parasites, apparently full grown and old, were of three or four times the average size and attained that of a red blood corpuscle. The parasites were found in all shapes from round and ovoid to irregularly ovoid and were free from pigment or spores. They were very few in the blood smear, not more than about thirty being demonstrable in the two films made when the patient presented himself as an outdoor patient. The patient came from Palanpur (North Gujerat), and was free from fever as well as parasites the next time he presented himself—forty-eight hours after his first appearance.

Vote of Thanks.—A vote of thanks was accorded to all those who had contributed the papers and notes.

ENCOURAGING work is being done by the Potteries Fund Committee, whose objects are the discovery and assistance of women and girls suffering from lead poisoning. Under the new factory regulations the health of female workers has improved, while by the Insurance Act a moderate income is now assured until compensation can be obtained, should incapacity for work be due to plumbism. During 1913 no female died from lead poisoning. This is cause for congratulation. Recovery from plumbism is at any time slow and tedious. The Potteries Fund Committee has therefore been of great assistance not only by providing for female potters change of air and nourishing food, but also by helping the workers to recover by legal redress the compensation to which their malady entitles them.

Reviews.

SURGERY.

IN considering a new textbook on surgery, one naturally inquires into the reason for its being. In our language there are several most admirable textbooks, sufficient, one might think, to meet the wants of student and practitioner, and as these books are re-edited periodically, a new textbook is a kind of challenge. In the preface to Mr. RUSSELL HOWARD'S *Practice of Surgery*[1] we find that the book "has been written at the request of many past and present students of the London Hospital, and it embodies, as far as possible in a textbook, the surgical teaching received by the writer in that medical school." There is here, then, a somewhat local appeal and a modest challenge. We feel it to be an unfortunate implication that the surgical teaching in one school differs from that in another. To our mind there should not be, and probably after all there are not, any serious discrepancies between the surgical teaching of one school and that of another. We have made a fairly thorough examination of Mr. Russell Howard's book, and think that it will readily earn for itself a good name amongst textbooks of moderate size. The style of writing is plain and straightforward, with no waste of words. The arrangement by short paragraphs, each with heading in bold type, lends itself to clearness and ready reference. Greater space and attention are given to diagnosis and treatment than to pathology, though it is by no means neglected. Elaborate operations are not described in detail, but their main intentions and features are indicated. The author apparently has a liking for a summing-up at the close of a chapter—a most useful means of focussing the reader's mind on the salient points of the section. The dogmatic mode of statement prevails throughout the volume; probably it is the best for the student, who as a rule has little patience and time for discussion. We are glad to observe the author's recommendation to avoid classical amputations in favour of procedures designed to meet the particular case. The illustrations on the whole are well selected; many are, however, very hazy and ill defined, especially some radiograms. The diagrams of Finney's operation and of posterior gastro-jejunostomy are very poor—the latter should show the "no-loop" operation rather than the other—while those of the mastoid regions are not very informing. Printer's errors are not many. On page 542 the numbering of the page is wrong; on page 842 "Koenig" should be "Kernig"; and on page 707 "excised" should be "incised." Mr. Russell Howard may well be satisfied with his work, and the students of the London Hospital may be congratulated on the possession of a clear and concisely written textbook containing sound and forceful teaching.

To present modern surgery within the limits of one volume is an ambitious effort, but that it is capable of successful achievement DACOSTA'S *Modern Surgery*[2] amply demonstrates. We have had occasion to commend earlier editions of this work, and we in no way stint our praise of the latest, the seventh. It is a bulky volume of 1500 pages, with plenty of pictures and diagrams. The great difficulty is to keep a book like this within reasonable bounds. The author says that the writer of such a book is held by a short tether. It is well that he should recognize this, so that he may not wander too far afield and sweep in great masses of undigested facts and untried theories. He must preserve in his mind a clear definition of what modern surgery is, and carefully incorporate matter not because it is new or modern but because it represents progress. This edition may quite reasonably be regarded by its author as the best yet issued. It is written in terse, precise style, with a total absence of verbiage, so that it has been found possible to pack into the volume everything that the inquirer, be he surgeon or practitioner, may seek. The author throughout the book quotes his authorities

---

[1] *The Practice of Surgery.* By Russell Howard, M.S.Lond.; F.R.C.S.Eng. London: E. Arnold. 1914. (Roy. 8vo, pp. 1234; 8 plates, 523 figures. 21s. net.)

[2] *Modern Surgery, General and Operative.* By J. C. Dacosta, M.D., LL.D. Seventh edition, revised and enlarged and reset. Philadelphia and London: W. B. Saunders Co. 1914. (Roy 8vo, pp. 1515; 1085 figures. 25s. net.)

and gives references very freely—a most useful procedure—and introduces short historical statements on each subject woven into the narrative in unobtrusive fashion. The arrangement follows the usual plan by dealing in succession with bacteriology, asepsis, and antisepsis, inflammation, repair, general surgical diseases, diseases and injuries of tissues, and diseases and injuries of regions. The upper digestive tract is dealt with separately from diseases of the abdomen. The index is, so far as we have been able to investigate it, complete. Perhaps the characteristics of this textbook which stand out most prominently are its fullness and completeness as a presentation of modern surgery and the practical everyday bearing of its teaching. Its place is in the highest rank of surgical textbooks.

DR. BRYAN states that the object of his *Principles of Surgery*[3] is to lay a foundation upon which an intelligent understanding of the detail of practical work may be built, and he has certainly achieved his object. A practical and accurate account is given of surgical pathology and bacteriology. Upon this is based the discussion of symptoms and the indications for treatment, but a detailed account of surgical procedures is not given. The work is undertaken from the general standpoint in contradistinction to regional. The book is to be commended, and will give to students the groundwork that is essential to a real knowledge of surgery. If they combine the knowledge to be obtained from this book with the practical detail to be obtained in the wards they will gain a more than average knowledge of surgery. The book embodies a method of teaching which is thoroughly sound; the illustrations are for the most part good.

DR. GARMO'S essay on the *Mechanical Treatment of Abdominal Hernia*[4] contains a clear account of methods of treatment by means of support. Full descriptions are given with numerous illustrations of every kind of truss, the correct method of measuring patients for trusses, and the special indications for different herniae. The work is intended for those who are occupied in fitting trusses; they will certainly find it useful, and if they carry out the author's recommendations will be enabled to make comfortable trusses that fit.

THE PROGNOSIS OF CONSUMPTION.

THE prognosis of the probable course of any disease can be reasonably founded only upon correct interpretation of the symptoms which it presents and of the manner in which those symptoms may be modified by other conditions.

The symptoms and physical signs produced by tuberculous disease of the lungs are fairly well recognized, but the conditions which accompany them may vary to an indefinite extent. Most writers have been content to summarize the main points which usually present themselves for solution, and a few only have made a systematic study of the whole subject. By far the most comprehensive work that has yet appeared has been put before the profession this year by DR. D. O. KUTHY of Budapest and DR. A. WOLFF-EISNER of Berlin.[5] The result of their labours may be described as an encyclopaedic record of the opinions of competent authorities on the whole question of prognosis in consumption and of the skilled observations and experiments upon which these opinions have been founded. The outcome of this laborious undertaking has been to prove that in the main the summaries of the less ambitious writers are correct, but in the course of so widespread an investigation many secondary points have come to light which have a bearing upon prognosis in difficult cases, and many others hitherto considered important have been relegated to their proper position of insignificance.

The whole work is arranged under definite headings, and reference to particular branches of the subject is thus rendered easy. A good deal of overlapping and repetition is perhaps inevitable and confusion may be saved thereby, but the bulk of the volume is proportionately increased.

The more intimate acquaintance with the pathology of consumption, which has served to permit of earlier diagnosis, has also had its effect upon the accuracy of prophecy, and many more considerations have to be passed in mental review in estimating the probable course of any given case than were thought necessary in less enlightened times. Etiological influences—heredity, environment and temperament, the indications afforded by study of physical conformation and the course of growth, the predisposing or immunizing effects of similar or different disease, the effects of changed metabolism at different periods of life, and all and every such possible condition that may bring some influence to bear upon the progress of tubercle and its attendant pathological changes—are examined with the greatest minuteness and mainly by the collation of expert observation and deduction. No fewer than a thousand references taken from the medical literature of the civilized world are tabulated, and hence every school of thought is represented. Many of the puzzling points remain as perplexing as ever. The question of long-continued inheritance, for example, implies a degree of hypersensitiveness to tubercle But long-continued inheritance has also been shown to afford a definite degree of immunity to minor infections, while it manifests increased susceptibility to larger doses. Experiment would thus seem to show that persons of a so-called scrofulous type may be at the same time in part immune and in part susceptible to the same poison.

Much difference of opinion has been manifested as to the importance to be attached to gain of body weight under ordinary or special lines of treatment, and the outcome of discussion does not indicate more than a general rule that such gain of weight may be held to show a capacity for general improvement.

Very many competent observers have endeavoured to obtain prognostic data from the chemical and microscopic examination of sputum. More attention has been paid to the stainable granules which appear in bacilli than was formerly the case. Regarded by some as merely degenerative, they have been held by others to represent a stage in development; but the evidence for and against such a view is not sufficiently conclusive for general acceptance. Staining methods have not yet reached perfection, and much yet remains in doubt.

Every phase of modern research into the relations believed to subsist between the various constituents of the blood and the bacilli and their products, is described and examined at length, and the results of modern treatment in relation to prognosis subjected to equally minute scrutiny.

The work as a whole may be said to contain reference to all that is worth referring to, and as such should be found useful by future writers. As a practical guide to prognosis it is far too large and lacks the summary, representing the judicial aspect of the vast amount of evidence adduced, which alone could render each branch of the subject to be of service to the busy practitioner.

THERAPEUTICS AND HYGIENE.

IN his textbook[6] of *Therapeutics, Dietetics, and Hygiene*, DR. J. W. SPRINGTHORPE has included a quarter of a century's experience of medicine in its widest applications, personal, private, and public. The work is an amplification of his course of university lectures, and covers a vast amount of ground. Beginning with a brief account of ultimate ontology and a review of the philosophy of medicine, the author devotes two-thirds of his first volume to the subject of hygiene in its most various personal and public aspects. The special points he wishes to emphasize are illustrated by the free use of statistics on the one hand, on the other by quotations from such poets as Robert Browning and Rossetti. But for all his wealth of detail and local colour—for it is to hygiene in Australia

[3] *Principles of Surgery.* By W. A. Bryan, A.M., M.D. Philadelphia and London: W. B. Saunders Co. 1913. (Med. 8vo, pp. 677; 224 figures. 18s. net.)

[4] *The Mechanical Treatment of Abdominal Hernia.* By William Burton De Garmo, Professor of Special Surgery, New York Post-Graduate Medical School. Philadelphia and London: J. B. Lippincott and Co. (Pp. 147. Price 6s. net.)

[5] *Die Prognosenstellung bei der Lungentuberkulose, mit eingehender Berücksichtigung der physikalischen und serologischen Befunde und der therapeutischen Prognostik.* Von Priv.-Doz. Dr. D. O. Kuthy und Dr. A. Wolff-Eisner. Berlin und Wien: Urban and Schwarzenberg. 1914. (Sup. roy. 8vo, pp. 583; 21 figures. (Br., Mk 18; Geb., Mk 20.)

[6] *Therapeutics, Dietetics, and Hygiene.* An Australian Textbook by J. W. Springthorpe, M.A., M.D.Melb., M.R.C.P.Lond. Vol. i, *Hygiene and Dietetics;* vol. ii, *Therapeutics.* Melbourne: J. Little. 1914. (Roy. 8vo, pp. 604 and 612; illustrated. 25s. net each volume.)

that Dr. Springthorpe devotes most of his attention—he is never deaf to the call of a possible generalization. Thus, in Victoria the ancestors of the present population were of the sanguine and nervous temperament, he says, and he deplores the fact that the modern conditions of climate and diet are now developing the hepatic and the hybrid bilio-nervous types of humanity. His figures show that in New South Wales about 260 lb. of meat are consumed per head of the population per annum; in England, the consumption is said to be 105 lb., in France and Germany about 70 lb. It is reported that sheep shearers may consume on the average over 2½ lb. of meat a day while at work. The second volume is devoted to therapeutics in the widest sense of the term, and contains many chapters on special subjects contributed by various Australian practitioners of medicine and specialists. Every imaginable form of treatment seems to find its place in this volume, and at its end are printed many pages of prescriptions and posological tables.

Both volumes are freely illustrated; portraits of such personalities as Hygiea (misspelt Hygeia), Apollo, Pasteur, and Florence Nightingale are given, and the scenic attractions of numerous Australian health resorts are copiously exhibited.

There are countless points in this highly interesting and original work that cannot be mentioned here for lack of space. In general design and execution it recalls the encyclopaedic scientific volumes of bygone centuries, written *de omnibus rebus et quibusdam aliis*. It contains a mass of detail and statistical evidence on all sorts of subjects connected with the health and hygiene of Australia, and the diets and modes of treatment that experience has shown to be of particular service in that country. But it also makes an appeal to many others besides medical men, and includes admirable practical instructions as to the most suitable modes of upbringing and life that should be welcome to those in need of instruction in these matters. The printer and publisher have done their work in a highly creditable manner, and many of the illustrations leave nothing to be desired. Dr. Springthorpe writes with *élan* and vigour, and his pages breathe on the whole a spirit of cheerfulness and optimism. His book is a thoroughly practical production, and may be cordially recommended to the attention of all who are interested in the many subjects with which it deals.

NOTES ON BOOKS.

THE call for a second edition of *Lunacy Practice*,[1] by Mr. W. H. GATTIE, is the best evidence of its usefulness. In no legal procedure with which medical men have to do is the need for precision so great as in that which deals with lunacy, and the cost of a mistake may be very serious. There is plenty of opportunity for going wrong, even with the experienced. It is a boon to the practitioner, layman, or lawyer to have the varied forms and procedures crystallized into reliable shape for rapid consultation. On two points we venture to make suggestions. First, as to the exact periods of time covered by the varying requirements of "seven clear days," "within seven days," "not more than seven days," etc. These might advantageously be translated by a lawyer, for the Lunacy Acts leave such important interpretations to judge-made law. Then, when the subject of absence from an asylum *on leave* is considered, it would be well to describe also absence *on trial*, in regard to which important decisions have been given of late, making it very necessary to limit the form of leave by words enabling the patient to be brought back before the expiration of the period of absence should he break down. Without such terms it would appear there would be no such power. We warmly commend the book to all who are concerned with practice in mental disease or with lunacy administration.

[1] *Lunacy Practice: a Practical Guide for the Certification and Detention of Persons of Unsound Mind.* Second edition. By W. H. Gattie. London: Shaw and Sons. 1914. (Feap. 4to, pp. 59. 2s. 6d. net.)

IT is stated that Dr. Alexis Carrel, of the Rockefeller Institute, New York, is serving as a medical officer with the French army. Dr. Carrel was awarded the Nobel Prize in Medical Science for his researches on the transplantation of organs in 1912.

MEDICO-PSYCHOLOGICAL ASSOCIATION OF GREAT BRITAIN AND IRELAND.

THE annual meeting of the Medico-Psychological Association was held at Norwich on July 14th and 15th.

The late Dr. Neil.

Reference in sympathetic terms was made to the death of Dr. Neil, of Warneford Asylum, Oxford, and a resolution of condolence with his widow was carried by the members upstanding.

Mental Deficiency Act.

Dr. HYSLOP, Chairman of the Committee on the Mental Deficiency Bill, presented the report. This showed that the committee had been concerned with the Elementary Education (Defective and Epileptic Children) Amendment Bill and in the provisional regulations in pursuance of the Mental Deficiency Act. It was hoped that the Mental Deficiency Act Regulations, which came into force in April, would be simplified when reissued. Several recommendations were made in the report. The Central Association for the Care of the Mentally Defective had taken the necessary steps to register itself as an incorporated association. Following upon a short discussion, Dr. Hyslop said difficulties were likely to arise, unless care were taken, owing to persons with no knowledge of mental conditions seeking to define the border-line between insanity and mental deficiency on the one hand, and between mental deficiency and health on the other. It was for the association to present a guiding memorandum. The report was approved, and the committee reappointed to continue its work. The President (Dr. Thomson) and Dr. Bedford Pierce (Chairman of the Status Committee) were appointed to act with the subcommittee of the Board of Control.

President's Address.

Dr. CHAMBERS introduced the new president, Dr. D. G. THOMSON, Superintendent of the Norfolk County Asylum, who delivered an address, in which he reviewed the legal and medical arrangements for dealing with the insane during the past hundred years. He said that since this was the centenary year of the establishment of the Norfolk County Asylum, the oldest county institution of its kind in the country, the stages in the evolution of treatment of mental alienation found illustration within its walls. Dr. Thomson discussed the origin and progress of the laws relating to the insane, beginning with the crude efforts in 1745. Though these were called laws for the regulation of "madhouses," there appeared to have been no amelioration of the awful lot of their unfortunate inmates until the later half of the eighteenth century. The first serious legislation in favour of the insane poor was enacted in 1808, in what was commonly called "Wynne's Act." This enabled each county, through its justices and quarter sessions, to build and equip institutions out of the county funds, so that parishes, for a weekly *per capita* payment, could send insane poor to the county institution instead of to gaols, houses of correction or industry. Only a few counties used this permissive power—namely, Nottinghamshire, Norfolk, Lancashire, Yorkshire, and Staffordshire. A Special Committee of the House of Commons in 1815 took evidence as to the deplorable state of the insane in privately owned madhouses, and even in a few public asylums. Dr. Thomson gave some lurid specimens of this evidence, and incidentally referred to the form of treatment meted out to George III for his mental aberration. The report of this Committee resulted in an amending Act, which sought to "enforce" the provisions of the Act of 1808. But it was not until the early years of the reign of Victoria—namely, in 1845—that the Act was passed which had been styled the "Magna Charta of the Insane," as it gave them, for the first time, full legal protection and supervision. Other beneficent forces were also by this time at work, for Dr. Gardiner-Hill, of Lincoln Asylum, had begun his great campaign against the use of restraint. His strenuous contention that chains and manacles and other coercive measures were unnecessary and harmful led people to declare that he was himself insane, but his views ultimately prevailed, and for many years mechanical restraint had been abolished, except in occasional in-

stances for surgical reasons. The year 1841 saw the foundation of the Medico-Psychological Association, by a few doctors concerned with the study of insanity, its etiology, prevention, and treatment. The chained lunatic now became a patient, and as time went on it was felt more and more that no time or trouble spent in efforts to ameliorate or cure his condition was wasted. County and borough asylums came into being all over the kingdom, private asylums for the well-to-do put their houses in order, and every institution for the insane was brought under the benign regulation and visitation of the Commissioners in Lunacy, now the Board of Control. Dr. Thomson paid a warm tribute to the memory of the late Lord Shaftesbury for his great work in this relation. Gradually the view that insanity was a possession of the devil, or the metaphysical idea of it as a manifestation not amenable to medicine, gave place to the conviction that it had a physical basis, like other affections; this altered view had resulted in great advance of knowledge, for alienists had not been slow to apply the great advances in general medicine to this speciality. In an eloquent passage Dr. Thomson animadverted on the barren theorems of a former day, ghosts of which, in brand-new shrouds, were being invoked to-day by advocates of various fads and "isms," such as faith healing, Christian Science, and the like. He dealt next with the more recent work of the Medico-Psychological Association, the system of training, certification and registration of mental nurses, the adoption by six universities of its recommendation in favour of special post-graduate training and diplomas in psychiatry, on lines similar to those in public health and tropical medicine. If the association had done nothing besides providing better doctors and nurses for mental disorders, its existence would have been justified, and its labours gratefully acknowledged by the public. Among other topics dealt with were the following: The disabilities of asylum medical service, and the resulting dearth of candidates; the absence of provision for early incipient forms of mental disorder without the dreaded legal certification and committal to the insane wards of workhouses and asylums; the absence of properly equipped clinics for this purpose and for the ante-graduate and post-graduate training of young men in psychiatry; the Mental Deficiency Act; the Elementary Education (Defective and Epileptic Children) Bill; and the unsatisfactory state of the law with regard to crimes committed by insane persons.

Intrathecal Treatment of General Paralysis.

DRS. MAPOTHER and BEATON said that in early cases of general paralysis attempts had been made to introduce salvarsan and neo-salvarsan, in aqueous solution, by intraspinous injection; but these had been followed by unfortunate sequelae, probably attributable to the vehicle in which the drug was dissolved rather than to the drug itself. A modification of method used by the authors consisted in the addition of arsenical drugs to the serum *in vitro*.

The Detection of a Dysentery Carrier.

Mr. H. SALTER GETTINGS and Dr. ETHEL WALDRON (of Wakefield Asylum) reported a case in which the dysentery bacillus was discovered in the loose stools of a patient who displayed no other symptoms; there had been no blood or slime and no rise of temperature. There had been one or more cases in her ward for four years, and soon after her transfer to another ward there was a fatal case of the disease. Since 1913 there had been in the asylum 14 cases, with 5 deaths. The opinion was expressed that the disease was disseminated by quiet, unobtrusive cases. A discussion ensued as to the difference between "carriers" and ordinary cases of chronic dysentery.

Status of British Psychiatry.

A discussion of the report of the Committee on the Status of British Psychiatry and of Medical Officers of Asylums was introduced by the Chairman of the Committee, Dr. BEDFORD PIERCE. Dr. ROWS, Honorary Secretary of the Committee, and Drs. SOUTAR, COLLINS, STANSFIELD, HAYES NEWINGTON, CHAMBERS, EDWARDS, DANIEL, and the PRESIDENT joined in the discussion, and the most part commended the recommendations made. The meeting approved the report, and it was agreed to forward copies to the Home Secretary, the President of the Local Government Board, the members of the Board of Control, the chairmen and clerks of asylum boards and visiting committees, and the corresponding officials in Scotland and Ireland. The Committee was reappointed. The report contains the following resolutions:

1. That it is desirable that provision be made for the detention of patients in psychiatric clinics for a limited time without certification.
2. That it is desirable that any form of detention under modified conditions, such as proposed in the Lunacy Bill of the year 1905, should not be confined to private houses, but should be extended to all institutions for the insane and clinics duly approved for the purpose.
3. That it is desirable that the provision already made for the reception of voluntary boarders into licensed houses and registered hospitals be extended to public asylums and psychiatric clinics.
4. That the psychiatric clinics be for the reception and treatment of voluntary boarders and notified persons.
5. That it is desirable that patients be admitted to county asylums direct from their homes without being of necessity taken to the Poor Law institutions—in this way making better use of the existing hospital accommodation at these asylums.
6. That urgency orders be made to apply to Poor Law cases.
7. That it is desirable that neighbouring asylums be enabled to establish and maintain joint laboratories.
8. That it is desirable that a Standing Committee of the association be formed, to be called the "Research Committee," and to have as its object the encouragement and guidance of original work in psychiatry.

Prizes.

The association's divisional prizes were awarded to Dr. Eager (Devon County) and Dr. Macphail (Newcastle). The Gaskell prize had not been awarded. The bronze medal was awarded to Dr. J. C. Wootton of Cane Hill Asylum.

Annual Dinner.

On July 15th the members were entertained to luncheon at the asylum, and in the evening Dr. Thomson presided over the annual dinner, at which the BISHOP OF NORWICH proposed the toast of the Medico-Psychological Association of Great Britain and Ireland. This was acknowledged by Dr. THOMSON.

ROYAL COMMISSION ON VENEREAL DISEASES.

THE following is the official report issued to the press by the Secretary of the Commission:

"The Alliance of Honour."

Mr. Edward Smallwood, L.C.C., Chairman of the Directors of the Alliance of Honour, said that this organization was an association of men who pledged themselves to purity. The Alliance had been in existence about eleven years, and had now some 500 branches in different parts of the country and a membership of 42,000, which was steadily growing. He believed that by inculcating principles of purity and chivalry, and by the work of moral education, the Alliance was attacking a great social evil, with its attendant diseases, at the source. Mr. Smallwood said that his experience showed that ignorance was one great cause of persons contracting venereal diseases. The Alliance was endeavouring to combat this ignorance by means of lectures and public meetings and by the dissemination of literature; the two branches of instruction—moral education and instruction in the actual physical dangers—were kept side by side. Official action was, however, extremely desirable on the subject of education. Instruction should be given to the young in schools and colleges on a properly graduated plan, and it would be necessary that carefully selected teachers should receive special training which would enable them to impart this particular kind of instruction.

Deafness.

Mr. Macleod Yearsley, senior surgeon to the Royal Ear Hospital, stated that in his opinion syphilis and its concomitants were as severe amongst children of the poor as they were when he started practice as an aural surgeon twenty-one years ago. He had found that amongst

children there were far more cases manifesting congenital syphilis among the poor than among the richer classes; this he attributed to the fact that in the latter the disease was recognized earlier, and therefore treated earlier. Among the poor syphilis very often went untreated, and this was specially the case with children. Records he had kept in connexion with work at special deaf schools showed that of the 845 children (427 boys and 418 girls) examined during a period of seven years, 61, or 7.21 per cent., were deaf from congenital syphilis; the females affected were greatly in excess of the males, the relative percentages being—boys 4.94, girls 9.56. The treatment of acquired syphilitic deafness nearly always failed. It had been pointed out that the children who became blind and deaf were those in whom syphilis went untreated in infancy. It was therefore important that treatment should be obtained as soon after birth as possible. The widest possible routine application should be made of methods of diagnosis, and the Wassermann reaction should occupy a prominent place. Advantage should especially be taken of school inspection for the purpose of applying the reaction in all suspected cases, not only of the school children themselves, but of the parents. All cases should be thoroughly treated as early as possible.

Mr. Macleod Yearsley stated that the National Bureau for Promoting the General Welfare of the Deaf, whose representative he was, had among its provisions for promoting the prevention of deafness, the notification of all cases of congenital syphilis and the facilitation of treatment for mother and child.

Facilities for Treatment at Hospitals.

Dr. James Galloway, senior physician to Charing Cross Hospital, stated that recent experience gained in dealing with venereal diseases in the army and navy greatly encouraged the expectation that these diseases might, if favourable conditions were obtained, be prevented and their evil consequences diminished in the general population. He did not think, however, that compulsory measures involving registration and treatment were likely to lead to satisfactory results. In dealing with the general community it was necessary that all efforts to cure and eradicate these diseases should be reinforced by the willing consent of the sufferers and by the sympathetic co-operation of the rest of the community. Social slur or stigma should, so far as possible, be removed from those under treatment. It should be strongly impressed upon the public that large numbers of persons suffered from venereal disease through no fault of their own. Facilities for efficient treatment should be provided for all classes of the community and for both sexes. It was more important from the point of view of the public health that poor and ill-educated patients should be successfully dealt with than those in better circumstances and presumably greater intelligence. In the case of the poorer patients these diseases (even when recognized) were often looked upon as matters of comparatively little importance. All hospitals willing to undertake the treatment of venereal diseases in their early or acute stages should be encouraged to do so. If this were done, facilities would immediately be at hand for the greater number of patients. It was especially desirable that hospitals with medical schools should undertake the treatment of these diseases in any general scheme of dealing with these maladies throughout the community. Opportunity would thus be provided for the instruction of medical students in the recognition and treatment of venereal diseases in a way which had been impossible in the past. Dr. Galloway thought that the cost involved in the treatment of these diseases on a large scale would be considerable, and, as the proper treatment and eradication of the diseases was a matter affecting the general health of the whole community, it was proper that the expense should be met by local authorities or by the State.

Mr. Pugin Meldon, senior surgeon at the Westmorland Lock Hospital, Dublin, gave evidence as the representative of a Joint Committee appointed by the Royal College of Physicians of Ireland, the Apothecaries Hall, Ireland, the School of Medicine at Trinity College, Dublin, and the National University of Ireland. The committee laid stress on the point that the difficulty in dealing with venereal diseases arose from the social stigma attaching to those suffering from it. This stigma was certainly a hindrance to early diagnosis and treatment, and this being so, it was not desirable to establish for the treatment of the general class of venereal disease patients special dispensaries and hospitals or special laboratories for diagnosis. As regards diagnosis, it was essential that clinical methods should be supplemented by the aid of the pathological laboratory, and arrangements should be made for the free diagnosis of venereal disease at the laboratories in the pathological departments of the universities and medical schools. The committee was of opinion that one cause which operated very extensively in deterring people from obtaining proper treatment was the penalization of venereal disease. Employers of all kinds were in the habit of either dismissing from their employment persons who were found to be suffering from these diseases or refusing them leave for the purpose of treatment. The result was that these persons either endeavoured to treat themselves or resorted to advertising quacks, and only sought a physician when the disease was so far advanced that they were unable to do their work. So long as this penalization persisted it was impossible seriously to suggest any scheme of notification and therefore any really effective method of prevention. Similar considerations led the committee to suggest that the Insurance Act should be amended so as to make it impossible to withhold sick pay and disablement pay in cases of venereal disease. The committee referred to the fact that some general hospitals had rules precluding the admission of venereal patients, and suggested that pressure should be put upon such hospitals to have these rules rescinded.

ROYAL MEDICAL BENEVOLENT FUND.

AT the last meeting of the committee eighteen cases were considered, and grants amounting to £130 voted to thirteen of the applicants. The following is a summary of the cases relieved:

Widow, aged 26, of M.R.C.S.Eng., with one child aged 21 months. Husband had been ill for some time before death. Friends only able to help slightly. Voted £10 in two instalments and referred to the Guild.

Daughter, aged 31, of M.R.C.S.Eng. Has endeavoured to earn her living by needlework, but her health has broken down. Voted £2, with leave to apply again in October, and referred to the Guild.

M.D.Edin, aged 58, unable to practise owing to bad health. Has endeavoured to run a nursing home, but has not been successful owing to the illness of his wife and self. Three children unable to help. Voted £12 in twelve instalments.

Widow, aged 44, of M.B.Aberd. Has endeavoured to maintain herself by letting rooms, but has been unsuccessful lately. Two children at school. Relieved seven times, £75. Voted £12 in twelve instalments.

Daughter, aged 63, of M.R.C.S.Eng. In ill health. Only income 5s. per week from friends, which pays for rent. Relieved seven times, £87. Voted £12 in twelve instalments.

Daughter, aged 58, of M.R.C.S.Eng. In bad health. Only income from another charity, 5s. a week. Relieved twice, £20. Voted £10 in two instalments.

Daughter, aged 64, of M.R.C.S.Eng. A confirmed invalid. Only certain income about £13 per annum. Relieved once, £12. Voted £12 in twelve instalments.

Widow, aged 57, of L.R.C.P. and S.Edin. Earns a little by taking in lodgers. Relieved eight times, £82. Voted £12 in twelve instalments.

Widow, aged 43, of L.R.C.P. and S.Edin. Seven daughters, ages 4 to 17. Only income about £57 per annum. Tried unsuccessfully to supplement income by taking in boarders. Relieved twice, £24. Voted £12 in twelve instalments and referred to the Guild.

M.R.C.S.Eng., aged 81. Blind. Eldest son now practically blind and unable to work; lives with his father. Joint income less than £50 per annum. Relieved once, £12. Voted £2 and deferred for further investigation.

Widow, aged 57, of L.R.C.P. and S.Glasg. Endeavours to earn a living by taking in boarders; recently not very successful; health indifferent. Relieved three times, £15. Voted £10 in two instalments.

Daughter, aged 58, of M.R.C.S.Eng. No income and too ill to work. Relieved nine times, £94. Voted £12 in twelve instalments.

Widow, aged 64, of M.R.C.S.Eng. Five children, none able to help. Rent paid by her brother. Relieved once £12. Voted £12 in twelve instalments.

Contributions may be sent to the Honorary Treasurer, Dr. Samuel West, 11, Chandos Street, Cavendish Square, London, W.

INDIAN SANITATION.

In a recent issue[1] we drew attention to an important memorandum addressed by the Government of India to local governments on the subject of sanitary administration and work. At a meeting of the East India Association last May an interesting paper was read by Colonel W. G. King, C.I.E. (I.M.S. retired), on the "Position of sanitation in the administration of India," and gave rise to a discussion in which Indian officials and natives took part. Colonel King's devoted and fruitful work in the promotion of scientific and practical sanitation in the Madras Presidency entitles his views to respect; and, although exception may be taken to some of his contentions, the motive and aim of his address are undoubtedly commendable and salutary. While fully acknowledging that, through the advice and agency of the Indian Medical Service, a great reduction of sickness and mortality has taken place in communities under organized sanitary control, he does not consider the position of sanitation in India to be sound or promising. He asserts that the policy of the Government of India is one of inhibition and restraint as regards sanitation. This, in the face of what has been accomplished by means of the arrangements and undertakings carried out by Indian administrations, is a surprising statement, and appears, indeed, to be inconsistent with the facts which Colonel King has recorded in this paper, indicating decided and progressive diminution of suffering and death consequent on persistent sanitary effort. He objects very strongly to the association of sanitation with education in the new department which has been established for the purpose of relieving congestion in the Home Office and securing closer attention to these important subjects. If this arrangement involves "the professionally and financially unjustifiable supremacy of education," it is of course objectionable; but the reputed supremacy is probably more nominal than real. A separate Ministry of Health would no doubt be a preferable plan; but the multiplication of central bureaux is a costly proceeding, and practical sanitation has in the past suffered in India from the creation of departmental heads, and the neglect to provide an educated sanitary executive to do local sanitary work. Colonel King also represents that sanitation is starved in favour of education; on the other hand, Sir George Birdwood expressed himself as "entirely opposed to the idea of beggaring public education in India for the richer endowment of public sanitation." There ought to be no rivalry or antagonism between these two important services; indeed, education is capable of materially aiding and advancing sanitation, and the lecturer in his reply fully acknowledged this. Much as has been accomplished in India in sanitary reformation, Colonel King shows that, as regards both area and population, very much more remains to be done. While cities, cantonments, and municipalities have been provided with sanitary appliances and agencies, rural areas—and these constitute some 90 per cent. of the whole—have not been reached, and the principal object of this address is to urge the provision of a skilled sanitary executive working under rural authorities for purposes of general and special sanitation. This system has been introduced to some extent, on Colonel King's initiative, in the Madras Presidency with excellent results. We must, however, enter a protest against the excessive isolation and specialization of sanitary business which is recommended in this address. Health depends on such an infinity of conditions—personal, domestic and communal—that it is necessary to obtain the consent and co-operation of men and women individually and collectively in order to achieve the most complete success possible. The proposed segregation of sanitary administration and work is carried to such an extreme that "mixing the cure and prevention of disease" is alluded to as an "old fallacy," and sanitation is referred to as a different profession from that of medicine—aiming at the "prevention, not the cure," of disease. This view is more emphatically stated by one of the speakers, Mr. B. N. Surma, who is reported to have said that "the medical and sanitary departments must be divorced from one another." This is a strange doctrine. The preservation of health is quite as much a function and duty of the medical man as the restoration of health. He is educated and qualified for both purposes, and the two offices rest on the same principles and facts, constituting two phases of the Ministry of Health. In all enlightened communities the medical practitioner and the sanitarian work hand in hand. In the matter of notification of infectious diseases the services of the family doctor are essential. In all infective cases medical management is a powerful means of limitation, and in some—venereal diseases, for example—cure is at present the only bar to spread—apart from moral restraints. The practitioner has welcome access to the home, and his advice is a potent stimulus to personal and domestic hygiene. From this point of view the benefits conferred by the Dufferin Fund and by the employment of educated nurses and midwives are effective in promoting general cleanliness, inculcating useful preventive measures, and reducing the terrible mortality among infants, to which Colonel King directs special attention. Indian women are very conservative of religious and social customs. Many of these are excellent, others objectionable, and as several speakers remarked and the Indian Government has laid down, sanitary reform must recognize and preserve the former and amend the latter; and the strong hold of usage on native life and the amenability to law of the people constitute powerful aids to sanitary amelioration. In fact, sanitation demands not contraction and specialization, but expansion and generalization; and in any community sanitary success must always depend largely on the concurrence and assistance of its members, and sanitary effort must be applied through the organizations established for communal purposes. At the same time the employment of a specially educated and trained executive is absolutely necessary for special sanitary work, and Colonel King's insistence on this principle, founded on useful personal experience, constitutes the main merit of his paper, which, while owning the importance of research and education, impresses the need in India of more extended and concentrated sanitary endeavour under the guidance of facts already ascertained.

[1] BRITISH MEDICAL JOURNAL, June 13th, page 1317.

ANNUAL REPORT OF THE CHIEF INSPECTOR OF FACTORIES AND WORKSHOPS FOR THE YEAR 1913.*

No important factory legislation has to be recorded for 1913. Separate reports by various factory inspectors were published dealing with such subjects as shipbuilding accidents, dust explosion, and illness among cotton weavers. Material is still, we are informed, being gathered for the industrial museum. The staff of the factory department has now reached 217—not too large a number considering that during the year nearly 300,000 works were inspected in which are employed in factories 4,488,774 persons, and in workshops 638,335. That really good work has been done by the department is shown by the fact that 425,000 visits of inspection were made. It is in inspection that the factory department of Great Britain compares so favourably with that of other countries. The fatal accidents have risen from 1,260 to 1,309, and the non-fatal accidents from 154,972 to 176,892. The increase is attributed to greater general trade activity, greater pressure of work requiring more general cleaning of machinery, and to more complete notification. From the divisional report, however, it is evident that all accidents are not being notified. Instances are constantly cropping up of non-compliance with the order, not necessarily from any desire on the part of employers to deliberately withhold information, but from a belief that it is only the more severe accidents which have to be reported. Ignorance of requirement and carelessness on the part of clerks are also responsible for the omission.

Although factory hygiene is far from being what it ought to be, there are signs of an increasing interest being taken in it by employers and of a disposition on their part to improve matters. There is still call for greater cleanliness in many works where sweets and chocolate are made, also in sausage factories. The floors of workshops are frequently bad. In certain works, where the manufacturing processes render them liable to be wet, no attempt is made

* His Majesty's Stationery Office (Cd. 7491), 1914. 1s. 7d.

to drain them. The advantages of good lighting are pointed out by several of the inspectors, not only in regard to diminishing the number of accidents but in securing greater comfort and in saving the eyesight of employees.

In previous reports attention has been drawn to the large number of minor wounds received by workmen which become septic through faulty dressing in the first instance. It is desirable that, especially in all large factories, there should be widespread knowledge of "first aid"; also that sterilized dressings should be kept in readiness. Managers are more alive to these necessities than formerly. In all shipyards there will be in the future an ambulance staff, a stretcher, and sterilized surgical dressings. This requirement of modern factory life is better developed in the United States than in this country. Not only is there a small, well-equipped receiving hospital in the works, but a trained nurse is always on duty to attend to injuries. Since it is the small wound and the minor injury which are so frequently followed by blood poisoning, it should be a regulation that every injury, however trivial, should be reported to the certifying factory surgeon.

Accidents in shipbuilding are usually severe. By stricter discipline and supervision of the staging, and manner of working, it is hoped to reduce the number of accidents. Fatigue and long hours are causes of accident. In one instance a man who suffered fatal injuries had worked 23½ hours. Of 81 accidents reported in one district 69 happened to persons who had worked from 12 to 15 hours.

The lady inspectors draw attention to a marked deficiency in the supply of women and girl labour in the textile trades of Glasgow, Dundee and Dunfermline, also in the hosiery factories of Hawick. In Dundee with its almost exclusive employment of female labour, particularly in the jute trade, it has been suggested that it would be well if male labour could be substituted in some of the departments in which work has hitherto been done by women.

Accidents in laundries have fallen from 409 in 1909 to 384 in 1913, notwithstanding the fact that the number of persons employed has considerably increased. There are fewer accidents involving the crushing and burning of hands, also fewer accidents due to wringers. Much suffering has been saved by better fencing of machinery in laundries.

The lifting of heavy weights by children and young persons still continues. It is wrong that boys and girls 14 years of age should be found carrying materials upwards of 50 lb. in weight. The fines imposed seem to be readily enough paid, but repetition of the offence should be followed by heavy penalties, for only thus will the gravity of the offence be driven home.

In welfare work considerable advance has been made, but we are still far behind some other nations. The social helper has come to stay, and is likely to play an important part in the factory life of the future.

The data furnished by the electrical inspector supply some of the most interesting reading in the annual report. In 1913 there were 418 electrical accidents with 17 fatalities, as against 283 with 15 fatalities for the previous year. To inadequate skilled supervision as regards the initial selection and installation of plant and its subsequent working many accidents are due. It is a blot upon British factory management and technical instruction that it should be possible to say:

> In many works of considerable size operated and lighted by electricity, there is no one employed who is technically qualified to look after the plant. Even if the plant is good and well installed in the first instance, it is often run without technical supervision until trouble arises and accidents occur.

In three of the fatal cases the voltage of shock was less than 220.

Dr. T. M. Legge is to be congratulated on his sixteenth annual report. Much good work has been done by him during the last decade and a half, in the latter part of which he has been ably assisted by Dr. E. Collis. The figures for lead poisoning compare most favourably with those of former years. In 1900 there were 1,058 cases notified, with 38 deaths; in 1912, 587 cases, with 14 deaths; and in 1913, 535 cases, with 27 deaths. The returns of lead poisoning for the china and earthenware trades are the lowest recorded, with the exception of 1909. The attack-rate per 1,000 employed is 9. In electrical accumulator work the number of cases of lead poisoning has increased. Much of the work is dusty and most of it can only be done by hand.

Six cases of arsenical poisoning occurred during 1913. Anthrax supplied 70 cases with 7 deaths, a higher death-rate than in previous years, and attributed to the increased number of cases caused by wool. Attention is drawn to "pitch ulceration," and to the fact that as manufacturers have introduced the necessary improvements, the draft regulations have for the present been withdrawn. "Paraffin cancer" as occurring in shale workers is mentioned as having been met with by Dr. W. W. Walker, Certifying Factory Surgeon of Mid Calder.

We cannot close this review of the report of the medical inspector without alluding to the excellent work which has again been done during the year by Dr. E. Collis upon dust and fumes, etc. His latest work, "Weaver's Cough," is an interesting contribution. He traces the affection to the threads becoming mildewed, and to obviate this he recommends the introduction of antiseptics into the "size" through which the cotton threads are passed.

TUBERCULOSIS SOCIETY.

DR. HALLIDAY SUTHERLAND, President of the Tuberculosis Society, informs us that in 1910 a small clinical society was formed in London whose members, for the most part, were medical officers to tuberculosis dispensaries and to sanatoriums. The rapid development of the tuberculosis service throughout the country led to the formation of a larger society in 1912. The society holds meetings in London on the third Saturday of every month from October to June, and three provincial meetings. The annual meeting will be held at the same time and place as the annual conference of the National Association for the Prevention of Consumption. The subscription is 10s. per annum.

A memorial in the following terms has been submitted to the Chancellor of the Exchequer and to the President of the Local Government Board:

MEMORIAL.

Your Memorialists represent the Tuberculosis Society.

The Tuberculosis Society is a body including in its ranks Tuberculosis Officers appointed to County Councils, County Borough Councils, and the Metropolitan Borough Councils in England, and to County Councils and Town Councils in Scotland, and also Medical Officers to sanatoriums, farm colonies, and hospitals for advanced cases. The newly constituted Tuberculosis Service consists of medical men engaged in the diagnosis, treatment, and prevention of tuberculosis under public bodies.

For the proper discharge of the duties which recent legislation in relation to tuberculosis demands, special training and experience are essential. An endorsement of the view that Tuberculosis Officers should be specialists in the work is to be found in the recommendations of the Departmental Committee on Tuberculosis, 1913.

The Local Government Boards have endorsed generally the recommendations of the Departmental Committee, and proceeded on the view that these officers are to be regarded as an independent service, so far as their clinical duties are concerned, and shall be responsible for the management of institutions to which they are attached.

It seems to your Memorialists most important that from the outset a satisfactory status and security of tenure should be ensured. Without this it will be difficult to induce the best class of men to enter a service for which years of special training are required. Your Memorialists consider it necessary to emphasize the fact that the Tuberculosis Service is mainly clinical in its duties, and does not therefore naturally lead on to transference to the ordinary administrative posts in the Public Health Service. To regard the Tuberculosis Service as a subsidiary branch of the Public Health Service would be to discourage special training in a department which constitutes one of the largest fields in clinical medicine.

In some other departments of State Medicine, such as the Lunacy and Prison Service, security of tenure and superannuation have been ensured for Officials of the same standing as members of the Tuberculosis Service. A claim for the extension of such treatment on the part of Medical Officers of Health and Sanitary Inspectors has recently been submitted to and friendly received by the Treasury and the Local Government Board.

Your Memorialists respectfully submit that the Tuberculosis Service has a similar claim to security of tenure and to superannuation, and that such a claim is in the highest interest of an important Public Service, and is entirely reasonable in respect of those who have entered or may enter this special department.

The honorary secretary of the society is Dr. W. O. Pitt, 66, Upper Walthamstow Road, Walthamstow, Essex, to whom inquiries may be addressed.

British Medical Journal.

SATURDAY, SEPTEMBER 12TH, 1914.

TO GUARD THE HEALTH OF THE TERRITORIAL AND NEW FORCES.

ALL members of the medical profession who admire the fine spirit which is being shown by the men of fighting age—and who is there who does not?—must feel very strongly that the first return that the country can make is at once to take the steps necessary to ensure that these men who are being made into soldiers and combined into armies shall not during their training be exposed to needless risks of disease. They feel equally that the men of the Territorial Forces who are now embodied deserve the same care.

We believe that if the public understood as medical men understand the serious risks that must always be incurred when bodies of men are brought together for military training and exercise, it would unanimously insist that a carefully thought out system for all Territorial troops and all units of the new forces now being raised should at once be applied to prevent preventable diseases. It will be justly indignant if, owing to some punctilio of etiquette between Government departments and public services, these early days, all-important from the health point of view, are allowed to slip by without effective arrangements being made. It is impossible for a medical journal to undertake an inspection of all the stations of the Territorial Force, but in following out the mobilization of the forces in one district our representative saw enough to create the strong impression that while the sanitary organization at the head quarters of the division was good and was receiving careful and anxious attention, the condition in the smaller units at isolated posts was most unsatisfactory. There is an absence of combined action and a lack of executive sanitary authority.

The tone of the circular issued on August 31st by the medical officer of the Local Government Board to medical officers of health on the need for co-operation between civil and military sanitary services is not reassuring. It begins, "It is likely that during the next few months there will be occasions when the military forces will desire the assistance of the public health service," whereas the Territorials have desired it, or at any rate needed it, for the past month. The medical officer of health is told in the circular that he should assist the military authorities by advising as to water supplies, by helping to secure disposal of garbage, and satisfactory drainage, and by making provision for the hospitalization of ordinary infectious diseases, for the care of typhoid convalescents, and for disinfection. As to water supplies, medical officers have on their own initiative and at the request of the Territorial medical officers given advice, but, as to drainage and the disposal of garbage, local sanitary authorities may be expected to object, and there is evidence that they do, to spending ratepayers' money on work which is properly military, although their officers may be ready to give facilities to the military for doing it. Similar remarks apply to the questions of hospitals, of the disposal of typhoid convalescents and as to disinfection. Few rural districts are adequately provided in these respects, and such provision as there is is required to meet the needs of the civil population, which, if epidemics arise in the military forces, will be in grave peril.

The circular concludes by stating that "a medical inspector will consult locally as to prospective arrangements when the need for this is indicated." This is a rather ambiguous sentence. We believe that a medical inspector has visited the head quarters of some divisions, and it may be the intention to send medical inspectors to the head quarters of all divisions, but they are least wanted there, where there is strict discipline and a full staff.

It is especially and urgently necessary that all the posts of the Territorial Forces and all the places in which the new recruits are to be billeted should be inspected and plans carefully thought out for dealing scientifically with army camps of exercise that are to be formed; the plans in both instances should include a rigorous system of sanitary policing. At present there appears to be uncertainty as to the relative responsibilities of the several authorities and a lack of money, material, and labour to carry out the scavenging and general sanitary supervision necessary to keep camps and villages where men are billeted clean and in good sanitary condition.

The relative responsibility of the Local Government Board and local sanitary authorities on the one part, and of the military (including the Territorials) on the other, should be clearly defined. Under this head would come the sanitary organization and administration of the new armies that are being formed in response to Lord Kitchener's appeal, and are, in some places at least, to be put into camp.

We do not wish to minimize the difficulties of the Local Government Board in interfering either with military or with local public health administration, even in present exceptional circumstances, but unless it is prepared to take the matter up strongly and at once, it might be the better policy for it clearly to state that it will not take any responsibility; that would clear the air and make the military authorities, both of the Territorial Forces and of the new armies, understand the full weight of the responsibility on them.

On the other hand, the scheme of the Territorial Force includes a Sanitary Service. This consists of (*a*) Sanitary Companies, and (*b*) Sanitary Officers. In the *Army List* for August there are only two Sanitary Companies (1st and 2nd London). But under (*b*) "Sanitary Officers whose services will be available on mobilisation," there are over a hundred names, and most if not all of them are or have been medical officers of health. The idea was that they would be available to advise and direct each in his own locality, but apparently little use has been made of them, and some at least of those who are supposed to be on duty seem to have no authority and no men under them.

SECRET REMEDIES AND PHARMACY LAW AMENDMENT.

THE report of the Select Committee on Patent Medicines, coupled with the ratification by Great Britain of the International Convention on Opium, Cocaine, etc., serves to emphasize the urgent need for a radical reform of our pharmacy laws. It is true that at the moment domestic legislation must stand aside, and the word "international," first coined by

Jeremy Bentham, must for a while disappear from our vocabulary. Nevertheless, the Committee's report and the ratification of the convention constitute events which in time to come cannot fail to have an important bearing upon national and international control of the sale and distribution of potent drugs.

One generalization stands out quite clearly, and that is that the law in relation to poisons, drugs (whether officinal or non-officinal), to medicated wines, and other quasi-therapeutical paraphernalia, is obsolete and chaotic, and stands in need of radical review and drastic amendment, such new legislation to be conceived upon not only a national but an international basis. The Select Committee naïvely summarizes its conclusion of the whole matter in the disquieting pronouncements that "for all practical purposes British law is powerless to prevent any person from procuring any drug or making any mixture, whether potent or without any therapeutical activity whatever (so long as it does not contain a scheduled poison), advertising it in any decent terms as a cure for any disease or ailment, recommending it by bogus testimonials and invented opinions and facsimile signatures of fictitious physicians, and selling it under any name he chooses, on the payment of a small stamp duty for any price he can persuade a credulous public to pay." The Committee finds "that the Privy Council Office, though supposed to be specially concerned with the sale of drugs, has no initiative in the matter, and, in fact, it fulfils no useful function in this connexion," and that, in order to remedy this "intolerable state of things," it is necessary to invoke "new legislation rather than merely" to effect "the amendment of existing laws." They prefer "new legislation *ad hoc*" rather than the amendment of the various statutes which are now supposed to control the traffic in drugs. They would have a special Department of State to deal with the matter, and sigh for a Ministry of Public Health. A special court or Commission is advocated to sit in judgement on the claims made on behalf of "every patent, secret and proprietary remedy," the composition of which is to be disclosed, not to the public, but to the aforesaid Department or Commission. The public are, however, to be enlightened as to the proportion of alcohol in medicated wines, and the advertisement of medicines purporting to make what are regarded as impossible cures is to be prohibited. False or misleading therapeutic claims are to be punished, like false trade descriptions, under the Merchandise Marks Act, 1887, are punished here, or as "misbranding" is penalized in the United States.

Doubtless much discussion will ensue as to the nature of the amending legislation which may be consecutive upon the interesting report of Sir H. Norman's Committee, and it will be well to keep in view certain principles upon which such new statute law should be based. It will also be wise to study attentively and comparatively similar legislative efforts abroad and in our own dominions. Our present Pharmacy Acts date from 1852 and 1868, and the principles underlying them are akin to those laid down by Mr. John Stuart Mill in regard to the sale of poisons in the fifth chapter of his famous essay *On Liberty*. It may well be that modern opinion will be prepared to sanction in this sphere of legislation, as in general politics, a greater intervention of the State in the direction of protecting the individual against his own ignorance or folly. Mill himself was prepared to go no inconsiderable length when inducements were laid before the individual "to alienate his freedom." "The principle of freedom," he said, "cannot require that he should be free not to be free." Herein comes the special and exceptional claim for strict and resolute control over the traffic in so-called "drugs of addiction"—drugs, that is, that enslave the will and are the insidious foes to all freedom of volition. Against such drugs was directed the International Opium Convention now signed by nearly every civilized nation in the world, and already ratified by many of them. Its object, as expressed in Article IX, is to enable the contracting Powers "to enact pharmacy laws or regulations to confine to medical and legitimate purposes the manufacture, sale, and use of morphine, cocaine, and other drugs liable to similar abuse, and to co-operate with one another to prevent the use of these drugs for any other purpose." To this end such drugs of addiction are, from the beginning of their manufacture to their eventual sale to individuals, to be kept under Governmental supervision. We understand that a Departmental Committee has for some months been engaged in drafting the legislation necessary to give effect to these provisions. The report of the Committee on Patent Medicines comes opportunely to enforce the need for limiting by law "to medical and legitimate purposes" the use of drugs potent for ill as well as for good, and around the sale and advertisement of which enormous vested interests have grown up and flourished, and which it will require much determination and disinterestedness to overcome and destroy.

ON A HOSPITAL SHIP.

As the hospital ship is something of a novelty in naval warfare, it may be interesting to give some account of the staffing and equipment of such a vessel. The following extracts from letters from a young surgeon of the Royal Naval Reserve Volunteers who is serving on one of them may give an idea of the organization of this modern adjunct to the medical service of the navy. They will also show the spirit in which our young doctors have gone to serve their country. After announcing during the early days of August that mobilization orders had arrived and that he was starting to join a hospital ship, he says: "Everybody tells me that getting on a hospital ship is about the best job one could get, so I am very lucky. I hope to goodness we get away before any action is fought." In a later note he describes his ship: "They have certainly spread themselves in doing us well. We have beds for about 190 patients, and our medical complement is principal medical officer, 6 surgeons, 6 dressers, 4 nursing sisters, and about 40 naval sick berth nurses (males). We have two theatres—really quite nice considering, with lifts down from the main deck to the wards, laundry, etc., in addition. Our own cabins are very nice, large and airy, with electric fans. There is quite decent bathroom accommodation. She is quite a large ship, employed in peace time as a troopship, and ought to be a pretty good sea boat. The crew have their own doctor quite apart from us. There is no doubt about it that this is the billet to get in war time. Our principal medical officer strikes me as being a very nice man. Somehow he knew that I was senior resident at the ——— Hospital. On the whole I think I am in for a thoroughly good thing, and I hope I am able to make the most of it." After the ship had sailed for her destination he writes: "We have been very busy getting everything straight and ready for business. All things considered we are really fitted up very nicely. We have two operating theatres, over one of which I have charge, and I also, of course, have my own ward to look after. My quarters are extremely comfortable."

THE RED CROSS ABROAD.

On August 13th President Wilson, as President of the American Red Cross Society, issued an appeal to the people of the United States for contributions to the Red Cross fund. On August 17th the Rockefeller Foundation made a contribution of £2,000 to the fund. A unanimous joint resolution was passed on August 18th by the National Congress authorizing the President to admit to American registry foreign built ships for use by the Red Cross. On August 19th the American Red Cross offer of relief had been accepted by Holland, Russia, France, Great Britain, and Servia. Among the first offers made to the French Government, says the *Boston Medical and Surgical Journal*, was that of the directors of the American Hospital at Paris to fit up a wing in a school at Neuilly as a hospital to accommodate 200 French wounded, and to provide a full staff of American physicians and nurses. On August 1st the municipal council of Moscow appropriated £1.000,000 for the Russian Red Cross Service. This service, which is one of the strongest in the world, comprises a board of administration, 8 boards of district administration, 509 local Red Cross committees, 60 communities of nurses, 90 ambulatory clinics, 6 emergency hospitals and 7 convalescent homes, besides numberless asylums and homes for the care of widows and children of soldiers. In Japan the permanent endowment fund alone is over £2,000.000. The estimated wealth of the French Red Cross Society amounts to nearly £1,000,000. In Austria there are over 63.000 members of the Red Cross, with unds estimated at abont £217,000.

VITAL STATISTICS AND WAR.

We learn from the *Medical Record* that the Department of Health of New York has recently issued a compilation of statistics which "explain why the Kaiser is able to put so large an army of young fighters into the field, and, perhaps, also indicate why Germany preferred fighting now to postponing the conflict." In 1880, it is stated, Berlin had the highest birth-rate of the large European cities—40 births per 1,000 of population. This lead it held from 1880 until 1893, at which time London took the leading place. In the following year the birth-rates in both London and New York were larger than in Berlin. "It is clear," says the *Bulletin* of the Department, "that the enormous birth-rate between 1880 and 1893 still shows its effect in the present German army, for all these individuals are now between 21 and 34 years old, and therefore constitute the flower of the fighting force. With the decline in the birth-rate, and especially since Berlin was passed by London in 1893, it must have been clear to the Kaiser that the prospects for a continuation of an overwhelmingly large army were becoming dimmed." The Napoleonic doctrine that Providence is always on the side of the big battalions is firmly implanted in the Teutonic military mind, and it is at least conceivable that those who direct the policy of Germany may have chosen the time to strike a blow for the mastery of the world before the shrinkage in the number of their "cannon fodder" began to make itself felt. It may be mentioned that in 1913 the birth-rate of New York was 26 per 1,000 of the population; of London, 23; of Berlin, 20; of Paris, 17; and of Brussels, 16.

MATERNITY BENEFIT AND OBSTETRIC TEACHING.

Mr. Edgar S. Kemp read a paper in May before the council of the Charity Organization Society in which he analysed the results of an inquiry into the effects which the receipt of maternity benefit by patients had had upon the various institutions which dealt with lying-in women in London. The paper has been published in pamphlet form, and contains some information of importance in respect of the working of the maternity benefit part of the Insurance Act. It was found that there were nineteen institutions in London (apart from Poor Law infirmaries) which provided treatment for women in childbirth as in-patients or out-patients: of these five were lying-in hospitals, treating both in-patients and out-patients, two were maternity charities with out-patients only, and twelve were general hospitals with medical schools and with in-patients and out-patients in some instances, and with only out-patients in others. The five lying in hospitals were the institutions most affected by the maternity benefit section of the Insurance Act: in 1913 as compared with 1912 the in-patients showed a reduction of 12 per cent., and the out-patients of no less than 41 per cent.; it is to be noted that in each of these hospitals the money charge was increased, or one was imposed where none had been previously demanded. Further, three out of the five made a fixed charge. To whom have the women who have left the hospitals gone? The answer is that district midwives attached to hospitals are now treating privately numbers of women who are in receipt of the 30s., and who would previously have applied to the hospitals. With regard to the two maternity charities, one showed a drop of 61 per cent. in its patients, whilst at the other about as many cases were dealt with in 1913 as in 1912. At the latter the women always paid according to their means, but after the benefit became available they were charged more (10s. 6d. or 12s. 6d.): in the former no charge at all had been or was made, but the production of a "letter" was demanded. The explanation of the big falling-off in the numbers treated at this charity was, however, easily found; no women in receipt of maternity benefit were given treatment in 1913. The committee has, however, reconsidered its policy, and insured women are now dealt with free of charge on the production of a "letter." With regard to the twelve general hospitals, there was found to be a falling-off of 13 per cent. in the out-patients in 1913, but the in-patients varied only slightly. None of the twelve made a charge before the Act came into operation (except St. Thomas's, which made a small charge for in-patients), but three of them now make or propose to ask payment. The general result is that nine out of nineteen institutions are now making a charge; in three it is a fixed charge, in three payments are assessed after inquiry by an almoner, and in the three others payments are invited and accepted without inquiry. In the majority of the cases the contributions are paid by the patient or her husband; but in some instances payments are made direct by the approved societies, sometimes with the help of an almoner who assesses the amount. There would seem, however, to be doubt as to the strict legality of some of the ways in which moneys have been handed from the society to the hospital. Some of the secretaries of institutions which exacted no payments stated that many of the women were quite unable to part with any of the 30s., for "it was often ear-marked already for back-rent, redemption of clothing from pawn," etc. With regard to the three methods of exacting or soliciting payment (the fixed charge, assessed payment after inquiry, and the simple invitation of contributions), Mr. Kemp does not state his preference, although he quotes one matron who reported very favourably on the third. After all, a good deal depends upon the necessities of the institution itself; if it has to supply cases for medical students and midwives pupils and is finding difficulty in so doing it will be tempted to make no charge and to exercise no discrimination. Mr. Kemp thinks it is doubtful whether the plea of keeping up the medical school is a sufficient excuse for some of the methods employed to attract cases; he is of opinion that a preferable plan would be the better allocation of the ground to be covered between the various competing institutions. He mentions the fact that a few square miles to the north of Oxford Street are served by four general hospitals, by a lying-in hospital, a maternity charity, the out-patient midwives of another lying-in hospital, and a women's hospital; certainly it would be

well if these various institutions were not jostling each other so closely. The report is of considerable value, and it serves to show that the coming of the maternity benefit has had a serious immediate influence upon maternity hospitals and the maternity departments of general hospitals, that the best way of adjusting these institutions to the new conditions has not yet been discovered, and that, in particular, the money difficulty has not yet been got over in a perfectly satisfactory way. It is doubtful if the money difficulty can be got over at all without a recasting of some parts of the Act.

THE LATER RESULTS OF SANATORIUM TREATMENT.

FOLLOWING its custom, established during the last few years, the Charity Organization Society has issued a further report[1] as to the present condition of the consumptive patients treated under its supervision in various sanatoriums since the year 1902. A total of 737 individuals have been discharged from these institutions up to the end of last year and of these no less than 48.30 per cent. are either at work or are fit for work. With each succeeding year the statistics must be affected by the deaths of those whose period of benefit has been short, but the fact that so large a percentage can be recorded after eleven years have passed, forms an effective answer to the pessimistic criticism of the work of the society which is too often forthcoming from those who have not taken the trouble to study the question. The report, which is drawn up by the Medical Advisory Subcommittee of the council of the society, presents many interesting statistical details; but it also contains some valuable comments which may appeal to practical workers with even greater force. The methods of selection of cases is simple. The opinion of an expert is relied upon before admission and the advice of the resident medical officer is followed before a patient is discharged. Thus every effort is made to apply sanatorium treatment only in such cases as present reasonable hope of benefit by it, and no restriction is placed upon the length of stay. In some respects the uninsured patient fares better than the insured. The latter, if he applies for sanatorium benefit under the Act, must of necessity become a marked man in his employer's eyes and hence such application is too often postponed until the time for effective arrest of the disease has passed and the sufferer becomes a permanent charge upon others. The insured patient with established disease may learn the lessons of hygiene in the institution, but thus far he is not placed under any effective home supervision. His panel doctor has too much to do to keep a watch upon the home conditions of all his consumptive cases, and even if he were able to do so, it rarely happens that such home conditions can be rendered truly hygienic. Under the Act, too, it must often happen that patients in very different stages of the disease are herded together in the same building or even in the same ward. The uninsured, under the society's plan, can generally secure earlier admission and obtain the full period of treatment which his case demands. He may sometimes be embarrassed for lack of decent clothes, but here again the society is able to give a helping hand. Yet another most important consideration is the condition of the teeth, not only on account of the supposed presence of the popular complaint known as pyorrhoea alveolaris, but on the more commonplace need for proper means of mastication. The society has rendered good service in the continued publication of its results and has certainly shown a strong case to justify its appeal for funds to carry on the work.

[1] The Sanatorium Treatment of Consumption. A Report of the Charity Organization Society's work in the years 1902-1913.

SANATORIUM REPORTS.

THE Society for the Prevention and Cure of Consumption in the County of Durham, founded in 1898, has recently issued its fifteenth annual report,[1] by which it appears that much good work has been done and that much more will have to be done to meet the existing demand in the county. Two sanatoriums are already established, at Stanhope and Wolsingham respectively, but during the past year the greater number of beds have been taken over by local authorities or Insurance Committees. Twenty beds are subscribed for by workmen, and a few are reserved for private patients. The average stay of each patient extended to thirteen or fourteen weeks, and the average weekly cost for each patient amounted to 21s. or 22s. The general results in early cases were satisfactory, and 48 out of 51 patients were able to return to work on discharge. Many of these, however, still showed bacilli in the sputum, and only 13 could be classed as cured. Tuberculin was not used in a sufficient number of cases nor in a sufficiently systematic manner to warrant any deductions as to its real effect. The medical officers rightly urge a strong protest against the admission of advanced cases, and advocate segregation apart from others either in hospitals or special homes. Their inclusion in a sanatorium brings discredit upon the treatment, and they derive no real benefit from it. They occupy the places of those who might so benefit, and they depress their fellow patients. The time must soon come when the advanced consumptive will be placed under some form of State control. It is only such cases as are daily distributing bacilli that can reasonably be regarded as a danger to the community. An interesting report,[2] furnished by Dr. Prest, the Superintendent of the Ayrshire Sanatorium, affords statistical and other evidence for comparison. Opened in 1906, this institution has received 702 patients up to March last. They have for the most part been kept under treatment for about five months, and the results among cases of incipient disease show a working capacity of 83 per cent., while 48 per cent. of the whole number of cases were reported as well and working up to last April. Far too many cases had already reached the incurable stages before admission. It would seem that the incidence of pulmonary tuberculosis among school children in Scotland is higher than would appear from published figures. The length of stay in the sanatorium is determined by the class of case, and where recovery of health is probable a much longer period of treatment is undertaken than in the more advanced case, where relief only can be looked for. The weekly cost for each patient works out at a little over 27s., and expenses seem to be decreasing rather than the reverse. Much support from various parts of the county, both in money and in kind, has enabled the managers to provide adequately for the present requirements of the consumptives in Ayrshire.

PORTSMOUTH MUNICIPAL DISINFECTANT STATION.

THE county borough of Portsmouth has followed the example of the metropolitan borough of Poplar and laid down a plant for the manufacture of disinfectant fluid by means of electrolysis. The method of production, as described by Dr. Mearns Fraser, the medical officer of health, is by running sea water in at the top of a series of four narrow tanks and allowing it to flow slowly through each of these to the outlet pipe. In the tanks it is forced by several weirs to come into contact with a series of electrodes by which it is exposed to an electrical current of about 40 ampères and 120 volts. The resultant fluid is discharged at the outlet pipe at the rate of 25 gallons an hour, and after the addition of a small amount of fixing solution the disinfectant is ready for use. In addition to its disinfectant qualities the fluid is a powerful deodorant. In experiments carried out with some of the most stinking

and decomposed organic material that could be obtained the effect was instantaneous, and the foul odours were at once destroyed. The disinfectant should, therefore, be especially useful for cleansing urinals. The capital cost of the Portsmouth installation was £678, and it is estimated that the annual cost entailed will be £210. Considerable economy will be effected in the use of the plant, for the annual expenditure in Portsmouth upon disinfectants is now about £700.

THE ACCOMMODATION OF HOP-PICKERS.

It is probable that no industry will be less interfered with owing to the military conditions now prevailing than that of hop-picking. Comparatively few able-bodied men are required in the hop-yards during the picking season, and the vast majority of those employed in actual picking are women and children. The reports from the hop-growing counties, both in the east and the west, indicate that there will be plenty of employment in this direction for some weeks, and the money earned should go a long way towards relieving distress among a certain proportion of the working classes. The incursion of many thousands of poor people into the hop districts necessitates for them the provision of sleeping and other accommodation, and there is no doubt that in many cases this has been and now is of a very indifferent character. Particular attention has been given in recent years, not only by the local authorities but also by the Local Government Board, to the improvement of the conditions of the hop-pickers, and there has just been issued by the Board a report[1] on inquiries made during 1913 by Dr. Reginald Farrar, one of the Board's medical inspectors. Comparing the result of his investigations with those made in previous years, Dr. Farrar considers there has been a distinct improvement in many respects. There are about thirty rural districts within whose areas of administration hop-yards are to be found, and all but three of these have adopted by-laws regulating the accommodation of the pickers. If these are properly enforced a great deal may be done in the way of improvement. There are still, however, many places where the sanitary accommodation is either entirely wanting or sadly defective; where the scavenging around the quarters occupied by the pickers is neglected; where water supplies are deficient in quality and quantity; and where there is no proper provision made for cooking. One of the most important and practical of Dr. Farrar's recommendations is that inspection of the quarters should be made several weeks before the picking begins, and that for this purpose where necessary additional inspectors should be appointed.

MR. SAMUEL stated in the House of Commons on Wednesday that the Government had offered to refugees from Belgium the hospitality of the British nation. We understand that among the refugees are a certain number of members of the medical profession or their wives and children. All such cases hitherto found have been dealt with by the private efforts of medical men in London, but whether there are other similar cases cannot at present be ascertained. The Editor would receive the names of any medical men who would be willing to help should occasion arise.

[1] Reports to the Local Government Board on Public Health and Medical Subjects. Dr. Reginald Farrar's Report on the Lodging and Accommodation of Hop-pickers. (New Series, No. 99.) London: Wyman and Sons, Ltd. (39 pp. 6d.)

ACCORDING to the *Boston Medical and Surgical Journal*, the New York City Health Department received on August 4th a cablegram from the Serum Institute of Vienna requesting the immediate delivery of 50 litres of tetanus antitoxin for use in the Austria-Hungarian army. This amount exceeded the supply on hand, but an order was sent to the laboratory at Otisville, where the antitoxin is prepared, to furnish the desired quantity as promptly as possible.

THE WAR.

THE PROTECTIVE INOCULATION OF TROOPS.

THE important letter published below is signed by some of the leading men of science in this country, and the number of names might, we are given to understand, easily have been largely increased had there been more time, and had not some of those very willing to sign been already engaged in various military capacities, so that they feel themselves excluded from addressing the public direct. It will be seen that the signatures include those of many of the most distinguished men who have themselves made important contributions to the particular department of pathological science concerned with protective inoculation, as well as those of senior men of scientific eminence who are well qualified to appreciate the value of the work done by the younger school.

SIR,—At this momentous crisis in the history of the empire one plain and simple duty is incumbent on the people of this country. It is to see to it without delay that the health and lives of our brave soldiers and of all the volunteers who are so nobly coming forward at their country's call to form new armies should be adequately protected against avoidable and unnecessary risks.

The gravest of all risks in time of war is that from devastating epidemics of infective disease. In the South African war there were more than 57,000 cases of typhoid fever. Of a total of nearly 22,000 deaths from all causes, over 14,000 were deaths from disease; 8,000 of these were due to typhoid fever, the deaths from this disease thus outnumbering all the losses due to wounds.

But it is not at the seat of war alone that danger exists. Among the men now collecting into camps at home or billeted about the countryside the same risk is present. Some of them are practically certain to be typhoid carriers, for about 3 per cent. of all cases of typhoid fever become chronic carriers. Hence an epidemic may arise at any moment under service conditions.

This danger can be obviated by means of antityphoid inoculation. The fact is proved beyond question, and the data are indisputable. In the British garrison in India, where about 93 per cent. of the men are now inoculated, the deaths from typhoid fever have been reduced from several hundreds per annum to less than twenty. In the army of the United States, where inoculation against typhoid is compulsory, there were last year among 90,000 men only three cases of typhoid fever and no deaths.

In the army of our French allies also antityphoid inoculation is compulsory. But in our own army, as Colonel Sir W. B. Leishman stated a few weeks ago, "antityphoid inoculation remains, unfortunately, on a voluntary basis;" and the Army Medical Department still has to proceed even in this time of war "by persuading officers and men first of the reality of the danger of typhoid fever; and, secondly, of the protective value of the vaccine." Yet even in the Turkish army, as has recently been stated, the soldiers are now not only vaccinated against small-pox, but also inoculated against cholera and typhoid immediately upon enrolment!

Besides the risk of epidemic typhoid fever, the danger of dysentery and cholera cannot be ignored in a war which involves the greater part of Europe, and in which troops from Russia and from the Balkans will continue to take part. Of ominous significance is the news published in the *Times* of September 5th that cholera has already appeared in Anatolia.

We therefore strongly urge that the time has now arrived when inoculation against typhoid fever ought at once to be made compulsory throughout our forces; and when the Army Medical Department should be given full discretionary powers to carry out such other protective

inoculations as they may from time to time deem necessary or advisable.—We are, etc.,

September 7th.

AN APPEAL BY SIR ALMROTH E. WRIGHT.

Sir Almroth Wright, in a letter to the *Times* dated September 3rd, from the Department for Therapeutic Inoculation, St. Mary's Hospital, Paddington, W., made a forcible appeal, in the course of which he said:

If it be permissible for the author of a method to recommend it for compulsory adoption, I would wish very earnestly to support that suggestion and to urge that every soldier should before proceeding abroad be inoculated against typhoid fever.

The absolute necessity of making provision against this disease by inoculation is now a commonplace of military hygiene. It is, however, as yet only the few who appreciate that in war the deaths caused by bacterial infections are many times more numerous than the deaths caused by the direct act of the enemy. Professor Koch reckoned them to stand in war in the proportion of 10 to 1. But the wastage from bacterial disease is greater than that. For ordinary wounds incapacitate chiefly by opening the way to bacterial infections taking the form of suppuration and blood poisoning. Against these also our army ought to be protected, and it is in connexion with wound infections—one of the things that has been placed beyond dispute—that these can, if taken in time, be rapidly controlled by the appropriate vaccines.

To ensure that this method of prevention should have a chance all that is required is to create a general demand for its application. The required "antisepsis vaccine" is available. In this connexion it is perhaps allowable to state that this department, which is presided over by Mr. Balfour, and which owes a great deal to the generous aid of Sir Ernest Cassel and a few others, has within the last three weeks supplied gratuitously to our army and navy, and also to the French military hospitals, a total of 180,000 doses of "antisepsis vaccine." In addition this department has, by working long hours in response to a War Office request, furnished, as a contribution, for the use of the army, nearly 280,000 doses of antityphoid vaccine.

TYPHOID FEVER AND OUR TROOPS.

The Presidents of the Royal College of Physicians (Dr. J. J. Graham Brown) and of the Royal College of Surgeons of Edinburgh (Professor Francis M. Caird) have published in the *Scotsman* the following letter, dated September 7th, a copy of which they have forwarded to us for publication:

On several occasions recently reference has been made in the press to the advisability of inoculating our troops against typhoid fever before sending the men abroad.

The high necessity of this procedure does not appear to be sufficiently recognized. Yet our experience in the South African war showed that, were typhoid fever to break out among such masses of men, it would destroy many more lives than the fire of the enemy could do.

So necessary and so effective is this precaution, that we would press on all commanding officers the importance of seeing that inoculation is widely carried out, especially in the case of all men who are likely to be sent abroad. It should, in our opinion, be made compulsory.

However, for reasons which are known to those most experienced, inoculation ought to be performed at least a fortnight before the man leaves this country. The procedure is simple, and but little inconvenience is suffered.

We know that the officers of the Royal Army Medical Corps are overburdened with work at present. They are doing what they can. To save them this additional work we suggest that arrangements could be made so that Fellows of our respective Colleges would undertake the task of inoculation.

The Laboratory of the Royal College of Physicians is prepared to supply the necessary vaccine, and when the organization is complete we calculate that many hundreds of inoculations could be performed each week.

This matter is not only extremely important but also very urgent.

ORGANIZATION REQUISITE.

We have received from a physician (whose name would command the respect of the profession were we permitted to publish it, but we are not because he is on military duty) a private communication of which we feel at liberty to indicate the general purport. It independently corroborates the importance of the practical point made by Dr. Graham Brown and Professor Caird.

Our correspondent comments on the need of working out a practical method of inoculating a large number of men: 100,000 men require at least 200,000 injections. Each injection, if properly carried out, requires time and care. The skin has to be carefully cleansed, and the needle for each injection has to be sterilized.

He formed the opinion that in the various chief centres of the country small groups of medical men, including laboratory workers, should be organized who would be ready to go on short notice to any place where Territorial troops were stationed to inoculate men who had given the medical officers of the force their consent to inoculation.

Recently our correspondent had an opportuity of putting the plan to the test. The medical officer of a corps which had been warned for foreign service addressed the men, strongly advising them to be inoculated. Striking the iron while it was hot, he communicated with our correspondent. A body of doctors, including several pathologists and laboratory workers, drove over to the camp in motor cars and inoculated some 500 men. He found that it took ten medical men—accustomed to such work—nearly two and a half hours to make the 500 inoculations. The same party will shortly make the second inoculation for these men. The work is very tedious, and if any one worker had overmuch of it to do he might easily get careless in sterilizing the needle and cleansing the arms.

He considers that, if the work is to be done on a large scale voluntarily, the men must be done in large batches; when they see their comrades coming forward they do not like to be left out, but it has to be remembered that the arm may be painful for a short time, and there may be some general malaise for a day or two. For this reason alone, if only small batches were inoculated daily by the medical officer in charge, volunteers might be discouraged.

[In this connexion readers may refer also to the Memorandum on page 470.]

NURSES.

SIR,—In the letters recommending antityphoid inoculation for all soldiers I see no mention of nurses, for whom it is even more essential. If our own army statistics prove anything, and if the American claim is sound that by inoculation they have so utterly wiped out enteric in their army that not a single death occurred in 90,000 men during twelve months, surely no nurse ought to be allowed to attend on typhoid patients unless she is inoculated. We all know how many nurses become infected, and how easily accidents happen when a nurse is hard worked and has many patients to attend to. Is it not time to insist that every typhoid nurse should be advised to receive protection whether she is working in a hospital or privately? The present state of things is not fair to them or to their patients.—I am, etc.,

Clifton, Bristol, Sept. 8th. G. PARKER, M.D.

THE BRITISH RED CROSS SOCIETY.

Relief to Minds as well as Bodies.

ONE of the surgeons of the Belgian unit of the British Red Cross Society who managed to escape from Brussels, where the other members are still detained, has brought some interesting news to London this week. Two British Red Cross nurses and one surgeon were allowed to be on duty at the railway station when a considerable number of British prisoners were passing through on the way from Belgium to Germany. In many hundreds of households in this country great anxiety must be caused by the publication of casualty lists owing to doubt whether soldiers described as "missing" are dead, wounded, or captured. The British Red Cross surgeon has been the means of relieving anxiety on this score in many homes. He was allowed to take the names and home addresses of every British prisoner passing through Brussels during several days, and the Society immediately communicated with the families, assuring them that the missing men, though prisoners, were sound and well. The surgeon, who has returned to England and who took the names of the prisoners in Brussels station, states that the men are well treated by the Germans.

German Attitude towards Red Cross Work.

There are no fewer than 102 British nurses in Brussels without any work to do; twenty of them belong to the Society, the others having been sent out by other organizations. The capture of two British Red Cross surgeons who were proceeding to the front at the request of the Belgian authorities, and the fact that they are still prisoners, no communication having been made as to their whereabouts, throws an unpleasant light on the spirit in which the Germans treat the Geneva Convention.

The Unit in France.

The French unit of the British Red Cross Society landed at Cherbourg, and has made its way northwards to get into touch with the British base. It is composed of twenty hospital-trained nurses, ten surgeons, and ten dressers. Lord Brassey has been kind enough to place his famous yacht, the *Sunbeam*, at the disposal of the Society for any service at home or abroad.

THE MEDICAL SERVICE OF THE NEW ARMY.

S. H. B. writes: I wish to support the excellent suggestion on page 164 of the SUPPLEMENT for training medical officers for the new army. I served as civil surgeon in the South African war, but had no special instruction whatever. I went out on a hospital ship with six or seven other civil surgeons. We had three weeks of absolute idleness on the voyage out. There was a major of the R.A.M.C. on board who certainly might have given us some idea of what would be expected of us. But we did not even accompany him on his daily round of inspection, and it was not till I had been for several months in medical charge of a regiment that I learnt that one of my duties was to inspect the cooking utensils and see that they were kept clean. Probably I never discovered what some of my duties were.

Mr. W. MCADAM ECCLES (Major R.A.M.C., T.F.) writes: The suggestion made in the SUPPLEMENT of September 5th that a special committee of medical men acquainted with army medical methods should be formed at once so as to organize the instruction of a number of the medical profession is an excellent one. It is not generally known that at least 350 officers of the Royal Army Medical Corps are needed for every 100,000 of troops. If medical men who are entirely ignorant of the military routine and the special drill of this corps are given commissions, much valuable time will be lost before they become efficient. If, therefore, competent lecturers could be appointed, say, by the British Medical Association in the larger centres, many medical men ready to offer their services could easily gain this preliminary training at once.

Dr. JOHN MUIR (Retired Captain, R.A.M.C.T.) writes:

I think that the suggestion in last week's SUPPLEMENT that the Association should serve as an auxiliary to the War Office is an excellent one.

I am one of many who have had some experience of R.A.M.C. work in the Territorial Force in past years, but whose present civil duties prevent from volunteering services whilst there are younger men available who are equally fitted professionally, and who are more free from responsibilities—personal and civil. But if there be any suggestion of shortage of medical officers, or if posts exist for which previous experience render such men especially fitted, we would at once offer ourselves.

The British Medical Association might well then get in touch with the Medical Department of the War Office, find out their wants at present and as time proceeds, and act as a bureau of information to members of the profession fitted and anxious, as we all are, to serve our own country in this time of emergency.

A classified register could be kept, as suggested, to which the War Office would have access, and from which they might select men to meet their requirements at any time.

I shall be pleased enter my name, with particulars of experience, on such a register immediately it is decided to open one.

I am meanwhile endeavouring to find out otherwise whether, and how, I can be of service, but it is difficult to obtain any definite information. Replies to each individual applicant can hardly be expected at present, but collective information might readily be obtained by the Association acting as suggested by your correspondent.

AN APPEAL FOR AMBULANCE OFFICERS.

Urgent.

SIR,—Eleven officers (medical men) are required to complete the establishment of the 3rd East Anglian Field Home and Foreign Service Ambulances.

Applications stating age should be sent here *at once*.—I am, etc.,

A. GRAHAM, M.B.,
Captain,
Acting O.C., 3rd E.A.F.A.,
Home Service.

Head Quarters,
3rd East Anglian Field Ambulance,
Church Hill, Walthamstow,
September 9th.

NOTES.

SCOTLAND.

Medical Service Emergency Committee.

THE following is the text of a model undertaking drawn up by the Scottish Medical Service Emergency Subcommittee for the signature of any medical practitioner sent to take up work in any place through that committee. At present there does not appear to be any serious pressure, but when winter comes on it will not be possible for a man to do the work of two practices as many are doing now. The motto, "Business as usual," which we see on every hand applies to medicine as well as to commerce. A man may serve his country just as well by attending to the needs of the civil population as by going to the front. At the present time there are, we are told, a number of men waiting for military employment who might put in their time in assisting in the medical work for the civil population. In Scotland, all such should send their names to the convener of the Medical Service Emergency Committee at the Royal College of Physicians, Edinburgh.

SCOTTISH MEDICAL SERVICE EMERGENCY COMMITTEE.

Royal College of Physicians,
Edinburgh.....

Dear Sir,—In asking you to agree to act as *Locum Tenens* for Dr....., I feel sure that you will not misunderstand the request that you should give the undertaking referred to below. It is obviously the duty of the Committee to take all reasonable steps to prevent any difficulties arising later. UNLESS IT IS OTHERWISE ARRANGED BETWEEN THE PRACTITIONERS CONCERNED IN WRITING, each *Locum Tenens* acting under the present arrangements shall, by the very fact of his so acting, be held to agree not to practise as a Physician, Surgeon, or Apothecary in the town in which he is acting for the regular practitioner, or within the distance of seven miles from such town—or from the regular practitioner's house where it is not in a town—for a period of five years from and after the date when the regular practitioner returns to work or ceases to serve with the colours from whatever cause; and to join with the regular practitioner or his representatives in submitting all questions that may arise in connexion with the practice to the Presidents for the time being of (*a*) the Royal College of Physicians of Edinburgh; (*b*) the Royal College of Surgeons of Edinburgh; and (*c*) the Royal Faculty of Physicians and Surgeons of Glasgow as joint arbiters; and to abide by their decision.

If you agree, please sign the docquet below and return this circular to me, when I shall have it stamped as a binding Agreement.

I am, Yours faithfully,

.....

I confirm the terms above set forth in connection with the practice of Dr. ..... of which I agree to take charge as *Locum Tenens*.

Sign as follows:—

IRELAND.

Dublin.

The large majority of the principal hospitals in Dublin have made arrangements, or are making them, to place from 25 to 50 beds each at the disposal of the military authorities. The Jervis Street, Meath, and the Royal City of Dublin Hospitals are each allotting 30 beds, Mercer's Hospital 25, and Dr. Steevens's Hospital has offered 30 beds immediately and another 30 if required. Most of the hospitals have also sent both nurses and doctors to the front. A member of the visiting surgical staff of the Royal City of Dublin Hospital is at present with the 1st Field Hospital, in company with the assistant physician and pathologist. The æ-rayist has been called up with the Reserves. The dentist has left to join his company in the Territorials, and the doctor in charge of the Nose and Throat Department has gone to the front as a civil surgeon. The house-surgeon was one of the first to leave Dublin, having obtained a commission in the R.A.M.C.; some twenty students of the hospital, most of whom have been resident pupils, and were recently qualified, have either obtained commissions in the R.A.M.C. or posts as civil surgeons. Three nurses, including a sister, have already left, and seven more are expecting to receive orders to proceed at any moment. A class of lady probationers has been admitted for a month's training, and it is expected that a further class will be formed as soon as the present course is finished.

A good deal of disappointment has been caused by the receipt of a notification from the head quarters of the British Red Cross Society, stating that the third and fourth Red Cross units organized in Dublin would not be required, at any rate for the present.

CANADA.

[From our Correspondent.]

Throughout the country there is evidence that the people of Canada are anxious to do their part and to help the Mother Country in every possible way. War is upon us, and response to the call to arms is heard from every part of the empire. The first Canadian division is mobilizing at Valcartier. In it is included a medical corps of fifty officers and men, and in the medical personnel of the militia are over 700 officers ready for service—one in every ten of the physicians in the country. Inoculation against typhoid is being carried out systematically, and although it is not compulsory, no objection appears to have been made by the men. The vaccine used is all supplied by the Ontario Board of Heath, and is obtained from a bacillus supplied by Sir William Leishman. Thus the inoculation will be uniform, and the results, apart from their first intention, should be of great statistical service. The women of Canada are engaged in raising funds to be used as the British authorities may deem best, and provision is being made for the care of those dependent upon the men who have joined the allied forces. At a recent meeting of the Toronto Academy of Medicine it was decided that members should undertake without charge the professional care of such needy dependants, and it is probable that some such action will be taken throughout the Dominion.

PORTSMOUTH.

There are some 140 patients in the 5th Southern General Territorial Hospital. A few sick Territorials have been admitted since the reception of the wounded and sick from the army on foreign service on September 1st. Medical cases (chiefly rheumatism) preponderate. There are but few wounds from rifle bullets; the larger number were produced by shrapnel. One death has occurred from acute tetanus following a shrapnel wound in the leg. There are no cases of sword or bayonet wounds or of severe sepsis. The soldiers have settled down very comfortably in their new quarters. Many luxuries that are good for sick folk have been given. There are ninety nurses, all with three years' hospital training, who are under Miss Alcock, Matron of the Royal Portsmouth Hospital, as the principal matron. The male personnel consists of ninety non-commissioned officers and men.

The military authorities consider that one emergency hospital is sufficient for the present, consequently two council schools which had been requisitioned and prepared as a Territorial hospital and Red Cross hospital respectively will not be utilized. School duties have been resumed in them, but all the hospital equipments are stored and kept ready for use in case it becomes necessary to increase hospital accommodation here.

A further batch of wounded (about eighty) arrived at the Alexandra Hospital, Cosham, on September 8th. The cases did not appear to be of a very serious character. There were no officers amongst the party.

A DIVISIONAL MOBILIZATION.

The following notes concerning the mobilization of one particular Territorial division are, we believe, typical, and will be of general interest. A Territorial division is a very complex body. All its members lead—from the date of mobilization—what is for them an abnormal existence, but their actual occupations vary very largely according to the nature of the units that they help to form, so it would not be easy to draw any but very broad conclusions as to the health effect of their common duty—namely, soldiering, but at a great distance from any opposed force—from the personal experience of individuals or individual units. This is the more obvious when it is remembered that, though a Territorial division is made up mainly of infantry battalions to the number of about 12,000 men (distributed in three brigades, each consisting of four battalions), its whole personnel is brought up to about 18,000 by the addition of mounted infantry, field and heavy artillery, engineers, ammunition and supply columns, and field ambulance units.

On the issue of the mobilization proclamation officers and men began to report themselves at the stations to which they had previously been allotted. Here the various units which they severally helped to make up were embodied, and then were gradually brought together in the neighbourhood of the town which had previously been selected as head quarters for the time being. Meantime, the training of each unit had been proceeding, the men being either billeted on the inhabitants of villages and small towns or kept under canvas.

When the different units had been assembled together into a division in being, it was found that the town previously chosen as head quarters—an average country town with a population of about 30,000—did not lend itself well to the suitable billeting of so considerable a force, so for billeting purposes the units were again separated. Some remained in the town itself, while quarters were found for others in two village suburbs. In either case the accommodation was of the same general order, some individuals being told off to private residences, others to barracks improvised by the transformation of schoolrooms, railway sheds, and public halls.

After a time the housing system, so to speak, was again changed, the whole division being placed under canvas on different convenient pieces of open ground in the neighbourhood of the town. This was not the last change, since about a month after mobilization the whole division — this time for purely strategic reasons — was moved away to a larger town of manufacturing type. In this town, which seems likely to be the division's head quarters for some time to come, the men have settled down very happily to their strenuous life. A large proportion are in private houses and the rest in various public buildings and secondary schools. The rule is lights out at 10 p.m. and no soldier is allowed to be served in a public-house before noon or after 8.30 p.m. The food all through has been ample in amount and fairly well cooked, and in the case of men billeted in private residences the regulation allowances have often been supplemented by the hospitality of the hosts. (The payment is 9d. a day for non-commissioned officers and men and 3s. a day for officers.) The various changes of station in respect of the division and its units have

thrown a great deal of work on the medical and engineering officers of the force in the matter of providing adequate latrine and other accommodation, and they have received much courtesy and assistance from county, borough, and local Medical Officers of Health. The men of the division received much kindliness from the inhabitants of all the towns and villages through which its units passed. Ladies, for instance, have helped the men in the matter of laundry work and the mending of clothes, and at the first head quarters the house-surgeon of the county hospital afforded men belonging to the ambulance units opportunities of visiting the casualty department and picking up knowledge regarding the practical treatment of injuries. A like course is being followed at the principal hospital of the present head quarters of the division, batches of ambulance men being admitted to the casualty department and even to the operating room.

At the first head quarters, cases of any importance were sent to the civil hospital, where they were received free of charge. At the present head quarter town a like arrangement exists (the actual cost of maintenance being charged) but in addition a building has been placed at the disposal of the medical staff to receive cases of minor importance and those still awaiting diagnosis. It is administered by half sections from each field ambulance.

From the date of mobilization up to the present the sickness rate has been very low (approximately 3 per cent.), and, save for a few cases of pneumonia, sore feet and slight accidents have furnished the majority of the patients. Curiously enough, considering the age of the persons concerned measles has given some trouble, so too has mumps. Men thus affected have been sent to civil isolation hospitals and the contacts kept apart from the rest of the troops. The lowness of the sickness rate is the more satisfactory because the men are living in totally novel conditions, and doing a very great deal of hard and often unaccustomed work and yet meantime are getting daily fitter in point of physique, and each man—including those of the ambulance units—more expert in the duties of his present life. The experiences of this division hardly justify the drawing of any conclusion as to the respective advantages of billeting men in private houses and keeping them under canvas. While billeted men certainly enjoy a greater degree of comfort, those under canvas seem perfectly happy and rapidly improve in physique. Still, when cases of infection occur, it is easier to deal with them without interfering with training when the patients are men billeted in private houses, and it is an open question whether any large body of men continuously kept under canvas would after some weeks figure well in respect of sickness returns. This at least is certain—only by the most unremitting attention to sanitation would a camp of any size remain healthy. The liability to an increased sickness rate would be very greatly augmented by the same camping ground being used by several different bodies of men in succession.

Medical Examination of Recruits.

The information which reaches us from various quarters points to the existence of a certain amount of confusion and misunderstanding with regard to the medical examination of recruits for the new armies. Conditions have been relaxed, but the degree of the relaxation does not seem to have been defined with sufficient clearness. This has an unfortunate effect in two directions: in the first place, recruits may be rejected at one office who would be accepted in another; in the second, if the examination is, as some recruiting officers seem to expect, perfunctory, men will be accepted who will be almost certain to break down before their training is completed. At the present moment especially, with eager recruits who find it difficult to gain admission to the units they prefer, this is doubly unfortunate. While in the present crisis no man should be rejected without good cause, no man there is good cause to reject should be accepted.

The most recent appeal by Lord Kitchener merely stated that:

"The age limit has now been extended, and any man may be accepted who is physically fit for active service, and between 19 and 35."

Further Casualties in the Medical Service.

The casualty lists published since our last issue contain the names of the following medical officers:

Navy.

Seriously Wounded.

Smyth, Staff Surgeon Thomas Aubrey (*Pathfinder*).

Army.

Killed.

Williams, Captain A. S.

Wounded.

Holden, Captain C. W.
Leckie, Captain M.
McConaghy, Captain W.
Morrison, Lieutenant W. K.
Perry, Captain H. M.

Missing.

Bell, Lieutenant T. H.
Brown, Captain G. H. J.
Brunskill, Major J. H.
Butler, Lieutenant P. P.
Crymble, Captain W.
Davies, Lieutenant E.
Davy, Captain P. C. T.
Dwyer, Captain P.
Edmunds, Captain C. T.
Graham, Captain J. H.
Hamilton, Captain E. S. B.
Hildreth, Captain H. C.
Kelly, Captain H. B.
Long, Major H. W.
Nelson, Lieutenant M. K.
O'Carroll, Captain A. D.
Rees, Captain G. H.
Shields, Lieutenant H. J. S.
Sinclair, Captain M.
Smales, Captain W. C.
Vidal, Captain A. C.

ORGANIZATION OF THE RELIEF OF DISTRESS.

Supplemental to the circulars noticed last week (p. 165) issued for the guidance of bodies concerned with the relief of distress arising in consequence of the war, the Local Government Board has drawn up a memorandum explaining for the general information of the public what the Government does for the families of soldiers and sailors. The document will be indispensable to any concerned with the administration of relief. It unfortunately bears out the criticism frequently made of late—that the separation allowance for the dependants of private soldiers, even when supplemented by the maximum sum a soldier can send home, does not reach the figure which social students have declared to be the minimum upon which town life can be supported. Nor is the separation allowance available to dependants other than wives and children. In regard to the payment of separation allowances it has been arranged that where the wife consents, or it is considered desirable, payment may be made weekly through a local relief committee.

The Government Committee on the Prevention and Relief of Distress has appointed inspectors, each to act as intermediary between it and a limited number of local committees. Experienced officers of the Local Government Board, the Board of Education, and the National Insurance Commission are to serve as inspectors.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

The Insurance Commission and the Medical Profession.

At a recent meeting of the County Cork Local Medical Committee a resolution was passed unanimously

approving of the proposal that the Irish medical practitioners should render every assistance in our national emergency to the Volunteer Medical Aid Associations, but at the same time calling the attention of the public to the fact that the Irish medical profession is at present ignored and insulted by the Irish Insurance Commissioners and some leading officials of approved societies in connexion with the medical administration of the Insurance Act.

It may be necessary to explain that while the Irish doctors are always ready to discharge their duties as citizens of the empire and as members of their profession, they strongly resent the insult and injustice offered them by the Irish National Insurance Commission—a Government department—whose attitude towards the Irish doctors is that they are "too dishonest" to be allowed to discharge under the Insurance Act those duties of medical certification which are entrusted to their colleagues in Great Britain. In some localities in this country the doctors have resented the insult and injustice inflicted on them at the hands of the Irish Insurance Commissioners by refusing to associate themselves with the Volunteer Medical Aid Association; though this is regrettable, it can

scarcely be wondered at, when the provocation they have received is considered. There is some reason to fear that the Irish Insurance Commissioners intend, under cover of the war crisis, to continue their present insulting and offensive campaign against the Irish doctors, notwithstanding that such a reckless and injudicious policy of a Government department must have a damping effect on the enthusiasm of Irish doctors who have gratuitously placed their professional services at the disposal of the Irish Medical Volunteer Aid Associations.

CANCER CURE.

An inquest was recently held near Clones, co. Fermanagh, touching the death of a woman, aged 56, who died two days after admission to the Fermanagh County Infirmary. The evidence showed that the deceased had been told by a doctor two years previously that she had cancer of the breast; he advised her to have it removed. She had then consulted a woman who was reputed to have a cancer cure, and received three plasters from her in the course of two months; she then became so weak that she consulted Dr. Fitzgerald, of Newtownbutler, who sent her into hospital at once. The woman who had treated the case gave evidence to the effect that she had a cancer cure which had been in her family for a long time, and that she had cured hundreds of people; the cure consisted in the application of a plaster she made herself, and she gave no internal medicines. When asked if arsenic was an ingredient, she said she preferred not to say what the ingredients were. She charged 10s. for a small plaster to cure; in this case, the plaster being large, she charged the deceased £1. The *post-mortem* examination showed a large abrasion on the right mammary gland, about 7 in. in diameter, which bore the appearance of having been caused by the application of a caustic. The brain, heart, and lungs were healthy. The mucous membranes of the stomach and intestines showed marked traces of congestion and inflammation. The inquest was adjourned in order to have an analysis of the viscera made. At the adjourned inquest a verdict of "Death from arsenical poisoning" was brought in, based on the expert evidence of Professor McWeeney, who found arsenic in the stomach, liver, duodenum, kidney, and rectum, and a considerable quantity in the diseased breast.

HEALTH OF BELFAST.

Dr. Bailie, the medical superintendent officer of health of Belfast, has issued his annual report for 1913. The population of the city is estimated at 396,000; the death-rate was 18.8 per 1,000, which is an increase of 0.7 over that of 1912. This increase is accounted for by the number of deaths due to diarrhoea and to scarlet fever; diarrhoea caused 457 deaths and scarlet fever 153. Diarrhoea may be taken as a rough index to the sanitary condition of the town, and education and improved home hygiene amongst the working classes would bring about a considerable improvement. The steady increase in scarlet fever during the last few years is rather a satire on preventive methods, for the city has been paying a large sum for the upkeep of the Purdysburn Fever Hospital, which has been occupied to its full extent with patients suffering from scarlet fever, yet the number of cases of this disease has risen steadily during the last four years. The number of deaths from phthisis was 844, an increase over the preceding year. There was a natural increase of population of 3,543, or 230 less than in 1912, and 379 below the average for the last ten years; 3,024 cases of infectious disease were notified, as compared with 1,436 in 1912.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

GIFT TO THE EDINBURGH ROYAL INFIRMARY.

On August 4th our correspondent, whilst passing along the main corridor of the surgical part of the Edinburgh Royal Infirmary, had his attention arrested by the spectacle of men laying down rubber flooring there; the incident was put on one side for the moment, but with the intention of further inquiry into its meaning later. The declaration of war that day and a rush of events of all sorts put the matter in the background; but now it appears that the india-rubber flooring, which covers the whole of the main right and left wing corridors and entrance hall of the infirmary, and measures over 800 square yards, was a gift to the institution from the Rubber Growers' Association, and was manufactured by the North British Rubber Company, Limited, Edinburgh. The flooring, which has large black and white squares suggestive of tesselated pavement, is resilient to the tread and perfectly quiet to walk upon, and it is said to be "practically everlasting," for it "gives" instead of wearing with use. It can also easily be kept clean. The formal presentation of the flooring was made in the board-room on August 31st by Mr. William Greenhill, C.A., on behalf of the association. Mr. Walter B. Blaikie, LL.D., presided, and sketched briefly the history of the Edinburgh Royal Infirmary from its projection in the year 1725 to the completion of the original building in that memorable 1745 when Prince Charlie came to the city, and when wounded soldiers from the battle of Prestonpans for a time were inmates, and so on down to the present time, when with its 921 beds, 42 cots, and 80 beds in the Convalescent House, the claim was made that it was the largest general hospital in the British Empire. Dr. Blaikie accepted the gift on behalf of the managers, and Dr. McKenzie Johnston also spoke of the value of the flooring.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

MANCHESTER AND DISTRICT.

MEDICAL INSPECTION OF SCHOOL CHILDREN IN SALFORD. At the beginning of 1913 the medical staff of the Salford Education Committee consisted of the medical officer of health, who is school medical officer, an assistant medical officer, a part-time assistant, and a specialist to examine the eyesight of the children. Early in the year the specialist tendered his resignation, and as the Health Committee required the full-time services of the part-time assistant, a full-time assistant medical officer, with special qualifications for dealing with eyesight, was appointed. It was also decided to appoint a full-time school dentist. During the year the medical officers conducted 17,704 examinations of children and teachers, but this figure does not include general examinations of whole schools which were made necessary by outbreaks of sore throat or scarlet fever, where no account was kept of the numbers examined. Whenever the inspection reveals defects calling for treatment the parents are first notified, and during the year medical treatment was advised in 717 cases. In no case are the parents advised to take their children to hospitals unless they state definitely that they cannot afford private medical treatment. In the course of their later inquiries, the inquiry officers found that treatment had actually been obtained in 456 cases, and parents had promised to obtain it in a further 154 cases, but in 107 cases the parents had refused to obtain treatment. The local authority itself undertakes treatment of visual defects, ringworm, tuberculosis, and certain complaints, such as running ears, impetigo, eczema, chronic nasal discharges, etc. At present the Education Committee has two centres for medical examinations, and parents are always invited to be present at the examinations, though less than half the parents avail themselves of the opportunity. A room at the education offices is used for retinoscopic examinations, but by far the greater number of the special cases reported for examination are seen at the new school clinic which has been established at a convenient centre adjoining the Tuberculosis Dispensary in Regent Road. At present the rooms at the clinic consist of a large waiting-room, two consulting-rooms and an *x*-ray room. A very complete and convenient *x*-ray apparatus, with all necessary safeguards, and costing about £175, was installed in April last year, and from that date to the end of the year 90 cases of ringworm were submitted to the rays. With very few exceptions it was found necessary to depilate the whole of the scalp with the rays by the five-exposure method of Kienbock, and the results are stated to have been singularly successful, all the children being able to return to school in an

average of thirty-five days, whereas treatment before the *x* rays began to be used generally extended to eighteen months. The children are now allowed to return to school, wearing a cap, as soon as epilation is complete and no stumps remain in the scalp. For some time after the treatment was commenced, many parents objected to it owing to reports of the evil effects of the *x* rays, but now there is rather an eagerness to obtain the treatment, for which the parents have to pay a nominal sum of 2s. 6d. for each child treated. One of the nurses at the clinic now devotes the whole of each morning to dressing cases of chronic discharge from the ear and nose and cases of impetigo, eczema, and minor skin diseases. This treatment is carried out under the direction of the medical officer, who devotes one half-day a week to the supervision and re-examination of the cases. The Education Committee considers that the beneficial results obtained quite justify the employment of the nurses in this way, as practically all the cases thus treated would otherwise in all probability receive no treatment at all. Among the routine inspection cases were found 142 cases of tuberculosis and 275 of suspected tuberculosis. There were very few advanced cases of phthisis, the great majority being in the early stages, but as such cases are adversely affected by compulsory attendance at the ordinary schools, the provision of open-air school accommodation is regarded as urgent. In addition to the above-named clinic, arrangements have been made for the establishment of a dental clinic.

Canada.

[FROM OUR SPECIAL CORRESPONDENTS.]

INSPECTION OF SCHOOLS IN VICTORIA, B.C.

FROM the report on the medical inspection of school children in Victoria, British Columbia, it is seen that of the 4,157 children examined during the year 1913, 50 per cent. had never been vaccinated. Examination disclosed 488 cases of enlarged tonsils, 406 cases of enlarged cervical glands, 116 cases of adenoids, 246 cases of malnutrition, 59 cases of goitre, 28 of ringworm, 23 of scabies, 2 of hare-lip, 3 of cleft palate, 1 of tuberculosis of the spine, and 1 of paralysis, in addition to a number of cases of defective sight, hearing, and teeth. The report comments upon the large number of backward children and their bad influence on the other children. The need for special classes for such children is very apparent.

MEDICAL HEALTH OFFICERS OF BRITISH COLUMBIA.

The medical health officers of British Columbia held their first annual convention at Vancouver on July 17th and 18th. Those in attendance numbered about thirty. Dr. J. J. Thompson, of North Vancouver, read a paper on the responsibility of public authorities and the general controversy concerning tuberculosis. He emphasized the importance of early notification and of treating problems connected with the spread of tuberculosis in a business-like way. Dr. G. A. B. Hall, of Victoria, in an address on epidemic infantile paralysis, cited instances to show the contagious nature of the disease. He thought that subsequent paralysis could be prevented in many cases if the disease were recognized early enough and the patient given absolute quiet. Dr. W. C. Hepworth, of Steveston, referred to some of the difficulties met with in public health work, and strongly recommended the erection of emergency isolation hospitals in small communities. Dr. T. V. Hunter, of South Vancouver, discussed medical inspection from the standpoint of parents, teacher, and physician, and Dr. McQuarrie delivered an interesting address on milk-borne scarlet fever, referring to the epidemic in New Westminster last year. In the afternoon Dr. F. F. Wesbrook, president of the University of British Columbia, spoke on the importance of greater co-operation among co-ordinate professions. A resolution of appreciation of the work of the Provincial Department of Agriculture in its efforts to eradicate bovine tuberculosis was passed, and the suggestion was made that a permanent health committee should be appointed. This matter was also taken up at a recent meeting of the Grandview Ratepayers' Association at Vancouver, on which occasion a similar resolution was passed. It was resolved also that, in the opinion of the members present, the most satisfactory course for the Government to adopt in reference to tuberculosis would be to provide financial assistance towards the prevention, care, and treatment of such cases, to enforce a more thorough examination of immigrants, and to prevent as far as possible the spread of the disease among Indians.

Hong Kong.

THE PUBLIC HEALTH IN 1913.

THE annual report on the health of the colony of Hong Kong for the year 1913 shows a total population of 489,114, of whom 90,594 reside in the purely agricultural district of the New Territories. The complete sanitary laws of the colony do not extend to this rural district, and the following figures are calculated, therefore, on a population of 398,520.

There has been a great demand for housing accommodation since the Chinese revolution of 1911, and during 1912 no fewer than 335 new dwellings were completed and occupied; the native quarters of the city and of Kowloon are still considerably overcrowded, a condition which was much aggravated by the further influx of from 50,000 to 60,000 Chinese during the renewed political disturbances of July to September, 1913. The rainfall for the year was 83 in., which is slightly above the average of the previous twenty years. The non-Chinese community, which comprises 11,000 whites, 6,130 East Indians, and 4,340 who are classed as mixed and coloured (Malays, Philippines, Japanese, etc.), shows a birth-rate of 15.8 per 1,000 and a death-rate of 10.9 per 1,000, while the Chinese rates were 8.9 per 1,000 (births) and 21.75 per 1,000 (deaths) respectively. Infant mortality is very high among the Chinese, the great majority of the deaths being attributable to tetanus neonatorum and other convulsive diseases.

Malaria.

Malarial fever shows a marked improvement on previous years; the deaths from this cause numbered 290 in 1913, as compared with 432 in 1912 and 338 in 1911. Antimalarial measures have been in progress since 1899, and since that date 11.6 miles of mountain streams have been trained and channelled at a total cost of nearly 300,000 dollars. Every death from malaria and every hospital case is investigated with a view to dealing with the source of infection; brushwood is kept in check in the vicinity of dwellings, the trained nullahs and channels are regularly swept and kept clear of water weeds and algae, pools are oiled, quinine is administered to school children in certain specially malarious districts, and the life-history of the mosquito and its relation to malaria are taught in all the schools. The military returns in regard to malaria show that the ratio per 1,000 among the white troops is the lowest on record—namely, 42.5, while among the native (Indian) troops it was 83.9 per 1,000.

Plague.

The incidence of plague during 1913 was comparatively light, only 408 cases being recorded, but the medical officer of health (Dr. Francis Clark) predicts that the rush of Chinese to the colony during the latter part of the year is likely to precipitate a severe epidemic in 1914, and this prognostication has unhappily been verified, as the present year has already produced a serious epidemic which is still in progress. Dr. Clark explains in this report that the overcrowding consequent on this sudden influx of refugees leads to a rapid increase in the susceptible rat population, owing to the increase in the available food supply for the rats and to the crowding of the houses not only by human beings, but also by their furniture, baggage and other lumber—conditions which afford hiding and breeding places for rats.

The regulations which aim at the gradual extinction of this disease comprise the concreting of the ground surfaces of dwellings and yards, the protection of drain openings and ventilating openings by iron gratings, the prohibition of ceilings and of hollow walls, the provision of metal rubbish-tins for the day's waste and its daily collection from houses, back lanes, etc., the destruction of

rats in infected quarters and in domestic and other buildings, the keeping of cats in dwelling houses, and the systematic house-to-house cleansing of the native quarters. A kerosine emulsion prepared from kerosine and soft soap is used for the destruction of fleas in infected premises, and rat runs are filled up with cement and broken glass wherever found.

Cholera.

The colony experienced a small outbreak of cholera—the first for many years—which originated among the boat population of a fishing village, and is thought to have been spread by the eating of infected fish. In all 116 cases were recorded, extending over a period of three months.

Diphtheria.

Diphtheria was more prevalent than in former years, the total number of cases recorded being 148 (49 Europeans, 75 Chinese, and the remainder other Asiatics): 56 of the Chinese cases, 2 of the European cases, and 2 "other Asiatics" died.

Midwifery.

With a view to a reduction of the mortality attending childbirth, a system of training midwives for work among the poor has been in vogue for some years past, and these women are maintained at the Government expense after completing their training: nine of them attended 2,329 cases of confinement during the year, with only 8 casualties, including 1 case of puerperal fever, 2 of placenta praevia, 2 of eclampsia, 1 of *post-partum* haemorrhage, 1 of cardiac failure, and 1 of hemiplegia.

Special Correspondence.

PARIS.

The Medical Situation in Paris.—Antityphoid Vaccination.

WRITING under date August 28th, our Special Correspondent says:

Medical progress in Paris is almost at a standstill. The societies have ceased to meet, except formally, and of lectures and discussions there are none. Such medical journals as still appear are greatly reduced in size and are entirely devoted to medico-military subjects. All medical men of serviceable age and physical fitness have been called to the colours, and hosts of students have been requisitioned. Many hospitals and laboratories have been almost denuded of their staffs, and it has been necessary in some of the important laboratories to call for voluntary assistance. Each hospital has a large proportion of its beds in readiness for wounded soldiers, and a great number of schools and private houses have been equipped as temporary hospitals. Staffs of medical men have allocated to them certain districts, the temporary hospitals in these districts coming under their care. The Americans resident in Paris have formed a Red Cross Society, and the response to their appeal for subscriptions has been excellent. Besides several houses, they have taken a large wing in the new Lycée Pasteur, and in the latter there are already 200 beds in readiness to receive patients. The British residents are also working strenuously, and although not yet officially under the Red Cross, the British hospital, which is admirably equipped for the reception of cases requiring operative treatment, has received many generous offers. A great drawback to the emergency hospitals in Paris is the lack of trained nurses, the profession of nursing in France not being cultivated to the same degree as in England.

The authorities have issued placards advising the people to be vaccinated against small-pox. This is done gratuitously in the different mairies. Up to the present no cases of small-pox have been reported. Professor Vincent's antityphoid vaccine is being extensively used both among civilians and in the army. The vaccine used here is polyvalent, the different strains of the bacillus being obtained from France, Morocco, and Tunis. Owing to the rapidity of the mobilization, very few soldiers at present on active service have been fully vaccinated against typhoid. Some have received two injections, the first of ¾ c.cm., and the second of 1½ c.cm. It is considered that these two injections give an appreciable immunity to the disease. The efficacy of Vincent's polyvalent vaccine is well demonstrated by the fact that in the garrison of Avignon from 1892 to 1912 there were 1,263 cases of typhoid, necessitating 44,133 days of treatment. In 1913 the garrison was vaccinated, and not a single case was reported during that year.

Correspondence.

THE "CONTROLLED" USE OF NEW TUBERCULIN IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

SIR,—In their paper on this subject Drs. Stockdale and Hodson have given a verdict on the whole adverse to tuberculin as a treatment in pulmonary tuberculosis. Their conclusions seem, however, to be vitiated by the facts, first, that they made no attempt to control the treatment, and, secondly, that they did not predetermine the suitability of the individuals chosen for treatment. A stereotyped method was adopted, and only varied when a definite reaction occurred. But in the treatment of febrile and intermittently febrile cases reactions indicate a false step. Since it was in this class of patient that the treatment did harm, it is possible that the dosage was incorrect. There are certain commonplaces in tuberculin therapy to which most experts would subscribe—namely, that not every individual is suitable, that each case must be treated on its merits, and improves only when the dose and interval are correct, and that each patient may require a different scheme of dosage.

In the febrile cases one would suggest at once that the initial doses were too large. It is also very doubtful whether the use of T.R. is justifiable in any febrile patient, unless no secondary infection is present—an extraordinarily rare occurrence. In the usual type of febrile case the secondary organisms should certainly, in common fairness to the patient, receive attention by appropriate vaccines before T.R. is given. Still better and safer is it to give a sensitized tuberculin (S.B.E.), with which reactions seldom, if ever, occur. Again, in the intermittently febrile cases, when occasional autoinoculations are upsetting all calculations, even greater care is required to adjust dose and interval to the patient. One hundred-thousandth of a milligram may be an excessive dose in many cases, and certainly one fifty-thousandth for the second dose would be liable to do harm. Here also one would be inclined to try S.B.E. rather than to risk reactions with T.R. The question of secondary infection also arises. One must surmise then that in Classes 2 and 3—

2. Intermittently febrile cases—that is, using the term "intermittent" in the sense that after a day or two rise the temperature would fall to normal, and then a further rise would be recorded.
3. Febrile cases.

—the method of treatment was improper. In Class 1 (afebrile phthisis) a favourable verdict is admitted by the authors. It is only in this class that tuberculin given without an exact method of control is likely to succeed.

With all due deference to the authors of the paper, whose root idea is undoubtedly most admirable, I suggest that it would have been better to have sorted out the patients by trial with a few doses of tuberculin to see that they were suitable for the treatment, and then to have discontinued treating half of these, keeping them to act as controls. The resulting statistical table would have included—theoretically at least—only such patients as were proved to be capable of responding in a reasonably satisfactory way to the drug. As it is, we have no indication whatever as to what number of the thirty-one patients who received tuberculin were likely to be favourable subjects. The communication of Drs. Stockdale and Hodson, as it stands, merely demonstrates that if tuberculin is given indiscriminately by a rule-of-thumb method results as good can be obtained without it—a proposition which few will now be found to deny—whilst had a definite procedure for controlling the dose and interval of the vaccine been adopted, together with a more rational method of selecting the cases, the resulting table would have marked

a considerable advance in our knowledge of this difficult subject.—I am, etc.,

Yelverton, July 27th. H. WARREN CROWE.

SIR,—The paper by Drs. Stockdale and Hodson on the above subject is very interesting. Here we have two medical men—indeed, three, for Dr. Batty Shaw was the final judge on the cases—spending at least three months in proving what has been proved often, but what few medical men when using tuberculin seem to remember—that is, that tuberculin is only of use in tuberculosis. They say that in every case they found the *B. tuberculosus*, but they do not say what other organisms were found. In their cases coming under Classes 2 and 3 I fear they were expecting tuberculin to clear up temperature, physical signs, and general ill health due more to other organisms than the tubercle bacillus. If the article is read in this light, then it proves the great usefulness of tuberculin in tuberculosis.

Might I suggest that they begin over again with cases in Classes 2 and 3 and make what I term a "differential" examination of the sputum, prepare a vaccine of the organisms found other than the tubercle bacillus and administer it. If this be done I believe they will be surprised how little of the temperature and physical signs was due to the *B. tuberculosus*, and I also believe they will appreciate the fundamental importance in vaccine-therapy of a correct bacteriological diagnosis. I have found P.T.O. the most useful of the tuberculin preparations in pulmonary work.

That tuberculin does not seem to exert its full specific powers in pulmonary tuberculosis is due, I believe, not to any fault in the tuberculin but to mistakes in our method of using it, and one of these, I submit, lies in our not fully estimating the power of the other bacteria and trying to get rid of them first.—I am, etc.,

Lisburn, July 25th. J. L. RENTOUL, M.B.

Obituary.

HUGO KRONECKER, M.D.,

PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF BERN.

BY the death of Professor Kronecker the scientific world has lost one of the foremost of modern physiologists. He was a younger brother of the famous mathematician Leopold Kronecker, and was born at Liegnitz in 1839. He was therefore 75 at the time of his death.

Kronecker received his preliminary education at the gymnasium of his native town, and afterwards studied medicine at Berlin, Heidelberg, and Pisa. In 1863 he took his doctor's degree at Berlin. He had already shown a marked inclination toward scientific research, and he had worked at physiological problems under Helmholtz and Wundt at Heidelberg. In 1865 he became private assistant to Traube at Berlin, and at the same time worked in the laboratory of physiological chemistry under W. Kühne. In 1868 Kronecker went to Leipzig, where, in 1871, he became assistant to Ludwig, who recognized his fine character and his great ability. At that time the Leipzig Laboratory was an international centre of experimental physiology. Kronecker went there well prepared for the work he had to do by his previous studies under Helmholtz, Wundt, Bunsen, and Kirchhoff, and was thus able to take a leading part in the researches pursued in the laboratory. He could converse in English, French, and Italian as well as he spoke his mother tongue, and this was an attraction to foreign students. In 1872 he qualified as privatdocent, and in 1875 he was appointed professor extraordinary in the University of Leipzig. In 1878 he was appointed head of a department in the physiological laboratory of Berlin, where he was closely associated in his work with du Bois-Reymond.

In 1884 Kronecker was called to the chair of physiology in the University of Bern, where he remained during the rest of his active life. He was sorry to leave Germany, for he was an ardent patriot who served in the wars of 1866 and 1870. At Bern he established an institute fully equipped in accordance with modern requirements, both for teaching and for research. By his special desire the institute was called "Hallerianum" in memory of the famous physiologist Albrecht von Haller, whose statue stands within the precincts of the university. He was one of the initiators of the International Congress of Physiology, which held its first meeting at Basel in September, 1889, under the presidency of Holmgren. Kronecker also took a leading part in founding the Marey Institute in Paris for the designing and control of physiological instruments and methods. He was its president in 1895. Kronecker also co-operated with Mosso in establishing the international research station on Monte Rosa, where he made a special study of mountain sickness. His last publication was a memoir on the cause of that disease, presented to the Royal Academy of Medicine of Brussels on April 25th, 1914.

Under Kronecker's direction the Hallerianum became like the Leipzig Laboratory—an international centre of physiological research. Foreign workers were always sure of a hearty welcome there.

His work, a considerable part of which he published through his pupils, covered nearly the whole domain of physiology. He devoted special attention to the respiration, the heart, the fundamental laws of reflex stimulation, animal heat, the assimilation of albuminous bodies, and other subjects which it is impossible to enumerate.

WE regret to announce the death of Dr. MARK JOSEPH WAKEFIELD of Moseley. Dr. Wakefield, who was in his 56th year, had been ill for a considerable time. He was a member of a well known Durham family and studied medicine at the Newcastle-on-Tyne College of Medicine, and took the degree of M.B. at Durham University in 1884. He was admitted M.R.C.S.Eng. in 1885. He practised for a time at Newcastle-on-Tyne, and some fifteen or sixteen years ago settled in Birmingham. During the illness of the medical officer of Winson Green Prison the Home Secretary appointed him deputy surgeon temporarily; later this appointment was made permanent, and Dr. Wakefield held it for ten or eleven years. Some four years ago his health broke down and he gave up practice. Dr. Wakefield was very popular with his patients, and his fine character endeared him to a large circle of friends.

THE death of Dr. CHARLES JACKSON has caused great regret in the town of King's Lynn, Norfolk, where he had practised for over a quarter of a century. He was born in Westmorland in 1850, and was educated at the Quakers' School, Kendal, and at Glasgow. He took the diplomas of L.R.C.P.Edin. and L.R.F.P.S.Glasg. in 1882. During his residence in King's Lynn he was physician to the West Norfolk and Lynn Hospital, and for twenty-two years was medical officer and public vaccinator for the north district of the Lynn Union. Dr. Jackson took a deep and active interest in all agencies for the social and religious welfare of the district. His hobby was gardening, and he was vice-president of the Lynn Horticultural Society. He died on August 18th, after an illness of several months' duration. The funeral, which took place four days later, was attended by a large number of members of the medical profession and other friends.

Universities and Colleges.

ACADEMIC POSITION OF STUDENTS ON MILITARY SERVICE.

THE Vice-Chancellor of the University of Manchester intimates that special arrangements are being made for the benefit of all students of the university who may be on active service during the war. All reasonable allowance will be made in respect of attendance, and scholarships awarded by the university will be continued to these students on their return. It is understood that many local education authorities have adopted a similar policy as regards their scholarships held at the university. There is every intention of opening the session on October 8th as advertised.

UNIVERSITY OF SHEFFIELD.

THE Council has decided to invite Dr. J. B. Leathes, F.R.S., at present Professor of Pathological Chemistry in the University of Toronto, to accept the Chair of Physiology rendered vacant by the acceptance by Professor J. S. Macdonald of the Chair of Physiology in the University of Liverpool.

UNIVERSITY OF DUBLIN.

THE following degrees were conferred at a meeting of the Senate on August 29th:

M.D.—G. Crane.

M.B., B.Ch., B.A.O.—R. R. G. Atkins, H. G. Browne, J. S. Dockrill, G. H. Elliott, F. S. Gillespie, H. B. Goulding, G. S. McConkey, P. W. McKeag, A. Newton-Brady, R. I. Sullivan, G. E. Tyndall, Dorothy E. Webb.

NATIONAL UNIVERSITY OF IRELAND.

THE following candidates have been approved at the examination indicated:

FINAL M.B., B.CH., B.A.O.—*J. Kennedy, *T. F. Kennedy, *V. O'Hea Cussen, *J. A. Pierse, †J. B. Minch, †M. McKeever, P. J. Corcoran, B. T. Cullen, W. Dixon, J. P. Huban, F. de C. Keogh, A. McGrath, J. V. McNally, J. Magner, O. J. Murphy, P. G. Murphy-O'Connor, T. F. Ryan, M. V. Sexton.

* First-class honours. † Second-class honours.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have been approved in the subjects indicated:

SURGERY (*Both Parts*).—H. Dudley, R. J. Hearn, A. R. Jennings, W. M. Lansdale, R. H. Leigh, L. E. Pimm, R. V. Powell, C. J. B. Way.

MEDICINE.—†D. Ancutt, †J. C. P. Bailey, †P. H. Burton, *C. H. Fischell, †R. J. Hearn, *†W. M. Lansdale, *†R. H. Leigh, *†R. V. Powell, *†C. J. B. Way.

FORENSIC MEDICINE.—H. H. Fairfax, C. H. Fischell, W. M. Lansdale, R. H. Leigh, R. V. Powell, C. J. B. Way.

MIDWIFERY.—C. H. Fischell, W. M. Lansdale, R. H. Leigh, G. D. Newton, R. V. Powell, C. J. B. Way.

* Section I. † Section II.

The diploma of the Society has been granted to Messrs. D. Ancutt, H. Dudley, R. J. Hearn, A. R. Jennings, W. M. Lansdale, R. H. Leigh, G. D. Newton, L. E. Pimm, R. V. Powell, and C. J. B. Way.

Public Health

REPORT OF MEDICAL OFFICER OF HEALTH.

Doncaster Rural District.—The estimated population of the Doncaster Rural District at the middle of 1913 was 41,974. During the ten years 1901–11 the population increased from 23,000 to nearly 38,000. The birth-rate in 1913 was 34.9 per 1,000, and the death-rate was 13.7. The infant mortality-rate was equal to 152 per 1,000 births. In a district which is so rapidly increasing it can only be expected that the question of housing would have to engage the attention of the sanitary authority. In the new colliery districts overcrowding is very general, for the demand for labour is very great; 760 working-class dwellings were erected during 1913, but Dr. Dunne states that it is extremely difficult, if not impossible, to state the number of extra houses needed, because of the great influx of the mining population. Parishes which are rural in character, and which may be situated some distance from a colliery, have miners living in them, so that where the accommodation may be sufficient for the ordinary wants of the population living and employed in that parish the present accommodation is insufficient when there are additions from without. There were 67 cases of typhoid fever notified during the year. The medical officer of health appears to have exercised a great deal of care in dealing with the cases, and is to be congratulated upon his success in removing every patient. It appears that the Rural District Council refunds to medical practitioners the cost of telegrams to the medical officers of health notifying infectious disease, and the practitioners freely avail themselves of this method of notifying cases. The practice must have been of considerable assistance to the medical officer of health.

Medical News.

THE late Dr. Henry O'Neill, of Belfast, left estate valued at £1,075.

QUEEN CHARLOTTE'S HOSPITAL, Marylebone Road, has undertaken to receive for their confinements any women amongst the Belgian refugees.

THE twenty-first annual dinner of the South-West London Medical Society has been postponed indefinitely on account of the war.

OWING to the absence on naval and military duty of a large number of St. Thomas's men, it has been decided to postpone the old students' dinner previously arranged for October 1st. At St. George's Hospital practically all the prize men of the year have taken appointments of one kind and another with the army or navy, so the prize distribution, address by the Master of Christ's College, Cambridge, and the students' dinner have all been postponed. The dinner of past and present students of King's College Hospital, arranged for October 2nd, will not take place this year.

Letters, Notes, and Answers.

☞ *Queries, answers, and communications relating to subjects to which special departments of the* BRITISH MEDICAL JOURNAL *are devoted will be found under their respective headings.*

ANSWERS.

"CUSTOMARY ARRANGEMENTS" WITH SUBSTITUTE.

A CORRESPONDENT asks: What are the "customary arrangements between neighbours" where a practitioner has made an arrangement with a medical neighbour to see to his practice in his absence?

*** It can hardly be said that there are any "customary arrangements." One party is compelled to trust the other, and if the latter proves dishonourable, the former is liable to suffer from his misplaced trust. It is always preferable where possible, to employ a locumtenent, who is bound by ordinary business obligations, which may be enforced in the law courts. None the less, where a practitioner, who had agreed to act for a medical neighbour in his absence, has acted in the manner alleged, his conduct might be brought before the local Division of the British Medical Association.

LETTERS, NOTES, ETC.

THE RESISTING POWERS OF THE SCREW-WORM.

MISS EVELYN A. CONSTABLE, M.B., B.S.Durh., writes: Hosain, aged 8 or 9 years, had been attending the C.M.S. Women's Hospital, Isfahan, Persia, for five months under the care of Dr. Catherine Ironside (by whose kind permission I quote the case), suffering from favus. In spite of treatment the greater part of the skin, as well as the hair follicles, were destroyed, leaving fairly healthy granulations amongst small islands of sloughs. On May 2nd the nurse who dressed the case noticed nothing unusual. On May 3rd the head was swarming with screw-worms (*Chrysomyia macellaria*).

We thought we would see which antiseptic would slay them first. The antiseptics used were carbolic acid (1 in 20), tincture of iodine, hydrogen peroxide, mercury perchloride (1 in 100), absolute alcohol, and formaldehyde (1 in 40). Tincture of iodine alone killed the worms, the three tested being all dead in twenty-five minutes. Six of those which survived in other fluids for twenty-five minutes were put into a mixture of absolute alcohol, corrosive sublimate (1 in 100), and formaldehyde (1 in 40) in a covered test tube. At the end of one and a half hours all were still alive, and two had escaped. At the end of twenty-four hours all at last had died.

These worms evidently have a very tough epidermis, which tincture of iodine alone seems capable of penetrating. The boy's head was treated with tincture of iodine, and no more screw-worms have been found.

"ENCYCLOPAEDIA MEDICA."

MESSRS. W. GREEN AND SON, LTD. (Edinburgh) write: We are at a loss to understand Dr. Jellett's letter, and do not know what else we could have said.

In the announcement of the new edition of the *Encyclopaedia Medica* we enclosed, as Dr. Jellett quotes from the prospectus, "a list of contributors to the first edition with the addition of the names of those who have so far agreed to contribute to the second." Why Dr. Jellett should take any exception to this or should, as he says, find it hard to believe that his name was included in this list we cannot conjecture. Does he for one moment mean to dispute the fact that he was a contributor to the first edition?

The statement is perfectly clear. The list contains: (1) The names of hundreds of specialists who kindly contributed to the first edition and who have either been or are going to be asked to revise the subjects on which they wrote; and (2) in addition to these, the names of new contributors who have kindly agreed to write articles for the second edition. We are anxious to make the work as perfect as possible, and accordingly many new subjects must be dealt with.

If Dr. Jellett will kindly re-read the paragraph, we have no doubt but that he will do us the justice of a public expression that he has been mistaken.

OPEN-AIR HOSPITALS IN WAR-TIME.

BY

ROBERT SAUNDBY, M.D., F.R.C.P.,

PROFESSOR OF MEDICINE, UNIVERSITY OF BIRMINGHAM; CONSULTING PHYSICIAN TO THE GENERAL HOSPITAL, BIRMINGHAM; LIEUTENANT-COLONEL R.A.M.C.(T.).

BUILDING committees have been in the past anxious to erect a structure which, as they say, should be worthy of the city in which it is placed and give those who subscribe to its cost something to look at and be proud of. Such sentiments have to my knowledge greatly influenced the builders of hospitals and have been put forward as the justification for a good deal of not strictly necessary ornament. During the last twenty years we have been learning the lesson slowly, but it is sinking in deeply, and already is thoroughly accepted by the leaders of the profession, both sanitarians and practitioners, that the usefulness of hospitals is almost in inverse proportion to their architectural merits and that our exaggerated notion of "comfort" is inconsistent with healthy surroundings. Draughts of air, low atmospheric temperature, dampness, are not the disease-bearing agencies they were once supposed to be, while bad ventilation and equable warm temperatures are depressing, debilitating, and retard recovery. Even dampness does no harm where there is a good current of air.

With the elaborate artificial system of ventilation introduced into the Birmingham General Hospital it was possible to maintain the wards and corridors at practically the same temperature day and night, and this was fixed at 60° F. as the recognized sick-room figure, but it was soon found that its very equability was a disadvantage; that those who had to work in these temperatures felt weakened, and within a few months after the building was opened for use the temperature of the corridors, and that of wards at night, was reduced to 55° F., the former figure of 60° being retained for the wards by day. By degrees complaints were heard, not from those who had to work in these temperatures or on their own account, but by and on behalf of the patients, especially the surgical patients and, above all, the children; complaints of delayed convalescence, of debility, and of retarded healing of wounds—results which would have been more seriously felt and less easily borne if it were not that the hospital has in the Jaffray branch a suburban dependency to which stationary cases can be transferred, thus relieving the beds of the parent institution. In spite of these advantages the complaints did not diminish, and the need for fresh air was urgently felt. By many members of the staff the elaborate system of ventilation was regarded as worse than a failure, but as it provided the only means of heating the building it was endured, and other means of remedying the evil were sought. Fortunately the architects had provided balconies—more for ornament than for utility—at the free ends of the wards, and to these balconies, enlarged in some cases by structural alterations, the patients are removed, being accommodated in long wicker chairs; but, even so, only a proportion of the patients can benefit by this treatment. A proposal to build large verandahs to each of the wards of the Jaffray branch, to which access should be given by windows opening down to the ground, was, although supported by the medical staff, rejected by the Committee on the grounds of structural difficulties and expense, and this highly desirable alteration still remains to be made.

It was at the Queen's Hospital that the first attempt was made, although only on a small scale, to treat ordinary hospital patients in an open-air ward. The ward is on the roof of the hospital, and is about half covered in, but quite open to the south. It certainly did not look "comfortable," and seemed open to the objection of getting all the smoke as well as the rain and snow. After it had been in use for some time I visited it with the late Professor Foxwell, who had suggested its creation, and what surprised me most was that patients and nurses seemed to like it, and my fears that it would be regarded as "uncomfortable" received no kind of encouragement from those to whom I spoke. Moreover, I found that they were not surgical cases only, but, in fact, were chiefly medical, and in particular I was shown a case of pneumonia which was doing very well. I climbed down from that visit to the roof converted—not to the advantages of open-air treatment only, for of that I had been long convinced, but of the practicability of carrying it out even in the middle of a smoky city like Birmingham.

During the meeting of the British Medical Association in Liverpool in 1912 I had the pleasure of visiting the Country Hospital for Children, where in a large ward quite open to the estuary of the Dee I found something like 150 children of ages from 2 to 10 or thereabouts. Their cots were placed close together and in three rows parallel with the long axis of the ward and to the open side. Here there was no question of floor space or cubic feet of air. They were in the fresh air, exposed to all the sun that shone on that shore and to all the wind and weather that might befall. These children from the slums of Liverpool were suffering from all sorts of diseases, medical and surgical, and were under the care of Dr. Macalister and Mr. Robert Jones. They were presumably ill, but they did not look it. They had rosy cheeks for the most part, and their appearance testified most strikingly to the vivifying effect of open air. They were as unlike the ordinary inmates of a children's hospital ward as it is possible to imagine.

Why have we been so slow to recognize that fresh air is the best tonic, the best antiseptic? It is cheaper, pleasanter, and undoubtedly more efficient than drugs. The successful treatment of tuberculosis in the open air led the way to the wider adoption of this method for other diseases. It was his observation of the results achieved by Dr. Huggard at Davos, whose advocacy of fresh air, and courage and success in inducing his patients to discard their prejudices in favour of "warmth and comfort," were so remarkable, that inspired Dr. Foxwell with the wish to give the same plan a trial in the treatment of ordinary diseases at the Queen's Hospital. Yet the open-air treatment of consumption has been carried out for only some twenty five years, although its value had been demonstrated by Mr. George Bodington of Sutton Coldfield, and explained by him in his little book on *The Treatment of Pulmonary Consumption*, published in 1840. Half a century had to pass away before the plan was revived, and this was not the direct result of Bodington's teaching, nor, we must regret to feel, was it due to the efforts or clear-sightedness of his own countrymen. The Warwickshire surgeon might know the truth, but his little lamp soon flickered out and his contribution to the knowledge of his profession was forgotten, although when its value was proved by the work of Walther of Nordrach and others it received the belated honour of being included in the 173rd volume of the New Sydenham Society's reprinted monographs (1901).

The experience of the American Civil War was all in favour of improvised hospitals or tents, but it preceded the enormous advance in surgical treatment due to Listerism, so that surgeons look back on those days with a shudder at results which were so poor even where there was abundance of fresh air and sunlight, owing to the existing ignorance of the causes of wound infection. Yet those who took part in the medical and surgical work of the war had no doubt, and in the report of Surgeon-General Billings, in Circular 4 of the Medical and Surgical History of the War, he says, speaking of hospital construction:

"*The object to be kept in view is to furnish shelter without diminishing that supply of pure air and light which is necessary to health.*"

Other points, such as locality, exposure, plan of construction, modes of heating and ventilation, are only of importance in so far as they secure that object. Wiser words were never written, but it is doubtful whether their meaning and importance have been fully appreciated or allowed due weight when the question of hospital construction has arisen. We have learnt that life in the open air is not only possible but pleasant—that cold air is a tonic, as George Bodington maintained; that warm rooms are debilitating; while a current of air that enters from ventilators or partly opened windows and other narrow openings causes draughts which, when they impinge upon the inmates, give rise to discomfort and complaint, too often resulting in their being stopped up.

It is to be hoped that these principles may be borne in

mind in the course of the arrangements that are being made and will have to be made in the provision for the sick and wounded during the present war. It is quite probable that the accommodation already made will prove insufficient and that large additional space will be needed. In the American Civil War and in the Franco-Prussian War the suitability of wooden buildings was abundantly proved, and with our increased knowledge and confidence in the advantages of simple structures it is to be hoped that no more money will be spent upon structural alterations for hospital use, but that simple erections will be made for which there are many good designs to be seen in the more recently erected sanatoriums for the treatment of consumption, none being better than that recently opened at Little Bromwich, outside Birmingham. Even these, in many respects, may be simplified in accordance with the temporary use to which they will be put.

Open wards dispense with all need for considering methods of heating and ventilation; windows and doors are not required, but it may be desirable in some places to have sliding wooden screens to afford a certain amount of protection in stormy weather. Flooring may be made of asphalt or simply beaten earth covered with a thick layer of pine sawdust, which can be renewed easily with a shovel, and which absorbs all damp to an extraordinary extent. The late Professor George Vivian Poore demonstrated the great value of pine sawdust as an antiseptic absorbent, and its special value for taking up and deodorizing such liquids as urine. He was asked by the South-Western Railway to suggest a simple form of urinal for the use of the men engaged in their works at Basingstoke, and he proposed the provision of a simple trough made by two planks put at an angle, filled with pine sawdust; when he was asked how often the sawdust would have to be renewed, he said, "Practically never." He was in the habit of showing his friends a flannel jelly-bag half full of sawdust, which he and his assistant had used in his room at University College for six months at the time I saw it, as a urinal; the effluent from it in the whole of that time amounted to something less than a pint of a pale fluid which smelt only of turpentine. If these hospitals are put up, as is proposed, in the grounds attached to buildings, or in unoccupied land in their neighbourhood, there ought to be no difficulty about the disposal of faeces, which should be superficially buried in shallow trenches. Soiled dressings should be burnt, and a proper furnace connected with the sterilizing apparatus would be a necessary adjunct to the hospital. The university buildings at Bournebrook, Birmingham, have been transformed at very considerable expense into a hospital of 600 beds, but it is likely that many more will be needed. There is plenty of room there for the erection of such an annexe as I have in mind, and there would be no difficulty in Birmingham in forming a committee to provide the money and equipment and to superintend the provision of all that is needed for such an extension. It is to be hoped that the medical press will support this plan and exert its influence to prevent the unnecessary expenditure of public funds in the costly transformation of originally unsuitable buildings. The campaign in favour of fresh air and sunlight is also that of efficiency and economy; and where, as has been pointed out by high authority, money may in the end be the decisive factor in this great struggle, there can be no justification for wasting it, especially when better results may be obtained by cheaper methods.

MISS FANNY CRESSWELL PARIS, daughter of the late Dr. John Ayrton Paris, formerly President of the Royal College of Physicians, and author of *Pharmacologia*, celebrated her 100th birthday at her residence at Yarmouth, Isle of Wight, on September 16th.

THE anniversary of Pasteur's death on September 28th is to be commemorated by the publication of a study, entitled *Pasteur and After Pasteur*, by Mr. Stephen Paget. This will form the first volume of a new series of "Medical History Manuals" to be issued by Messrs. Black. It will be followed by *Sydenham and Clinical Medicine*, by Sir William Osler; *The Predecessors of Lister*, by Dr. Alexander Miles; *Galen and Roman Medicine*, by Dr. J. M. Comrie; *Medieval Medicine*, by Dr. James J. Walsh; and *The Artist Anatomists of the Cinquecento*, by Dr. E. C. Streeter.

STERILIZATION OF WATER SUPPLIES FOR TROOPS ON ACTIVE SERVICE.

BY PROFESSOR G. SIMS WOODHEAD, M.D.,
LIEUTENANT-COLONEL, R.A.M.C.(T.), SANITARY SERVICE.

SOME years ago, whilst working at the sterilization of the Cambridge water supply, I found that it was not necessary to make a bacteriological examination in order to determine whether the *Bacillus coli* group had been killed by the addition of certain quantities of bleaching powder (chloride of lime) to the water under observation. Working with very dilute solutions of bleaching powder, I found that the amount of "available" chlorine required to be added to the Cambridge water to "sterilize" it was frequently only about 1 part in 7,000,000. In such cases the number of bacteria present was very small and the amount of organic matter very low, and I found, even after the addition of the above small quantity, that if I obtained a blue or a violet-blue reaction with potassium iodide and starch as much as a litre and a half or even two litres of the treated water did not contain a single "living" *Bacillus coli communis*. In some earlier experiments I was able to demonstrate that the typhoid and cholera bacilli were no more resistant to the action of hypochlorous acid than was the *B. coli communis*, and I now realized that water to which bleaching powder had been added, and which at the end of a quarter of an hour gave the above blue reaction, could contain no living members of the *B. coli communis* group, the dysentery bacillus, or any of the pathogenetic organisms mentioned capable of development in bile salt broth or on special media. I suggested, therefore, that this chemical test might be utilized to take the place of a bacteriological examination wherever waters, varying from time to time in their bacterial contents or in the amount of organic matter contained in them, were being treated with bleaching powder as a sterilizing agent; this test taking a few seconds only, against the twenty-four to ninety-six hours required for a bacteriological examination.

Carrying out a further series of experiments, and following the lines laid down, first in this country and then more completely worked out in America, I satisfied myself that if the particulate matter could be removed from a water by means of any of the ordinary filters, it was possible to render even a highly polluted water perfectly safe for drinking purposes by the addition of appropriate amounts of chlorine, and that these appropriate amounts could be determined by means of the iodine and starch test.

Quite recently I have heard from Colonel Horrocks, who has given considerable attention to this question, that instructions have been issued from the War Office that a definite quantity of bleaching powder should be added to any suspicious water after careful filtration through a good rough filter. Moreover, Colonel Horrocks informs me that he has devised a specially large and serviceable filter for the removal of particulate matter from water that is to be treated with this bleaching powder. I believe that by these means he has greatly reduced the risk of typhoid and other infections being conveyed through waterborne bacilli. I realize, of course, the difficulties in the way of getting the test described below carried out in the field; but the importance of keeping the amount of bleaching powder as low as possible (so that there may be no taste of chlorine given to the water)—whilst at the same time resting assured that a sufficient amount of bleaching powder has been added to render the water sterile—is so great that I venture to ask you to publish the following method of testing and sterilizing water for the information of those in charge of the water-cart tanks supplying troops on active service:

ALL WATER EXCEPT THAT FROM PUBLIC TAP WATER POTABLE SUPPLIES MUST BE REGARDED AS DANGEROUS AND UNFIT FOR DRINKING.

Filter through the best rough filter available—for example, army service filter, improvised sand filter, etc.

Pollution in water may be detected and the water rendered safe for drinking by the following method:

Test before Treatment in Bulk.

Instruction I.

Rinse a clean service enamelled iron or earthenware reputed pint mug (1, Fig. 1) with the water to be tested,

leaving a few drops in the vessel. Add the 2 grams of bleaching powder—chloride of lime, chloro-hypochlorite of lime — contained in one of the glass tubes "A" (white label) and make into a thin paste, rubbing it down with a clean stylographic pen, penholder, pencil, or glass or other similar clean rod available. Then add 500 c.cm., or 18 oz. of water (that is, fill to within ½ in. of the lip of the enamelled mug or ⅜ in. of the lip of an earthenware mug) and mix thoroughly by pouring into a second mug (Fig. 2), and then back into 1. The quantities indicated below of the resulting solution may be used for testing purposes; the remainder is used for sterilizing the water. This solution should contain 0.66 gram of available chlorine.

Fig. 1.

Fig. 2.

Instruction II.

Now fill four service reputed pint mugs to within ½ in. of the top with the water to be tested. Then allow the bleaching powder solution to rise in a pipette graduated to contain 0.15 c.cm. (Fig. 8) to the mark (b); wipe the outside of the pipette and blow the contents into one (Fig. 3) of the four mugs of water to be tested. Add two similar charges of the pipette to a second of these mugs (Fig. 4), three charges to a third (Fig. 5), and four charges

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 7.

to a fourth (Fig. 6), in each case mixing thoroughly (as under Instruction I), and allow to stand for fifteen minutes. Then into a clean mug (Fig. 7) crumble one of the small tablets of potassium iodide contained in tube "C" (red label); also after powdering in the corner of an envelope or between a couple of layers of clean paper, one of the compressed starch tablets "B" (blue label)—other forms of soluble or boiled starch may be used if these tablets are not available—and pour into it the water from 3, and

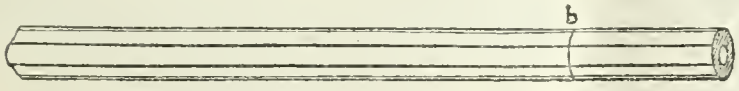

Fig. 8.—Natural size; capacity to b, 0.15 c.cm.

mix by pouring backwards and forwards from one vessel to the other. Add potassium iodide and starch to 4, 5, and 6, treating in the same way. When a blue colour appears in any of these mixtures it is an indication that the chlorine has not all been used up in that mixture; what remains sets iodine free from the potassium iodide, which, acting on the starch, gives a blue colour—that is, more available chlorine than was necessary to carry oxygen to the organic matter and less resistant organisms has been added, and the water treated in bulk as under Instruction III is rendered "safe." To free the water from the *Bacillus coli communis* and from non-spore-bearing pathogenetic waterborne organisms it is not necessary to add more bleaching powder than is indicated as required by the test.

Sterilization of the Water.

Instruction III.

Should No. 3 give a blue, violet, or brown colour (best seen by daylight) the contents of No. 1 (Fig. 1) may be divided into two equal parts, each of which is sufficient to sterilize 110–120 gallons of water. Distribute this amount, pouring equal quantities into each of the four divisions of the service tank when it is about half filled, and when filled allow to stand for twenty minutes. The water may then be used for drinking without filtration or further treatment.

Should No. 3 give no colour but No. 4 become blue, add the whole of the contents of No. 1 to 110–120 gallons, distributing in the same way and rinsing the mug several times so as to wash into the tank the whole of the bleaching powder.

Should No. 4 give no colour but No. 5 become blue, dissolve a second sterilizing powder "A" (2 grams of bleaching powder), and add half of it along with the contents of No. 1 to the 110–120-gallon tank.

Should No. 5 give no colour but No. 6 become blue, add the whole of the contents of the two tubes "A" to 110-120 gallons. In each case allow the water to stand for twenty minutes before issuing it for drinking. Should No. 6 give no colour the water should be regarded as highly polluted, and as palatability is a matter of some importance, it should be boiled. By the addition of more bleaching powder, however, up to 6 or 8 grams per 110-120 gallons it may be rendered innocuous, though in some cases it may be less palatable.

N.B.—1. The great advantage of this method is that it is not necessary to await the result of a bacteriological examination. The amount of bleaching powder required to render the water safe for drinking purposes may be determined in twenty minutes. Where a new or a variable water has to be used, this is a matter of prime importance.

2. Other advantages are that with the exception of the pipette no special apparatus is required, and that as the same solution is used for both testing and sterilizing, any fall in the available chlorine content of the sterilizing powder is equalized by a similar fall in the test solution, and the need for the addition of more sterilizing powder at once indicated.

3. If for any reason the supply of standard sterilizing tubes should fail, it will be found that three times as much fresh, clean, dry, loose bleaching powder (which should contain 33 per cent. of available chlorine) as can be lifted on a sixpenny piece grasped at the edge between the thumb-nail and the tip of the first finger, and used as a spoon, weighs 2 grams, and corresponds to the amount contained in one of the standard sterilizing tubes.

4. A rough test of the condition of the water to which bleaching powder has been added may be made by taking a cupful of water from the tank fifteen minutes after the addition of the sterilizing powder, dissolving in it one each of the tablets "B" and "C" (starch and KI) and mixing thoroughly.

Should no colour appear, add another charge to the tank, and again apply the rough test.

5. A treated water, to be "safe," should at the end of fifteen minutes, always give a blue "reaction" on the addition of the tablets "B" and "C."

This method may also be used for the testing and sterilization of the water supplies of small communities. I hope shortly, as a result of a series of experiments now nearly completed, to publish further information on several important points concerning the action of bleaching powder on spores, the effect of "killing" the chlorine, etc.

In the meantime, I wish to express my thanks to Messrs. Parke, Davis and Co. for their valuable help in working out the details of a really practical method, and for agreeing to supply the testing outfit containing bleaching powder and tablets of potassium iodide and starch; to Sir John Brunner, Bart.: to Messrs. Burroughs and Wellcome; and to the United Alkali Company—all of whom have assisted me with valuable information. Finally, I must place on record my indebtedness to my assistant, Mr. W. A. Mitchell, who has carried out a number of the experiments for me and kept them going when I was occupied with other work, often of a very different kind, that has had to be done during the last few weeks.

AN American Red Cross steamer, carrying 125 nurses and 30 surgeons, sailed from New York about a week ago. Her first call will be at Falmouth.

SINCE the date of publication of the last Nyasaland Protectorate Sleeping Sickness Diary (December 31st, 1913), 20 more cases of the disease have been diagnosed, 15 in the Dowa District, 4 in the Marimba, and 1 in Zomba. This makes the total number of cases discovered in the Protectorate 192. A native boy, diagnosed on May 19th, 1913, is still alive and apparently well. Clearing of the bush round villages is still being carried on, and a small grant of money has been sanctioned for the purpose.

SOME POINTS ON THE EXAMINATION OF RECRUITS OF THE TERRITORIAL FORCE AND THEIR EARLY TRAINING.

BY

BASIL HUGHES, M.A., M.B., B.C.CAMB., B.Sc.LOND., F.R.C.S.ENG.,

BRADFORD; LIEUTENANT, R.A.M.C.(T.), 6TH WEST YORKS. REGIMENT.

SINCE the mobilization of the Territorial Force some six weeks ago some interesting matters have manifested themselves, both in examining recruits and also during their early training. I have carefully noted certain points, and I think they are worth recording, both from a point of interest and also, perhaps, being of some use to others.

Teeth.

In examination of recruits much stress has been laid upon the condition of the teeth. So far, I have had practically no trouble at all with men's teeth, and after careful observation I can find no relation to exist between bad teeth and gastritis, diarrhoea, or other gastro-intestinal disorders. Men with what would be called bad teeth have on the whole had no difficulty whatever in masticating army rations, and have not complained of indigestion. They have improved physically, and with this improvement their mouths on the whole have shown a marked change in the right direction. I think, then, we should be careful about rejecting recruits, unless the condition of the teeth be very bad.

Hernia and Varicocele.

Hernia and varicocele speak for themselves, and I think, if present, should debar a man from being enlisted until they are permanently corrected by surgical treatment.

Feet.

It is with regard to the feet that some interesting points have been observed. When examining recruits I was at first anxious to reject all those with flat-foot except those suffering from a minor degree of the condition. A great many of these men told me their feet had given them no trouble before; others, who were being re-examined, and who had been at previous camps, told me their feet, after fifteen-mile marches, had only ached slightly, and I had confirmation of this from their officers. On the strength of this we passed them. With graduated marches and early morning physical skill, coupled with good food, these feet have improved to an amazing degree, and most of these men can now perform twelve and fourteen mile marches carrying their full kit without any suspicion of foot trouble.

I have during this six weeks quite convinced myself that physical drill, open-air life, with plain, substantial food, coupled with graduated marches, is one of the best treatments we have for flat-foot, and that flat-foot should not debar a man from enlisting until he be given a fair trial under the above conditions.

What has given more foot trouble than anything else amongst the men of this battalion have been cases of foot deformity, such as hallux valgus, hammer-toe, and any other condition that tends to take any one toe out of the plane of its fellows. Such cases have been very troublesome owing to the rubbing of bony points against the boots, and a number have had to be sent home. These are the cases that should be rejected at first unless they be of a very minor degree.

"Rheumatism."

Another very troublesome symptom has been aching and "rheumatism" in the feet. This has been observed chiefly in men over 25 years of age. This was a very puzzling condition. At first one was inclined to think these men were malingering. A number of them complained also of pain in the back, and I ascertained, after careful inquiry, that some did not sleep at night owing to the pain. After careful examination these cases turned out to be true cases of venereal rheumatism. The majority of them had had gonorrhoea previously, and after well squeezing the penis I was able to obtain slight quantities of discharge, non-purulent, but what I consider to be typical of an old, neglected gonorrhoea. There were also evidences of past trouble in the epididymis in such cases. In all these cases of aching in the feet, in the back, and other fibrous structures, aggravated by living under canvas, gonorrhoeal rheumatism should be thought of and treated. The lesson is to go carefully into the history of gonorrhoea before accepting a recruit past the age of 25 years. If he has had gonorrhoeal rheumatism, he should have a course of gonococcal vaccines, and be completely cured of the complaint before he is accepted. I am quite convinced that much of the rheumatic pain which men get under such conditions can be proved to be genuine gonococcal, and should be treated as such.

Arteries.

In older men, examination of the arteries, liver and urine, especially in old soldiers who have been in India and other places abroad where syphilis and drink have been plentiful, should not be forgotten. I have found that these men cannot stand marches or the work generally. Too often they exert a bad influence on the younger men, and unless absolutely sound they should be rejected from the Territorial Force. I have had more trouble with them as a whole than with all the rest.

Early Training.

A recruit when once he enlists comes under entirely new conditions:

1. He leads a perfectly routine life; he has regular outdoor exercise.
2. He comes under new sanitary conditions; a number of these men are drawn from poorer homes where the sanitary standard is low.
3. He comes under new conditions of personal cleanliness.
4. He comes under new, and in many cases better, conditions of food. Food is plentiful, good, and taken at regular intervals.

These conditions cannot be suddenly forced on any man who is unused to them without giving rise to some constitutional disturbance, and it is while these conditions are new and early that the recruit should be watched. These conditions, coupled with sleeping under canvas, at first swell the list of early morning sick parade. They will complain of a "bad cough," "headache," "inability to sleep," "constipation," "various pains about the body," "tonsillitis," etc.

The whole clue to the prevention and cutting short of these conditions lies in the proper sanitary care of the alimentary canal. Constipation or diarrhoea is often at the bottom of it all, and a good efficient purge, such as pill No. 9, has, in the majority of cases, been all that is necessary. The men often, at first, overeat themselves.

Diarrhoea.

This important symptom should always be investigated, and usually a cause can be found. It may simply result from the change of food and conditions, but it may also exist in an epidemic form. I had several cases of diarrhoea, and the disease once looked like becoming epidemic.

Careful investigation showed that it all originated from the men's mess-tins. The men had been cleaning out their mess-tins with sand and grass. Surface soil at this time of the year is by no means free from Gaertner's bacillus, and the diarrhoea was traced to this cause. Secondly, sand and grass did not efficiently wash out particles of meat and food. As these men take tea, meat, etc., out of this tin at different times of the day, it is easy to see that neglect to clean them thoroughly may be a potent cause of diarrhoea.

Since an abundant supply of boiling water was given them and supervision of the washing of these tins was instituted I now see practically no cases of diarrhoea. "Cramp in the stomach," causing men to fall out during a march, is in the majority of cases due to the use of the water-bottle on the march, and this should be carefully watched. Ice-cream vendors and coster-barrows containing unripe or over-ripe fruit, tripe stalls, and the like should be barred.

Prevention of Sore Feet.

One of the most troublesome of complaints is that of the feet, and the question arises, How can we prevent the occurrence of sore feet?

That much foot trouble can be prevented I am convinced, and I am pleased to say that we have in this battalion been able to reduce it to a minimum by taking the following precautions:

1. Secure properly fitting boots.
2. Properly prepare such boots.
3. Anticipate the trouble in the feet themselves and adopt prophylactic treatment.

The service boots, such as are served out, are not wholly satisfactory. They are roughly tried on at no particular time of the day, and in a hard, rough condition.

The correct time to try on such a pair of boots is at the end of a day's work. If they fit properly at this period, it may be taken that they are correct, as far as size is concerned.

The boots are hard and unyielding. They should be well softened before serving out. I find the best softening agent is crude castor oil. Such boots should be immersed in this material for five or six days before giving them to recruits. The stiffest parts, or the parts of the boot most liable to give rise to sores, are just above the heel, the instep, and about the great toe, and such parts should be thoroughly softened before the boot is given to the recruit.

As before stated, marching, properly graduated, is an excellent treatment for flat-foot, coupled with good food and physical drill. It is really astounding how these cases of extreme flat-foot have recovered themselves under this treatment, and I cannot too strongly emphasize this point. A number of men present the conditions of bromidrosis and hyperidrosis, and these are the feet which easily develop sores.

The routine treatment I have adopted for all is as follows:

The socks are washed every second or third day and thoroughly dried, so preventing the accumulation of stale sweat, which is a powerful irritant to the feet.

The feet are washed daily with soap and cold water, carefully dried, and then rubbed with methylated spirit; they are then dusted over with boracic powder.

Before a march the socks are soaped well and dusted with boracic powder.

These prophylactic measures are simple, and perhaps old, but they have answered the purpose so admirably that I have thought it wise to mention them, for in a battalion of over 1,000 strong sore feet have been the exception.

It would seem that some better designed boot could be possible, and I am hoping soon to suggest a pattern whereby certain parts in the structure of the boot may be altered to avoid chafing over the favourite sites.

Marching and Work.

Lastly, I would issue a word of warning against expecting too much at first in the way of marching and work from men of the Territorial Force newly mobilized. Short and easy marches at first, carrying only a portion of their kit, increased gradually while they are becoming accustomed to their new surroundings, are most important points, but very apt to be overlooked.

Beer in moderation and pipe tobacco are far preferable, in these men, to aërated waters and cigarettes. Regular attention to the bowels and a daily shower-bath after a march are most desirable, and the sanitary squad have done much good in assisting in seeing that these have been carried out, and also in explaining to the men the importance of them.

I have left out of this article the hygiene of tents, occurrence of lice, and other complaints which require special treatment, as such is all laid down. What I have tried to set forth is early and prophylactic treatment of Territorials suddenly coming under new conditions—a state new to them, but old to the regular army—and to suggest a few points which I have found by practical experience have been of great service to me as medical officer to this battalion.

IT is estimated that in the Franco-Prussian war of 1870-71 rifles were responsible for 90 per cent. of the deaths, artillery for 8 per cent., and the bayonet for 2 per cent. In the Russo-Japanese war, thirty-four years later, the rifle killed fewer—82 per cent., and the gun more—16 per cent. But this does not reach anything like the proportion of the present war, when the chief execution so far has been done by artillery.

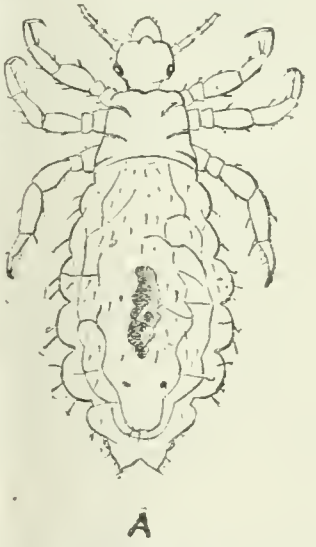
INSECTS AND WAR:

LICE.

By A. E. SHIPLEY, Sc.D., F.R.S.,
MASTER OF CHRIST'S COLLEGE, CAMBRIDGE.

LICE form a small group of insects known as the *Anoplura*, interesting to the entomologist because they are now entirely wingless, though it is believed that their ancestry was winged. They are all parasites on vertebrates. In quite recent books the *Anoplura* are described as "lice or disgusting insects, about which little is known," but lately, owing to researches carried on at Cambridge, we have found out something about their habits. As lice play a large part in the minor discomforts of an army, it is worth while considering for a moment what we know about them.

Recently the group has been split up into a large number of genera, but of these only two have any relation to the human body. I do not propose, in the present article, to consider one of these genera—*Phthirius*—which frequents the hairs about the pubic region of man and is conveyed from one human being to another by personal contact. We will confine our attention to the second genus, *Pediculus*, which contains two species parasitic upon man—(*Pediculus capitis*) the hair-louse, and (*Pediculus vestimenti*) the body-louse. Both of these are extremely difficult to rear in captivity, though in their natural state they abound and multiply to an amazing degree.



Pediculus vestimenti (Nitzsch). A, Magnified 20 times; B, natural size.

Wherever human beings are gathered together in large numbers, with infrequent opportunities of changing their clothes, *P. vestimenti* is sure to spread. It does not arise, as the uncultured think, from dirt, though it flourishes best in dirty surroundings. No *P. vestimenti* occurs that is not the direct product of an egg laid by a mother and fertilized by a father. In considerable collections of men drawn from the lower classes, some unhappy being or other will turn up in the community with lice on him, and these swiftly spread to others in a manner that will be indicated later on in this article.

Like almost all animals lower than the mammals, the male of the body-louse is smaller than the female. Its body attains a length of about 3 mm., and is about 1 mm. broad. The female is about 3.3 mm. long and about 1.4 mm. broad. It is rather bigger than the hair-louse and its antennae are slightly longer. Its colour is said to vary with the host upon which it lives, and Andrew Murray gives a series of gradations between the black louse of the West African and Australian native, the dark and smoky louse of the Hindu, the orange of the Africander and of the Hottentot, the yellowish-brown of the Japanese and Chinese, the dark brown of the North and South American Indians, and the paler brown of the Esquimo, which approaches the light dirty-grey colour of the European parasites.

The latter were the forms dealt with in the recent observations undertaken by Mr. C. Warburton in the Quick Laboratory at Cambridge, at the request of the Local Government Board, the authorities of which were anxious to find out whether the flock used in making cheap bedding was instrumental in distributing vermin. Mr. Warburton at once appreciated the fact that he must know the life of the insect before he could successfully attack the problem put before him. He found at an early

stage that *P. vestimenti* survives longer under adverse conditions than *P. capitis*, the head-louse.

The habitat of the body-louse is that side of the underclothing which is in contact with the body. The louse, which sucks the blood of its host at least twice a day, is when feeding always anchored in the clothes by the claws of one or more of its six legs. Free lice on the skin are rarely found, but the under side of a stripped shirt is often alive with them. After a great many experiments Mr. Warburton succeeded in rearing these delicate insects, but only under certain circumscribed conditions, one of which was their anchorage in some sort of flannel or cloth, and the second was proximity to the human skin. He anchored his specimens on small pieces of cloth which he interned in small test tubes plugged with cotton-wool, which did not let the lice out, but did let in air and the emanations of the human body. For fear of breakage the glass tube was enclosed in an outer metal tube, and the whole were kept both night and day in contact with the body. Two meals a day were necessary to keep the lice alive, and to do this the pieces of cloth, which the lice would never let go of, were placed on the back of the hand, hence the danger of escape was practically *nil*, and once placed upon the skin the lice fed immediately and greedily.

This means of keeping lice alive was but the final result of many experiments which had failed. A single female but recently matured was placed in the test tube, and a male admitted to her on the second day. The two paired on the sixth day and afterwards at frequent intervals. Very soon after pairing an egg was laid, and during the remaining twenty-five days of her life the female laid an average of five eggs every twenty-four hours. The male died on the seventeenth day, and a second male was then introduced, who again paired with the female. The latter, however, died on the thirtieth day, and the second male survived.

The difficulty of keeping the male and female alive was simple compared with the difficulty of rearing the eggs. Very few hatched out. The strands upon which they were laid had been carefully removed and placed in separate tubes, at the same time being subjected to different temperatures. It was not, however, until the eggs were left alone undisturbed in the position where they had been laid and placed under the same conditions that the mother lived in, that 8, and only 8, of the 24 eggs laid on the cloth hatched out after an incubation period of eight days. The remaining 16 eggs were apparently dead. But the tube in which they were was transferred to the waistcoat pocket and subjected to normal temperature of the room at night (on occasions this fell below freezing point), and after an incubation period of upwards of a month 6 more hatched out. Hence it is obvious that, as in the case of many other insects, temperature plays a large part in the rate of propagation, and it becomes clear that the eggs or nits of *P. vestimenti* are capable of hatching out up to a period of at least from thirty-five to forty days after they are laid.

Difficult as it was to keep the adults alive, and more difficult as it was to hatch out the eggs, it was most difficult to rear the larvae. Their small size made them difficult to observe, and, like all young animals, they are intolerant of control, much more apt to wander, and less given to clinging to the cloth than their more sedentary parents. Naturally they want to scatter, spread themselves, and pair.

Like young chickens, the larvae feed immediately on emerging from the egg. They apparently moult three times, at an interval of about four days, and on the eleventh day attain their mature form, though they do not pair until four or five days later.

Mr. Warburton summarizes the life-cycle of the insects, as indicated by his experiments, as follows:—

> Incubation period: Eight days to five weeks.
> From larva to imago: Eleven days.
> Non-functional mature condition: Four days.
> Adult life: Male, three weeks; female, four weeks.

But we must not forget that these figures are based upon laboratory experiments, and that under the normal conditions the rate may be accelerated. From Mr. Warburton's experiments it is perfectly obvious that, unless regularly fed, body-lice very quickly die. Of all the verminous clothing sent to the Quick Laboratory, very little contained *live* vermin. The newly hatched larvae perish in a day and a half unless they can obtain food.

With regard to the head-louse, it is smaller than the body-louse, and is of a cindery-grey colour. The female measures 1.8 mm. in length and 0.7 in breadth. Like the body-louse, it varies its colour somewhat with the colour of the hair on the different branches of the human race. It lives amongst the hair of the head of people who neglect their heads; it is also, but more rarely, found amongst the eyelashes and in the beard. The egg, which has a certain beauty of symmetry, is cemented to the base of the hair, and at the end of six days the larvae emerge, which, after a certain number of moults, become mature on the eighteenth day. The methods adopted by many natives of plastering their hair with coloured clay, or of anointing it with ointments, probably guards against the presence of these parasites. The Spartan youths, who used to oil their long locks before going into battle, may have feared this parasite. I have been told that the German soldiers before going to war shave their heads. If this is so, they would afford no nidus for *P. capitis*, but, if it is the case, the fact has escaped the lens of the photographers and the pens of the artists. The wigs worn in the late seventeenth and at the beginning of the eighteenth centuries undoubtedly owed something to the difficulty of keeping this particular kind of vermin down.

This article, however, attempts to deal more with the troubles of the camp, and *P. capitis* is in war time less important than *P. vestimenti*. The former certainly causes a certain skin trouble, but the latter not only affords constant irritation, but, like most biting insects, from time to time conveys most serious diseases. *P. vestimenti*, undoubtedly, is the carrier of typhus. This was, I believe, first demonstrated in Algeria, but was amply confirmed last year in Ireland, when a serious outbreak of this fever took place, though little was heard of it in England. Possibly, *P. capitis* also conveys typhus, but undoubtedly both convey certain forms of relapsing or recurrent fever. The irritation due to the body louse weakens the host and prevents sleep, besides which there is psychic disgust which causes many officers to fear lice more than they fear bullets. They are the constant accompaniment of all armies, and in the South African war as soon as a regiment halted they stripped to the skin, turned their clothes inside out, and picked the *Anoplura* off. As a private said to me, "We strips and we picks 'em off and places 'em in the sun, and it kind o' breaks the little beggars' 'earts."

In conjunction with the Quick Professor of Biology at Cambridge I have drawn up the following rules. Most of them will not be possible at all times, but some of them may be possible at some time in the campaign. At any rate, by acting on these rules, a relative of mine who took part in the South African war was able to escape the presence of lice on his body, and the general commanding his regiment told me on his return that he was not only the only officer but the only man in the regiment who had so escaped.

RULES.

1. Search your person as often as possible for signs of the presence of lice—that is, their bites. As soon as these are found, lose no time in taking the measures noted under paragraphs 4 and 5.

2. Try not to sleep where others, especially the unclean, have slept before. Consider this in choosing a camping ground.

3. Change your clothing as often as practicable. After clothes have been discarded for a week the lice are usually dead of starvation. Change clothes at night if possible, and place your clothing away from that of others. Jolting of carts in transport aids in spreading the lice, which also become disseminated by crawling about from one kit to another. Infested clothing and blankets, until dealt with, should be kept apart as far as possible.

4. All discarded clothes, as shirts and vests, should be collected and burnt or buried or put under water. Socks are not so important as body clothing, as lice rarely affect the forearm, the hands, or the feet. Cholera belts were in many cases early discarded in the South African war, owing to infestation of lice.

5. If lice are found on the person they may be *readily destroyed by the application of either petrol, paraffin oil, turpentine, xylol, or benzine* to the head in the case of *P. capitis*. The application may be repeated on two more days if the infestation is heavy. Fine combs are useful in detecting and removing vermin from the head. Tobacco extract has been advocated, failing other

available remedies. In the case of *P. vestimenti* the lice can be killed as follows: Underclothes may be scalded, say, once in ten days. Turn coats, waistcoats, trousers, etc., *inside out*, examine beneath the folds at the seams and expose these places to as much heat as can be borne before a fire, against a boiler, or allow a jet of steam from a kettle or boiler to travel especially along the seams. The clothing will soon dry. If available, a hot flat-iron may be used to kill vermin in clothing. Petrol or paraffin will also kill nits and lice in clothing.

6. As far as possible avoid scratching the irritated part.

7. Privates would benefit by instruction in these matters.

8. Apart from the physical discomfort and loss of sleep induced by the attacks of lice, it should be noted that they have been shown to be the carriers of typhus and relapsing fever from infected to healthy persons. Typhus, especially, has played havoc in the past, and has been a dread accompaniment of war.

EIGHTY-SECOND ANNUAL MEETING
OF THE
British Medical Association.

PROCEEDINGS OF SECTIONS.

SECTION OF ANATOMY AND PHYSIOLOGY.

ROBERT W. REID, M.D., President.

CARDIAC FIBRILLATION AND ITS RELATION TO CHLOROFORM ANAESTHESIA.

By J. A. MACWILLIAM, M.D.,
Professor of Physiology in the University of Aberdeen.

So long ago as 1837 I advanced the view that many cases of sudden death depending on cardiac failure are due to the sudden occurrence of fibrillation in the ventricles, the function of the cardiac pump being thus destroyed. Evidence was adduced to show the inadequacy of the current view of syncope to account for the facts in many instances of sudden dissolution, by the assumption of a sudden failure of the heart to contract, and the strong probability of the true cause lying, not in an abrupt enfeeblement or paralysis of the contractile power, but in the supervention of the useless and disastrous form of inco-ordinated activity known as "fibrillar contraction" or "fibrillation." In a paper in the BRITISH MEDICAL JOURNAL I urged the probability of this explanation as applying to various conditions in which sudden death occurs.[5] But the gulf between experimental physiology and practical medicine in this branch of study was vastly wider then than it is now, thanks, above all, to the labours of James Mackenzie and his followers. In recent years the view I propounded in 1887 has been adopted by Gibson, Mackenzie, and others, and evidence corroborating it has been brought forward by Hering.[1]

Former Observations.

At the time of my old papers, and for some years afterwards, the central question in regard to chloroform was that of respiratory failure *versus* primary cardiac failure, or rather the possible occurrence of primary cardiac failure, it being admitted that respiratory failure is the usual one when chloroform is steadily pushed to a toxic stage. My conclusion was an emphatic affirmation of the occurrence of primary cardiac failure as a form of chloroform collapse, in opposition to the conclusions of the Hyderabad Commission and other observers. Fibrillation had often been noted in the course of my experiments, especially as a result of the sudden intake of strong chloroform vapour, but I was not at that time satisfied as to its occurring in the absence of at least a temporarily excessive intake of chloroform. There was no evidence to warrant the assumption that such a mode of cardiac failure was an operative one in the administration of chloroform in the ordinary way in healthy animals, meaning by the latter phrase the *continuous* administration of the anaesthetic by the animal being put in a box* with chloroform, and allowed to inhale the vapour until complete anaesthesia is induced.

That with such continuous administration there is immunity from collapse due to fibrillation is a conclusion I wish to reaffirm to-day in view of experience spread over nearly thirty years. But when one comes to review the results of irregular or intermittent administration a very different tale has to be told—a tale of trouble and disaster that in the case of laboratory experimentation has given chloroform a bad reputation as compared with other anaesthetic agents, and has led to its falling into comparative disuse.

Further Evidence.

In the course of the last twenty years we have in this laboratory had entirely conclusive evidence of the liability to cardiac failure of this sort, especially in cats, in what is clearly a condition of light anaesthesia, while the conjunctival reflex may be distinctly present, and a tendency to reflex movements in response to afferent impulses very marked. In a series of sixteen cats, examined a year or two ago in conjunction with Dr. G. Spencer Melvin, intermittent administration of chloroform was employed, and collapse clearly due to fibrillation occurred in nine of the sixteen animals.

It is clear that in the case of the ordinary (healthy) laboratory animals, and especially in the cat, the exclusion of collapse from ventricular fibrillation would render chloroform, when used with reasonable care, a safe anaesthetic.

It is perfectly practicable to readminister chloroform again and again, using due care, without inducing fibrillation, while a sudden readministration or a sudden increase in the strength of the vapour inhaled during the sensitive stage may readily induce collapse from fibrillation. In this respect the use of mixtures of air and chloroform of known strength offers obvious advantages.

In some exceptional instances (cats) so excessively sensitive a cardiac condition may be developed, after lightening of the original anaesthesia, that recommencement of the inhalation of even low percentages of chloroform is apt to be attended by the speedy occurrence of fibrillation.

It may be noted that the hypodermic administration of such drugs as omnopon and chloral, while assisting the development of anaesthesia, do not afford any protection against chloroform fibrillation, if they do not, indeed, make the heart more prone to fibrillate; in any case, they tend towards the prolongation of the stage of insufficient chloroform which is associated with the liability to fibrillation.

Some Relations of Ventricular Fibrillation.

Ventricular fibrillation may occur at two phases of the action of chloroform: (1) In the early stage, this being by far the more common case; or (2) at a very advanced stage of the toxic action of the drug when the heart is greatly enfeebled and dilated. In some kinds of animals fibrillation may occur with great regularity as soon as the chloroform is pushed to a certain extent, weakening and dilating the heart.

Dilatation of the heart is not necessarily protective against the onset of fibrillation. Dilatation depends on diminished contraction—force and tone, while insensitiveness to fibrillation depends solely on a quite distinct condition—depression of excitability—which may or may not be associated with dilatation. Enfeeblement and diminution of tone are certainly often associated with dulling of excitability, but not necessarily so. There are cases of diminished sensibility associated with no sign of dilatation, and, on the other hand, marked proneness to fibrillation with marked dilatation.

The special incidence of chloroform fibrillation on the ventricles as compared with the auricles is noteworthy. The latter commonly preserve their rhythmic action, though they sometimes may fibrillate also.

There are some animals that seem to be specially liable to fibrillation under chloroform. In them we have very often found great resistance to the induction of anaesthesia, a very large amount of chloroform being required; during the induction marked excitability and tendency to struggle, quick irregular pulse, high blood pressure and defective vagus control over the heart. The complex and striking irregularity of the heart beat in cats in the earlier phases of chloroform administration attracted my attention very many years ago, and are mentioned in

* Analyses recently made by Mr. E. S. Edie of the air in the box as regards O and CO_2 at the end of the induction of anaesthesia showed quite trivial differences.

a paper in 1899.[5] These irregularities have recently been carefully studied by Lewis and Levy,[3] and their electrocardiographic features elucidated. It must be noted, however, that all the above-mentioned peculiarities in the behaviour of the animal may be present in a very marked degree without fibrillation occurring, and, on the other hand, an animal may go under the anaesthetic quite readily and quietly, to succumb to fibrillation at a later stage when the anaesthesia has become a light one, and there has been a recommencement or increased administration of chloroform by inhalation, especially (but not necessarily) of strong vapour, or the excitation of afferent impulses by some other cause. The onset of fibrillation is, as a rule, preceded by the development of complex irregularities.

Influence of the Vagus Control.

The relation of tonic vagus control over the heart is very important in this connexion. With normal or increased vagus tone the tendency to irregularity under chloroform is checked and fibrillation prevented.* Sudden diminution or removal of vagus tone, like cessation of (artificial) vagus stimulation, is sometimes associated with the sudden development of fibrillation. In this way variations in the activity of the vagus centre during chloroform administration, under the influence of afferent impulses (for example, operative interference during insufficient anaesthesia), constitute an element of danger in cases where fibrillation is in question. In another way also, under similar conditions, vagus slowing followed by acceleration, causing marked alterations in the blood flow, and usually associated with disturbances of the respiration —temporary arrest followed by rapid exaggerated breathing—has the undesirable effect of interfering with the steady intake of the anaesthetic, and giving effects in some degree resembling those of an intermittent or irregular supply of vapour from without.

It is in such ways that the vagus plays an important part, not in the way of causing a permanent arrest of the heart by reflex inhibition. For the latter view no shred of evidence has been found in our long series of observations; it may be set aside as quite destitute of foundation. Serious depression of cardiac efficiency by continued central stimulation (for example, excitation of the vagus centre by chloroform) has found only very rarely any illustration in our experience; in only one or two cases was much good done by removal of the vagus influence (by section of both vagi). These conclusions apply to animals (cats especially) anaesthetized with chloroform alone, no morphine or other drug being used.

The Acapnia Hypothesis.

The variety of ways in which fibrillation may be provoked under chloroform tempts one to look for some common factor beyond the tolerably obvious condition of increased irritability. The condition of acapnia, depending on an abnormal diminution of the CO_2 of the blood, suggested by Yandell Henderson[2] as a very important factor or the chief factor in chloroform collapse, naturally comes under consideration. But the production of respiratory failure is what he emphasizes, whereas our experience has left no room for doubt that the failure in early chloroform collapse is primarily cardiac. In a series of cats referred to by Henderson there was nothing to show what was happening in the heart at the onset of collapse. We are not able to find anything in the acapnia hypothesis at all adequate to meet the facts observed by us.

Recent Investigations.

The conditions associated with ventricular fibrillation under chloroform have been investigated on an extended scale by Levy[4] in recent years, and with the majority, though not with the whole, of his conclusions as applied to animals our results in this laboratory are in general agreement. The same worker has developed a comparison between the features of early collapse in cats and in man, bringing out a striking similarity in the essential features in both cases.

Experiments on Animals and Anaesthesia in Man.

In attempting to correlate these results of animal experiment with what occurs in the human subject, it must be remembered that the results described above were obtained from animals for the most part healthy, as contrasted with the various morbid conditions present in the human subjects of anaesthesia. On the other hand there is evidence that the proneness of the cardiac muscle to fall into fibrillation is greatly augmented in certain morbid conditions; the influence of disease may tell in one direction or the other, as seen in diseased animals.

The higher nervous organization and mental development of man have often been invoked as considerations in connexion with the action of chloroform, but it is important to note that the fatality of chloroform in the instances under consideration essentially depends on its action on fundamental vital functions of the vascular and respiratory systems, and not on the higher developments of the central nervous system.

Further, it is necessary to bear in mind the extraordinary sensitiveness in this respect—as regards liability to fibrillation under the influence of chloroform—in such an animal as the cat. Unquestionably the susceptibility of the latter is enormously greater than in man, otherwise the death-roll from chloroform would, under certain conditions, be an appalling one, such as would render the use of chloroform prohibitive.

It is to be noted that all the ordinary laboratory animals do not by any means (for example, the rabbit) show the same height of susceptibility as the cat. In the rabbit there may be pretty sudden cardiac failure with enfeeblement and dilatation of the heart, the rhythmic contractions persisting but being very inefficient. Such a form of failure may occur in the cat, but in the light of our evidence it is a rare form in this animal. In view of all the facts one would naturally exercise much caution in applying the results of animal experiments. At the same time there may be a susceptibility to fibrillation in the human heart essentially similar in nature to that present in the cat, though immensely less in degree, and the study of the striking and easily verified phenomena of the cat's heart may afford a clue to the hidden accidents of chloroform anaesthesia in the human heart.

The essential features of fibrillation and the general conditions favouring and determining its occurrence are so strikingly constant in all the warm-blood animals examined that there is no warrant for assuming an exception in man, but, on the contrary, a strong presumption in favour of a broad similarity in the essential nature of its behaviour in man and in mammals and birds.

Further, there is the striking resemblance between the general features antecedent to or associated with early collapse in the cat and in many recorded instances in man —tendency to excitement and struggling, with disturbance of respiration (holding the breath, exaggerated breathing, etc.). There is also a remarkable resemblance between the recorded phenomena of many cases of early collapse seen in man and those observable in the cat.

The conclusion is warranted that ventricular fibrillation is certainly the chief cause of early chloroform collapse in the cat, and is probably a very important cause of early chloroform collapse in man. No other explanation meets the facts so well as regards many such recorded cases in man; indeed, there is no other hypothesis that stands on any secure foundation.

* This is quite a different matter from the question of vagus influence on fibrillation once it has occurred. Vagus stimulation fails to *arrest* fibrillation.

SOME OBSERVATIONS ON BLOOD PRESSURE.

BY

G. SPENCER MELVIN, M.D., and J. R. MURRAY, M.D.

RECENT advances in methods of estimating blood pressure have given a great impetus to the study of the subject. It would seem desirable, therefore, to review the methods now available. A recognition of the importance of a knowledge of diastolic pressure and of pulse pressure has made it essential to consider as methods of blood-pressure estimation only such as permit of the determination of these pressures.

Of such methods two have been prominently advanced, and one, at all events, has been considerably utilized. The two methods are the maximum oscillation method and the auditory method. An extended study of these two methods has enabled us to appreciate the value and

the defects associated with one or other method, and we propose to bring forward such points as determine in our own minds our adherence to one of the methods. In the application of the oscillation method we have made use of two instruments: (*a*) the Erlanger sphygmomanometer, which yields a graphic record, and (*b*) the Pachon sphygmo-oscillometer, in which the oscillations are examined by visual inspection. As index of systolic pressure we adopted that known as the Recklinghausen-Erlanger index—namely, the pressure corresponding to the point at which, with falling external pressure, there is an appreciable increase in the magnitude of the oscillations. With regard to the estimation of diastolic pressure, we have departed from the index suggested and employed by Erlanger. Prolonged investigation with an experimental schema convinced us that diastolic pressure was to be read at a lower level, and from the results brought forward in that experimental study we decided to adopt as the index of diastolic pressure the pressure corresponding with the point on the record at which, with diminishing external pressure, the oscillations showed an appreciable diminution in magnitude.

The indices of systolic and of diastolic pressures with the auditory method are very definite. Systolic pressure is clearly determined by noting the pressure at which the first sound is heard. Diastolic pressure is as clearly indicated by the pressure at the point at which the sound becomes diminished in intensity and duller in character—at the beginning of the fourth phase as it is called. For the present, we will omit discussion of the controversy that has centred round the acceptance of this as the diastolic index.

Our method of study consisted in the concurrent application of these two methods in a large number of cases, and in the correlation of the results obtained from each. Roughly, two classes of individuals were examined—first, a set of healthy young adults of average age 20.9—a series we have nominated as "normals"; and secondly, a series of old people and of patients manifesting pathological conditions of circulation—a class we have nominated as "pathological."

In the "normal" series we examined 59 cases, and in all were able to make some determination of diastolic index from the tracing obtained by the Erlanger apparatus. In 19 cases, that is, 31 per cent., however, there was a discrepancy amounting to 10 or more millimetres between the oscillation and the auditory readings. Yet the average diastolic pressure of these 59 cases differed by the two methods by only 2.3 mm. Were the Erlanger index of diastolic pressure to be taken—that is, the reading corresponding with the last stage at which the oscillations are maximal—then the averages differed by 12.6 mm., with the oscillation reading higher than the auditory. In such cases as there occurred a marked difference between the oscillation and the auditory readings we accepted the latter, and for these reasons: At the systolic level similar differences frequently obtained, but at this point the pressure estimated by the tactile method confirmed the auditory reading. There is thus a suggestion of unreliability imparted to the oscillation method. The teaching of the experimental schema is decidedly in favour of the auditory indications being the more definite. Again, direct experiment on animals, in which the actual pressures obtaining were accurately determined and correlated with the readings concurrently obtained by the auditory method, proved conclusively the accuracy of the auditory method. Moreover, it is recognized that the oscillation magnitude depends on a complexity of conditions liable to great variation. We are thus led to accept as definite the readings obtained by the auditory method. The actual pressures which we regard as the normal pressures may then be given as follows: Systolic pressure normally amounts to 111.8, diastolic to 65.7, and pulse pressure to 46 mm. This estimate of diastolic pressure is decidedly lower than the values commonly given, and the estimate of pulse pressure correspondingly higher.

The average pulse rate was 80.1 per minute, but we failed to establish any definite relationship between the variations in the pulse rate and diastolic pressure level.

Taking the "pathological" series, there is at once apparent a striking difference. In consideration of the abnormal circulatory conditions prevailing, and the consequent influences affecting the changes in transverse diameter and length of the artery with each pulse beat, there is to be expected an instability of the oscillation indications. So it is found. There is frequently great difficulty in making a reading of diastolic pressure from the tracing. There is frequent and serious discordance between readings thus made and the auditory reading. It may happen that the auditory and oscillation readings agree, but it just as frequently happens that they do not. In the latter case we have noted that the auditory reading may be correlated with a definite change in the tracing—a change other than that acceptable as the diastolic index, which itself, as a rule, then lies at a lower level. Again, we have noted the diastolic level indicated by the auditory method unrepresented in the tracing by any change at all distinctive. Here, as before, we accept the auditory indications. As the cases examined in this series yield a collection of pressure values in many varied conditions, there is little value in assessing averages. What we have done is to compare the ranges of variation of the different pressures with the corresponding ranges in the "normal" series. Thus, in the latter diastolic pressures from 82 to 50 were obtained, while in the "pathological" series, values from 150 to 50 were got. Similarly, the range of variation of pulse pressure was respectively in the normal and the pathological series 73 to 22 and 163 to 26. There is thus a much greater range of variation in the pathological series.

This investigation we made, brought out definitely a point of considerable importance in the application of the auditory method. In examining the "normal" series, we were struck by the remarkably low level of pressure to which the sound persisted. As we indicated earlier, this point is one of great moment. It has been suggested that the auditory index of diastolic pressure is the point at which all trace of the sound is lost—the lower limit of sound—the fifth phase. We early found, however, that between the beginning of the fourth phase—the true index, as we believed, of diastolic pressure—and the end of it there lay a wide and varying range of pressure.

We can select out of our 59 cases 14 in which the average duration of the fourth phase was 38.3 mm. The serious problem was that if we were to accept the lower limit of sound as the indication of diastolic pressure, we should have to assign to that pressure a normal value of 42.2, and to admit such incredible values in individual cases as 10, 14, 20, etc. We felt confirmed, therefore, in our acceptance of the fourth phase as the index of diastolic pressure. Further confirmation was obtained by animal experimentation previously referred to. We ascertained conclusively that the actual diastolic pressure within the artery of the animal was faithfully recorded by the distinct alteration in the sound characterizing the onset of the fourth phase, and that abolition of the sound came much later.

Now, duration of the fourth phase, variously estimated, has never been assigned such high values as we have given. It may be that light is shed on this discrepancy by results we ourselves have obtained in other series of investigations. In children, middle-aged and elderly persons in ordinary health, and in persons with thickened arteries, the fourth phase is extremely short; there is usually no serious or, indeed, appreciable error in taking the abolition of the sound as the diastolic reading, for such abolition almost immediately follows the dulling and weakening which constitutes the true diastolic index. It is in young adults that the danger of grave error becomes manifest. It is a curious fact that the occurrence of a long fourth phase should apparently be restricted, or almost restricted, to this period of life. This fact, we say, may explain the discordance between the results that have been obtained by ourselves and by other observers. Highly trained investigators have put the duration of the fourth phase at only a few millimetres, and have naturally regarded the abolition of the sound as being a sufficiently accurate guide. These observers have probably worked mainly with hospital cases and with middle-aged or old persons. It was only when we examined a series of normal young adults that we became impressed with the great variability and frequently long duration of the fourth phase.

We advance its simplicity, accuracy, and applicability as reasons for the adoption of the auditory method as the most satisfactory method of blood-pressure estimation.

VENTRICULAR FIBRILLATION THE CAUSE OF DEATH UNDER CHLOROFORM.

By A. GOODMAN LEVY, M.D., M.R.C.P.,
Physician to Out-patients, City of London Hospital for Diseases of the Chest.

THE latest of the Registrar-General's reports (1911) indicates a total estimated mortality of 243 deaths from chloroform and its mixtures in the year; this entails an incidence of two deaths every three days in England and Wales alone. The problem of the prevention of death under chloroform has evidently remained unsolved up to the present moment.

If in considering this matter I carry you back to the researches of John Snow, it is because the problem has remained largely as he left it, and because he made important observations which have become obscured in the swirl of subsequent controversies. His observations fall under two headings:

(*a*) *Clinical;* he concluded definitely that, in man, death under chloroform was signalized by a stoppage of the heart whilst the respirations were yet unimpaired—an instantaneous event occurring without warning. This conclusion is of the first importance, but it has become slurred over and ultimately lost sight of by subsequent writers; and why? Because up to the present moment no experimental observations have ever been made either by Snow or any one else which afford a satisfactory explanation of it.

(*b*) *Experimental;* he found that by administering chloroform vapour to animals in any concentration up to 6 per cent. for a sufficient period of time the respirations were first depressed and then ceased, and the heart failure, which was gradual and never sudden, was a subsequent event to the respiratory failure. He likewise pointed out that in reported cases of death under chloroform in man, in no case had it occurred in this gradual sequence.

Snow's attempt to investigate the clinical condition of death which he recognized, namely—sudden cardiac syncope—forms the least convincing portion of his experimental work, but briefly his conclusions amount to this—that vapours of 8 to 10 per cent. value may cause sudden stoppage of the heart, but vapours of 6 per cent. and under do not do so, and therefore are not responsible for fatalities. I have already pointed out the fallacy of the few experiments which Snow performed with the higher percentages elsewhere, but they need not detain us, for we now know that vapours of 8 to 10 per cent. value are outside the range of percentages available with the ordinary appliances in clinical use,* and we are therefore driven to conclude that Snow never did, as he is generally credited with doing, provide a satisfactory explanation of death occurring in the course of the administration of chloroform. However, the general result of Snow's researches has been that death under chloroform in man has been ascribed to overdosage, although, with the exception of Embley's work, no subsequent evidence has been adduced to make the position any more satisfactory. The strength of vapour which Snow deemed it advisable not to exceed for clinical purposes was 4 per cent., but deaths continued despite mechanical control of the vapour to this limit. Later on Paul Bert and his school narrowed the limit down to 2 per cent., and this percentage was declared sufficient for all purposes. Bert's teaching was strongly insisted upon by a more recent Committee of the British Medical Association, but deaths still continue and multiply; in fact, the more the limitation of chloroform vapour is insisted upon, the more frequent do chloroform fatalities become.

Later physiological research has mainly centred around the mechanism by which life is suppressed in conditions of deliberate overdosage, but little of outstanding scientific value became added to our knowledge until Embley, working on fresh lines, adduced a fact of some apparent importance. He showed that in dogs a primary cardiac failure might occur resulting from vagal inhibition of the heart as a result of the direct excitation of the vagal centres by an excess of chloroform. Embley, I think, overrated the importance of his discovery, owing to the unrestricted use of morphine in addition to chloroform; a very strong vapour is evidently requisite to produce this reaction in non-morphinized dogs—strong enough, in fact to reduce the blood pressure very rapidly, and evidently stronger than anything employed in ordinary clinical routine. Moreover, Embley neglected to study the effect of artificial respiration in relation to recovery of his inhibited hearts, and this is the more important because there exists evidence of a strong tendency towards spontaneous recovery after inhibition. Furthermore, Embley's theory would account for death during the induction period of anaesthesia alone, for the vagal inhibition does not occur in the later stages of anaesthesia, and it is therefore limited in application.

I have briefly indicated to you the unsatisfactory nature of the theories of death by overdosage, but let me for the purpose of argument admit its *possibility*. What is its *probability?* An answer to this question may be found in a consideration of clinical evidences. In a recent publication[1] I have analysed 93 cases of death under chloroform collected by a committee of the late Medical and Chirurgical Society. In 48 per cent. the patients are described by the committee itself as incompletely anaesthetized at the moment of death. A further 14 per cent. I find, on careful investigation of the original reports, afford perfectly definite evidence of light anaesthesia at the moment of death. In a further 25 per cent. there is perfectly definite evidence that the patients were not being overdosed at the moment of death; in the majority of these latter cases the chloroform had been in fact withdrawn when death occurred, and it would tax the ingenuity of Snow's most ardent apologists to attribute death to overdosage in such cases. In a further 6 per cent. overdosage appears to be improbable, and if the remaining 7 per cent. be open to question, yet there is no direct evidence of overdosage in any single one of them. It is incredible, if overdosage were in fact the common cause of death, that its symptoms should not be unmistakably delineated in at least some one of these 93 reports. We may conclude from these clinical evidences that in at least 87 per cent., and possibly in a much larger proportion of cases, death was not conditioned by overdosage with chloroform.

I will now turn very briefly to the subject-matter of the title of this paper—death under chloroform from ventricular fibrillation. The experimental basis of my theory has already been submitted in various publications; briefly, I have demonstrated that in animals lightly anaesthetized with chloroform the heart responds to sufficiently powerful stimulating influences by exhibiting a series of ventricular extra-systoles, which may on occasion, and on occasion only, culminate in ventricular fibrillation and death. Full clinical anaesthesia depresses the ventricles, and they therefore become immune to fibrillation. The requisite stimulation may be supplied through accelerator nervous influences, originating in subconscious emotions, or as a reflex from powerful sensory excitations. The stimulation may otherwise be a "passive stimulation," such as results when the vagi are cut, or when the depressing influence of the chloroform is removed, or, in other words, when the chloroform is "taken off." Again, it may occur when chloroform is suddenly reapplied after taking it off, and this is probably partly a sensory reflex, partly a direct stimulation of the cardiac muscle—an instance of the early excitory action of chloroform.

When animals die from this form of cardiac syncope the event is startlingly sudden; the respirations are not depressed at the time, and are, in fact, generally exaggerated thereafter as a result of cerebral anaemia; they eventually fail entirely, but may show a pronounced tendency to recovery for a considerable time. When ventricular fibrillation is fully established it is generally fatal; death is the rule and recovery the exception.

Here, then, is an array of experimental facts which explains every clinical condition of death at all stages of anaesthesia conforming to the clinical evidence of death by primary cardiac syncope, and likewise conforming to the clinical evidence that death is not conditioned by overdosage. When once these facts are grasped, the theory of death by overdosage perforce assumes a secondary position, and it remains to be demonstrated by clinical evidences that any deaths ever occur in practice from overdosage, my own impression being that few, if any, are so conditioned. Of course, overdosing is common enough in practice, and, admitting that the overdosed patient, with

* It is difficult to obtain a stronger vapour than ¾ per cent. from an ordinary open fabric mask.

his heart's action and respiration seriously depressed, may be in a critical condition, yet I cannot conceive any qualified medical man guilty of bringing his patients into such a profoundly overdosed condition and delaying restorative measures so long that recovery becomes impossible. For the safe administration of chloroform it is necessary to assuage the *fear of overdose* which has been fostered by extremists, and which has led to the exercise of an excessive caution in its administration. Under such circumstances there may arise a condition favourable to the onset of ventricular fibrillation, and consequent death. Provided that the vapour is administered in *fully sufficient concentration* and that it is administered *continuously*, I hold that there need be no fear of a fatal termination.

The theory of death by overdose has, in my opinion, been a most deplorable one for humanity; it is, I believe, the most unfortunate theory to which physiological science has ever set the impress of currency. I would urge upon those who still continue to lay exaggerated stress upon the risk of death by overdosage that they assume a grave public responsibility in regard to the perpetuation of chloroform fatalities.

THE RÔLE OF CARBOHYDRATE IN NUTRITION.

By E. P. CATHCART, M.D., D.Sc.,
Physiology Department, Glasgow University.

A COMPARATIVELY few years ago it was generally accepted that, provided the diet contained a sufficiency of protein, the fundamental consideration was that the caloric intake be adequate. The question of the relative amounts of carbohydrate and fat was believed to be of little moment, especially after the enunciation of the isodynamic law by Rubner, in which it was stated that carbohydrate and fat were mutually replaceable in a definite proportion, the sole limitation being that imposed by the digestive organs.

No doubt it is true that, to a limited extent, fats and carbohydrates are mutually replaceable in isodynamic amounts, but, at the same time, modern work has demonstrated quite conclusively that the metabolism of these substances is very different. Although the method of assessing the value of a diet solely on its caloric value is of use, provided the diet be a good mixed one, it is futile to use this method alone as the criterion of the value of the diet in question, for it deals only with the energy value of the food, and takes no account of the chemical form in which it is supplied. A minimal amount of carbohydrate and fat respectively may be a vital necessity for the processes of cell life, and, in addition, it may be that the energy supplied in the two cases is not equally or as readily available.

There is no doubt that fats, or lipoids generally, play a most important part in the life of the cells: indeed, it may be said that no cell in the body can exist without the presence of lipoid matter in some form or other, but it has yet not been definitely established that the presence of lipoid material in the diet is absolutely essential, although the balance of evidence (Stepp, Mendel and Osborne) favours the view that lipoids cannot be wholly replaced in a dietary by carbohydrate. The possible synthesis of fat from carbohydrate, however, may permit of the amount of preformed lipoid actually required being reduced to a very small fraction.

When we consider carbohydrate we find, in man at least, that still less of the carbohydrate in a diet can be replaced by fat. The organism demands that there be a constant supply of carbohydrate circulating in the body fluids; even in advanced starvation the glucose content of the blood varies but little from the normal.

That carbohydrate cannot be replaced in a diet by an isodynamic amount of fat has been conclusively proved by feeding experiments both in man and animals, in which the variation in the output of the nitrogenous products has been investigated. Landergren and I have both carried out a series of experiments in which the diet throughout was poor in protein, but at one period consisted almost exclusively of carbohydrate, and at another of fat. The results of these experiments are well seen in the following table:

TABLE I.

Total Nitrogen Output in Grams per Diem.

	Carbohydrate.	Fat.
Landergren	8.91 ; 5.15 ; 4.30 ; 3.76	4.28 ; 8.85 ; 9.64
Cathcart	6.40 ; 4.77 ; 4.79 ; 4.39	4.83 ; 8.13
(Only two days)	8.12 ; 6.65	5.25 ; 9.01 ; 13.30

It will be noted that on the carbohydrate diet there is a steady fall in the output of total nitrogen, whereas when the diet is changed to an exclusively fat one the output of total nitrogen rapidly rises.

Recently Ringer has published a valuable paper on the metabolism in phloridzin diabetes, in which he has shown quite definitely that the hypothesis first advanced by Landergren to explain the rise in the output of total nitrogen on a fat diet, namely, the increased protein catabolism (which is well marked after phloridzin) is the result of the demand of the organism for sugar—the sugar here being supplied, as Lusk and others have shown, by certain of the amino-acids. This increased protein breakdown cannot be inhibited by the administration of fat.

In conjunction with Mr. Lang, I have again investigated this problem, particularly as to the amount of carbohydrate which is necessary to check this destructive action of the fat—that is, the amount of carbohydrate required to inhibit the increased protein catabolism. Mr. Lang acted as the subject of the experiments, in which given amounts of olive oil, which served as the basal ration, were replaced by approximately isodynamic amounts of sugar. In these experiments no protein was present in the diet, which consisted either of the finest olive oil, or olive oil *plus* pure anhydrous glucose. Unfortunately, owing to the highly objectionable nature of the diet, it was found impossible to carry on the experiments with any degree of accuracy longer than three days. The effect on the output of total nitrogen of the addition of comparatively small amounts of sugar to the basal oil ration are clearly seen from the following table:

TABLE II.

323 Grams Oil.*	310 Grams Oil + 30 Grams Glucose.	297 Grams Oil + 60 Grams Glucose.	279 Grams Oil + 100 Grams Glucose.	257 Grams Oil + 150 Grams Glucose.
10.95	9.41	9.78	7.97	10.18
14.35	11.72	9.31	7.95	9.95
14.18	10.23	8.60	7.12	7.37

* A certain amount of muscular work was done during this experiment.

The addition of the carbohydrate had also a very marked effect on the output of certain of the other nitrogenous products, such as creatin and uric acid.

The very marked influence which a fat diet has on the output of acetone, diacetic acid, and β-oxybutyric acid is, of course, well known, and was excellently demonstrated in these experiments, as is shown, for example, in the following protocol:

TABLE III.

320 Grams Olive Oil Daily.

No.	Total Nitrogen, in Grams.	Total Acetone (Acetone and Diacetic Acid), in Grams.	Acetone per Cent. of Total Acetone.	β-oxybutyric Acid, in Grams.
1	14.78*	0.134	28.0	0.411
2	14.96	0.389	17.9	0.626
3	13.51	0.807	11.4	1.273
4	9.51	0.089	—	0.206

* High total nitrogen output, as previous day's diet was very rich in protein (23 grams N.). Lag in nitrogen output also accounts in part for the high nitrogen output on second day.

On the morning of the fourth day a meal, carbohydrate rich but not protein poor, was taken, with the result that there was an immediate fall both in the output of total nitrogen and in the degree of acidosis. In addition to

this, the definite psychical effect of the taking of carbohydrate after the prolonged use of a fat diet was particularly well marked; the subject within an hour or two was bright and cheery, whereas previously he was dull and heavy; at the same time the feeling of physical debility and tiredness disappeared.

There is no doubt, then, that both protein and carbohydrate, and almost certainly fat, are all essential for the physiological functioning of the organism, and that these substances are only replaceable to a limited extent; in isodynamic or any other amount they are not isotamientic —that is, equal sparing. One is apt to overlook the fact that the active material of the body cells, the bioplasm, is a substance of unknown constitution; it is not simply a heterogeneous collection of more or less disintegrated food molecules. Such collections of foodstuffs as we recognize as present in the cell are probably present there as reserves, not as currency, although Hopkins recently has advanced the view that "the integrity of the metabolic life of a liver cell is as much dependent on the coexistence of metaplasmic glycogen, however small in amount, as upon the coexistence of the nuclear material itself." But even this part of the food which is not utilized for structural repair may be divided into securities and currency. The currency is available at any moment, but the securities have to be liquidated—a comparatively slow process—before they can be used. Now, carbohydrate may be regarded as the currency which is readily available, and fat the security, but a security which cannot apparently be so fully liquidated as to take its place as a universal currency.

RECENT EXPERIMENTS BEARING ON THE HISTORY OF SUGAR IN THE ANIMAL BODY.

By J. J. R. MACLEOD,

Western Reserve Medical School, Cleveland, Ohio, U.S.A.

THE problem of the history of carbohydrates in the animal body is at present being attacked with renewed vigour, and this, no doubt, largely because of the very considerable improvements which have recently been made in the methods for the estimation of sugar and glycogen in animal tissues.

Much of this recent work has concerned either the consumption of sugar in the muscles or the glycogenic function of the liver. The work bearing on the former of these problems has in general consisted in observing the behaviour of the reducing power of the nutrient fluid perfused through the surviving mammalian heart or of the blood circulating in eviscerated animals—that is to say, animals in which no sugar can become added to the blood from the liver, etc. Although, so far, the results have been of such an inconstant and uncertain nature that no definite conclusions can be drawn from them, this much is clear—namely, that the conditions which control the consumption of sugar in the muscles are extremely complex, and that to study them we must determine, not only the amount of sugar which disappears in a given time from the perfused nutritive fluid, but also the changes which occur in the carbohydrate (glycogen) that is stored in the tissues themselves.

It is, however, more particularly with regard to the controlling function which the liver exercises on the systemic blood sugar that I desire to deal in the present communication. Since the time of Claude Bernard it has commonly been held that the surplus of dextrose absorbed during digestion into the portal blood is retained as glycogen in the liver, to be subsequently given up to the systemic blood as this requires it to make good the losses due to tissue consumption. Although there is nothing to indicate that this view is not in general correct when the conditions are strictly physiological, yet there has accumulated a large amount of evidence which indicates that under abnormal conditions the stored glycogen may, in part at least, become removed from the liver otherwise than as dextrose.

There are several ways by which such a disappearance of glycogen might be demonstrated. The most satisfactory would be by comparisons under various conditions between the total amounts of dextrose discharged from the hepatic veins into the inferior vena cava and of glycogen meanwhile disappearing from the liver. For technical reasons, however, it has so far been impossible to secure data from which such comparisons can be made. We have accordingly to be satisfied with the much less reliable information which is supplied by comparing changes in the percentage of sugar in the blood and the percentage of glycogen in the liver. It is obviously only when there is a very marked lowering of the percentage of glycogen accompanied by no, or practically no, increase in that of the blood sugar that any conclusions can be drawn from such experiments. In hydrozine and in certain stages of phosphorus poisoning such changes have been conclusively shown to occur. In several other conditions —such as in ether anaesthesia in sugar-fed dogs, and possibly in certain animals after removal of the adrenal glands—there is less conclusive evidence that the same process occurs.

The fact that in such conditions as the above glycogen may disappear from the liver without hyperglycaemia developing leads to the suggestion that even when hyperglycaemia does become established, as in the ordinary forms of experimental diabetes, some of the glycogen may also be converted into other substances than dextrose.

To demonstrate this we cannot, however, depend upon comparisons between changes in the percentage amounts of liver glycogen and blood sugar. We must rather seek in the blood issuing from the liver for the presence of such possible derivatives of glycogen. We have been trying to do this partly by histological and partly by biochemical methods; and, as conditions exhibiting an abnormally rapid breakdown of hepatic glycogen, we have chosen puncture of the fourth ventricle, stimulation of the splanchnic nerve, and temporary obstruction of the blood supply to the liver.

The histological observations in this connexion were first of all made by Ishimori working in Hofmeister's laboratory. Both in his and in our own experiments rabbits have been employed, the liver being removed immediately after death by stunning, fixed in alcohol, and stained by glycogen by the admirable carmine method of Best. At the outset it was shown by numerous controls that after feeding with excess of carbohydrates the hepatic lobule was uniformly crowded with glycogen, and that after starvation it contained only a trace, located in the cells immediately adjacent to the central vein, with, perhaps, a narrow fringe at the periphery of the lobule. After a moderate meal of carbohydrates, a picture intermediate between these two extremes was met with—namely, the central and the peripheral portions of the lobule contained glycogen, but the intermediate areas were quite free of it. It was found that ether anaesthesia for over an hour did not disturb these relationships.

When, on the other hand, the liver was taken from fed rabbits, in which, while under anaesthesia, the greater splanchnic nerve had been stimulated off and on for some time, or on which *piqûre* had been performed, a very different picture was obtained, for it was found that the glycogen had become discharged from the lobule in a very irregular manner, some parts being still tightly packed with it and others empty, but in quite a different manner from that observed after partial starvation. The most remarkable fact of all was made evident by examination under the high power -namely, that masses of carmine-stained material were located in the blood vessels, which we have never observed to be the case in the preparations from normal animals.

As far as can be judged from such observations, it would appear as if the glycogen had been extruded from the liver cells, perhaps not actually as glycogen but at least as some colloidal substance (probably a dextrine). This would explain why we are often unable to detect any increase in blood sugar, although glycogen is rapidly disappearing, for the colloidal material would obviously become precipitated along with the proteins, which must be removed before the reducing power can be determined. This colloidal material will not, however, exist as such in the blood for long, for it will very quickly become hydrolyzed by the very powerful diastatic enzyme therein present, so that it is not surprising that Lepine and his co-workers should have found that under certain conditions there is more free sugar (*sucré actuel*) in blood taken from the carotid artery than in that taken simultaneously from the right ventricle. Although

I think it would be rash to draw any final conclusions from these observations, yet I consider that they offer us much encouragement to prosecute this matter further, not only because of their bearing on the present problem, but because they indicate that it is not necessary for a colloidal substance to become broken down before it can pass through a cell membrane.

The biochemical investigations have been undertaken in order to see whether any of the glycogen that disappears becomes transformed to lactic acid. For this purpose it has been necessary to use dogs, the animals being either decerebrated or kept deeply under ether throughout the experiment, and killed while still under anaesthesia. Blood was collected from the hepatic veins through a cannula inserted in the inferior vena cava, and the amount of lactic acid in it determined by the method of von Fürth and Charnass. To serve as a normal control one sample of blood was removed at the start of the observation, after which some condition known to cause hyperglycaemia was established and other samples of blood removed. The conditions investigated have been stimulation of the splanchnic nerve, general asphyxia, and temporary occlusion of the blood supply to the liver. So far, however, the only one of these conditions which has been found to cause lactic acid as well as dextrose to appear in large amounts in the blood is the last mentioned. In a typical experiment it was found, for example, that the normal percentage of dextrose was 0.128, and of lactic acid 0.043: after applying a clamp to the portal vein and hepatic artery for five minutes, the sugar percentage rose to 0.226 and the lactic acid to 0.057, and these values fifteen minutes later were 0.107 and 0.076 respectively.

The local asphyxia produced in the liver cells by cessation of blood supply was therefore followed by an increased discharge of sugar and lactic acid. In the case of the lactic acid invariably, and in the case of the sugar in nearly all of our experiments, the increase was most marked, not in the blood which escaped immediately after the removal of the clamp, but in that collected fifteen minutes later. We may therefore conclude that the local asphyxia of the liver cells causes sugar and lactic acid to be produced in very excessive quantities; and although in this fact alone there is no warrant for concluding that glycogen is the source, yet from numerous other experiments in which the glycogen has been determined we are almost certain that this is the case.

Experiments by Embden and his collaborators have also shown that when the liver is perfused outside the body lactic acid appears in the perfusion fluid, only provided the liver contains glycogen or the perfusion fluid an excess of dextrose.

We may sum up by saying that the products of glycogen breakdown in the liver may comprise, besides dextrose, some colloidal substance (a dextrine) and lactic acid.

THE INFLUENCE OF EXCESSIVE WATER INGESTION ON THE EXCRETION OF CREATIN AND CREATININ.

BY

DAVID BURNS, M.A., B.Sc., Physiology Department, Glasgow University.

and J. B. ORR, M.A., B.Sc., M.B., Ch.B., Craibstone Nutritional Research Station, Aberdeen.

In 1910 Fowler and Hawk published the results of an experiment that seemed to indicate that creatin exists in muscle in such loose combination that it can be removed without the accompanying total catabolism of the muscle tissue. On the addition of 3 litres of water per day to a creatin-free diet given to a human subject creatin appeared in the urine in quantities up to 0.128 gram of creatin nitrogen per day. They also found a diminution of creatinin during the increased water ingestion.

A research was undertaken, of which the primary object was to investigate the accuracy of these findings. Four normal healthy male adults were obtained as the subjects of experiment. They were put upon a fixed creatin-free diet for several days, until nitrogenous equilibrium was obtained. At that point a given quantity of water was drunk each day for three days, and thereafter the diet was continued without the addition of extra water for three more days. The summary of results obtained are recorded in Table I:

TABLE I.

Experiment No.	Non-water Days.		Water Days.		Extra Water Drunk.
	Creatinin. Average per Day.	Creatin.	Creatinin. Average per Day.	Creatin.	
I	1.406	—	1.366	—	3 litres.
II	1.370	—	1.360	—	,,
IIIA	1.605	—	1.533	—	3.6 litres.
IIIB	1.605	—	1.531	—	,,

There is seen to be a constant decrease in the amount of creatinin excreted on the days of increased water ingestion, which appears to confirm the result obtained by Fowler and Hawk.

After these three experiments were completed, however, certain observations made by one of us in another connexion caused it to be believed that the decrease recorded might be due to an error of analysis arising out of the great increase in the volume of the twenty-four hour samples of urine that occurred on the water days. On these days, on account of the dilution of the creatinin, we were forced to depart from the regular routine mode of analysis adopted on the non-water days. We did so in accordance with the suggestions made by Folin in his original description of the colorimetric method of analysis, where he states that, when the creatinin is in great dilution, 20 c.cm. of urine may be taken for analysis instead of 10 c.cm., or, after development of the colour, dilution may be carried only to 250 c.cm., instead of 500 c.cm.

In Experiment III the former method was adopted, and in Experiments I and II. the latter method. On investigation it was found that both of these deviations are productive of error, giving results which show a less amount of creatinin than is actually present. Thus, 10 c.cm. of urine diluted to 500 c.cm. after development of the colour gave a reading of 10.33, indicating 7.8 mg. of creatinin, while 10 c.cm. of the same urine with dilution carried to 250 c.cm. gave a reading of 5.57, indicating 7.25 mg.—that is, the deviation which we adopted on the water days was capable of showing a decrease of creatinin which is quite fictitious. This is in agreement with observations made by Thomson and others (1913). In Experiment III. as the bulk of the urine was increased about threefold, 30 c.cm. of urine was taken instead of 10 c.cm. This deviation is also productive of error, as the following example shows: 10 c.cm. of urine gave a reading of 8, corresponding to 10.1 mg. of creatinin: 10 c.cm. of the same urine *plus* 10 c.cm. of water, carried through exactly the same process, gave a reading of 8.2, corresponding to 9.9 mg., showing again an apparent decrease which is quite unreal.

We concluded, therefore, that the apparent decrease of creatinin got by us on the water days was entirely due to our method of analysis, and that the corresponding result obtained by Fowler and Hawk was most probably due to a like error.

Two further experiments were therefore conducted. In them the urine was from the first diluted to 5.000 c.cm., this uniform dilution and a rigidly uniform process of analysis being adhered to throughout. Table II gives the results:

TABLE II.

Experiment No.	Non-water Days.		Water Days.		Extra Water Drunk.
	Creatinin.	Creatin.	Creatinin.	Creatin.	
IV	1.324	—	1.319	—	3 litres
V	1.335	0.01	1.362	0.01	,,

In Experiment IV the subject was upon an abnormally low protein diet—namely, 0.27 gram per day. This diet was continued for nine days before the extra water was added. During the period there was a continual excretion

of nitrogen in excess of the intake, indicating a loss of protein tissue. The body weight fell from 67.8 to 65.8 kilos. The creatinin excretion decreased from 1.367 to 1.313 grams per day. The figure given—1.324—is the average for the two days immediately preceding the increased water intake. During the three water days the amounts excreted were 1.330, 1.315, 1,313—an average of 1.319 grams per day. Thus, where there was a constant decrease in the excretion of creatinin, the addition of the extra water almost completely arrested the downward tendency.

In Experiment V the subject was upon a diet with sufficient protein—namely, 0.111 gram per day. There was no loss of weight, and the excretion of creatinin was maintained fairly constant, averaging 1.335 grams daily. On the addition of the extra water the average rose to 1.362. We believe, therefore, that the apparent decrease got by us in Experiments I, II, and III are quite fictitious, and that increased water ingestion, in so far as it exercises any influence on the excretion of creatinin, tends to produce a slight increase.

In Experiment V there is a small amount of creatin excreted both on the water and on the non-water days. On no other occasion throughout the course of the research could any creatin be detected. In Experiments III, IV, and V creatin was tested for by the diacetyl qualitative test described by Walpole (1911). Except in V, as above noted, on no occasion was the reaction positive.

We are forced to conclude, therefore, that increased water ingestion, even up to 9.6 litres per day, has no effect in flushing creatin out of the tissues.

SOME EXPERIMENTAL WORK ON THE ACTION OF ENZYMES.

By E. S. EDIE, M.A., B.Sc.,

Lecturer in Biochemistry, Physiological Department, Aberdeen University.

In the last few years experiments by various workers have gone to show that Ehrlich's side-chain theory can be applied to the action of enzymes. According to this, the action of an enzyme takes place in two stages. The first consists in the union of the enzyme with its substrate, and the second is the specific digestive or hydrolytic action of the enzyme, which is finally set free to attack a fresh quantity of substrate. In such a case the first set of side-chains merely serves as a link between the substrate and the specific hydrolytic part of the enzyme molecule.

Following on this conception, it has been shown by Bearn and Cramer, Bayliss, and various Continental workers that a modified form of the enzyme or "zymoid" can be obtained in which the characteristic action of the enzyme is lost, while the power of combining with the substrate remains. This modification is obtained by heating a solution of the enzyme to a moderate extent. Excess of the zymoid solution, if added to a small quantity of the fresh enzyme, will now inhibit the action of the latter, owing to most of the substrate being combined with the zymoid, which has no longer any digestive action. Heating to a higher temperature may destroy all the active chains, in which case excess of boiled enzyme has no inhibitory effect on the fresh enzyme.

A consideration of the general similarity of the action of pepsin and trypsin on protein led me to the idea that both enzymes might unite with protein by combining with the same side-chains, but that the specific digestive side-chains differ by being active in acid and alkaline solution respectively. If this were so, we might expect that pepsin, however, would be able to unite with protein in an alkaline solution, and trypsin would similarly unite with protein in acid solution, neither enzyme being in such cases able to exert any digestive action on the protein. In the former case the pepsin would act similarly to the zymoid of trypsin, excess of pepsin inhibiting the action of trypsin on protein. Excess of trypsin, on the other hand, might be expected to inhibit the digestion of protein by pepsin in acid solution. Experiments have shown that such is the case. If pepsin is mixed with excess of trypsin, its action on protein in acid solution is inhibited, the amount of inhibition being roughly proportional to the amount of trypsin present. For these experiments boiled fibrin was principally used as the substrate.

This inhibition is not simply due to the presence of a considerable amount of protein attached to the trypsin, as it has also been found that the action of pepsin on a solid protein such as fibrin is not affected by the presence of another protein in solution, such as egg albumen or caseinogen. It might be supposed that the best way to test the truth of such a hypothesis would be to try the effect of excess of boiled trypsin, on the supposition that all power of the trypsin to combine with protein is now lost. As has been shown previously, however, the trypsin molecule is comparatively stable, and will digest fibrin or caseinogen, even after having been boiled under suitable conditions. The side-chains by which trypsin unites with fibrin are still more difficult to destroy than those with which the enzyme digests the protein, and I have in some cases observed trypsin to have a strong zymoid action even after being boiled for several hours.

It is of great importance, however, to test such solutions very carefully. In a number of cases I have found that boiled trypsin inhibits the action of fresh trypsin on fibrin, but not on caseinogen. This would seem to show that trypsin unites with fibrin by means of side-chains which are more thermostable than those with which this enzyme unites with caseinogen.

In this connexion it may be pointed out that Poliak found that treatment of trypsin with acid of a certain strength hardly affected the action of the enzyme on gelatine, while it almost destroyed its action on some other proteins. It was found that the power of trypsin to inhibit the digestion of fibrin by pepsin gradually got less the longer the trypsin was boiled, but I have never found it to disappear altogether.

It was not found satisfactory as a rule to test the effect of trypsin on the digestion of caseinogen by pepsin, this protein being but very slowly digested to the stage at which an appreciable amount of change could be conveniently estimated, such as by precipitating unaltered protein, meta-protein and proteoses by means of tannic acid.

In a manner similar to that described, it was found that excess of pepsin acting in an alkaline solution inhibits the action of trypsin on proteins, the inhibition again being proportional to the amount of pepsin present. In the case of the action of trypsin on fibrin the inhibition is again not due to the enzyme attacking the dissolved protein in association with the pepsin before acting on the solid substrate.

It may be said that both enzymes acting in appropriate solution begin to digest fibrin practically immediately, there being no preliminary interval during which any dissolved protein is first broken down into simpler products. While boiled solutions of pepsin varied considerably in their behaviour, I found in some cases that practically all power to inhibit the action of trypsin was destroyed when the pepsin was boiled for half an hour, but different specimens of the enzyme show great variations in their power to resist destruction by heat. It will be seen from these observations that the usual textbook statement that enzymes are destroyed in solution at a temperature of 70° or 80° C. must be modified. If trypsin solutions can be boiled in presence of acid without being destroyed—and in some cases without any appreciable loss of activity—there seems no inherent reason why other enzymes under suitable conditions should not resist considerably higher temperatures than they are generally supposed to withstand.

A NOTE ON A CONGENITAL ANOMALY OF THE DUODENUM ENCOUNTERED DURING OPERATION.

By SIDNEY BOYD, M.S., F.R.C.S.,

Lecturer on Applied Anatomy, University of London, King's College.

In the following case the patient was a middle-aged woman upon whom the performance of a posterior gastro-jejunostomy was contemplated for gastric ulcer. A paramedian epigastric incision had been made in the

abdominal wall. There was no congenital defect in the stomach and pylorus.

On lifting up the transverse colon and mesocolon to secure the most proximal coil of the jejunum no small intestine could be found in the immediate neighbourhood, and the duodeno-jejunal flexure was conspicuously absent from its usual situation or immediate vicinity. It was therefore decided to trace the duodenum distally from the pylorus. The latter having been picked up, the first stage of the duodenum was found to be normal in all respects, and the proximal part of the second stage also began normally and passed down behind the right extremity of the transverse colon.

From this point, however, the duodenum passed to the right and emerged as a coil of jejunum from under cover of the hepatic flexure, thence passing vertically downwards through the right loin lateral to the ascending colon to the right iliac fossa, where it lay on the lateral side of the caecum. It then passed over the pelvic brim into the pelvis, beyond which point it was not traced. There was thus a complete absence of the third and fourth stages of the duodenum and of the duodeno-jejunal flexure, and an abnormal position of the proximal part of the jejunum. The latter had, however, a well-marked mesentery which allowed it to be brought in a U-shaped manner across the ascending colon to be anastomosed with the posterior surface of the stomach, an opening being made in the transverse mesocolon for this purpose in the usual manner.

In view of the frequent performance of the operation of gastro-jejunostomy, congenital anomalies of this type, although uncommon, are of considerable importance. Variations in the exact form of the duodenum and in the position of the duodeno-jejunal flexure are not uncommon, as pointed out by Thomas Dwight.[1] Such gross defects as I have described are, however, far less often encountered, and can probably be explained by defective rotation of the primitive U-shaped intestinal loop upon its mesenteric axis, which normally brings the duodeno-jejunal flexure into its usual position.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

AN ANOMALOUS CASE OF HETEROPHORIA.

THE following case is a modification of a concomitant internal strabismus, more or less relieved by glasses, and becoming an external squint on fatigue. Occasionally both eyes swing apart momentarily from adduction to abduction and back again. It somewhat resembles three cases published by Maddox and Stirling.[1]

Mr. T., aged 21 years, states that in childhood his right eye deviated outward on fatigue.

When aged 7 years he was ordered by an oculist distant glasses (+2.00 D. sph., near glasses, +2.25 D. sph., with 1.5° prism base in each eye). He wore these irregularly for twelve years, but was never comfortable. On re-examination by an oculist, though seldom replying twice alike to the muscle balance tests, he was ordered six months' rest, and the constant wear of strong prisms base out. In consequence he became prostrate with headaches.

He now, one year later, presents the following features: Vision in the left eye is less acute than in the right (⅔), but with convex glasses (+2.00 D. sph., in the right eye, and +1.50 D. sph., with +0.50 D. cyl. in the left eye) he reads ⅔ with each eye. The right eye converges slightly, and when covered moves slightly outwards for a distant object and markedly so for a near. On covering the left eye usually both are turned conjointly to the right until the right eye fixates, and on uncovering again both return to their original position. But at times, on covering the left eye, it deviates outwards instead. With the plain red glass in front of the right eye marked homonymous diplopia develops, increasing on looking to the left. The left eye gives no diplopia at all. The Maddox rods give a variety of results, usually homonymous diplopia of 11° in the right eye and 2° in the left. But, strange to say, at times crossed diplopia as much as 8° was obtained with the right eye. And, again, occasionally about 2° right hyperphoria was present. Bar reading and other tests revealed total suppression of the image in the right eye. At all times with glasses on, the deviations were less in all directions.

[1] *The Ophthalmoscope*, vol. xi, No. 2. A. W. Stirling and E. E. Maddox.

The condition is perhaps more truly described as one of convergence excess, with exophoria on fatigue, chiefly implicating the right eye. The occasional sudden transit from convergence to divergence, and the occasional hyperphoria are most probably due to prolonged muscle strain and fatigue.

The most satisfactory treatment of such a case, after careful prescription of lenses, is covering the weak eye—in this instance the right—while doing near work. Six months' rest in this way would still allow of desk work, and might then enable one to decide which movement was chiefly at fault, and an attempt to correct by prisms or operation could be more safely made.

Eastbourne. HORATIO MATTHEWS, M.D.

INTRAPERITONEAL RUPTURE OF THE BLADDER.

DR. NORMAN FLOWER'S note in the JOURNAL of August 29th (p. 398) reminds me of a similar case which I had a few weeks ago, in which transperitoneal drainage of the bladder was intentionally adopted. The patient had unfortunately suffered from the condition for three or four days before entering the infirmary, having apparently been drinking, having himself no knowledge of any injury, and having only complained vaguely of abdominal pain. His condition was, as might be expected, desperate, and no operative procedure of any length could possibly have resulted in anything but his death. I found that the tear was entirely intraperitoneal and just big enough to take a large drainage tube. I hastily put one in and another into the pelvis and did nothing more. He died of exhaustion after five or six days, having survived quite long enough to show that as far as the local condition was concerned the method was satisfactory for a desperate case of that sort. He had no abdominal pain after operation and the abdomen was soft and free from tenderness. There was, of course, considerable sepsis, with sloughing of the edges of the wound.

ON

MEDICAL AND SURGICAL PRACTICE IN HOSPITALS AND ASYLUMS.

GENERAL HOSPITAL, COLOMBO.

TETANY FOLLOWING GASTRECTOMY.

(By R. L. SPITTEL, F.R.C.S.Eng.)

THE following is a case in which tetany developed seven days after the performance of a partial gastrectomy combined with a posterior gastro-jejunostomy. The patient was making a good recovery when a severe form of tetany suddenly supervened and carried him off within twenty-four hours of its onset.

A. M., 25, male, a Moor, was admitted on January 28th, 1914, in a nervous and emaciated condition, complaining of pain in the abdomen, vomiting, haematemesis, and progressive emaciation of six months' duration. He also complained of constipation—evidently from the lack of food—and frequency of micturition. The pain was chiefly located at a point in the linea alba about 2 in. above the umbilicus; it was also present around the umbilicus; it came on about five minutes after meals and persisted for about fifteen, at the end of which time he usually obtained relief by vomiting. Latterly vomiting had been a daily occurrence and followed almost every meal. The vomitus always showed either macroscopic or microscopic evidences of blood. He had an inclination for food, but was afraid to eat. There was pain and tenderness over an area in the epigastrium that would be covered by the palm of the hand. In the face of this history and the absence of findings associated with neighbouring organs and of constitutional disease, the diagnosis of chronic gastric ulceration with rapidly progressing obstruction was not difficult.

Operation.

On January 31st morphine gr. ¼ was administered subcutaneously, and half an hour later laparotomy was

performed. It disclosed an extensive indurated ulceration which occupied the pyloric half of the stomach; the lesser curvature and the anterior surface were particularly involved; the organ was puckered to such an extent as to render its cavity barely pervious to the tip of the little finger. Extensive adhesions connected the stomach to the pancreas and the under surface of the liver. A partial gastrectomy was performed combined with a posterior no-loop gastro-jejunostomy, with a 2¼-in. opening. A drainage tube was inserted down to the field of operation, with a gauze packing around it. There were what looked like two miliary tubercles on the under surface of the liver, but none were apparent lower down the intestines or elsewhere. Owing to the extensive adhesions and the puckering of the gastro-hepatic omentum, the operation was tedious and occupied nearly two hours. At its completion the patient was in a state of profound shock, from which he was revived by saline transfusions, the maintenance of the recumbent position with the foot of the bed raised, and other measures. The adoption of the Fowler position shortly after operations of this nature, followed by severe shock, was, I had learnt from previous experience, a likely means of courting disaster.

Microscopically the ulcer proved to be of the simple chronic variety; there was no evidence of carcinomatous change or of tubercle.

After-History.

On the evening of the operation the patient's condition had considerably improved. On the afternoon following the operation, however, he was delirious, restless, and apprehensive of death; he had also torn away the dressings, and was fingering the wound. (This change for the worse was probably due to an incident that afterwards came to my notice—namely, that he had drunk from a jug of water which the attendant had been careless enough to leave within reach of his hand.) He was quietened by injections of morphine and hyoscine. For the next seven days the patient was making a good recovery, except for a slight discharge from the wound, an occasional rise of temperature in the evening, and slight oedema of the feet. By February 6th he was taking 10 oz. of liquid food in twenty-four hours.

At 4 p.m. on February 7th, however, he complained for the first time of a feeling of weakness and of a drawing sensation in the muscles of the right upper arm and chest, which he could not control: his eyeballs showed a tendency to roll under the drooped upper lids. The next morning his temperature was normal, but the symptoms noted the previous evening were distinctly worse, and in addition new symptoms of a grave character were in evidence. There was well-marked trismus from rigidity of the masseters; rigidity of the neck and abdominal muscles was present; the eyeballs kept rolling up under the lids; there were contractures of the muscles of the upper arm and thigh, but contractures of the fingers and toes, so characteristic of tetany, were conspicuous by their absence. The patient was unable to speak or swallow, and respiration was much embarrassed owing to rigidity of the thoracic muscles. The muscular rigidity and contractures persisted with periods of exacerbation from onset until death, which supervened at noon, about twenty hours after the symptoms of tetany were first noticed. A necropsy was not available.

Remarks.

The features of interest in this case were: The rapidity with which the symptoms of tetany developed and progressed to a fatal issue, uninterrupted by intervals of complete relaxation, as far as I could make out. The onset was marked, not by typical contractures of the fingers ("accoucheur's hands"), so characteristic of tetany, but by contractures of the muscles of the shoulder, chest, and thigh. The third degree of tetany of Trousseau was well manifested, the spasms affecting the muscles of the pharynx, tongue, and larynx, and making speech and deglutition impossible. Had it not been for the characteristic rolling of the eyeballs it would have been difficult to distinguish the symptoms from those of true tetanus (especially as the patient had once torn away the dressings in his delirium), in which disease this phenomenon never, to my knowledge, occurs.

The onset of tetany in this case may have been due to feeding disproportionate to the stomach capacity and distension of that organ (proved by necropsis to be a potent cause of tetany), aided, perhaps, by inadequacy of the outlet I had established; but I had taken the precaution to make a 2½-in. gastro-jejunostomy opening. Mayo Robson's view is that gastric tetany is due to absorption of the stagnant contents of the dilated stomach, poisoning nerve centres and thereby increasing reflex irritation. Nearly all reported cases showed that tetany was relieved promptly by a drainage operation, such as gastro-jejunostomy, pyloroplasty, etc. But in this case it followed such an operation, and so it did in a case recently reported by Rodman,[1] where it developed in a young man on whom a gastro-enterostomy with a 2½-in. opening had been performed, and who was saved from death by very copious lavage of the stomach.

I had no recourse to lavage, but exhibited bromides, chloral, and other sedatives per rectum, and subcutaneously, without effecting any amelioration in the symptoms.

Reviews.

WOMEN'S VOLUNTARY AID DETACHMENTS.

IN his *Manual for Women's Voluntary Aid Detachments*[2] Lieutenant-Colonel GABBETT addresses himself to a class of workers whose status is somewhat indeterminate. Their aim is to benefit the Territorial Forces, and though their position in the official arrangements is not well defined, their existence is approved by the authorities, and their help might be, and probably will be, much more utilized in the future. The increased and increasing mobility of modern armies has to a large extent altered the meaning of the term "base," and has so extended its use as to deprive it of much of its original significance. Still, so far as concerns the medical arrangements of all armies, the original idea remains unaltered; it is to get the sick and wounded moved as rapidly as possible from the fighting line to a base hospital sufficiently far in the rear for its patients to be reasonably free from the risk of being made prisoners of war, and equipped and staffed in such fashion that they have every chance of recovery. In the British army, for instance, the sick and wounded, after receiving initial treatment at a field dressing station, are, if not detained in the field ambulance—a purely mobile unit—sent back to a semi-mobile unit known as a "clearing hospital," a few miles in the rear. As soon as they are fit for transport to a considerable distance they are forwarded by ambulance train or otherwise to a stationary or other thoroughly equipped hospital at some temporary or permanent base. In the Territorial Force, however, there is no hospital unit intermediate between the mobile field ambulance and the general or "base" hospital. Presumably the authorities consider that in this country where distances are so short, and towns with well appointed hospitals are so numerous, "clearing" hospitals are superfluous. It is an open question whether this view be well or ill founded, but it is one of the factors that led to the institution of Voluntary Aid Detachments. In the view of their founders these are necessary in order to supplement the work of the field ambulances, furnish and staff improvised clearing hospitals, provide rest stations for convalescents and the slightly injured or ill, and to attend to the seriously sick and wounded during their transport from the front to a general hospital.

So far as the members of women's Voluntary Aid Detachments are concerned, Lieutenant-Colonel Gabbett holds that they should limit their technical duties to providing and working temporary hospitals, acting therein as nurses but being prepared to assist the surgeons at operations, and to do a certain amount of independent first aid work when absolutely required, taking charge of cases of typhoid fever, at all events for a time. He also assumes that all of them will already have been trained in home nursing and first aid. Consequently he limits himself in his manual to a description of the equipment and work of a temporary hospital, and of the fashion in which the members of the detachment should carry out their duties as nurses and surgical assistants, and to

[1] Rodman, *Journal of the American Medical Association*, February 21st, 1914.

[2] *A Manual for Women's Voluntary Aid Detachments.* By Lieutenant-Colonel Gabbett, I.M.S. (ret.). Second edition. 1914. Bristol: John Wright and Son, Ltd. (5×4, pp. 115. 1s. net.)

notes on first aid from the point of view of military surgery, on methods of training women's Voluntary Aid Detachments, and on the sort of equipment with which each member should provide herself with a view to her own comfort when living in improvised quarters. As to the manner in which the author has achieved his task it is possible to express an opinion quite briefly. The booklet is clearly written from end to end, and worth placing in the hands of every member of a woman's Voluntary Aid Detachment, if only for the purpose of convincing her of the greatness of the responsibilities that she and her fellows are called upon to undertake. All statements as to equipment and training are detailed and comprehensive, and those made on the subject of nursing summarize a vast subject with considerable skill.

In regard to the planning of the book, this is excellent so far as it goes, but in a future edition it would be well to include chapters dealing with other duties that these detachments can and should perform; for instance, attending to the needs of convalescents and stragglers, providing hot soup and other suitable food for the wounded on their arrival at railway stations or during detention elsewhere on their way to hospital, as also refreshments for troops conveyed by train, or men on the march. Attention might also be paid in a future edition to the apparent inconsistency of advising that for training purposes the detachments should be divided into three sections, one being a cooking section (p. 100), and yet expressing (p. 20) the opinion that while cooking classes are no doubt useful training, it would be far better to engage professional cooks for the hospital, and reserve the amateur (cooking) skill for emergencies.

Though this view may, perhaps, be perfectly sound it is curious to find it upheld in such a context, for, when all is said and done, it remains somewhat doubtful whether improvised hospitals staffed by amateur nurses can ever be of real value, even if in this country any hospital unit intermediate between the field ambulance and the general hospital be truly required. The more imperfect the tools, the more skilled should be the workers. Still, the number of Voluntary Aid Detachments in existence is very large, and if it be essential that they should include the provision and working of temporary hospitals among their duties, the more thoroughly their members study a book of this order the better for all concerned.

SURGERY.

THERE are not many books on surgery that survive the twenty-fifth anniversary of their first appearance, but there is no indication of any failing vitality in the sixteenth edition of CAIRD and CATHCART's *Surgical Handbook*.[3] The new edition has been revised throughout and considerable additions have been made, but there have been many excisions also, so that on balance the new edition contains only about forty pages more than the old. The most considerable alterations seem to have been made in the chapters on fractures, on anæsthesia, and on spinal caries. In the first of these the method by massage and early movement introduced by the late Lucas-Championnière is recommended. "The operations on recent fractures," the authors say, "require much surgical skill and a thoroughly reliable technique, otherwise bad functional results, amputations, or even deaths are liable to result. This makes it desirable to find a method which is more widely applicable with safety and yet gives satisfactory functional results. Such we believe to be furnished by Lucas-Championnière's massage and movement treatment." After admitting that the method requires more time and attention than that by immobilization, they say:

> In the suitable cases the results amply justify the trouble taken. The principles involved can be grasped, and the manipulations required can be learnt, by any medical man, and he can have the treatment carried out in most cases by some sensible friend or relation of the patient under his direction. In mining or other industrial centres it ought to be quite possible to have persons suitably trained to carry out the treatment under the local doctor's instructions.

Many of the older diagrams used to illustrate earlier editions have been replaced by new ones. The book retains its position as a thoroughly trustworthy guide, and is still in bulk a real handbook.

Of the *Manual of Minor Surgery and Bandaging*,[4] written originally by Christopher Heath as far back as 1851 and subsequently revised and edited by Bilton Pollard, a fifteenth edition, bearing the name of Mr. MORRISTON DAVIES, has been issued this month. It contains over ninety new illustrations, and the whole of the contents have been brought thoroughly into line with existing knowledge and the most advanced technique. Quite rightly the original title of the work has been preserved, but it can no longer be said to convey a full conception of its nature. In effect, the volume is a compendium of all the technical knowledge that should be possessed by a medical man called upon to perform the kind of work that is entrusted to resident surgical officers in institutions where these are given a fairly free hand in the matter of treating casualties and cases requiring operations of the simpler kind. Moreover, the treatment of different points is in most cases thorough: for instance, despite the fact that the author lays it down as a general principle that fractures of the patella should be treated by operation, a detailed and adequate description of their treatment by other methods is supplied. No doubt most of the contents represent what is already more or less familiar knowledge to men of house-surgeon rank, but in view of its comprehensiveness and precision of statement it is likely to be useful to all those about to take up resident posts, as also to those called upon to do work of a corresponding kind without having had the advantage of holding a responsible position in the surgical wards, and to the many who at the present time are called upon to fill positions involving surgical work after long and perhaps exclusive devotion to other branches of medicine.

The book which Dr. J. G. MUMFORD, Lecturer on Surgery in Harvard University, has published on *The Practice of Surgery*[5] is inscribed to his "friends and associates in the Society of Clinical Surgery," and, as might be divined from this dedication, he has assumed throughout the book that the reader has some preliminary training in surgery. He has deliberately assigned the greater part of his space to what may be called everyday surgery. The first part of the volume is on the abdomen, and the first chapter in it is on appendicitis; this is an example of his plan of treating surgical diseases in what he considers to be "their order of interest importance, and frequency so far as this may be done with due regard to a proper sequence." The second part deals with the female organs of generation, the third with the genito-urinary organs, the fourth with the chest, the fifth with the face and neck, and the sixth with the head and spine. Thereafter follow chapters on minor surgery, on shock and the surgery of the circulation, on tumours, on fractures and dislocations, with a brief chapter on orthopædic surgery and a concluding chapter on amputations. The volume contains a large number of illustrations which are clearly drawn and well selected. Taken as a whole, the book is not only very practical, but very personal, and its value as a contribution to surgical literature rests on these two qualities.

MEDICINAL AND DIETETIC PREPARATIONS.

Hedley's Malted Milk.

WE have received for examination a sample of Hedley's Malted Milk, the wholesale agents for which are Messrs. Sanger's, Ltd. (42A, Hampstead Road, London, N.W.). This preparation is in the form of a dry powder, which makes a milky mixture with water. Our analysis showed the sample to contain: Protein (calculated from nitrogen), 12.4 per cent., fat 13.9 per cent. It possessed a considerable diastatic power, rather more than one-fifth of its weight of dry starch being digested in half an hour at the temperature of the body. It appears to possess the qualities of a nutritious food, easy of assimilation.

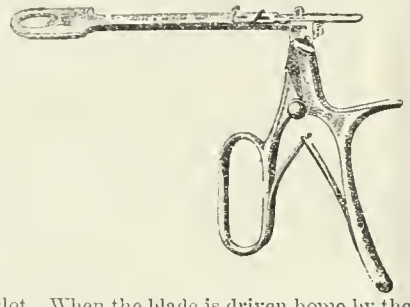
[5] *The Practice of Surgery.* By J. G. Mumford, M.D. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders Co. 1914. (Roy. 8vo, pp. 1052; 681 figures. Cloth, 30s. net.)

MEDICAL AND SURGICAL APPLIANCES.

A Tonsillotome.

MESSRS. MAYER AND MELTZER, of 7, Great Portland Street, W., have made to Dr. T. Muirhead Martin's instructions the tonsillotome for the enucleation of tonsils shown in the accompanying illustration. It is, Dr. Martin (London, N.E.) writes, a modification of that of Ballenger of Chicago, but the handle is at right angles to the shaft, and when the blade is driven home the angle becomes obtuse. Again, the length of the shaft is 15 cm., and keeps the handle clear of the patient's face. The shaft is strong and does not bend when pressure is exerted in raising the tonsil forwards. The ring is thin, having an oval opening, the length of which is 22 mm. and the width thereof 20 mm. The edge of the blade is dull, and is received into a shallow roughened slot. When the blade is driven home by the scissors-like pressure of the right hand, the left hand remains free to manipulate the tonsil well into the ring and to steady it, and so protect the anterior faucial pillar as the blade—which cuts immediately behind the upper surface of the ring—enters between that pillar and the tonsil. The whole instrument can be readily and quickly taken to pieces and boiled.



A Note on Central-eyed Needles.

Mr. PERCIVAL P. COLE, F.R.C.S. (London), writes: I have for some time been using needles with a central eye and pointed at both ends. With the aid of a needle holder—an ordinary pair of Spencer Wells's forceps—any fingering of the needle or thread is easily avoided. The movements of supination and pronation are made use of so that the same grip that pulls the needle through serves to reinsert it. The thread or gut is knotted together at the ends and the first stitch is fixed, not by tying, but by passing the needle through the loop. Thereafter, the suture is continued with a double thread, thus permitting the use of a finer suture than would otherwise be safe. The needles are very handy for stitching the pelvic peritoneum in such operations as hysterectomy, where the ordinary needle is withdrawn at every stitch to allow the grip to be shifted. The needles are made straight and curved, the straight being the more generally useful. With the straight needles an ordinary overstitch, a blanket stitch, a *post-mortem* stitch, or a continuous Connell stitch can be readily and quickly inserted. The curved needles cannot be used for any form of overstitch, but serve for the insertion of continuous mattress or *post-mortem* stitches.

FULL SIZE

The straight needles can be obtained from Messrs. Allen and Hanburys, Limited, 43, Wigmore Street, London, W., and from Messrs. A. Browne of Leicester. The former firm will also be in a position shortly to supply the curved needles of this type.

MOTOR CARS FOR MEDICAL MEN.

TESTING A CAR FOR COLONIAL USE.

By H. MASSAC BUIST.

THE Royal Automobile Club has lately completed a test on novel lines of a colonial Napier chassis of nominal 20 h.p. and 19.6 h.p. according to Government rating, the bore measurement of the four-cylinder engine being 89 mm. and the piston travel 187 mm. In the condition in which we travelled—I made one of the daily stages—the machine weighed very little less than two tons. Starting from London, on the way down to Surrey we quitted the main road to plunge through the river Wey, which was 3½ ft. at its deepest where we crossed it on the day in question. This caused no difficulty, either to ignition or carburation, for all these details are admirably contrived to enable these sort of manœuvres to be accomplished as matters of course. Then we proceeded to Hankley Common, which is a series of hillocks clad in gorse to a depth often above the hub caps.

The point of this part of the test was incidentally that it is impossible in the circumstances to foresee the holes and ruts of the way into which you are dropping. After each passage of the car the thick undergrowth springs back again, so that no trace is left behind to serve as a guide for the next journey over the same route; nor was the way flagged. Therefore we drove only by direction and by total mileage, no two journeyings over the route giving the chassis the same series of shocks. That they were shocks may be judged from the fact that a monocle of one of the passengers was shaken out of its gold rim, in addition to which we lost our caps as we bounced about when the wheels fell into ruts and holes. Yet the axles never once cracked against the frame of the car, therefore, though we had plenty of bouncing, we had no jars and sustained no bruises.

Nor did the car go at the work at a crawling pace. On the contrary, it revealed a very ready acceleration, while the brakes came in for good testing when we suddenly found ourselves coming along the edge of a hill and perceived the land disappear in front of us. The machine made a descent down the heather-clad side in cat-like fashion. The chassis was twisted in all manner of ways, but invariably sprang back on the car passing on to more level ground.

After doing fourteen miles of this each morning and afternoon for four consecutive days, the car was driven an additional four miles over a sand route the loose surface of which was sometimes quite 18 in. deep, while the hard under portion was of exceedingly irregular contour. Only when we got on to the high-road again did we realize how refined a vehicle this is. It was a real test of a practical character, which served to reveal the machine as being capable of withstanding the shock of overseas service in districts where roads are conspicuous chiefly by their absence, and that, in addition, the Napier firm, which is making such a speciality of cars for colonial service, has contrived in most ingenious fashion to embody those particular qualities of refinement which are perhaps the most distinctive feature of the first-class British motor carriage for home service.

TYPHOID FEVER IN CAMPS.

THE EXPERIENCES OF THE UNITED STATES DURING THE WAR WITH SPAIN.

IN 1898, in consequence of the outbreak of war with Spain, commonly called the Cuban war, the United States assembled a large force of volunteers under conditions not very dissimilar to those existing in this country to-day. The camps of the volunteers were very severely visited by typhoid fever. The history and causes of this serious outbreak were fully described and discussed in an elaborate report by a board of medical officers (Mayors Reed, Vaughan, and Shakespeare) appointed on August 18th, 1898.

The full text of the report was not issued immediately, but shortly after it reached this country, in 1905, it was subjected to a very careful and detailed examination for this JOURNAL, and it was shown that a study of the facts and discussions in the report rendered the following inferences obvious.[1]

GENERAL CONCLUSIONS.

In military expeditions, and in any encampments which are to be occupied for a prolonged period, it is of first importance at the outset—or rather, beforehand—to appoint a sufficient number of expert officers to be on the look-out for the first cases of typhoid fever which are sure to occur sooner or later, and for the insidious and abortive cases so liable to escape notice.

In the second place, it is of no less importance to give the medical officers every facility for the separation of such cases from the crowded tents, and for the thorough disinfection of their excreta, bodies, clothing, and tentage.

Without such precautions and provisions all encampments occupied for longer than a few weeks will be liable to disastrous typhoid epidemics.

HISTORY OF THE OUTBREAKS.

From the report it appears that about the end of April or beginning of May, 1898, over 100,000 volunteers had

[1] BRITISH MEDICAL JOURNAL, July 15th, 1905, p. 137.

assembled and encamped in their respective States. After two or three weeks, most of the various regiments were drafted to large national encampments on selected sites in Virginia, Florida, Georgia, Pennsylvania, and Alabama.

It was found that "typhoid fever became epidemic in camps located in the Northern as well as those located in the Southern States."[2]

It was computed that more than one-third of these regiments had cases of typhoid amongst them by the time that they arrived at the national camps; whilst 98.11 per cent. of the regiments developed the disease within eight weeks after their arrival.

In the five months, May to September inclusive, among 107,973 officers and men in ninety-two regiments, 20,738—that is, very nearly one-fifth—are reported to have become infected; and, 1,580—that is, 14.63 per 1,000 of the mean strength—died of the disease.

In arriving at these figures the Board took into account the cases recognized as typhoid fever by the army medical officers, and so recorded in army returns, and also a number nearly equal to those recognized, which the Board was satisfied were really typhoid fever, though appearing in the first returns as diarrhoea, malaria, or fever. Detailed examination of the full report leads to the conviction that the numbers of "probable" cases, as estimated by the Board, were approximately correct, and that about half the cases which occurred were either missed or wrongly diagnosed by the regimental surgeons. No discredit attached to them on this account. The Commission testified to the fact that the medical officers both in the volunteer and in the regular service were men of more than ordinary professional ability, but, "owing to the wise rule that all cases of forty-eight hours' sickness should be sent to the division hospital, the regimental officers had the majority of these cases under observation for so short a time that it was impossible in a large percentage of the cases to make a positive diagnosis."

On account of these and other conditions of camp life, abortive and ambulant cases of typhoid were generally overlooked. Consequently these cases, which were distinctly infective, remained in the camp unseparated from their fellows, with no provision for the disinfection of their excreta, clothing, bedding, etc., and many conveyed the infection to a large number of their comrades before the presence of typhoid was even suspected. Numerous instances of this kind were to be found in the regimental records of the report.

The exhaustive inquiry made by the Board into every case reported sick with any germ of intestinal or febrile disease in forty-eight regiments, numbering 55,829 men, revealed the fact that a marked immunity from typhoid fever was enjoyed by those who had been reported as sick from malaria and transient fever, or diarrhoea, as compared with those who had been exempt from such attacks. These facts indicate that a large proportion of those cases recorded as cases of malaria, transient fever, or diarrhoea must have suffered from attacks of typhoid, slight in character, but sufficient to confer immunity. The importance of these observations and conclusions can hardly be overrated. They plainly show the necessity of providing the means for detecting the abortive and ambulant cases of typhoid in camps if epidemic invasion is to be prevented, and of appointing especially experienced officers for this purpose.

Causes of the Epidemic.

The Board came to the conclusion that "infected water was not an important factor in the spread of the epidemics." The most important conclusions contained in the report were as follows:

Typhoid fever is more likely to become epidemic in camps than in civil life because of the greater difficulty of disposing of the excretions from the human body.

A man infected with typhoid fever may scatter the infection in every latrine in a regiment before the disease is recognized in himself.

Camp pollution was the greatest sin committed by the troops in 1898.

Some commands were unwisely located.

In some instances the space allotted the regiments was inadequate.

Many commands were allowed to remain on one site too long.

Requests for change in location made by medical officers were not always granted.

Superior line officers cannot be held blameless for the insanitary condition of the camps.

Greater authority should be given medical officers in questions relating to the hygiene of camps.

It may be stated in a general way that the number of cases of typhoid fever in the different camps varied with the methods of disposing of the excretions.

The tub system of disposal of faecal matter as practised in the Second Division of the Seventh Army Corps is to be condemned.

The regulation pit system is not a satisfactory method of disposing of faecal matter in permanent camps:

"*In many camps orders were issued requiring each man to cover his faeces as soon as deposited; but we did not inspect the pits of a regiment in which we did not find exposed faecal matter.* Moreover, in our camps in 1898 flies swarmed so numerously that the first droppings of faecal matter were often covered with them before the act of defaecation was completed."

In permanent camps, where water carriage cannot be secured, all faecal matter should be disinfected and then carted away from the camp.

To guard against the contamination of the water supply, troops in the field should be provided with means for the sterilization of water.

Flies undoubtedly served as carriers of the infection.

It is more than likely that men transported infected material on their persons or in their clothing, and thus disseminated the disease.

Typhoid fever, as it developed in the regimental organizations, was characterized by a series of company epidemics, each one having more or less perfectly its own individual characteristics.

It is probable that the infection was disseminated to some extent through the air in the form of dust.

A command badly infected with typhoid fever does not lose the infection by simply changing location.

When a command badly infected with typhoid fever changes its location it carries the specific agent of the disease in the bodies of the men, in their clothing, bedding, and tentage.

Even an ocean voyage does not relieve an infected command of its infection.

After a command becomes badly infected with typhoid fever, change of location, together with thorough disinfection of all clothing, bedding, and tentage, is necessary.

Except in case of the most urgent military necessity one command should not be located upon the site recently vacated by another.

The fact that a command expects to change its location does not justify neglect of proper policing of the ground occupied.

It is desirable that the soldiers' beds should be raised from the ground.

In some of the encampments the tents were too much crowded.

Medical officers should insist that soldiers remove their outer clothing at night when the exigencies of the situation permit.

In military practice typhoid fever is often apparently an intermittent disease.

[Not that the apparent intermissions were afebrile, but that men sick with the disease had periods of improvement so marked that regimental surgeons sometimes returned to duty, probably at the request of the men, those who were suffering from typhoid fever.]

The report was written before the existence of "carriers" of typhoid fever infection was suspected, otherwise the Board might have found in this condition, the reality and relative frequency of which is now so well established, an explanation of the fact that "certain tents were badly infected, and the majority of all their inmates developed the disease, while other tents wholly escaped."

MESSRS. METHUEN announce the immediate publication of *Nursing in War Time*, by M. N. Oxford, author of a *Handbook to Nursing*. The new book will be issued at a shilling.

British Medical Journal.

SATURDAY, SEPTEMBER 19TH, 1914.

THE JOURNAL DURING THE WAR.

On the outbreak of war it was announced that it had been found necessary materially to reduce the number of pages in the weekly issues of the Journal and Supplement. The financial and commercial dislocation produced at the outset made it imperative that the British Medical Association should practise careful economy, and though the position in both respects has improved, it is still very far from normal. The effect of the efforts to develop British trade in new markets is not yet felt, and the supply of paper for printing is at present limited, and its price, therefore, materially higher than before the war. How soon the market will be able to adjust itself to the new conditions cannot be foreseen, and prudence dictates husbanding the resources of the Association. We have no doubt that members will approve the policy which circumstances have compelled the officers of the Association to follow. We have, indeed, gratifying evidence that this is the case in the ready response with which the request made to members desirous of addressing the Journal that they should write as succinctly as possible has generally been met. Every effort will be made to minimize any inconvenience to members, and to enable the Journal to render its customary services in the same way and over the same ground though on a smaller scale. In order that this policy may be successfully carried out we would appeal to all members for their support.

It is hoped that no member will be deterred by the necessary diminution in its size from sending communications to the Journal on matters of medical, surgical, or sanitary importance, more especially such as have a practical bearing on the many difficult problems which the profession must face in preserving the health of the forces now on foot, and in restoring the fighting efficiency of the sick and wounded.

We are able to publish this week four articles dealing in a practical way with matters of vital importance. Professor Saundby discusses the value of open-air hospitals in war-time. After referring to the value now known to attach in civil life to the treatment in open-air wards, not only of consumption and tuberculous bone disease, but also of other disorders of which perhaps septic infection is the most apposite example, he quotes from a circular of the late Surgeon-General Billings the definite statement that the object to be kept in view in the construction of military hospitals is "to furnish shelter without diminishing that supply of pure air and light which is necessary to health." Professor Saundby's suggestions seem to be particularly applicable to the extension of hospitals, whether in the grounds of general hospitals which are placing some of their beds at the disposal of the military authorities, or of the general hospitals of the Territorial Force, which in many cases have been established in colleges and schools, or in other buildings not primarily intended for hospitals.

Professor Sims Woodhead describes in detail a rapid method of testing and sterilizing water supplies which he has proved to be reliable in practice. Not only can it be very quickly applied, but it gives, he finds, trustworthy information as to the absence of members of the *B. coli communis* group, and of such pathogenic organisms as those of typhoid fever and cholera. The method seems to be particularly applicable to any suspicious water supply which may have to be utilized in camps or at small stationary hospitals. In the field the difficulties must be great, but, owing to the speed with which the test can be made, not always insuperable. Further, the test indicates a means of rendering even a highly polluted water safe for drinking, and he outlines a method by which this can be done.

The epigram, attributed to Napoleon, to the effect that an army marches on its belly was more telling in the days before railway trains and motor cars, for now we think of army corps being entrained and detrained, and of supplies of food as well as ammunition being brought up by strategic railways. But during the great march of the German hosts through Belgium to Meaux they had little help from railways for the transport of men, and the British army apparently had none during its retreat from Mons. Both operations show how even under the most modern conditions the rate of movement of an army is dependent on the pace of its foot soldiers, and to how great an extent that pace and the cohesion of the units depend upon the feet of the foot soldier. Therefore a particular interest, even a popular interest, attaches to the very practical paper contributed to the Journal this week by Mr. Basil Hughes of Bradford, who is serving as a medical officer with one of the West Yorkshire regiments. It deals with such commonplace subjects as stomach-ache, diarrhoea, and sore feet, which, however, assume epic proportions when the greatness of the issues they influence is remembered. There must be something peculiarly mortifying to a keen soldier in being rendered useless, and worse than useless, by blisters and excoriations due to want of care in the fitting of boots and inattention to the hygiene of the feet. It was one of Mulvany's early experiences to have a boot gall. "Our docthor, who knew our business as well as his own, he sez to me—in the middle of the Tangi Pass it was—'How often have I tould you that a marchin' man is no stronger than his feet—his feet—his feet,' he sez. 'Now to hospital you go,' he sez, 'for three weeks, an expense to your Quane, an' a nuisance to your counthry. Next time,' sez he, 'perhaps you'll put some av the whiskey you pour down your throat, and some av the tallow you put into your hair, into your socks,' sez he. Faith he was a just man." Mr. Hughes gives some practical directions for the care of the feet, and the method he recommends is more cleanly than the old German plan of rubbing the feet with mutton suet, to which 2 per cent. of salicylic acid was sometimes added. It is stated[1] that the modern German military method is to paint the feet with a 5 per cent. solution of chromic acid, and that formalin has been used extensively with excellent results in the French army, the feet being bathed in a 1 per cent. solution.

We are indebted to the Master of Christ's College, Cambridge, for some notes on insects and war, the first of which—on lice—is published this week. Apart from the risk of the conveyance by these insects of typhus and relapsing fevers, the presence

[1] Norman Walker's *Introduction to Dermatology*.

of lice in the clothing is particularly revolting, and not only interferes with sleep and the comfort of the body, but also with comfort of mind. Dr. Shipley gives a set of rules which he has drawn up, in consultation with Dr. Nuttall, Quick Professor of Biology at Cambridge. Happily, though it may be difficult under service conditions for even the most cleanly wholly to prevent infestation, it must usually be possible to free the garments of vermin, for the methods and materials required are comparatively simple and usually available.

THE EFFICIENCY OF OUR ARMY AS A FIGHTING MACHINE.

In an article published last week attention was drawn to the absolute necessity of taking prompt action to safeguard the health of the Territorial and of the new forces against preventable diseases during this immense campaign. We hope that the medical and sanitary department of our fighting machine may now establish a new reputation in the history British wars. But if this is to come about, the of lessons taught by experience dearly bought in the past must be applied. Sanitary administration in its attempt to prevent such avoidable diseases as typhoid and dysentery, has hitherto invariably broken down in every great war in which the British nations have been engaged. The tens of thousands of our soldiers stricken down by these diseases in the South African war meant even more than that these tens of thousands dropped out of the fighting machine; it meant, in addition, that a large section of the Army Medical Department, and of the hospitals, and the energies of many thousands of men were withdrawn from the real fighting machine to mitigate evils that foresight might have prevented. The chief reason for the breakdown of preventive measures was to be found in the fact that during the early, and in this respect the vitally important, stages of a campaign too little absolute power was given to the medical officers to enable them to carry out with a sufficient staff the absolute essentials of a healthy camp. Military exigencies must not be allowed to dominate medical necessities to the detriment of the value of the army as a fighting machine. Commanding officers have a great responsibility to the country in this matter, and should personally see to it that the medical officers have sufficient authority and means for dealing with the hygiene of camps. It is as essential to act promptly in the field of prevention as it is imperative in another department of professional work to cure by immediate operative interference. The one is to-day recognized to be a truism; the other, unfortunately, is not yet, judging from conditions we have ourselves seen and from opinions that reach us from reliable quarters.

The Army Medical Department is on its trial. Will it come out as triumphantly as did the Japanese Army Medical Department in the Russo-Japanese war, after its reorganization only a few years before the outbreak of that war? We hope so, but cannot feel confident that adequate measures are being taken to ensure this happy result.

As to the reality of the danger, there are no two opinions among experts, but, in order to illustrate the subject by a concrete example, we publish this week (p. 510) a brief analysis of the elaborate report of the special committee appointed to inquire into the causes of the great outbreak of typhoid fever which occurred among the volunteers assembled by the United States military authorities in camps during the Cuban war One-fifth of the volunteers in these camps became infected within five months; it is impossible to suppose that any large proportion of these men were afterwards of any military value, and it is known that 14.63 per 1,000 of the mean strength actually died of the disease. We have quoted textually a number of the conclusions of the commission of inquiry because they seem particularly applicable to the conditions existing to-day in this country where large bodies of volunteers are being enlisted and must be assembled for training. One or two of the commission's conclusions we have ventured to print in italics because they go to the root of the matter, and indicate the means that must be taken to remedy defects in principle which affect the whole organization of the Territorial and the new forces, and the errors in detail which we know exist in some districts.

The responsibility for safeguarding the health of the Territorials and the new troops must be fixed. At present it is not fixed. The War Office, no doubt, recognizes that it has responsibilities at certain stages and in certain directions, but we have, or are shortly to have, somewhere about a million and half men, young or in the prime of life, taken out of civil life and brought under military control. At present many are only nominally under military control, but this stage will soon pass, and the gigantic task the War Office has undertaken must include the organization of an efficient sanitary medical service for the new forces. At present this sanitary medical service does not exist except in embryo. New conditions have arisen and call for new methods. The aid of the local civilian sanitary service is needed, and will, we do not doubt, readily be given, but we hope to see the Local Government Board giving a strong lead.

MEDICAL PROVISION FOR DEPENDANTS OF MEN SERVING WITH THE COLOURS.

The medical profession throughout Great Britain will read with satisfaction the correspondence printed in the SUPPLEMENT for this week setting out the cordial response of the Government to the offer of the profession to give gratuitous medical attendance to the dependants of men called away from their ordinary employment to do military service for the country, and of the pharmacists to co-operate in this great national work. As Mr. Peaso informs the public in his letter to the press, the scheme originated in an offer made by the British Medical Association and the Pharmaceutical Society of Great Britain The Chairman of Council and the Medical Secretary of the Association are issuing, through the Honorary Secretaries of the Divisions, a letter to members of the profession engaged in general practice in Great Britain, and there can be no doubt about the response, for the movement to make this offer was entirely spontaneous and began simultaneously in many widely separated parts of the country. It was evident that careful organization would be necessary if this generous offer was to be utilized to the best advantage and abuses avoided. The Central Committee for the Relief of Distress has set up a special subcommittee, with the Duke of Devonshire as chairman; it contains representatives of the British Medical Association and the Pharmaceutical Society, as well as of the National Insurance Commissioners whose experience it is believed will be helpful in bringing the scheme into operation. The details of the scheme are set out in the letter from Dr. Macdonald and Dr. Cox which is published in the SUPPLEMENT. It will be seen that great care has been taken to make the working of the scheme as simple as possible, and by co-operation with the local committees to obviate abuse. The Executive Committee of the Prince of

Wales's Fund will defray the cost of medicines and appliances supplied in connexion with the scheme, so that it will be available entirely free of cost to those for whose benefit it is intended. Mr. Pease in his letter states that the Government fully recognizes the magnitude of the sacrifice entailed on the two professions and the expenditure of labour involved on the part of their organizations—the British Medical Association and the Pharmaceutical Society.

THE CARE OF THE WOUNDED IN WAR.

To the current number of *Blackwood's Magazine* Major F. A. Symons, M.B., R.A.M.C., contributes an article on the care of the wounded in war, and it will be observed that the arrangements he describes apply to an army which is advancing or stationary. They must immediately become dislocated during a rapid retreat such as that of the British Army from Mons. Taking a division of 18,000 men of all arms as a basis, he says that of this force only about three-fifths will be actually engaged with the enemy, the rest being employed in various non-fighting capacities. Of the 10,000 actually engaged 10 per cent., that is 1,000, must be expected to become casualties. Of that number 20 per cent. will be killed. Of the 800 left to be dealt with, 20 per cent. will be able to walk to the divisional collecting station. There having received what surgical aid they need they will remain till the end of the engagement, when they will return for the remainder of their treatment to their units; 640 are therefore left for admission to hospital; 60 per cent. of the 800 can be carried in the ambulance wagons sitting up; 15 per cent. will require lying-down accommodation; and 5 per cent. will be unfit to be moved from the place where they fell. Each infantry company has two regimental stretcher bearers trained in first aid work, who at the beginning of an action are posted in the rear, under the command of a medical officer. When a soldier is hurt first aid is at once applied by the bearers, and the wounded man is carried to the shelter of a rock, a ditch, or trees that may be near. Each officer and soldier carries in a pocket in the left-hand skirt of the khaki jacket a first field dressing consisting of two bandages and two antiseptic pads in a hermetically sealed cover; one pad is for the aperture of entrance, the other for that of exit. Fractured legs and other serious injuries are treated later when the opportunity occurs, or if the case is very urgent, by means of improvised splints. The wounded having been deposited in their temporary resting places, the bearers continue to advance in the rear of the fighting line. Each of the three brigades in a division is provided with a field ambulance of three sections, each consisting of a bearer and tent subdivision. In action one tent subdivision is usually pushed forward as near the fighting line as seems to be safe, in order to establish a dressing station. From this station the bearer subdivisions, equipped with stretchers and supported by ambulance wagons, set out to search for wounded over a definite part of the fighting zone. In this way the wounded are gathered from an area of perhaps several miles from the regimental aid posts and are conveyed to collecting stations, which consist of groups of ambulance wagons. These wagons, when full, proceed to the dressing station, where, if necessary, wounds are dressed afresh, more elaborate appliances than the first field dressing are used, and urgent minor operations may be performed. The wagons then load up again from the dressing station and proceed to the full tent subdivisions of the field ambulances in the rear, perhaps three miles off, which have tents accommodating 150 wounded and an operating tent. As a field ambulance is essentially a mobile unit which may be required to move forward at any hour with its advancing brigade, the wounded must be taken as rapidly as possible back to the nearest railway. A new mode of evacuating a field ambulance is now being tested for the first time in actual warfare. This is the manner of removing the wounded on the evening of a day of battle from the field ambulances to the clearing hospital of the division. It is established either in tents or suitable buildings and is expected to accommodate 200 patients. Its position is at the nearest rail-head. It has no beds, but is provided with stretchers and a complete equipment of cooking and operating arrangements. What is now being tried is the utilization of the motor lorries of the Army Service Corps which carry the rations for the troops. The clearing hospital, being warned of the hour of departure of the lorries, sends small parties of R.A.M.C. trained orderlies with them. The field ambulances, having also been warned, carry their wounded in their horse wagons to the refilling point, and there load them into the returning empty motor lorries under the care of the clearing hospital staff sent forward. Stretchers and straw are provided, and the lorries can be made nearly as comfortable as a motor ambulance wagon. As these lorries convey food up to a distance of twenty-five miles from the rail-head, it will at once be seen how valuable their speed may be as compared with the old method of horse ambulance transport. From the clearing hospital the wounded are transferred direct to an ambulance train equipped for some 350 cases, and provided with well-appointed berths, a kitchen, food, and a trained nursing staff. It runs between the rail-head and the base, but if the lines of communication are long it may be confined to one section of the line. Stationary hospitals (tented or otherwise), each accommodating 200 cases, are located at suitable places on the line of rail. The base or general hospital is equipped for 520 cases, and possesses a staff of skilled operators, nursing orderlies of the Royal Army Medical Corps, and about forty nursing sisters. Except that it may be under canvas or in improvised buildings, such a hospital is as well appointed as a first-class hospital in England. The patients treated in it either return, cured, to the front or are dispatched in hospital ships to the home hospitals. At certain points along the line of communication there are "advanced dépôts of medical stores," where the various field units can get fresh medical and surgical equipment. The scale of such equipment may be gathered from the fact that an operating tent is provided with a modern operating table, up-to-date utensils, and elaborate sterilizers; and through a hole in the canvas projects a tube carrying acetylene gas from a generator outside, which supplies a great operating lamp. In addition to this organization for treatment, there is a sanitary service, consisting of sanitary sections and squads under skilled sanitary officers of the Royal Army Medical Corps. The value of this modern effort of science to win battles by keeping the fighting men fit, and especially protected against such diseases as enteric fever and cholera, which are more deadly than bullets, cannot be overestimated.

CASUALTIES IN MODERN WAR.

Some idea of the amount of maiming and killing to be expected in the present war may be gained from a recent book by Dr. Octave Laurent, of Brussels, an abstract of which is published in the *Boston Medical and Surgical Journal* of August 20th. Dr. Laurent, writing from experience of the war between Bulgaria and Turkey, says that Bulgaria put into the field in the two wars more than 500,000 men drawn from a population of about 4,300,000. The number killed was 46,000 and of wounded 115,000, giving a total of 161,000, representing one-third of the effective force of the whole army. The proportion of deaths among the wounded was 1 in 4. During July (1913) 150,000 men were killed or wounded on both sides. Taking these figures as a basis of calculation, Dr. Laurent arrived at the estimate that in a war between two first class Powers there would

be not less than 1,500,000 killed and wounded in the course of the first month. The high proportion of the killed to the wounded in the Balkan war is, he thinks, a feature of modern warfare. Shrapnel shells were responsible for more than half the number of deaths, but for less than one-fifth of the wounded. Rifle fire was comparatively ineffective, the wounds made by bullets being small and clean, and healing quickly without complications. This seems to be the general experience of the present war. Another feature which is being repeated is the infrequency of amputation; the percentage in the Balkan war was less than 1 per cent. of all the cases treated in the hospitals. Laurent's statistics show from 82 to 84 per cent. of bullet wounds, from 15 to 17 per cent. of shrapnel wounds, and 1 per cent. of wounds by cold steel. Infection in the course of the projectile was observed in 40 per cent. of cases by shrapnel, and from 10 to 28 per cent. of bullet wounds. The number of wounds cured without any complication was 75 per cent. Shrapnel bullets have a much less penetrative force than rifle bullets, at any rate when the shrapnel does not burst close to the soldier.

LOUVAIN.

THE University of Louvain, which has fallen a sacrifice to the spread of Teutonic culture, was founded in 1425 by Duke John IV of Brabant. In the sixteenth century, when the university was at the height of its fame, it had 6,000 students. One of its most famous teachers, Justus Lipsius (1547–1606), whose statue is one of the few monuments left standing by the Germans, says that if one looked at the town from a neighbouring hill there was hardly a prominent building that was not connected with the university. There were four literary schools known respectively from their insignia as the *paedagogium castri* (fort), *porci* (pig), *lilii* (lily), and *falconis* (falcon). There was also a *Collegium trilingue Buslidianum* founded by Hieronymus Busleiden, who died in 1517; this was specially intended for the teaching of Latin, Greek, and Hebrew. Louvain was in old times, as it is is still—or was till the other day—chiefly celebrated as a school of theology, but for anatomists it had almost a sacred association owing to its connexion with the great name of Andreas Vesalius. The reformer of anatomy was a student in the *paedagogium castri* and also in the *Collegium Buslidianum*, where he gained that knowledge of the ancient tongues which was to prove of such service to him in the scientific controversies of his later life. It was when he was at Louvain that Vesalius secured a human skeleton by climbing the gallows outside the town. He had to convey the bones home secretly, re-entering the town by a different gate from that by which he had gone out, and articulating his stolen treasures in his rooms. He was afterwards spared the work of "resurrection" by the liberality of the burgomaster, who placed abundance of material for dissection and demonstration at his disposal. In 1536 or 1537 he dissected and lectured publicly. He seems, however, not to have been altogether comfortable in the theological atmosphere at Louvain, and some remarks which he made on the seat of the soul excited the suspicions of the heresy hunters. A short history of the early days of the University of Louvain will be found in Hastings Rashdall's *Universities of Europe in the Middle Ages* (vol. ii. part i, Oxford, 1895). The original university was suppressed by the Belgian Government in 1835, but soon afterwards restored as a Catholic institution with four colleges and fully equipped faculties of theology, law, medicine, literature, and science. The total number of students at Louvain in the academic year 1912–13 was 2,855, of whom 324 were foreigners. Among the present medical professors the names of Van Gehuchten the neurologist, Denis the bacteriologist, and E. Masoin the psychiatrist, who is the Dean of the Faculty, are well known. Dr. Noyons, professor of physiology, has recently distinguished himself by his heroic conduct in remaining with his wife among the ruins of Louvain ministering to the wounded—Germans as well as Belgians. The *Times* of September 12th, quoting from a correspondent of the *Nieuwe Rotterdamsche Courant*, says that when the population of Louvain was informed that every inhabitant of the town must leave immediately, in order that the town might be razed to the ground by artillery, Dr. Noyons and his wife decided to remain in order to protect the 150 wounded who could not be removed in time.

POLIOMYELITIS IN LANCASHIRE AND WESTMORLAND.

DURING the summer and autumn of 1913 an epidemic of poliomyelitis occurred in the almost detached part of Lancashire lying to the north-west of the county, and in the neighbouring part of Westmorland. At the end of the year Dr. H. A. Macewen investigated the epidemic on behalf of the Local Government Board, and his report[*] has recently been published. Between the end of March and the beginning of November there were at least 56 cases of the disease, with 11 deaths; there were 30 cases with 9 deaths in Barrow-in-Furness, with a population of some 65,000. The onset of the disease was often described as resembling that of influenza or a bad cold; headache, vomiting, and drowsiness were not rare, and one case was definitely of the abortive type. After investigating the circumstances of the epidemic, Dr. Macewen comes to conclusions that are for the most part negative. Maps of the affected area are given, and show little evidence of any direct continuity of spread of the poliomyelitis. It is true that the cases mainly arranged themselves into four fairly definite, localized, geographical groups, but there is nothing to show that the disease spread from case to case in its neighbourhood. It was apparent that the milk supply could not be the vehicle of infection, nor could the food; most of the victims at Barrow were children under school age, and it was impossible, apparently, to attribute the epidemic in any way to school infection. As for insect bites, there was no reason to suppose that they could have conveyed the virus of poliomyelitis; on the other hand, house-flies, encouraged by the method employed locally for the disposal of house refuse, were very abundant in Barrow during the time of the epidemic. No similar disorder was noted in the domestic animals or pets. A severe outbreak of so-called influenza, however, did occur in the town during the spring of 1913. Consideration of the question of poliomyelitis-carriers showed a few instances in which the patient, or some person coming in contact with the patient, may have transmitted the infection to others. But against all theories of the personal carriage of infection is the striking fact that there was not a single example of multiple cases in the same house in the whole of the 56 instances of poliomyelitis investigated; yet there were 139 persons, brothers and sisters of the patients, only 7 of them aged 18 and over, living in the houses where cases occurred. It seems difficult to reconcile the supposition that the disease had been spread by direct or indirect personal contact with this fact, unless, indeed, it is assumed that the total number of persons susceptible to the virus of poliomyelitis is very limited indeed.

CRAWFORD'S HISTORY OF THE INDIAN MEDICAL SERVICE.

AMONG other untoward consequences of the present war is the postponement of the issue of Crawford's elaborate and exhaustive history of the Indian Medical Service, which was on the eve of publication by Messrs. Thacker and Co. when the war broke out. Lieutenant-Colonel D. G. Crawford, I.M.S.(ret.), has for many years devoted his

[*] Reports to the Local Government Board. N.S., No. 98. London. 1914. Price 8d.

special gifts of laborious research and unflagging industry to this work, which records minutely and systematically the growth of the Indian Medical Service from its earliest beginnings in or about the year 1600 to its full development in 1913—from the employment of medical men singly in East Indiamen and factories to the great organization of the present day. The history displays the increase and progress of the service in relation to the gradual extension of British rule in India, and shows how the members of the Indian Medical Service aided in this great consummation, not only by performing invaluable professional work, but also by fulfilling important offices—military, political, literary, and scientific. It is a monumental work, which will be duly reviewed in this JOURNAL as soon as it is published.

WE regret to have to announce the death, on September 15th, in his 73rd year, of Sir Henry Greenway Howse, Consulting Surgeon to Guy's Hospital, and President of the Royal College of Surgeons of England in 1901–3.

WE have to announce, with sincere regret, the death of Dr. W. H. Gaskell, F.R.S., Lecturer on Physiology in the University of Cambridge. Dr. Gaskell particularly devoted his attention in the early part of his life to the investigation of the visceral nerves, but he afterwards turned his mind to the philosophic discussion of the origin of the vertebrae, on which subject he in 1908 published a work which aroused much attention, and not a little controversy.

THE opening of the winter session, 1914–15, of the Middlesex Hospital Medical School will take place as usual on Thursday, October 1st, at 3 p.m., when an address will be given by Dr. C. Hubert Bond and the prizes for the past year will be distributed by Sir John Bland-Sutton in the museum which forms part of the new Institute of Pathology presented by him. Owing to the war no formal invitations will be issued, but all who are interested in the hospital and medical school are cordially invited to be present. The annual dinner has been postponed.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Health of the Territorials and New Forces.

THE Prime Minister, in moving, on September 10th, for an additional number of land forces not exceeding 500,000 of all ranks, said that the Secretary of State for War had appealed to the County Associations to help in dealing with the great influx of recruits; the number of training centres had been multiplied and was still being increased. The recruits for whom it was impossible to find accommodation for the time being would receive the sum of 3s. per day. Taking the value of what might be called the board and lodging of a soldier receiving 1s. a day when accommodated in barracks at 2s., it was their hope that the men for whom there was no immediate accommodation would not be worse off than if they were actually in barracks. The country would eventually be able to put into the field enrolled as its regular army something like 1,200,000 men; this was exclusive of the Territorials and the National Reserve and of the magnificent contributions promised from India and the Dominions. He desired to make it clear to those who were showing all over the kingdom their patriotic desire to assist their country in one of the most supreme and momentous crises in the whole of its long history, that they should not be treated either in a niggardly or unaccommodating spirit, but that they were going to be welcomed, and every possible provision made for their comfort and well-being, so that under the best possible conditions they might take their place and play their part in the magnificent army which had never shown itself more worthy of the long centuries of splendid traditions than in the past fortnight. In concluding the debate the Under-Secretary of State for War said that all officers in charge of dépôts ought to realize that they had full power to make all arrangements for the comfort of the troops, and that where arrangements had broken down it was the fault of the local officers, who were not able fully to appreciate the situation and the resources at their disposal.

Sir Ivor Herbert on September 15th asked the Under-Secretary of State for War whether his attention had been drawn to the danger to the public health caused by the condition of some of the Territorial camping grounds; and whether he had any statement to make thereon.—Mr. Tennant said: The War Office have been in constant communication with the Local Government Board as to the precautions necessary in connexion with the aggregation of troops, prisoners and refugees in camps and other places, and on August 31st the Board's medical officer sent a circular letter to the medical officers of health of all sanitary districts, inviting them, if there were troops in their districts, to co-operate with the military medical authorities in all sanitary matters connected with the troops. The War Office sent copies of this circular to the General Officers Commanding-in-Chief of all military districts, asking them to do all in their power to maintain thorough sanitary supervision. Inspectors of the Local Government Board are now visiting various districts in which troops are congregated, conferring with the military and civil medical authorities, and reporting to the Board on the arrangements made. There appears to be no evidence at present that the condition of any Territorial camping ground is such as to endanger the public health. If my hon. and gallant friend has such information, perhaps he would communicate it to the War Office. Inspections could thus be made, and we should be glad to make inquiry, and I am assured we shall have the assistance of the Local Government Board in any inquiry we institute.

THE WAR.

PROTECTIVE INOCULATION OF TROOPS.

LETTER FROM SIR WILLIAM LEISHMAN.

WE have received the following important letter from Sir William Leishman:

Sir,—In my letter to you of August 22nd I appealed for the support of the profession in the matter of antityphoid inoculation of the troops and I have abundant evidence of the response, which has been of the greatest assistance to the Army Medical Service.

In some of the letters which have since been published on the subject, both in the medical and the lay press, and also in private communications to myself, there appear, however, some misconceptions which I may take this opportunity of removing.

A considerable number of medical men have offered, in a most generous fashion, to prepare the vaccine, to address the soldiers or to carry out the inoculations in various areas. As far as possible I have replied personally to those who have made such offers, but it may be well to make the actual position more generally known.

1. *Compulsory Inoculation.*

The military authorities have once more definitely pronounced against the inoculation being made compulsory, while renewing their instructions that no effort should be spared to induce the men to come forward.

2. *Preparation of the Vaccine.*

Numerous and most generous offers to prepare vaccine have been received from laboratories and pathologists throughout the kingdom. As mentioned in my earlier letter, the arrangements made by the Vaccine Department of the Royal Army Medical College, with the assistance of the Lister Institute and of Sir Almroth Wright, have assured a supply of vaccine ample for all requirements. If it can be avoided, it is undesirable that vaccines should be used differing, possibly, in constitution and in the method of standardization from that which has proved of such value in the army in recent years.

At the same time, all such offers have been carefully recorded, and we should not hesitate to avail ourselves of them should the need arise.

3. *Distribution of the Vaccine.*

It will be obvious that it is essential from an administrative point of view, and to avoid confusion and overlapping, that all vaccine should be issued from one central place. This has been arranged for, and all vaccine is stored at and issued from the Vaccine Department, Royal Army Medical College, London.

4. *Influencing the Officers and Men.*

All medical officers of the Regular and Territorial Forces were instructed in their duties in this direction within the first few days of mobilization, and were furnished with full information as to the procuring of vaccine and the carrying out of the inoculations. Steps have also been taken through the usual official channels, to keep touch with the progress of inoculation and to see that it is efficiently carried out.

To assist in the work I have myself been directed to visit the various commands, and in the last few weeks have interviewed general officers and the commanding officers of a large number of units, explaining to them the subject, and inviting, in the name of the War Office, the exercise of their personal influence upon the officers and men serving under them. The response has invariably been most cordial, and in most cases has resulted in the prompt inoculation of practically all officers, and in steady progress with the men.

5. *The Carrying Out of the Inoculations.*

This is the duty of the medical officers, and is carried out under the directions of the Assistant Director of Medical Services of the Division. In some instances, however, the local assistance of trained pathologists has been offered and accepted, and I feel sure that such voluntary trained help might be most welcome in other stations where the pressure of routine medical and sanitary work is heavy.

In spite of the absence of compulsory powers, there is good reason to anticipate that the voluntary response will be almost universal.—I am, etc.,

W. B. LEISHMAN,
Colonel, R.A.M.C.

War Office, Sept. 15th.

ORGANIZATION OF ANTITYPHOID INOCULATION.

We are indebted to the senior medical officer of a large camp composed of four battalions of infantry with all their transport, a brigade of the Royal Field Artillery, one ammunition column, Army Service Corps, and the Royal Army Medical Corps, for the following interesting practical account of the method which has been followed in the camp. The details will, we are sure, be of value to other Territorial medical officers.

We started inoculating, he writes, on September 9th and 11th, and by September 13th had done over 1,200 men and officers. The way in which we carry the work out is as follows:

A list of names and regimental numbers of all the men who volunteer for inoculation is prepared on the previous day. The men are advised to take no alcohol for twelve hours before and twenty-four hours after inoculation. The men are paraded, and six of them were admitted into the room at once; a non-commissioned officer, R.A.M.C., is instructed to paint over a small area about one inch below the centre of the left clavicle; the men then sit down on a seat beside a table on which a small sterilizer is kept boiling; three syringes are used; an assistant, not a medical man, puts the syringe and needle into the sterilizer as it is used, and we continue using the same needles until they become blunt; as a rule one needle is good for about fifty or sixty punctures. After inoculation the puncture is sponged and pressed with a small antiseptic pad, and only in very rare cases does any bleeding occur. We find that making the injection in the breast causes much less discomfort and pain to the men; they are all right for duty in about twelve hours, with the exception of a few who may be off duty for two or three days. We give the second dose about ten days afterwards in the right breast.

Working in this way, about seventy to eighty can be done in an hour. The points to observe are:

1. Not to let a large number of men watch other men being done.
2. To do officers first.
3. To try and do all the men in one complete unit at the same time.
4. To advise the men to avoid alcohol before and after inoculation for the periods above stated.

It is much better for each medical officer to do his own men as they have more confidence in him as a rule.

THE RESEARCH DEFENCE SOCIETY.

We are informed that the following letter has been sent to the newspapers by the Research Defence Society:

Sir,—On behalf of the Research Defence Society, which represents the general opinion of all who have studied the facts of antityphoid inoculation, we desire to say that the Society very strongly approves of this treatment for all men and women who are likely in the near future to come in contact with typhoid fever. We have accordingly offered the services of this Society to the Royal Army Medical Corps.

We remain, yours faithfully,

LAMINGTON,
President.

F. M. SANDWITH, M.D., F.R.C.P.,
Honorary Treasurer.

STEPHEN PAGET, F.R.C.S.,
Honorary Secretary.

21, Ladbroke Square, W., September 11th, 1914.

SANITATION OF CAMPS.

THE article on the duty of safeguarding the health of the Territorial and new forces has brought us copies of two handbills issued in the West Riding Division of the Territorial Force which will, we have no doubt, be useful to the medical officers of other divisions who may, perhaps, find in them hints for improving any notices they may themselves have prepared. Dr. Kaye, the divisional sanitary officer who has compiled them, is the chief medical officer of the West Riding of Yorkshire.

WEST RIDING DIVISION—TERRITORIAL FORCE.

URGENT NOTICE!

"A DIRTY CAMP IS A SICKLY CAMP,"

and

OUR ENEMIES are FLIES and GERMS.

THEY ARE KILLED BY:

Cleanliness wherever men are assembled, for example, tents.
Removal and destruction of refuse and filth.
Overflowing urine tubs and uncovered faeces are specially dangerous.
Protection of food from flies, which means their starvation; better still avoid their creation by the absence of filth to nest in.
All latrines, troughs, and urinals should be freely cleansed and disinfected.

Nature's disinfectants are sunshine, fresh air, and clean earth and cost nothing.

REMEMBER!

FEVER FOLLOWS FLIES;
FLIES FOLLOW FILTH;
FILTH FOSTERS FEVER.

J. R. KAYE, Lieut.-Col.,
Div. San. Officer.

WEST RIDING DIVISION TERRITORIAL FORCES.

WANTED IMMEDIATELY:

1. Your doing and acting, not thinking only.
2. Your co-operation, not grumbling.
3. Clean bodies, clean hands, feet, and teeth.
4. Clean tent-floors, and a clean camp surface, not polluted with urine or excrement.
5. Clean food, not fly-poisoned.
6. All refuse and filth rendered harmless by fire, burial, or disinfection.
7. Open tents to let in the sunshine and fresh air, and keep away the doctor.

JAS. ROBT. KAYE, Lieut.-Col.,
Div. San. Officer, W.R. Div. T.F.

THE BRITISH RED CROSS SOCIETY.

The Hon. Arthur Stanley has taken over the duties of Chairman of the Executive Committee of the Society.

The British Unit in Brussels.

The British Red Cross unit in Brussels is now free and will be able to resume work on a larger scale. This unit numbers forty, less the two surgeons taken prisoners. Fears having arisen that small-pox would break out in the camp of refugees at Ostend an urgent application came from Belgium for vaccine and 3,000 tubes were sent immediately, with a large consignment of chloroform and iodine, both of which the Belgians need greatly.

Searching for the "Missing."

Already a party has been sent out to scour the country traversed by the British in their retreat. The object has been to discover and bring aid to any British wounded left behind and so to account, to some extent, for the "missing." The party is well supplied with motor-cars. So great does the importance of this work appear to the Society that another party of surgeons, orderlies and nurses, with motor-cars is being sent on a similar errand.

Nature of Wounds.

A large British Red Cross Hospital is being formed at Rouen, and a party of surgeons, nurses, and dressers have landed at Cherbourg *en route* for service there. The civilian surgeons, who are having their first experience of war surgery, write expressing astonishment at the comparatively light effect of the Germans' rifle fire, and, on the other hand, commenting on the disastrous results of shell fire. It is only fair to say that no case has been reported to the Society of British wounded having been ill-treated in any way by the Germans.

British Prisoners at Brussels.

We stated last week (p. 485) that a surgeon of the British Red Cross Society had been permitted to take the names and home addresses of British prisoners passing through Brussels. Inquiries have reached the Journal on behalf of anxious relatives, and it may be well to repeat what was said last week—that the Society forthwith sent letters to the addresses so obtained. If a letter has not been received, it means that the Society has no information in that particular case.

The Servian Red Cross.

No British Red Cross unit has been sent to Servia, as stated in the lay press. Up to the present no request for Red Cross help has come from Servia.

St. John Ambulance Association Nurses.

We are informed that the St. John Ambulance Association (Foreign Service Department, St. John's Gate, Clerkenwell, E.C.) has heard from various nurses in the last few days that the ninety-two nurses belonging to the association, and sent out to Brussels, are all well. Their letters have been severely censored by the German authorities; but they are working very hard and Brussels is quiet. They have no outside news.

THE RECEPTION OF THE WOUNDED.

Considerable numbers of wounded soldiers continue to be received at Southampton and other channel ports. They are drafted forthwith to various hospitals in all parts of the country, every endeavour being made to send them into districts where they will be amongst friends. Thus far there is ample accommodation at the various institutions which have offered to provide beds. It may be said that all offers have been accepted at the terms on which they were made to the Government; accommodation has been in no sense "commandeered."

The London Territorial General Hospitals.

The four general hospitals for which the Territorial Forces scheme provides in London are situate in the suburbs convenient to the medical staffs, and especially the consulting members. Each hospital is to accommodate about 520 cases, and will not be limited to men of the Territorial Force. When the first batches of wounded arrived in this country the London Territorial General Hospitals were still being brought into existence, as (in three cases) considerable adaptations of buildings not erected for the purpose were required. Consequently the voluntary hospitals were relied upon to deal with the first cases.

1st City of London General Hospital.

Lieutenant-Colonel W. A. Atkinson is in command at this hospital, which is still in process of being installed at St. Gabriel's College, a large modern building overlooking Myatt's Fields, a pleasant County Council park. An elementary school adjoining is also being prepared for convalescent cases, and in the grounds temporary administration offices are being erected. The installation of sanitary arrangements is the most considerable work required to render the buildings suitable for their new purpose. The hospital will not be ready for the reception of patients for some time.

2nd City of London General Hospital.

A description of this hospital, which is located at St. Mark's College, Chelsea, and adjoining buildings, was given in the Supplement of September 5th, p. 165. Patients are now being received. They consist of cases of overstrain and injury during the training of troops in this country, and are drawn from many districts outside London. No epidemic or serious cases have been received nor any from the front.

3rd City of London General Hospital.

The Royal Victoria Patriotic School, on the borders of Wandsworth Common, has been allotted to this hospital. The buildings are old and cover a considerable area. Much alteration of windows was needed to secure adequate light and air, and additional sanitary accommodation had to be provided. There is only room for about half the required number of beds in the main building, but accommodation for over 200 cases is being provided in hut hospitals, for which there is ample space in the extensive grounds. Each hut will contain 20 patients, and there will be separate wards for special cases. The huts are still in course of erection, and outbuildings are being adapted for the purposes of an operating theatre, sterilizing room, *post-mortem* room and mortuary. In the main building the school hall, adjoining the entrance, is to serve as a reception ward, from which patients will be drafted to appropriate wards. Electric lifts and additional sanitary and kitchen accommodation have been installed, and all is ready for the reception of patients so far as the main building is concerned. Some cases of sickness amongst Territorials which would have been received at the hospital in the ordinary course have been sent to the Middlesex Hospital pending the completion of the scheme. At any time now, however, the Commanding Officer, Lieutenant-Colonel H. E. B. Bruce-Porter, expects to receive a number of wounded men from the front.

4th City of London General Hospital.

The fourth of the London Territorial General Hospitals is accommodated in a wing of King's College Hospital, Denmark Hill, S.E., and contains at present a few cases of injury and sickness amongst men in training at various military camps in this country.

Norwich.

The Norfolk and Norwich Hospital.

Within a few days after the declaration of war 100 beds within the hospital walls were at the disposal of the Admiralty. The children's ward was cleared, and the Jenny Lind Children's Hospital took over the children then in hospital, and all convalescents whose condition admitted were discharged. The erection of strong marquees with substantial wooden framework and wooden floors was at once commenced and promptly completed, and the beds fully equipped. Sanitary arrangements in convenient proximity to the marquees were provided, and a small auxiliary kitchen fitted up. These marquees were expected to provide about 75 beds but have been found easily to accommodate more. In addition, should necessity arise, the hospital has a call upon additional tents which can promptly be erected, the hospital grounds being fortunately tolerably spacious. In order to secure smooth

working in the event of a sudden call, one of the marquees has been taken into use and has been occupied by Territorials, of whom above 100 have been treated in the hospital. As yet no wounded men have arrived. It was at first thought that the Admiralty might require 250 beds, but as it is now believed that a much smaller number (about 100) would suffice, the beds released have been offered to the War Office. The transit of wounded from the railway station to the hospital has been undertaken and organized by the local Red Cross association.

SOUTHAMPTON.

A hospital ship with 500 wounded from the front arrived at Southampton on Monday night (September 14th). On the following morning a large contingent was removed to Netley, and 27 cases were taken by hospital train to Cosham and in motor ambulance wagons to the Alexandra Hospital. There are some serious cases from shrapnel fire. One invalid succumbed to his wounds within sight of land. On Wednesday morning 23 British and 14 Germans were admitted into the 5th Southern General Territorial Hospital.

EDINBURGH.

Dental Department at Craigleith.

The military hospital at Craigleith, near Edinburgh, has recently been presented with a completely equipped dental department; for this it is indebted to the generosity of Captain Guy, who is Dean of the Edinburgh Dental Hospital School, and Consulting Dental Surgeon to the Royal Infirmary. A large amount of work has already been done in the department in the conservation of the teeth of the men, and it is proving of special service to soldiers who have been debarred from service on account of bad teeth.

Nurses for the Expeditionary Force.

At a meeting, on September 7th, of the managers of the Edinburgh Royal Infirmary, a letter was read from Queen Alexandra, in which her thanks were sent to the matron of the hospital for the response made to the appeal for nurses who had been selected and sent out to the seat of war.

IRELAND.

An Ambulance Train.

The first ambulance train for Ireland has just been completed by the Great Southern and Western Railway. The train is composed of nine bogie coaches—two passenger carriages and seven parcels vans—taken from the main line and altered to suit the requirements of the War Office. The whole train was finished within nine days after the declaration of war. The main part of the train consists of five wards, each fitted with twenty cots in two tiers. These are converted from the 50-ft. parcel vans, and communicate with a pharmacy car in the centre, also altered from a van, and subdivided into a surgery, pharmacy, linen stores, offices for medical officers, etc., and provided with the necessary receptacles for drugs, bandages, nursing utensils, and requirements. The surgery is lined all round and on the floor with zinc, the corners being well rounded to facilitate cleaning. The various compartments are reached from a corridor, wide enough to accommodate a stretcher. There is a dining car for the medical, nursing, and ambulance staff, lavatory and toilet accommodation being added, and seats fitted of a type suitable for the addition of bedding, thus converting this coach into a sleeping car as required. This vehicle communicates with another coach provided with sleeping accommodation at either end for two doctors and two nurses respectively, the central part of the car comprising a mess-room and pantry, with one compartment of the original coach unchanged, giving sleeping accommodation for two attendants. At the other end of the train a side-corridor coach is attached to the end ward car; it is fitted out as a stores car, and has accommodation for six attendants. Steam heating and electric bells are provided throughout the train, the total length of which, including a 30-ft. guard's van at the rear, is 550 ft.

Training in Emergency Nursing.

The Committee of the Richmond, Whitworth and Hardwicke Hospitals some weeks ago admitted twelve ladies to a special course of preliminary training in hospital work. The results promise to be so good that the committee has decided to elect another twelve candidates out of the very numerous applications they have already received.

Boys' Brigade—Dublin Battalion Ambulance Corps.

At a meeting held last week a large number of past and present members gave in their names for immediate enlistment in the Royal Army Medical Corps and the Military Home Hospitals Reserve; those for the R.A.M.C. are to leave Dublin at once for Aldershot. Those for the Military Home Hospitals are awaiting instructions from the St. John Ambulance Brigade.

British Red Cross Society.

The question of the organization of the Red Cross Society in Ireland has been receiving the attention of the Executive Committee of the Red Cross; and it has been decided that the best method is to proceed by counties as in England. It is hoped each county will form a branch of the Red Cross, which will be in direct communication with the head quarters of the Society in London, as in the case of the English and Scottish branches.

NOTES.

THE OVERSEA DOMINIONS.

EVERYWHERE our Oversea Dominions are organizing help for the Mother Country in her time of trial. This is a striking proof of our success as colonizers, an enterprise in which the Germans, notwithstanding the boasts of von Bernhardi and other prophets of Teutonic predominance, have so conspicuously failed. We are requested to state that the High Commissioners of Canada, Australia, and South Africa view with favour the formation of the Colonial Infantry Battalion, which has been authorized by the War Office and is now proceeding at the White City, Shepherd's Bush entrance. The High Commissioners will co-operate as far as possible, and advise all those men who have at present or have had association with the Overseas Dominions and Colonies, and who have not already enlisted elsewhere, to apply for enrolment in this battalion of Colonial Infantry. Applications in person or by writing should be made to Colonel Arthur du Cros, M.P. The committee which is raising this regiment consists of Colonel Arthur du Cros, M.P., Major J. Norton Griffiths, M.P., Colonel A. Hamersley, M.P., and the Hon. Gideon Murray.

Canada.

In the issue of the JOURNAL of September 12th it was stated that the first Canadian division was mobilizing at Valcartier. Now it is stated that the Government has decided to increase the Canadian oversea expeditionary force by two cavalry divisions. These regiments will be in addition to the cavalry squadron organized to accompany the First Army Division.

Sir William Osler and Mr. Donald Armour have undertaken the organization and equipment of a hospital of fifty beds, with power to increase it to 100 or more beds, for the general use of the King's forces. By special permission of Her Majesty, it is to be known as "The Queen's Canadian Military Hospital," and it has been officially recognized by the War Office. The organization of this hospital is the outcome of an arrangement made by the Canadian War Contingent Association (the Hon. G. H. Perley, M.P., president) with the Army Council, through the Queen's Committee of the Order of St. John of Jerusalem, of which his Royal Highness the Duke of Connaught is Grand Prior. The equipment and maintenance for twelve months of a hospital of 100 beds, and the care and supervision of the sick and wounded during convalescence, will, it is estimated, require about £20,000. Subscriptions should be sent to the Honorary Treasurer of the association, Mr. G. C. Cassels, Bank of Montreal, 47, Threadneedle Street, E.C.

Australia.

Australia is providing additional medical units including ambulances and hospitals for nearly 2,000 patients. Many well-known doctors have volunteered.

BOMBAY.

AT an emergency meeting of the Bombay Medical Union held on August 12th, it was, on the motion of

Dr. K. K. Dadachanji, seconded by Dr. F. N. Kapadia, unanimously resolved as follows:

That in the grave emergency confronting our benign Government, the members of the Bombay Medical Union do hereby respectfully offer their professional services, whenever required, either in the military or civil capacity. The Union has no doubt that the whole profession will co-operate in this movement in order to raise a sufficiently large corps of Medical Volunteers.

That a Provisional Bombay Medical Volunteers Register be opened at the Union Rooms to enlist the names of all professional members desiring to join it, and to that end an Urgent Notice be sent to every member of the local profession.

That the Managing Committee of the Bombay Medical Union should for this purpose act as a Special Medical Volunteer Committee with power to add to its numbers, and it should undertake efficient organization of the Volunteers Corps, prepared for any emergency at a short notice.

That the Special Committee should communicate and co-operate with the Committee of the Indian Field Hospital, being raised by our local philanthropists.

In accordance with these decisions the joint honorary secretaries, Dr. D. M. Gagrat and Dr. K. K. Dadachanji issued a reply postcard to medical practitioners in Bombay inviting them to state whether they were willing to place their names on the roll of the provisional Bombay medical volunteers.

Medical Examination of Recruits.

We have received from a medical examiner of recruits for the regular army in the south-east of England the following statement of the results of the examination of 514 applicants:

Number of candidates examined from August 31st to September 12th inclusive	514
Rejected	113
Causes of Rejection:	
1. Defects of vision	23
2. Deficient chest expansion	25
3. Weight below 8 st.	25
4. Rupture	5
5. Hydrocele	2
6. Heart disease	8
7. Otorrhœa or deafness	4
8. Impediment of speech	2
9. Height below 5 ft. 3 in.	6
10. Lateral curvature	2
11. Skin eruption	2
12. Loose internal semilunar cartilage ...	1
13. Age under 18 or over 35	3

Out of 401 passed, 250 had vision right $\frac{6}{6}$, left $\frac{6}{9}$.

The condition of the teeth was not allowed to disqualify so long as nutrition appeared to be good. Similarly, varicocele did not disqualify unless very pronounced.

We are informed that scandalous rumours have recently been in circulation reflecting upon the manner in which some doctors are alleged to have treated the recruits who submit themselves to medical examination. We are confident that these rumours are without foundation, and that medical examiners of recruits who are compelled to reject candidates on medical grounds do so with discreet tactfulness.

Care of the Feet.

The British Red Cross Society has issued a leaflet giving directions for the prevention and treatment of sore feet in troops. There has been already a good deal of invaliding from the expeditionary force from this cause, and unless special care is taken it is to be feared that a still larger proportion of cases of sore feet will occur among the Territorials and the force now newly raised.

Sore Feet.

1. Feet should be washed with soap and water, and very gently dried—not rubbed.
2. Dab with methylated spirit on cotton wool, except where the skin is broken.
3. When dry, dust with powder composed of equal parts of starch and boracic powder or Fuller's earth.
4. Bandage with clean bandage, preferably of domette, not too tight—or else put on clean socks. All dirty socks should be washed and dried before use.
5. Reddened skin or *recent* blisters should be protected by strips of strapping.
6. All corns should be protected by strapping. Open sores require surgical advice, and this should be sought whenever possible, especially if the surrounding redness of the foot is extending.
7. Toenails should be cut short.
8. Hard boots should be well greased—mutton fat is the best. They should be well dusted inside with starch and boracic powder.

Proposed Cholera Corps.

Applications have been received to date from 17 doctors, 42 nurses, and 3 cooks for service with the proposed Cholera Corps offered to the Russian and British Red Cross societies. It is intended, in order to diminish expenses, that units of one doctor and two nurses, or multiples of such units, shall be sent out as required rather than that the corps should be embodied as a whole. We are informed that no reply has been received from either the Russian or the British society to date, although cholera may be expected in Russia at this season.

Further Casualties in the Medical Service.

Army.

Killed.

Fraser, T. P., M.B., West African Medical Staff. (In Cameroon.)

Wounded.

Painton, Captain G. R., R.A.M.C.

Missing.

Rankin, Lieutenant H. C. D., R.A.M.C.

Captain T. W. Browne, R.A.M.C., is reported missing, and not Captain G. H. J. Brown, R.A.M.C., as previously announced.

Prisoner of War.

Information has been received that Major P. H. Collingwood, R.A.M.C., reported missing in the list issued on September 3rd, was alive and well, but a prisoner of war on August 31st.

Ireland.

Memorial Window to a Doctor in Belfast.

At the morning service of Sunday, September 6th, at St. Jude's Church, Belfast, a handsome window, erected by a brother to the memories of the late Dr. William Baird McQuitty, M.A., of his brother, the late Mr. George H. McQuitty, and of his sister, the late Miss E. S. McQuitty, was dedicated by the Lord Bishop of Down (Right Rev. Dr. D'Arcy). All three had been members of the congregation; Mr. G. H. McQuitty had been honorary organist, and his place was often taken by Dr. McQuitty, who amongst his manifold accomplishments was a musician of a high class order. The memorial is in the form of a three-light window; the central figure is that of St. Luke, to the right is the figure of Dorcas, and the left that of David carrying a harp, types of the aims and virtues of the sister and two brothers. The colouring is rich; the general treatment of the ornamental portion is in delicately painted grisaille pattern, based upon examples in the church of St. Serge, Angers, and in Salisbury Cathedral. The bishop referred in glowing terms to the characters of the three whose memory will thus be kept green by the affection of a brother, and spoke of Dr. McQuitty's eminence as a physician and of his high personal qualities.

Dublin Water Supply.

The supply of water in the reservoir at Roundwood is now 13.8 ft. below the level of the sill, the average diminution for the past few weeks being 1½ in. a day, and the average daily consumption 12,396,000 gallons. Every effort is being made to reduce the daily consumption; about forty inspectors are employed with this object, but their efforts have so far not been very successful, and the Waterworks Committee have been obliged to give notice that they can no longer permit the use of Vartry water through hoses for garden purposes or for washing house or shop fronts, and that automatic flushing cisterns must be dispensed with. The committee deny that there is a leakage in the reservoir, as rumour had suggested.

India.

[FROM OUR SPECIAL CORRESPONDENTS.]

Opposition to Antimalarial Campaign.

The difficulties the municipal and sanitary authorities have to face in their efforts to bring about a healthy populace in Bombay are well demonstrated in the campaign against malaria, says the *Advocate of India*. A large number of wells and tanks have been condemned by the Malaria Department of the Bombay Municipality as breeding places for mosquito larvae, and they have been either filled up entirely or else covered over, and many more are about to be dealt with similarly. These are the most elementary precautions advocated by all medical experts, for the wells are prolific breeding grounds for the dreaded *Anopheles stephensi*. But it would not be Bombay if someone did not raise a protest; therefore we learn that discontent has been caused amongst certain of the Indian communities in the city owing to this action, as there are persons amongst Hindu and Parsi communities who hold strong views against using water from the municipal main in connexion with certain religious ceremonies on religious grounds. The malcontents also hold that the action of the municipal authorities is fraught with danger to the populace, as they say they would be forced to go without water in case of sudden breakage to the municipal water main. With a view to giving the grumblers an opportunity of expressing their feelings of resentment, and possibly to obtain redress from the municipality, the Indian Piece Goods Merchants' Association of Bombay has resolved to convene a meeting of the citizens of Bombay, and has appointed a committee to arrange the preliminaries.

Mosquitos in the Nilgiri Hills.

The prevalence of mosquitos in the Nilgiri has been for some time past the cause of complaint of the residents of and visitors to the hills. In Wellington the mosquitos have increased very much recently, and it is stated that the services of an expert have been requisitioned to investigate the matter. In Ootacamund there were no mosquitos years ago, but nowadays complaints have become too frequent. This year in particular, it is said, the mosquitos are increasing. It is stated that the lake in "Ooty" is the breeding place.

Women's Medical Service.

Miss E. C. Houlten, M.B.Lond., of the Tropical School of Medicine, has been appointed a member of the Women's Medical Service of India, with effect from July 1st. Dr. Houlten has been posted to the United Provinces, but will officiate in the Ripon Hospital vice Miss George on leave.

Civil Surgeons in Bengal and Assam.

A scheme has been sanctioned for the amalgamation of the cadres of civil surgeons of Bengal and Assam upon lines designed to safeguard the interests of the officers of both provinces. It has been decided that medical officers belonging to Bengal before the redistribution will not be liable to transfer to Assam; also that Assam officers will not be posted to Bengal until they have put in five years' service in their own province.

The Health of the New Capital.

The Health Officer of Delhi, Major Cook-Young, I.M.S., has just published his annual report. In a preliminary survey of the situation he refers to the passage in the previous year's report wherein he detailed in advance the good results that were hoped for from the prosecution of the vigorous campaign then inaugurated. A study of the succeeding pages leaves no doubt that Major Cook-Young's trust was not misplaced, revealing, as they do, solid progress in several directions. We find that "during the year small-pox was little in evidence." "There was very little cholera; . . . what cases there were were all imported." "The deaths from plague were only five, compared with twenty in the previous year. These cases were all imported, so that Delhi may be said to have been free from the disease during the year." "Only five cases of enteric were reported, with one death." Towards the close of the year came an outbreak of relapsing fever, but it was of a mild nature, and "no deaths were reported from this cause." The decreased mortality at Delhi from small-pox was considerable—111 deaths, against 44 in 1912. The disease was most prevalent in April and May. Of the cases treated in hospital 51 were cured and 4 died. Cholera deaths dropped from 103 in the previous year to 26, the first case being imported from Lucknow. The extremely low mortality from plague—5 deaths, 8 cases treated—is apparently due to the ruthless campaign conducted against rats in the city. That campaign was no doubt successful, because as the report says, "the destruction of rats goes on permanently." Although Delhi escaped lightly as regards small-pox, cholera and plague, there is, of course, a darker side to the picture. From April up to the middle of August the rate of mortality in the city was unduly high, largely owing to the ravages of malaria. Every effort is being made to combat the disease, particular attention being directed to the numerous wells within the city's confines. The danger of open wells in houses and compounds was explained to the people, who were urged to cover their wells with wood or cement, and to provide mosquito-proof wire gauze trap-doors, while a large number of wells were filled in or hermetically sealed. The main difficulty lies in dealing with the wells in houses, the people preferring well water to tap water, it being cooler to drink, a consideration that appeals with some weight to all in the hot weather.

It is when we come to that part of the report dealing with pulmonary diseases that the worst state of Delhi is revealed. Deaths from pneumonia are given as 209, but the real total is known to be very much higher; while phthisis is still more virulent. Major Cook-Young says there is conclusive evidence of the prevalence of tubercle in Delhi, which in certain quarters of the city is very marked. Everything, he points out, is on the side of the disease—the ignorance of the people, their disregard of advice, the congestion in certain areas, and the lack of arrangements for medical assistance. The control of tubercle presents a serious problem demanding immediate attention.

During the year under review, however, notwithstanding all the acknowledged defects, the death-rate dropped by 5.47 per mille, representing 921 lives saved. This is a good augury for the future, and, with plenty of money to spend, further substantial progress may be confidently expected.

The League of Mercy.

His Serene Highness Prince Alexander of Teck has sanctioned the formation of an Indian Branch of the League of Mercy. The Hon. Colonel Sir Henry MacMahon, G.C.V.O., K.C.I.E., C.S.I., is President, the Hon. Sir Henry Burt, K.C.I.E., is Chairman, and Major R. J. Blackham, C.I.E., V.H.S., is the Honorary Secretary of the new branch.

Special Correspondence.

BUDAPEST.

Decision of Hungarian Insurance Companies with regard to Fees for Medical Examinations.—University Statistics in Hungary.—Work of the Red Cross Society in Hungary.

Hungarian doctors have at last triumphed in their protracted struggle with the insurance companies to obtain higher fees for medical examinations. The dispute over these fees, which have not varied for the last eighty years, has raged since last September; and the success of the doctors is testified by the following regulations which have been laid down for their future guidance and protection: (1) The fee for a medical examination and certificate will in future be 10 crowns for all persons insured for a sum not exceeding 5,000 crowns, and 20 crowns for those insured for sums exceeding that amount. No extra fee can be demanded for examination of the urine, which is included in the general examination. (2) The minimum fee for a medical examination and certificate in the case of accidents is 4 crowns (about 4s.) (3) In

cases where a doctor is called upon to examine a candidate living at a distance exceeding 2 kilometres (about 1 mile) he is entitled to claim either the actual means of transit or the corresponding fare. If a carriage be provided, it should be one that is in every way suitable for the rank and position of the doctor, whilst if an equivalent in money be offered it should cover the usual charges for a first-class carriage. (4) Should the prospective policyholder live at a distance exceeding 2 miles, the doctor is entitled to claim compensation (at the rate of 50 hellers, or 5d. per kilometre) for the loss of time involved in the journey as well as the actual cost of the journey itself. (5) The insurance companies are responsible both for fees and compensation in cases where no examination is made, if this omission be due to no fault of the doctor.

According to the latest official bulletin issued, the total number of students in Hungary during the last session amounted to 13,210. Of this number, 11,908 matriculated at Budapest and the remainder in Kolozvár. The Budapest students comprised 3,492 students of law, 3,054 of medicine, and 559 students of philosophy: and in this connexion it is interesting to note that the number of medical students in Hungary has increased enormously during the last decade. Whereas in 1903 there were about 1,200, this number had risen six years later to 2,500, and in 1913 it reached 3,054. This great influx of students is giving rise to serious inconvenience in the medical schools, since few of them are capable of accommodating more than 200 or 250 students, and they are now called upon to provide room for more than double that number.

The Hungarian Red Cross Society, whose aim has always been to keep itself in constant readiness to take the field, issued shortly before war broke out a circular in which it was stated that in the event of war Hungary would probably find herself responsible for 100,000 wounded and 250,000 sick soldiers, many of whom would be Hungarian subjects. The circular further stated that it had been estimated that, in addition to those of the military nurses, the services of some 7,000 civilian nurses would be required to meet this sudden demand; and since the number exceeded the total number of trained nurses throughout the whole of Hungary, it was obvious that it could not be recruited from the ranks of the nursing profession alone. Even when the country was at war the work in the general hospitals would have to be carried on as usual, and if, as was quite likely, an epidemic broke out, would become considerably heavier; it was therefore a matter of necessity to obtain the assistance and co-operation of all women who were willing to offer their services as nurses in time of war. The response to this appeal was both prompt and gratifying. In almost every town in Hungary courses of lectures were at once organized, and held in the wards of the local hospitals, and at the conclusion of each course the candidates were examined in the presence of a delegate of the Red Cross Society and other civil and military authorities.

Correspondence.

UNQUALIFIED LOCUMTENENTS.

Sir,—At a meeting of the Executive Committee held to-day the President made a statement in regard to certain correspondence received by the Registrar respecting unqualified locumtenents and kindred matters, and the steps that had been taken in regard thereto.

He read the following letter, which had been sent to the practitioners concerned, which the Committee approved and directed to be entered in the minutes:

> "Sir,—With reference to your letter of , I am directed by the President of the General Medical Council to inform you that, in terms of the enclosed Warning Notice, any registered practitioner who entrusts his professional practice to an unqualified person or who signs medical certificates on such person's behalf, renders himself liable to be summoned before the Council, and after due enquiry to be adjudged guilty of grave professional misconduct.
>
> "The circumstances of the present situation do not, in the President's opinion, afford any excuse for action which the Council has described as 'fraudulent and dangerous to the public health.'
>
> "Means are available whereby the services of registered practitioners can be obtained in substitution of those of practitioners who may be called away from civil practice on military service: and it is the plain duty of the latter to make arrangements for the proper professional treatment of their ordinary patients during their absence.
>
> "I am to add that copies of your letter, and of this reply, will be laid before the Council should occasion arise for a judicial inquiry into the matter.—I am, etc.....Registrar."

—I am, etc., A. J. Cockington.
Acting Registrar.

General Council of Medical Education and Registration of the United Kingdom, 299, Oxford Street, London, W., September 15th.

INFECTION OF CHILDREN WITH THE BOVINE TUBERCLE BACILLUS.

Sir,—My experience of seventeen years' practice in the Straits Settlements goes to support the view of Dr. Lassablière expressed in his letter, which appeared in the British Medical Journal of July 11th, p. 96. Fully 95 per cent. of Straits-born Chinese babies are fed on condensed milk imported from Europe, and tuberculous peritonitis, bone and joint disease, adenitis, and meningitis are very rare indeed amongst them. This is all the more interesting in view of the fact that in adults of the same race phthisis is one of the greatest causes of mortality. They have not yet realized the danger of contagion from phthisical patients, so that no steps are taken to diminish the risk. A Chinaman suffering from phthisis expectorates freely anywhere in his house, and it is no unusual thing to find one sleeping in a room all the windows of which are tightly closed, and under a thick mosquito curtain, along with one or more children, who are thus placed under the best conditions for infection.

If tuberculous peritonitis, bone and joint disease, adenitis, and meningitis were due to infections with the human tubercle bacillus, it is certain that these diseases would be very common, so that their rarity would point to their being due to the bovine tubercle bacillus, which is presumably destroyed in the process of manufacture of the condensed milk.—I am, etc.,

T. Hill Jamieson, M.D., D.T.M.H.Edin.

Penang, S.S., Aug. 14th.

SECRET REMEDIES AND PHARMACY LAW AMENDMENT.

Sir,—Your article under this heading will fill with dismay if not disgust the minds of those who have been working in this question for many years. The article will befog a mass of practitioners who look to the Journal for enlightenment: it will puzzle the lay reader, it will put heart into the world of quackery, and will encourage the mass of newspapers that from high to low divide among them more than £2,000,000 annually from advertisements to the character of which they are fully alive. The Report, when dealing with the press, suggests "that the extent to which criticism of secret remedies is excluded from the press may probably be judged by any one who will take the trouble to see how much attention is bestowed by the newspapers on your Committee's report." The army of astute rascals amassing wealth by the means now for the first time irrefutably exposed may, it seems probable, be able to cite the Journal as one of those—albeit representative of the medical profession—that does not concern itself seriously with the matter. The Select Committee—very strong by virtue of the distinction of its individual members—has demonstrated the existence of vast evils which it states call for immediate legislation. They state that the present situation is intolerable. They have for the first time since medical legislation was invented put into the hands of the profession a weapon which may enable them to make an end of a system of cunning fraud which, as the Select Committee proves, is the cause of an incalculable amount of preventable suffering, misery, and

death. Into this great work of humanitarianism the profession, who have nothing to gain by it, are bound to throw themselves, and they can rightly demand the most strenuous assistance of the JOURNAL in their efforts.—I am, etc.,

Earlswood Common, Sept. 12th. HENRY SEWILL.

THE TREATMENT OF ACUTE GONORRHOEA IN MAN.

SIR,—Adverting to Dr. Hayes's article on the above (BRITISH MEDICAL JOURNAL, September 12th, p. 469), I suggest that the treatment of gonorrhœa should be adopted as a subject for discussion at the next meeting of the British Medical Association. No disorder more clamorously calls for reconsideration and review of treatment.

Dr. Hayes gives a succinct digest of modern views on gonorrhœa, but a somewhat extended experience has led me to think that the net result of all active treatment may be to do more harm than good. The natural history of the disease shows a tendency to cure. Like Dr. Hayes, I have found urotropine of much value in checking the early inflammatory symptoms, but I fear it renders the disease more chronic. What conceivable microbicidal action has permanganate of potash, 1 in 10,000, in a mucous tract? Saline solution, I suggest, is much better.—I am, etc.,

Dublin, Sept. 12th. J. C. MCWALTER, M.D., F.R.F.P.S.

Universities and Colleges.

UNIVERSITY OF SHEFFIELD.

DR. J. B. LEATHES, F.R.S., has accepted the invitation of the council of the University of Sheffield to become Professor of Physiology in the University.

UNIVERSITY OF BIRMINGHAM.

Special Notice.

AT a special meeting of the Council of the University held on September 4th, the following resolutions were unanimously adopted:

1. That the University will as far as possible continue its work for the benefit of those students who are prevented from undertaking active service in the army or navy, but that the University's advice to members of the staff, students, laboratory and other assistants, and college servants who are of suitable age and physically fit is that they should enlist and serve their country. That students who propose to enlist should consult the Vice-Principal or the Dean of the Faculty of Medicine, and (if minors) should obtain the written consent of their parents or guardians before sending in their applications.
2. That with a view to encouraging enlistment, the University undertakes to allow leave of absence to any of the above-mentioned persons during their naval or military service; that they be reinstated on their return with no loss of position or emoluments consequent on their enforced absence; that the Council pay them (or such other person or persons as they may appoint) such sums as with the pay and allowances they receive from the Government will make up their full salary or wages: and that students shall be entitled to postpone any scholarships or other aids which they may hold, and, where possible, may be allowed to shorten the time of attendance at lectures necessary for a degree, without, however, the remission of any essential requirements in respect of examinations prescribed for their course.

GILBERT BARLING,
Vice-Chancellor.

UNIVERSITY OF EDINBURGH.

German Teachers.

IT is understood that the University authorities have, in consequence of the present state of matters, sent letters to three gentlemen of German nationality who are at present members of the staff giving them an opportunity of resigning their appointments. Only one of these, a lecturer in the department of physiology, is in the medical faculty. This action has called forth some protests in the local press.

UNIVERSITY OF ST. ANDREWS.

AT a meeting of the University Council on September 12th Dr. David Waterston, Professor of Anatomy in King's College (University of London), was appointed to succeed Professor Musgrove in the Bute Chair of Anatomy, United College, St. Andrews.

QUEEN'S UNIVERSITY, BELFAST.

Election of Senators and of Chairman of Convocation.

THE first senate of the University will cease to exist on October 31st, and a new senate has to be elected by various bodies before that date. Convocation has power to elect eight senators holding office for five years; the election was held on September 9th, when four medical men obtained places—Mr. J. Walton Browne, B.A., M.D., M.R.C.S.Eng., Mr. T. Sinclair Kirk, M.B., B.A., Dr. William Calwell, M.A., and Dr. Richard W. Leslie, LL.D. All the other bodies have made their selection, so that the senate is now complete with the exception of the Crown nominees who are always the last, and of certain co-opted members. At the same meeting Dr. John Campbell, F.R.C.S.Eng., M.A., LL.D., was unanimously elected Chairman of Convocation for the next three years. It is gratifying to the profession that the importance of the medical school should be thus recognized by the whole body of graduates.

AN APPEAL TO EXAMINING BODIES.

The Higher Diplomas.

VOLUNTEER writes: I write to suggest that the various examining bodies should postpone all their higher examinations and only hold those necessary for qualification during the war. There must be many, like myself, who have given up our original intentions to go up for such examinations as the F.R.C.S., M.R.C.P., etc., in order that we may give our services to the country, and it seems unfair that those who do not recognize their obvious duty at this time should be allowed to gain any advantage over us. At any rate, the higher examinations might be reserved for those who are over the military age.

Obituary.

CAPTAIN AUGUSTUS SCOTT WILLIAMS is reported as killed in action during the recent fighting in North-Eastern France. Neither the date nor place of his death appears in the return. He was educated at St. Bartholomew's Hospital, took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1905, and, after serving as house-surgeon to the West London Hospital, entered the R.A.M.C. as Lieutenant on January 30th, 1906, becoming Captain on July 30th, 1909. He was recently stationed at the R.A.M.C. College, Millbank, and had seen no previous war service.

LIEUTENANT-COLONEL RAGLAN WYKEHAM BARNES, R.A.M.C. (retired), died at Dorchester on September 6th. He was born on September 29th, 1854, educated at University College, London, and took the diplomas of L.K.Q.C.P.I in 1875, and the membership in 1880, the L.S.A. in 1876, and the L.R.C.S.Edin. in 1878. He entered the Army as surgeon on March 6th, 1880, became Surgeon-Major on March 6th, 1892, Lieutenant-Colonel on March 6th, 1900, and retired on November 17th, 1900. He served in the Nile expedition of 1898, when he was present at the battle of Omdurman, was mentioned in despatches, and received the medal with a clasp. In the South African war in 1899–1900 he served in operations in Cape Colony and Orange River Colony, and was in charge of a general hospital. Since his retirement he had been in charge of troops at Dorchester.

BRIGADE-SURGEON JAMES EDWARD CLARK, R.A.M.C. (retired), died in London on September 9th, aged 77. After becoming M.R.C.S. in 1858, he entered the Army as assistant surgeon on February 1st, 1859, becoming surgeon in 1871, and surgeon-major in March, 1873. He retired with a step of honorary rank on April 18th, 1885. He served in the Egyptian war of 1882, receiving the medal and the Khedive's bronze star given for that campaign.

SURGEON-MAJOR WILLIAM HENRY HAYES, Bengal Medical Service (retired), died at Farnham, Surrey, on September 8th, 1914, aged 80. He was born on November 27th, 1833, took the diploma of M.R.C.S. in 1855, and entered the Indian Medical Service as assistant surgeon on August 4th, 1855. He became surgeon on August 4th, 1867, surgeon-major on July 1st, 1873, and retired on April 16th, 1878. He served in the Indian Mutiny, in Chota Nagpur, and was wounded in a skirmish near Chaibasa, in Sinhbhum district, on January 14th, 1858. After the mutiny he entered civil employment in the Bengal Commission, and in 1863 was appointed Deputy Commissioner (magistrate) of Sinhbhum, a post which he held till his retirement. He was the last survivor of the few medical officers who were thus employed in purely magisterial posts.

WE regret to announce the death of Dr. AUGUSTE ELISÉE CORDÈS, of Geneva, who frequently contributed short notes, mainly on obstetrical subjects, to our columns.

Born at Lyons in 1843, he graduated Doctor of Medicine at Paris in 1869, the subject of his thesis being the treatment of nervous complications in pregnancy with potassium bromide. After working in the ambulances in Paris during the war of 1870 he settled at Geneva in 1871, and when the faculty of medicine was founded in the university of that city in 1874 he was appointed lecturer in obstetrics. In 1886 he gained by competition the post of assistant surgeon in the Obstetrical Clinic. He was one of the general secretaries of the International Congress of Gynaecology and Obstetrics held at Geneva in 1896, took the diploma of M.R.C.P.(Lond.) in 1889, and was a Fellow of the Royal Society of Medicine of London and a member of the British Medical Association. He translated Barnes's lectures on obstetric operations and his treatise on diseases of women.

In the obituary notice of the late Lieutenant-Colonel S. E. Duncan, R.A.M.C., in the Journal of August 29th, it was stated that he served in the South African war during 1900–01. This should have been 1899–1902; Lieutenant-Colonel Duncan served throughout the whole campaign, from its commencement in October, 1899, till peace was made in May, 1902.

Medical News.

The annual prize distribution at St. Mary's Hospital Medical School, previously arranged to take place on October 1st, has been postponed.

Dr. F. M. Sandwith, Gresham Professor of Physic, will give a course of four lectures on heredity, at Gresham College, E.C., on October 6th, 7th, 8th, and 9th, at 6 p.m. on each day.

Dr. A. C. Farquharson, at present serving as Captain R.A.M.C.(T.F.) with the 6th Durham Light Infantry, has been unanimously adopted prospective Liberal candidate for the North Leeds Division.

Dr. Josiah Oldfield, Major R.A.M.C.(T.), commanding the 3rd Reserve East Anglian Field Ambulance, states that there are several vacancies in the ambulance as well as in the service unit. Communications may be addressed to him at the Drill Hall, Walthamstow.

The President of the Pharmaceutical Society of Great Britain will present the Pereira medal on the occasion of the opening of the seventy-third session of the School of Pharmacy on Wednesday, September 30th, at 3 p.m., and the inaugural sessional address will be delivered by Dr. Lauriston E. Shaw.

The Huxley Memorial Lecture on recent advances in science and their bearing on medicine and surgery by Sir Ronald Ross, K.C.B., F.R.S., originally fixed for Thursday, October 1st, has been postponed to Monday, November 2nd. The lecture, which will be delivered in the out-patients' hall of Charing Cross Hospital at 3 p.m., is open to all members of the profession.

Public Health

REPORT OF MEDICAL OFFICER OF HEALTH.

Ramsgate.—The estimated population of the borough of Ramsgate in 1913 was 30,043, the birth-rate based on this population was 18.6 per 1,000, the death-rate 13.9 per 1,000, and the infant mortality rate was equal to 92 per 1,000 births. The medical officer of health, Dr. James Dundas, gives some interesting information with regard to the social conditions of that portion of the population which came under the notice of the health visitor. As regards 200 families, the income was less than 16s. a week in 48 instances, and in 174 instances it was under 25s. a week. The rental paid by 35 families was under 4s. 6d. a week, and by 112 families it was between 5s. 6d. and 7s. 6d. a week. Active measures were taken during 1913 under the by-laws with respect to tents and vans, and they are said to have been effectual in ridding the district of van dwellers and gipsies. Dr. Dundas considers that there is an undoubted demand for single or two roomed dwellings in Ramsgate which is not satisfactorily met. In one particular district there are many six roomed houses designed for occupation by single tenants, but let out in single or two-roomed tenements; in such houses the closet and washing accommodation is invariably too limited, and the equipment of the furnished rooms is too meagre for comfort and decency. The standard of cleanliness of these houses is said to be much below that of the common lodging-houses, and the smell arising from dirty clothes and bodies, so well known to workers in slum districts, constantly assails the nostrils of the visitor. The medical officer of health suggests that these houses should be licensed annually.

LETTERS, NOTES, ETC.

Oedematous Fetus.

Dr. John P. Shine (Barnsley) writes: On August 12th I was sent for by a midwife. The head was born; it was remarkably blue, swollen and oedematous. After trying traction without avail I liberated both arms and eventually delivered the fetus (dead for at least two days). The abdomen was swollen four times more than normal, the genitals and legs were extremely oedematous; it weighed about 24 lb. Congenital ascites and general dropsy seems to be a very rare condition.

Treatment of Gunshot Wounds in the Seventeenth Century.

The following "observation" from Scultetus's *Armamentariam Chirurgici*, written in 1672, and translated into English two years later, may be of interest at the present moment. "In the year 1634 Johannes Philippus Schmid, captain of the watch at Ulme, was wounded with a bullet through the shoulder in the battel near Nordlingen; and coming to Ulme fell into the hands of an unskilful chyrurgion, who kept open the orifices of the wound, not with tents but with a seton passed through, which caused so great a pain that a gangreen followed upon the inflammation, to whom coming by chance, I presently removed the seton and applied a cataplasm made of the meal of mallows and rose-water, and keeping his belly open with a lenitive glyster, for revulsion sake, I took away seven ounces of blood from his left arm, which was bilious and serous; and the next day the gangreen amending, the patient took a potion to purge choler, which gave him ten stools." The ingredients of the potion were syrup of roses, extract of rhubarb, diacarthamum, magistery of tartar, and "burrage water." The slough separated, and the wound healed. "The wonderfull efficacy of this cataplasm, the patient being recovered, thinks he can never enough commend, and ascribeth to it the sole preservation of his arm."

Pneumonia in the Highlands of New South Wales.

Dr. A. G. Cribb (Millthorpe, New South Wales) writes: I think the type of disease described in Sir James Barr's lecture must differ considerably from that met with in this district. It is situated 3,000 ft. above sea level, and about 150 miles in a direct line from the sea coast. It is extraordinarily healthy, but pneumonia is prevalent both in the depth of winter and in the height of summer. Expectoration is very scanty in the first stage, so I have never found it necessary to give calcium chloride. I give liquor ammoniae acetatis with spirits of nitrous ether in full doses to promote expectoration, also quinine every two hours. Directly the disease is localized I apply antiphlogistine to the part affected. This reduces the temperature from 1½° to 2°, eases pain, promotes expectoration, and assists the patient to sleep. I take a measurement from apex to base of the lung behind, also round the chest at the nipple line. I then cut a shape out of an old piece of blanket to fit the lung like a sleeveless waistcoat, being guided by the measurements I have taken. Shoulder tapes and two to meet in front complete the poultice. I find this method of application superior to the directions given by the manufacturers, as one can gauge the heat more accurately after spreading it on the shape before applying to the skin, it is more economical, and if properly fitted, is cleaner and handier. I change the poultice every twelve hours during the acute stage and continue the applications until the temperature has been normal for twenty-four hours. I use the manufactured vaccines in every case, varying the dose from 10 million in children to 100 million in adults. Nothing under 50 million is any use in the adult. I have given an initial dose of 100 million in a very bad case with good results. I have had no fatality at any age during the last five years.

An Address
ON
THE EVOLUTION OF TOXAEMIC IRITIS.

DELIVERED AT THE OXFORD OPHTHALMOLOGICAL CONGRESS, JULY, 1914.

BY W. M. BEAUMONT,
FORMERLY SURGEON TO THE BATH EYE INFIRMARY.

A SHORT time ago I read a paper on iritis at the Royal Society of Medicine, and it is with some hesitation that I return to the subject.[1]

The origin of inflammation, not only of the eye, but also of all parts of the body, is engaging the attention of workers in the field of biology, with the result that the science and art of medicine and surgery are profoundly influenced by modern conceptions.

As practitioners of a speciality which is as much medical as it is surgical, we are daily confronted by problems which enable us to test the value of the new pathology, the acceptance of which fundamentally affects our treatment. We find that an alveolar pocket or a duodenal ulcer may be a central bureau for the distribution of lethal diseases to all parts of the human economy.

The haematogenous theory has led to the etiological dethronement of iritis from the position of an independent disease to the secondary one of a complication. More than ever we did in the past do we now not alone direct our treatment to the local manifestation, but we search the furthest limits and probe the most hidden depths for the *causa causans*.

In the remarks which I have to make I shall confine my attention almost entirely to manifestations of toxaemia as seen in the iris and ciliary body. Not that I minimize the importance of infection of other parts of the eye, but because what I have to say with regard to the iris applies *mutatis mutandis* to the choroid and other structures.

The stress of the poison usually does not spread from the iris to the choroid. This localization conforms with the usual rule in disease of these parts: the immunity of the choroid being due to the fact that although the venae vorticosae collect the blood from the ciliary body and iris there is no exudation of morbid products in the transit through the choroid.

In reviewing iritis, no matter how it may be caused, we cannot fail to be struck by the frequency with which it is associated with arthritis, or at least with arthritic pains. It is noteworthy, too, that the arthritic and iritic symptoms are often so accurately coadjusted that exacerbations in the eye and joint frequently recur synchronously.[2,3] On the other hand, practically never is acute rheumatism coincident with iritis. It is this anomaly which explains, perhaps justifies, the position of doubt taken up by some ophthalmic surgeons for many years, on the question whether iritis is ever rheumatic; a position which is enormously strengthened by the modern theory that acute rheumatism is a disease clinically distinct from what until recently has been called chronic rheumatism.

In acute rheumatism it would seem that the toxins do not find in the iris a suitable nidus.

When doubts about the etiology of iritis were first broached it was shown that many cases of so-called rheumatic iritis occurred in the subjects of gonorrhoeal infection. There was, however, a residuum of cases in which there was no suspicion of gonorrhoea. The next step was the suggestion that none of these residual cases were rheumatic, but that they were initiated by some blood-borne poison from a distant focus, in a manner possibly analogous to the iritis of syphilis and gonorrhoea.

Idiopathic iritis, a diagnosis which I think surgeons were always chary of making, also became suspect. It is a term which implies that the case is not syphilitic, gonorrhoeal, tuberculous, or rheumatic. But it is a name which suggests that the iritis has arisen spontaneously, that is, in the absence of any pre-existing disease. Does this ever occur? Is not iritis always a symptom rather than a disease *sui generis*? If so, then iritis from a toxaemic condition becomes extremely probable. An exhaustive account of the pathogenesis of toxaemia in relation to irido-cyclitis was given by de Schweinitz at the seventeenth International Congress of Medicine last year.[4]

The suggestion that iritis might be due to such a toxaemic infection is, I think, coeval with the doubts regarding rheumatism as a frequent cause of iritis. It was somewhere about the end of the nineteenth century that these views were first expressed, but the repudiation of rheumatism required some audacity, for that disease enabled the physician to give a name to all obscure aches and pains situated in any part of the body. To doubt that such a convenient diathesis caused iritis was then tantamount to a recantation of one's professional creed. But now pathologists and physicians have followed the example of the doubter, and chronic rheumatism has no friends. So rapidly is the bacteriologist supplying the clinician with food for thought that the most omnivorous finds it difficult if not impossible to assimilate the gargantuan feast.

In a discussion initiated by the late John Griffith, at a meeting of the Ophthalmological Society, in 1900, he pointed out how frequently iritis was called rheumatic when in reality it was gonorrhoeal.[5] Gonorrhoeal iritis had of course been recognized since the days of Brodie (1818), but the cases so designated were usually well-marked examples in which gonorrhoea was more or less acutely present. But the prolonged vitality of the gonococcus, and its far-reaching constitutional effects, were not realized. The surmises of Griffith regarding the dormancy of the gonococcus were based upon clinical observation and induction, and they have since been amply supported bacteriologically by Schnitzler, who has shown that pyogenic cocci may remain latent in the human body for thirty-five years, and then become virulent "on some chance disturbance of the normal processes of metabolism."[11] By this discussion at the Ophthalmological Society attention was focussed on the intimate etiology of rheumatic iritis, and as a sequence the status of the term "rheumatic," as applied to iritis, was questioned, for it was found to be too vague, too ill-defined, and too inclusive. Such was the swing of the pendulum, however, that some of us went so far as to doubt whether rheumatism ever caused iritis. For this view support was found in the researches of Bouchard, the founder of the modern teaching regarding rheumatism. In 1881 he claimed for acute rheumatism an etiology essentially distinct from that of the heterogeneous mass of infective arthritides. But although his views received scant attention at the time, it was an epoch when bacteriology was being actively cultivated and the theory of the toxic origin of disease was being evolved. The result of Bouchard's work could not long be overlooked. In 1900 William Hunter[6] drew attention to the importance of pyorrhoea and other types of oral sepsis as sources of systemic infection. This expression, "oral sepsis" was, I believe, first used in the sense in which we now use it in that year. In close sequence we find Arbuthnot Lane canvassing the possibility of toxaemia as a factor of unbridled energy in the causation of abdominal disease, and later he was demonstrating the faith that was in him by operating for intestinal stasis at Guy's Hospital. Coincidentally, Lang was advocating at the Middlesex Hospital and at Moorfields the desirability of treating pyorrhoea when it existed, in cases of irido-cyclitis, choroiditis, scleritis, and other diseases of the eye. In 1902 R. J. Llewellyn maintained that rheumatoid arthritis was the outcome of a gastro-intestinal toxaemia, and others have reiterated this view. To-day throughout the whole domain of medicine and surgery, at home and abroad, toxic states of the blood plasma are credited with an all-pervading influence. Whether the pendulum has swung too far time alone will show.

Opinion took on a new phase when chronic rheumatism was allotted, under the term "fibrositis," an anatomical basis, and thus sharply distinguished from acute articular rheumatism. If chronic rheumatism, with which iritis had hitherto been closely connected, was a totally distinct disease from acute rheumatism, with which iritis was not associated, the position of rheumatic iritis became questionable. Those who had anticipated the new pathology with their doubts about rheumatic iritis were supported in their scepticism. The relationship of fibrositis to iritis, and whether the association exists in all manifestation of the forms, call for immediate investigation. What is fibrositis?

Luff is of opinion that it is toxic in origin, and that is, I take it, the important point for us. The experiments of Rosenow of Chicago[13] respecting interstitial myositis in rabbits will probably throw light upon the subject, but they are not yet complete, and we must wait for further knowledge. Until the exact relationship of rheumatism, fibrositis, myalgia, and all forms of muscular and articular aches and pains are more precisely codified we cannot, I think, dogmatize as to the connexion of iritis with them. Theoretically, as there is fibrous tissue in the iris, there should be fibrositic iritis. Is not every iritis a fibrositis? Rheumatism was a convenient term because it predicated nothing, and its flag waved over a heterogeneous battalion of diseases. That flag now lies trampled in the dust.

Although we have isolated instances in which iritis has been produced experimentally by inoculation of the *Diplococcus rheumaticus* from the cardiac lesions of malignant endocarditis, I am not aware of any indisputable clinical proof that iritis occurs as a result of acute rheumatism. If, then, we still postulate a rheumatic iritis it is associated with the chronic form of rheumatism, as opposed to the acute articular; the former is now accepted as distinct from the latter, inasmuch as the typical anatomical lesions are admittedly capable of production by a variety of organisms, including various strains of streptococci of attenuated virulence. The deduction is obvious that iritis occurring in association with the clinical features of chronic rheumatism should, like the other phenomena, not be classed as rheumatic, but referred to the particular organism responsible.

Present views regarding iritis make it necessary for us as practical surgeons to get behind the veil and to track back the infection to its birthplace. The almost invariable success of our search shows that there are very few cases of iritis not intimately connected with an infection or subinfection. In the dyscrasia of syphilis and in that of gonorrhoea a source of infection is clear and unmistakable. In traumatic iritis, due to a perforating wound, germs obtain direct access to the iris, and even in operating under the strictest asepsis the surgeon's path of incision may become the road of sepsis.

Possibly, too, in sympathetic ophthalmitis toxins are elaborated in the exciting eye, which have a specific affinity for the iris and other structures of the sympathizing eye.

There is an ill-defined type of iritis arising from a dislocated lens in which there is apparently no path of entry for organisms from without. It is noteworthy that the iritis in such cases shows few signs of inflammation, although there are discoloration of the iris and posterior synechiae. Such a low form of infection is probably caused by organisms of attenuated virulence.

In diabetes the marked tendency to the dermic formation of boils and carbuncles of obviously infective nature may possibly explain the source of iritis, but, on the other hand, they may be the coeffects, with the iritis, of a common infection.

Iritis, although credited to malaria, is a rare complication in paludal disease; while that which sometimes follows late in cases of herpes of the fifth nerve would seem to be undoubtedly of infective origin. I have seen iritis in association with adiposis dolorosa, but as the patient suffered at the same time from dental sepsis it was probable that the latter was a factor common to both, inasmuch as adiposis dolorosa is due to an inflammation of the fibrous tissue of the panniculus adiposus.

Except in sympathetic ophthalmia the iris does not appear to be readily accessible to microbic invasion following injuries of distant parts of the body.

There is a side issue with regard to gonorrhoea which I think is of some importance—namely, that not only iritis but also conjunctivitis may be produced endogenously by that disease.[7 8] In these cases of conjunctivitis there is usually evidence of systemic infection, such as metastasis either in joints, tendons, endocardium or in other structures. In the purulent discharge from the eye, however, if we accept the authority of Elschnig, there is absence of the bacteriological certainty of its identity, for although gonorrhoeal it is not gonococcal. The fact that these cases lack the unanswerable proof of gonorrhoeal origin—that is, the presence of the gonococcus—explains their being overlooked. In ophthalmia neonatorum the gonococcus is absent in a certain percentage of cases, and in such it may occasionally happen that the disease has been conveyed endogenously. For although the fetal vascular circulation is not actually continuous with the maternal, yet so intimate is their coaptation that practically they may be considered indivisible, and there is nothing to prevent the gonorrhoeal poison from being carried to the eyes of the embryo transplacentally. Ophthalmia being produced endogenously by gonorrhoea it is probable that other specific infections may similarly initiate conjunctivitis. Garrod has pointed out that dysentery is a cause of muscular rheumatism, and also he says of conjunctivitis, an association which supplies food for thought.[9] Passet and Longard have shown that in inoculated mice staphylococci pass into the conjunctival secretion.[15] In mucopurulent ophthalmia, in which both eyes may be affected, we are apt to assume that the patients have been infected by microbic dust or air-borne germs. Possibly some of these cases are not exogenous.

The diagnosis of toxaemic iritis is obviously surrounded by difficulties, and in pursuing the germ we cannot confine our quest within the borders of our speciality; we have to become general physicians in the fullest interpretation of the term, and wander far afield to seek a focus of infection in oral, naso-pharyngeal, auditory, gastro-intestinal, or genito-urinary regions. We explore the digestive tract from its alveolar gates, through its devious windings, to its nethermost terminals for some breach in the armour.

Much may be learnt from the nature of the joint pains and swellings which are so often present. For, although these symptoms are common to tubercle, syphilis, gonorrhoea, fibrositis, and rheumatoid arthritis, there are considerable differences of material assistance in the diagnosis. The "rheumatism" associated with toxaemic iritis is frequently situated in the big joints of the lower limbs usually of mono- or of oligo-articular site, and in the plantar fasciae, but affection of the latter is rarely so severe as in the worst cases of gonorrhoea, or so prolonged as in tubercle. The iritis which sometimes occurs in the early stage of rheumatoid arthritis may often be diagnosed by the spindle-shaped finger-joints. When writing on this subject in 1908[10] I was unable to hazard an opinion whether the iritis was caused by the rheumatoid arthritis or whether both were independently the offspring of a common parent.

Iritis in toxaemia generally indicates an intense systemic infection, and there are usually present the dull, sallow complexion, constipation, neurasthenia, and lassitude. Given a patient with these symptoms well marked, who is not syphilitic, and the diagnosis may not be difficult. But in other cases we have to contend with the uncertainties which always attend a diagnosis by exclusion.

It is not for those of us whose connexion with toxaemia is chiefly clinical to consider whether the pathological process is an autointoxication, a term which Adami so much objects to, or whether it is better described as a low infection.[11] As practical surgeons we recognize and treat the cause and the results. Lawford has pointed out that at present we have to be satisfied with the general term "toxaemia" as a working hypothesis,[12] but there is every reason to believe that in the near future we shall be able to recognize diverse species. In specific and tuberculous iritis, for instance, we have clinical similarity with pathological dissimilarity. The clinical similarity, however, is not clinical identity, and we can diagnose syphilis from tuberculosis by the ocular symptoms. But at present cases of iritis due to many forms of pyogenic organisms cannot be distinguished one from the other by clinical methods alone. The diagnosis and the treatment of iritis require the harmonious co-ordination of the laboratory and the ward, the mutual collaboration of the bacteriologist and the clinician.

The association of dental disease with iritis is perhaps more generally observed than are other sources of sepsis. The patient may complain of joint aches, myalgic discomforts, and little else besides. On examination of the teeth there is found to be pyorrhoea alveolaris, which we are told has existed for some months or even years. Lang's statistics[13] show that about 64 per cent. of cases of iritis attributed to sepsis, are caused by pyorrhoea. Less frequently we find otitis, sinusitis, or some gastro-intestinal infection. The difficulty in the diagnosis is the connecting link. The iritis is there, the septic focus is there, and we

conclude that the blood vessels are the highway of communication. But clinical investigation gives us little evidence that the stream is toxaemic. We are, too, continually confronted by the difficulty of deciding whether *post hoc* is in conflict with *propter*, or on the same side. The characteristics of the iritis are not pathognomonic. Deposits on the posterior surface of the cornea may or may not be present. The iritis is an anatomical lesion capable of initiation by manifold organisms, but it is an iritis and nothing more. Lacking the nodules of tubercle, and the condylomata of syphilis, it begins insidiously, progresses leisurely, and clears up tardily. If the iris alone be treated relapses will occur, but if the cause be discovered and removed a satisfactory prognosis may confidently be given.

It is, I think, agreed that pyorrhoea alveolaris is the most frequent source of toxaemic iritis, and the reasons would seem to be, first, the great prevalence of pyorrhoea, and, secondly, that the infection in these cases is direct into the circulation, whereas in many other forms of alimentary toxaemia the toxins have to undergo the ordeal of the hepatic furnace. But this prevalence of pyorrhoea may lead us astray if, on finding it present, we at once conclude it to be the cause. It cannot be too insistently brought to mind that a patient with pyorrhoea may also be a sufferer from syphilis or gonorrhoea. There may also be present more than one source of "gastro-intestinal autointoxication," evidences of which may be unexpectedly manifested when the urine and faeces are examined. Whatever organ is discovered at fault it should receive treatment at once, the patient being referred to the proper authority—physician, surgeon, laryngologist, rhinologist, aurist, or dentist—without delay. In the case of pyorrhoea the latter will naturally wish to save as many teeth as possible, but when iritis is already established the bias should be in favour of drastic treatment of the periodontal foci of disease. The slower methods by autogenous vaccines, and by local applications to the alveolar pockets, may suffice before the onset of iritis, but the important point is to stop the auto-intoxication by the most expeditious method; that is, to remove all the affected teeth. The cure of the iritis is of paramount importance, and it is better to lose thirty-two teeth than one eye. Whether the oral sepsis is the cause or the result of intestinal stasis should make no difference in the verdict; the teeth must suffer the penalty for guilt as accessories before or after the event. When dental treatment has been carried out, although immediate cure may not follow, we have at least removed a fruitful source of general ill-health, thereby increasing the power of resistance and simplifying the work which atropine will consummate. In the treatment of iritis the primary cause calls with insistent voice for detailed hygiene. Salicylic acid may have a specific action in acute rheumatism, but in iritis, apart from its anodyne effects, it is probably quite useless. The old formula of mercury and chalk is beneficial, but vaccines have proved disappointing. Occasionally a case seems to respond most satisfactorily, but in many no advantage accrues.

I will not take up time by considering the question of diet, except to remark that we shall see less pyorrhoea, and therefore less iritis, when finely ground flour as an article of food is banished from our homes. Some day perchance it will be illegal to bake or to buy, to sell or to swallow, bread made from flour which bakers call "firsts."

The autointoxication theory of the origin of fibrositis, rheumatoid arthritis, and other diseases involves such a reversal of old teaching, such a change in diagnosis and treatment, that it is not easy to view the subject in all its bearings. As far as the eye is concerned, the iconoclastic conclusion to which we are led is that iritis is an indication of an infective process in some part of the body, and, conversely, that infection or subinfection is an indication that iritis may be threatening. I have called the subject of this address toxaemic iritis in order to intimate the point to which I wished to draw attention, but the infective theory connotes a toxaemic basis for all types of iritis. No iritis is primary; it is invariably secondary, always infective.

In the future statistics should show a decreased incidence of diseases of the eye if it be proved that those rheumatic twinges which have hitherto been accounted for by morning mist or evening chill are early warnings of a chronic septic invasion.

INSECTS AND WAR:

II.—*THE BED-BUG (Cimex lectularius).*

BY

A. E. SHIPLEY, Sc.D., F.R.S.,

MASTER OF CHRIST'S COLLEGE, CAMBRIDGE.

In "x" finita tria sunt animalia dira;
Sunt pulices fortes, cimices, culicumque cohortes;
Sed pulices saltu fugeunt, culicesque volatu
Et cimices pravi nequeunt foetore necari.

AMONG the numerous disagreeable features of the bed-bug is the fact that it has at least two scientific names—*Cimex* (under which name it was known to the classical writers) and *Acanthia*. The latter name is favoured by French and some German authorities, but *Cimex* was the name adopted by Linnaeus and is mostly used by British writers, and will be used throughout this article. One cannot do better than take the advice of that wise old entomologist, Dr. David Sharp, and allow the name "*Acanthia* to fall into disuse."

The species which is the best known in England is *C. lectularius*, but there is a second species which is much commoner in warm climates (*C. rotundatus*). As regards carrying disease, this latter species is even more dangerous than its more temperate relative. Other species, which rarely if ever attack man, are found in pigeon-houses and dove-cotes, martins' nests, poultry-houses, and the homes of bats.

Fig. 1.—*Cimex lectularius*, male. × 15. (From Brumpt.)

The common bed-bug seems to have arrived in England about the same time as the cockroach—that is, some four hundred years ago. Apparently it came from the East, and was at first confined to seaports and harbours. It seems to have been first mentioned by play-writers early in the seventeenth century. How the insect got the name of "bug" is unknown. It has been suggested that the old English word "bug," meaning a ghost or phantom which walked by night, has been transferred to *Cimex*. This may be so, but the *Oxford Dictionary* tells us that proof is lacking.

The insect is some 5 mm. in length and about 3 mm. in breadth, and is of a reddish or brownish rusty colour,

fading into black. Its body is extraordinarily flattened so that it can readily pass into chinks or between splits in furniture and boarding, and this it does whenever daylight appears, for the bug loves darkness rather than light. The head is large, and ends in a long piercing, four-jointed proboscis, which forms a tube with four piercing stylets in it. As a rule the proboscis is folded back into a groove, which reaches to the first pair of legs on the under surface of the thorax. The head bears two black eyes and two four-jointed antennae. Each of the six legs is provided with two claws, and all the body is covered with fairly numerous hairs. The abdomen shows seven visible segments and a terminal piece. The bug has no fixed period of the year for breeding, but as long as the temperature is favourable and the food abundant generations will succeed each other without pause, but should the weather turn too cold the insects become numbed and their vitality and power of reproduction are interrupted until warmth returns.

Like the cockroach, the bed-bug is a frequenter of human habitations, but only of such as have reached a certain stage of comfort. It is said to be very rare in the homes of savages, but it is only too common in the poorer quarters of great cities. Its presence does not necessarily indicate neglect or want of cleanliness. It is very apt to get into trunks and luggage generally, and in this way is conveyed even into the best kept homes; it is also very migratory and will pass readily from one house to another, and when an infested dwelling is vacated the insects usually leave it for better company and quarters. Their food supply being withdrawn they make their way along gutters, water-pipes, etc., into adjoining and inhabited houses. *Cimex* is particularly common in ships, especially emigrant ships, and, although unknown to the Indians of North America, it appears to have entered that continent with the *Mayflower*.

One of the most disagreeable features of the bed-bug is that it produces an oily fluid which has a quite intolerable odour; the glands secreting this fluid are situated in various parts of the body. The presence of such glands in free-living, hemipterous insects undoubtedly is a protection—birds will not touch them. One, however, fails to see the use of this property in the bed-bug. At any rate it does not deter cockroaches and ants, as well as other insects, from devouring the *Cimex*. There is a small black ant which is said to clear a house of these pests in a few days, but one cannot always command its services. Another remarkable feature is that the insect has no wings, although in all probability its ancestors possessed these useful appendages. As the American poet says:

> The Lightning-bug has wings of gold,
> The June-bug wings of flame,
> The bed-bug has no wings at all,
> But it gets there all the same.

The power of "getting there" is truly remarkable. Man, their chief victim, has always warred against bugs, yet, like the poor, bugs are always with us. I have heard it stated, when I was living in Southern Italy, that if you submerged the legs of your bed in metal saucers full of water and placed the bed in the centre of the room, the bugs will crawl up the wall, walk along the ceiling and drop on to the bed and on to you. Anyhow, whether this be so or not, there is no doubt that these insects have a certain success in the struggle for life, and only the most systematic and rigorous measures are capable of ridding a dwelling of their presence.

The eggs of the bed-bug are pearly white, oval objects, perhaps 1 mm. in length. At one end there is a small cap surrounded by a projecting rim, and it is by pushing off this cap through the orifice thus opened that the young bug makes its way into the outer world after an incubation period of a week or ten days. There is no metamorphosis, no caterpillar and no chrysalis stages. The young hatch out, in structure miniatures of their parents, but in colour they are yellowish-white and nearly transparent. The young forms feed readily, and feeding takes place between each moult, which are five in number, before the adult imago emerges. This it does about the eleventh or twelfth week after hatching. These time limits depend, however, upon the temperature after hatching, and the rate of growth depends not only upon the temperature but on the amount of food. When bred artificially and under good conditions, the rate of progress can be "speeded up" so that the eggs hatch out in eight days, and every following moult takes place at intervals of eight days, so that the period from egg to adult can be run through in as short a time as seven weeks. Unless fed after each moult, the following moult is indefinitely postponed. Hence it follows that in the preliminary stages they must bite their host five times before the adult form emerges, and this in turn must have a meal before it lays its eggs. These are deposited in batches of from five to fifty in cracks and crevices, into which the insects have retired for concealment.

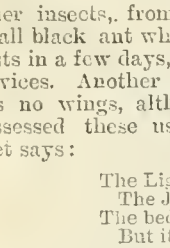

Fig. 2.—Egg of *Cimex lectularius*. Enlarged.

Bugs can, however, live a very long time without a meal. Cases are recorded in which they have been kept alive for more than a year incarcerated in a pill-box. When the pill-box was opened, the bugs appeared to be as thin as paper and almost transparent, but they had managed to produce some offspring. De Geer kept several in a sealed bottle for more than a year, and this power of existing without food may explain the fact that vacated houses occasionally swarm with bugs even when there have been no human beings in the neighbourhood for many months.

The effect of their bite varies in different people. As a rule, the actual bite lasts for two or three minutes before the insect is gorged, and at first it is painless. But very soon the bitten area begins to swell and to become red,

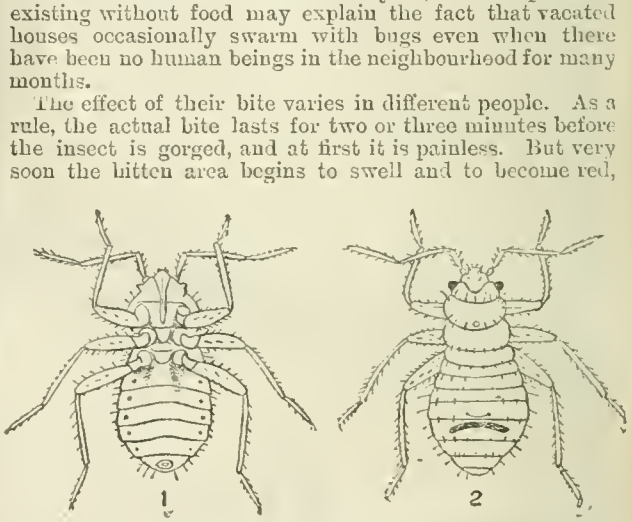

Fig. 3.—Newly hatched young of *Cimex lectularius*. 1, Ventral view; 2, dorsal view. Enlarged.

and at times a regular eruption ensues. The irritation may be allayed by washing with menthol or ammonia. Some people seem immune to the irritation, and I know friends who in the West Indian islands have slept through the attacks of thousands of bugs, and only awoke to their presence when in the morning they found their night clothing and sheets red with their blood, which, in rolling over in their sleep, they had expressed from the bodies of their tormentors.

As a rule, the uncovered parts of the body—the face, the neck, and the hands—are more bitten than the parts which lie under the bedclothes.

The bug has been accused of conveying many diseases—typhus, tuberculosis, plague, and a form of recurrent fever produced by a spirochaete (*Spirochaeta obermeieri*), but a critical examination throws some doubt upon the justice of the accusation, and Professor C. J. Martin writes as follows:

> There is really no evidence to incriminate the bed-bug in the case of either typhus or relapsing fever. It is possible to transmit plague experimentally by means of bugs, but there is no epidemiological reason for supposing this takes place to any extent in nature.
>
> There are two differences in the habits of bugs and those of fleas and lice which may possess epidemiological significance. The first concerns the customary intervals between their meals. Bugs show no disposition to feed for a day or two after a full meal, whereas fleas and lice will suck blood several times during the twenty-four hours. The second is in respect to the time the insects retain a meal and the extent to which it is digested before being excreted. Fleas and lice if constantly fed freely empty their alimentary canals, and the nature of their faeces indicates that the blood has undergone but little digestion.

Both these insects evacuate such undigested or half-digested blood per rectum during the act of feeding, and the remnants of the previous meal are thus deposited in the immediate vicinity of a fresh puncture. It is not unlikely that, should the alimentary canal of the insect be infected with plague bacilli, spirochaetæ, or the organism responsible for typhus fever, these may be inoculated by rubbing or scratching. Bugs have not this habit, and in all the cases I have examined their dejections were fully digested, almost free from protein, and consisted mostly of alkaline haematin.

Whether bugs be guilty of these crimes or not, they are the cause of an intense inconvenience and disgust, and should, if possible, be dealt with drastically. At the present time there are rumours that one of our largest camps is infested with these insects, and there seems no doubt that some of the prisoners and refugees to this country have brought their fauna with them, and this fauna is very capable of spreading in concentration camps. The erection of wooden huts, no doubt a pressing necessity, will afford convenient quarters for these pests.

Among the measures which have been most successful in the past has been fumigating houses with hydrocyanic acid gas, but this is a process involving considerable danger, and should only be carried out by competent people under the most rigorous conditions. In all fumigating experiments every crack and cranny of a house should be shut, windows closed, keyholes blocked, and so on. A second method of fumigation is that of burning sulphur. Four ounces of brimstone are placed in a saucer, which in its turn is placed in a larger vessel. This protects the floor of the room from a possible overflow of the burning material. After all apertures have been successfully plugged, four or five hours of the sulphurous fumes are said to be sufficient to kill the bugs, but to ensure success a longer time is needed. This is not only a much less expensive but a much less dangerous operation than using hydrocyanic acid gas. Two pounds of sulphur will suffice for each thousand cubic feet of space, but it is well to leave the building closed for some twenty-four hours after the fumigation. Another more localized method of destroying these pests is the liberal application of benzine, kerosene, or any other petroleum oil. These must be introduced into all crevices or cracks with small brushes or feathers, or injected with syringes. In the same way oil of turpentine or corrosive sublimate has proved effective. Boiling water is also effective when it can be used, and recently in the poorer quarters of London the "flares" which painters use in burning off paint have proved of great use in ridding matchboarding, or wainscoting, or wood for hoarding, of bugs. Passed quickly along, the flame does not burn the wood, but it produces a temperature which is fatal to the bug and to its young, and to its eggs.

THE TREATMENT OF ACUTE GONORRHOEA IN THE MALE.

By W. WYNDHAM POWELL, F.R.C.S.Eng.,
SURGEON TO THE WESTMINSTER GENERAL DISPENSARY.

As one who studied this subject under Janet in Paris, and under the late Dr. Valentine of New York, nearly twenty years ago, and has been since constantly engaged in the irrigation treatment, may I be allowed to offer a few remarks?

The nature of this disease, and the secrecy with which its treatment is surrounded in this country, accounts in a great measure for the haphazard way in which it is treated, and for the unsatisfactory nature of the teaching on the subject. The article by Dr. Hayes in the BRITISH MEDICAL JOURNAL of September 12th, p. 469, and the remarks thereon by Dr. J. C. McWalter in the ensuing number (p. 523), show that opinions are still divided as to whether the active or the expectant treatment is the better in acute gonorrhoea.

The reason is not far to seek. The irrigation treatment, judging by what one sees and hears, is not easy to learn. Faulty technique is probably at the bottom of most failures. The two-way tube or nozzle which is often used is inferior to the one-hole nozzle as recommended by Janet and Valentine. It is essential to flush out the anterior urethra with considerable force if the treatment is to be effective. A hydrostatic pressure of at least 6 ft. is necessary. The urethra must be ballooned out, and, what is also important, rapidly emptied, so that the fluid spurts out with great force. These essentials are obtained by using a nozzle with a bore equal to 8 or 9 of the French scale, and its partial removal from the meatus or the relaxation of the finger and thumb pressure blocking the meatus around the nozzle ensures a rapid emptying of the canal in the moment following its over-distension.

The process, then, consists of a quick filling and partial emptying of the urethra. This ensures a free circulation of powerful currents right up to the compressor urethrae muscle. The over-distension of the elastic urethra and its recoil facilitate the entry of the fluid into the lacunae and ducts of Littre. With the two-way nozzle the distension of the urethra is a sustained one, with probably no circulation of the fluid in the neighbourhood of the bulb of the urethra. Only in hyperacute cases is it necessary to go a little more gently, and also rarely when the spongy body itself has been allowed to become infiltrated. In these cases, even with a 2 per cent. solution of cocaine, the proceeding may be painful.

In the early stage, where only the first 2 or 3 inches of the urethra are involved, the whole anterior urethra should be irrigated with the usual full pressure. A splice of healthy mucous membrane treated with potassium permanganate irrigations offers an almost insuperable barrier to the inward spread of gonorrhoea. This salt is almost a specific in these circumstances. Irritating solutions such as those of silver nitrate, by lowering the vitality of the healthy membrane, favour rather than retard the spread of the disease in acute cases. The same may be said of all irritating hand injections. Permanganate may be used by means of a hand syringe, but the effect is infinitely inferior to that of irrigation.*

A few of the chief points to be kept in mind may be briefly stated:

A strength of from 1 in 5,000 to 1 in 2,000, or even stronger, is used. The temperature of the solution used is 98° F. to 100° F., and the quantity 5 or 6 pints.

For the first three or four days the irrigation is repeated morning and evening with a solution of medium strength, say 1 in 3,000. Then once daily the irrigation is given with a solution of 1 in 2,000. A solution of 1 in 5,000 strength is to be used in very acute and painful cases; 20 drops of a 2 per cent. solution of cocaine may be injected into the urethra and held in for two or three minutes just before irrigating in all sensitive cases. It is astonishing how quickly a painful condition will become painless under this treatment.

Rapid disappearance of the discharge and recovery is the rule. Should, however, a bead of yellow pus persist, endoscopy will show the lacunae of Morgagni to be greatly swollen and their outlet obstructed. This is evidence that treatment was not begun early enough and that the fluid now cannot penetrate them. In other cases which persist, but with less discharge, the superficial glands of Littre will be found more or less extensively involved. This also is found in cases which have been neglected at the beginning. When these conditions exist, in order to hasten recovery and to prevent the organization of infiltrations, the gentle use of Kollman's dilator is indicated, and I can recommend the irrigating dilator. This instrument may be used once or twice a week and very delicately screwed up until just the faintest pressure is felt. It is a powerful machine and requires care in use. The solution mostly used is mercury oxycyanide 1 in 4,000 or stronger. The intraurethral treatment of these affections requires the surgeon to be an expert urethroscopist. An account of the writer's method may be found in the BRITISH MEDICAL JOURNAL, September 26th, 1908, p. 878.

I have purposely not touched on the subject of the drug treatment of gonorrhoea, as being beyond the scope of this article, and the subject of vesical irrigations for posterior or membrano-prostatic urethritis may be left for a future occasion.

* An account of the irrigation treatment of early gonorrhoea may be found in the *Clinical Journal*, June 24th, 1908, p. 170, where also my irrigator is fully illustrated.

THE mixed council of the Armenian patriarchate has decided that couples wishing to get married must first present a medical certificate of health to the proper authority.

EIGHTY-SECOND ANNUAL MEETING

OF THE

British Medical Association.

Held in Aberdeen on July 29th, 30th, and 31st.

PROCEEDINGS OF SECTIONS.

SECTION OF GYNAECOLOGY AND OBSTETRICS.

F. W. N. HAULTAIN, M.D., F.R.C.P.Edin., President.

DISCUSSION ON THE TREATMENT OF FIBROMYOMATA OF THE UTERUS.

OPENING PAPERS.

I.—ARCHIBALD DONALD, M.A., M.D.Edin.,

Professor of Obstetrics and Gynaecology, Victoria University, Manchester.

(Abridged.)

THE treatment of fibromyomata of the uterus may be considered under the following heads:

1. *Expectant Treatment.*—My view is that this should now be given up in all cases of fibroids causing symptoms, save in exceptional cases. A small intramural tumour in a woman over 46 years, giving rise to only slight troubles, may be left alone, provided the patient is under supervision. Additional experience confirms the view that the climacteric does not always bring relief. The tumours may not disappear, and may not even diminish. Old age may cause complications: An intramural fibroid may become submucous or polypoid; diminishing size may cause incarceration in the true pelvis; degenerations are certainly not uncommon and malignant changes occur.

2. *Palliative treatment* for haemorrhage and other symptoms is not discussed.

3. *Curetting.*—In small tumours this may have a good effect in relieving haemorrhage for a time, but is not to be recommended, as it may have the opposite effect and may cause an intramural fibroid to become submucous by thinning the endometrium and stimulating uterine action. It is true that as a further result the tumour may become polypoidal and a cure may be effected by removal of the polypus, if the fibroid is solitary.

4. *Operative Treatment.*—(*a*) *Vaginal operations* are only advised in exceptional cases, such as for polypi or submucous fibroids bulging into the cavity and felt through a dilated cervix. In sloughing polypi the vaginal route is preferable. The uterus may be separated from the bladder and the anterior wall split up and the tumour removed. In all other cases the abdominal route should be chosen. Vaginal hysterectomy for fibroids should be abandoned. As long as our aseptic methods were uncertain it had a place, but now the method which enables us to see clearly what we are doing should be adopted. (*b*) *Abdominal operations.* Myomectomy should always be performed, if possible, in women of child-bearing age, unless there are numerous fibroids. It is a good plan in some cases to begin by enucleating, as it often makes the subsequent hysterectomy (if it has to be performed) easier.

In performing hysterectomy the choice lies between (1) supravaginal amputation, or subtotal hysterectomy, and (2) total or panhysterectomy. Each operator will choose his own methods. The writer's personal bias is towards the subtotal operation. The risk of the occurrence of cancer in the cervix after this operation does not seem worth considering. As for (3) double oöphorectomy, this should not be practised now. The risks are as great as those involved in the other abdominal operations, and the results are much more uncertain.

In regard to the *mortality* of abdominal hysterectomy, I have taken my own cases since the beginning of 1910 up to the first week of the present month—a period of four and a half years. The operations have been performed in the Royal Infirmary and in St. Mary's Hospital, Manchester, and in two nursing homes. In the nursing home cases I have included the last six months of 1909, as this brings the number to just 100. The results are as follows:

> Infirmary, 101 cases with 3 deaths:
> St. Mary's Hospital, 108 cases with 5 deaths;
> Nursing home, 100 cases with 1 death;

a total of 309 cases with 9 deaths, or a mortality of 2.9 per cent. But I have recorded every case of hysterectomy for fibroid, and in 3 of the fatal cases there were complications, which largely influenced, if they did not entirely cause, the fatal result. In one case the patient suffered from chronic bronchitis with dilated heart, and death occurred from heart failure. In one case the tumour was infected; it occurred in an unmarried woman of 31; several coils of small intestine were firmly adherent to the tumour, and had to be stripped off, with the result that a faecal fistula formed and leaked into the peritoneal cavity. In one case the operation was undertaken as an urgency for acute intestinal obstruction caused by a fibroid. If we deduct these 3 complicated cases, we have 6 deaths in 306 operations, or a mortality of 1.9 per cent. Of the 6 uncomplicated cases, 2 died of cardiac failure, presumably embolism, on the tenth day after operation; 1 died from secondary haemorrhage; 2 died from peritonitis, and 1 died from intestinal obstruction.

It is interesting to note that the results in the private cases were better than in the hospital cases—1 per cent. as against 2.3 per cent., after deducting the complicated cases which all occurred in hospital. This is doubtless partly explained by the fact that hospital patients are drawn from a class that are more poorly fed and housed, and that their ailments are often neglected until the trouble has become very urgent. But I believe there is another explanation to which I shall refer later.

As to the technique of the operation, I shall only draw attention to three points. The first of these is my preference for clamping the broad ligaments and uterine arteries and removing the uterus before applying any ligature. The advantages of this method are that when the uterus and tumour are removed one can see what one is doing much more clearly, and that there is less tension on the sutures and ligatures when they are applied after removal of the tumour. The second point is, that I am not in favour of the continuous suture, as I consider it not so safe as interrupted sutures. If one point of a continuous stitch gives way the whole of the stitching is rendered useless.

The third point—which is more likely to give rise to discussion—refers to the advisability of leaving one or both ovaries. Many operators believe that it is of great importance to leave at least one ovary if possible. My own practice is to remove both with the uterus, unless the patient specially desires that one should be left. In quite a considerable number of cases the ovaries are diseased or degenerated, and if they are left there may be subsequent trouble from cystic degeneration; or the ovary may become adherent to the pelvic scar and cause so much discomfort that a subsequent operation may be necessary. When they are both removed, the result is a clean pelvic floor with a linear scar running from one side of the pelvis to the other.

The chief difficulties in operating are met with in intraligamentous and subperitoneal fibroids, and in cervical fibroids. These difficulties are best overcome by high division of the peritoneal investment of the tumour and careful stripping of it downwards. In some cases a free incision into the capsule, followed by enucleation of the tumour, helps considerably.

In my opinion the symptoms of an artificially induced climacteric are not so severe as is often supposed, and this opinion has been formed as the result of inquiries sent out by one of my house-surgeons to a large number of patients who have had the radical operation. Only a very small number (not more than 3 per cent.) complained of what might be called acute symptoms. One patient complained very bitterly of all sorts of physical and mental disturbances, but it was found, on referring to the notes, that in her case one ovary had been left. The conclusion I have come to is that the severity of the symptoms depends more on the type of patient than on the operation. If a woman is of a highly nervous temperament she may have all sorts of symptoms when neither ovary is removed, while, on the other hand, many patients have practically

no discomfort after the radical operation. The great majority, for about twelve months after the radical operation, have a moderate degree of discomfort from flushes or flatulence, and other minor troubles.

The dangers of the operation apart from complications and accidents are chiefly thrombosis and embolism in patients who are profoundly anaemic after long-continued or profuse haemorrhage. This is the risk that has been most difficult to overcome, but it has yielded to a most scrupulous asepsis. Some years ago it was not uncommon to find swollen legs after hysterectomy. The occurrence was thought to be unavoidable, and fortunately most of the patients recovered. Now and again a patient died suddenly from heart failure, as the result of thrombosis or embolism. These unfortunate accidents became less frequent with the improvement in asepsis and technique. I have not seen a thrombosis of the leg after a hysterectomy for years. Sudden death from cardiac failure unfortunately still occurs, but is now limited to patients who have been blanched by prolonged haemorrhage and whose hearts are feeble and irregular. Such cases are always formidable, but I am convinced that even these may be brought to a successful issue if the strictest precautions are taken. During the last few months I have operated on 5 such cases with a good result, and I think they would have had a very poor chance but for the precautions observed. All of them had weak irregular hearts, in fact all of them had been told that they had heart disease; they were all fat and flabby and very pale.

The precautions I refer to may be summed up as (1) the observance of the aseptic ritual in its most thorough form, and (2) what is known as "team" work in operating. As regards asepsis, I am obliged to confess that I was slower than some others in adopting the modern methods, but that now I am convinced that the elaborate details of gloves, sleeves, masks, tetra-cloths, etc., all have their effect in the smooth recovery which is now the rule after severe operations, and that they are of the utmost importance in operations on very anaemic patients. It may seem late in the day to refer to this point, which some may think was settled years ago, but I am so convinced that it is an essential one for success that I feel bound to emphasize it. Further, we hear of a reaction against the use of gloves in some quarters, and I know personally of one important Continental clinic where they are not used. The advantages of "team" work are obvious. It is of importance that in major operations the surgeon should operate in surroundings with which he is familiar and with assistants who know his ways so that the whole of his attention can be devoted to his work, without the distractions inevitable if he has to keep a supervising eye on all that goes on. It is often a delicate matter to indicate to the doctor who has accompanied the patient that he will not be required to assist, but I think it is best to make a rule and to allow no exceptions—save in cases of urgency where the patient cannot be moved. As regards the assistants I think it is possible to have men who are too good for that post. I believe my best results are obtained with the help of one or two nurses who have been drilled in the strictest aseptic details and who simply do as they are told. They never come in contact with "dirty" cases (in the surgical sense), and their hands are smooth and easily sterilized.

Treatment by X Rays.—I now pass to a subject on which there seems to exist a wide diversity of opinion. I refer to treatment by *x* rays. I may state at once that I hold strong views on the subject and that I am opposed to this treatment for uterine fibroids. The objections may be stated as follows:

1. All who are engaged in gynaecological work know how difficult it sometimes is to be sure that we are dealing with a fibroid and not with some other condition. Mistakes are not uncommon: (*a*) In cases of pelvic inflammation where hard masses are found inseparable from the uterus; (*b*) in cases of solid or tense ovarian tumours, especially if they are adherent to the uterus; (*c*) in cases of ovarian and tubal disease associated with uterine fibroids; (*d*) in sarcomata and adenomyomata of the uterus, where the diagnosis is only made with certainty after the tumour has been removed; (*e*) in carcinomata of the uterus associated with a fibroid, or in large cancerous growths in the pelvic cellular tissues; (*f*) degenerations in fibroid tumours, especially red degeneration and calcareous change. I have analysed 201 of the cases in which I have operated (those at the infirmary and those at the nursing homes), and I find the following complications were present: Ovarian cyst, 13 cases; red degeneration, 12 cases; suppuration in tube or ovary, 6 cases; appendicitis, 4 cases; calcareous degeneration, 5 cases; fibro-cystic tumour of uterus, 2 cases; carcinoma in the fibroid, 2 cases; adenomyoma, 2 cases; necrosed polypus, 1 case; hydroperitoneum, 1 case—that is, we found complications in 44, or in nearly one-fourth of the cases.

2. Sufficient time has not elapsed since the introduction of the *x*-ray treatment for fibroids to enable one to state that there will be no further troubles after the haemorrhage has ceased. But judging from what has happened in many cases after the expectant treatment there is every reason to believe that many of the tumours which seem for the present to have been successfully treated by *x* rays will cause serious trouble in the future. The later degenerative changes are just as likely, if not more likely, to occur after this treatment as after the expectant treatment. Further, if operation has to be undertaken at a later stage there is reason to believe that it will be more difficult after *x*-ray treatment. I have no experience on this point—I am expecting to have it ere long—but I am informed by surgeons that the removal of a thyroid gland which has been treated by *x* rays is a much more formidable operation than in cases where there has been no previous treatment.

The advantages of operative as compared with *x*-ray treatment may be summed up as follows:

1. The mortality of the operation is now very small—in cases suitable for *x*-ray treatment it is under 2 per cent. (3 cases are deducted from the 9 fatal cases as unsuitable for *x*-ray treatment—1 case of acute intestinal obstruction, 1 case of infected fibroid, and 1 case of large calcareous fibroid where death occurred from peritonitis). The mortality following *x*-ray treatment cannot be estimated for many years.

2. The cases in which operation was most dangerous (cases of profound anaemia) a few years ago, may now be undertaken with little risk.

3. The patient after operation is at once and for all relieved of any anxiety concerning the tumour.

I believe the *x*-ray treatment has a place in gynaecology in the treatment of cases of chronic metritis associated with profuse haemorrhage at the menopause. But I believe it should be given up in cases of fibromyomata of the uterus.

II.—Karl Gauss,
Professor of Gynaecology, Freiburg.

(Abstract.)

When the subject of myomata comes under discussion in Germany very little is nowadays to be heard of operative treatment. Ray-therapy has become such a matter of course that it might be imagined that no doubts had ever been entertained as to its value; yet only five years ago it attracted hardly any attention, and up to two years ago it was still violently opposed in many quarters.

A statistical summary of all the cases of myoma and metropathy treated by ray-therapy, of which reports had been published prior to January 1st, 1914, is very instructive. I take the following figures from a paper to be published shortly by Johannes of the Freiburg Hospital for Diseases of Women. The cases fall into three groups according to the strength of the dose of radiation employed.

	No. of the Treated Cases.	Cure.	Death.	Recurrence.
Group I (50–175 *x*)	693	72%	0.5%	4%
Group II (175–500 *x*) ...	544	82%	0%	3%
Group III (500–1,500 *x*) ...	158	95%	0%	0%
Total	1,395			

The first group embraces a total of 693 cases, in which total doses of 50 to 175 of Kienböck's *x*-units were applied. The second group includes 544 cases, the dose being from 175 to 500 *x*-units. Finally, Group III includes 158 patients, who were given doses amounting to from 500 to 1,500 *x*-units. Corresponding to the rise of the total doses in the three groups, there is a rise also in the percentage of

cures from 72 to 82 and 95. It can be seen from this that the success attained is greater in proportion to the dose of radiation applied to the surface of the body. The difference does not, however, lie only in the size of the dose employed. There was a difference also in the quality of the rays employed in the three groups. Corresponding to the various stages of the gradual development of the methods, Group I consists almost entirely of cases treated either without a filter or with very thin filters—that is, with very soft rays. Filters were used in all the cases of Group II, but they were not so thick as those employed in Group III.

Moreover, in addition to these differences, the class of patient treated was entirely different in each group. Thus, Group I consists almost entirely of cases which, in consequence of the method not being at that time very reliable, were specially selected. Group II represents cases undertaken when advances in technique had somewhat lowered the qualifications demanded for admission to Roentgen treatment; and Group III embraces, as far as can be gathered from the reports, practically all the cases of myoma and metropathy that presented themselves for treatment; at all events, this was the case so far as the Freiburg clinic is concerned. Consequently the improvement shown in Group III must be due not to the character of the cases, but to improved technique.

Only in Group I were there any deaths—namely, 0.5 per cent.—but the records do not attribute them to the method of treatment.

Among the patients in Group II and Group III there were no deaths. This fact alone justifies a claim that all cases of myoma should be treated by radio-therapy, for the lowest mortality ever claimed for operative methods is from 3 to 5 per cent. The figures for recurrence appear also to have been continuously reduced by the increase in the doses employed and the improvement in the quality of the rays of which they consist. Whilst in Group I the recurrences work out at 4 per cent., and in Group II at 3 per cent., Group III has no cases of recurrence to record.

The evidence of the table given above, compiled from data from a number of different hospitals, and varying greatly in value, is still further corroborated by our own experience in the Freiburg Hospital for Diseases of Women.

The 205 cases of myoma and metropathy which we have already reported in detail[1] have been supplemented by another 195 cases of our own, not including any cases still under treatment, which will shortly be reported in detail in a paper by Momm.[2] We have therefore at our disposal as data 400 cases of our own. The first 205 cases constitute a mass of evidence of very unequal value, as they belong to a time when our methods were still in process of development. In the last 195 cases, on the contrary, as a consequence of the experience already acquired, an almost unvarying technique has been employed. As this second group of our cases fully confirms the good results obtained in the earlier cases, it will probably be admitted that we are in a position to pass final judgement on the method.

In the case of two women among these last 195, we aimed at producing not amenorrhoea but only oligomenorrhoea, and this was obtained. Twenty-four patients ceased to attend before treatment was complete, although nothing calculated to reduce their chances of recovery had taken place. In all the remaining 169 cases the desired amenorrhoea was obtained. As all cases of myoma or metropathy which came to the hospital were treated with Roentgen rays, with a few exceptions which appeared to be necessary for special reasons, our former assertion that nearly all cases of myoma can be cured by Roentgen rays finds renewed confirmation.

Our experiences as to permanency of results are equally satisfactory. Of the patients hitherto summoned for supplementary subsequent examination, we have exact knowledge of their state in 174 cases. There was relapse—that is, a recurrence of the menstruation—only in 3 cases, that is in 1.7 per cent. In all but one of the cases of recurrence the supplementary course of radiation, which is now our routine, was omitted—a mistake we are not likely to repeat.

There is little to say as to our technique. We mark out on the patient a series of about twelve areas on the abdomen and about six on the back, each area being 4 to 6 cm. square. With the focus at a distance of 20 cm. from the skin, each of these areas is treated below an aluminium filter 3 mm. thick. The first series of applications of the rays, consisting on an average of about 400 *x*-units, is followed at an interval of seventeen to twenty days by a second, and so on until the desired amenorrhoea is obtained; on an average this is the case after four series. As a precaution the two so-called supplementary series are then administered at like intervals to prevent recurrences. No injuries have resulted from this technique, which has now been employed by us for years.

Nevertheless, for some few cases radio-therapy appears to be contraindicated. Sanious myomata, submucous myomata that protrude from the uterus, and those myomata which cause serious and acute compression symptoms are better treated by operation. On the other hand, the majority of women suffering from myomata and metropathies who have recourse to a hospital will, however, in the future always be treated by Roentgen therapy.

DISCUSSION.

Dr. HASTINGS TWEEDY (Dublin) said that Dr. Donald had fairly expressed the views of British gynaecologists, and the data put forward by Professor Gauss were not sufficient to justify their abandonment. There were many symptoms other than that of haemorrhage which called for operative treatment. Palliative measures might cause disaster if the diagnosis were mistaken, and who could say that mistakes were impossible or even unlikely? Apart from actual disasters much valuable time might be lost to those who had eventually to submit to operation.

Dr. NIGEL STARK (Glasgow), after allusion to the fact that dangerous degenerations of fibroids were known to occur even after the menopause, said that the operation of choice was a subtotal hysterectomy. This removed the tumour permanently and entirely, and that the risk was small was shown by the result of his last hundred operations, among which the death-rate was only 1 per cent. Professor Gauss's statistics seemed to him to be vitiated by the inclusion of cases of myopathy, which he took to mean cases of chronic metritis with haemorrhage. It was already well known that electrical treatment of various kinds had a favourable effect in inflammatory conditions, and he trusted that it would go forth as the opinion of the Gynaecological Section of the Association that at present the only sure and sound treatment of myomata lay in hysterectomy, more especially the subtotal variety.

Professor MURDOCH CAMERON (Glasgow) expressed himself as being in agreement with the views of Professor Donald. Little had been said as regards diagnosis, but there was an essential point in determining treatment. He had had experience of cases where very eminent men of world-wide fame had proved in error as to the character of growths under observation. Professor Gauss had spoken of reserving certain cases for operation, but these seemed to him to be the very cases that should answer to Dr. Gauss's own methods, as he understood that by *x*-rays the growths entirely disappeared.

Sir JOHN BYERS (Belfast) thought that the right attitude at present was one of scientific scepticism in regard to the methods described by Professor Gauss. As for operative treatment, though a woman with a uterine fibroid should usually have it removed, yet now and again such tumours might subside. But all such cases, even if free from symptoms, should be kept under observation, and if the growth enlarged, immediate operation should be done.

Professor KYNOCH (Dundee) agreed as to the futility of expectant, or medicinal, treatment. In all cases of fibromata causing symptoms he advocated operation. He had entirely given up vaginal hysterectomy except in cases of small interstitial fibroids in multiparous patients. Oöphorectomy still had a limited field of application, as, for example, in small bleeding fibroids in nulliparous patients with enormously thick abdominal walls. His experience of enucleation had led him to give it up in favour of hysterectomy. He practised the subtotal in preference to total hysterectomy unless there was evidence of involvement of the cervix. In the reported cases of malignant disease

occurring later on in the cervix, the condition had been present but unrecognized when the fibroid was removed, or had developed at such a remote period as to prove that it had no connexion with the primary disease. His own results confirmed what Professor Donald had said as to the advantages of the subtotal operation. The occasional occurrence of a cervical leucorrhœa was the only unfavourable sequel he had noted. In patients under 40 he favoured leaving one or both ovaries (unless obviously diseased), and also a small piece of endometrium. The late results of several of his cases showed that the patient's comfort was greatly increased by the occurrence of even slight and irregular menstruation. As regards the *x*-ray treatment, he had visited with an open mind the Freiburg and other Continental clinics where this method was extensively employed. He believed it would have a field of usefulness in certain selected cases, and would not have the short-lived career of the Apostoli treatment. It was important to bear in mind that just as the good results now obtained by operative treatment had only been reached by a perfected technique, so in the same way the good results reported from those clinics had been obtained by a perfected technique developed from a very primitive one. This primitive technique produced most disappointing results, cases having been reported in which uterine haemorrhage had increased, but from what he had seen he believed that with the greatly improved technique, haemorrhage due to uncomplicated interstitial fibroids could be cured and the tumour diminished in size. But all cases before being submitted to the *x*-ray treatment should be most carefully examined in order that the diagnosis might be as correct as possible, and complications excluded. To prove this he demonstrated fresh specimens of fibromata, complicated with carcinoma, sarcoma, and red degeneration, cases where even the most enthusiastic supporter of *x*-ray treatment would advocate operative treatment.

Dr. PURSLOW (Birmingham) stated that his usual practice was to perform supravaginal hysterectomy. As regards total hysterectomy, he asked Dr. Donald's opinion as to its advisability in cases where erosion of the cervix existed; in these, if the cervix were left, the patient still complained. He believed that in some of the worst cases of climacteric symptoms suggestion formed a strong element, owing to the popular view that serious results would follow removal of the ovaries. He had had slight experience of *x*-ray treatment of fibroids, having placed some cases under the radiologist of the Queen's Hospital, Birmingham. In one of these haemorrhage had lessened, and the size of the tumour had distinctly diminished.

Professor B. P. WATSON (Toronto) pointed out that the effects produced by *x*-ray treatment were to a great extent due to the atrophic effect on the ovaries. From this point of view the treatment was in the nature of a harking back to the old operation of oöphorectomy. There was, of course, also some direct action on the tumour, but the results obtained must be principally due to the action on the ovaries. Just as at the natural menopause, so after the menopause induced by Roentgen therapy degenerations of various kinds might occur.

Mr. BECKWITH WHITEHOUSE (Birmingham) fully concurred with the view expressed by Dr. Donald as to removal of the ovaries when it was necessary to sacrifice the whole of the uterus. This was the practice both of Dr. Thomas Wilson and himself. If, however, it was possible to conserve any portion of the uterine endometrium he considered that the ovaries should be left, inasmuch as it seemed probable from experiments performed by him, and recorded in his Hunterian Lecture, that the secretions of the uterus and ovaries acted in conjunction. The ideal method was to conserve both endometrium and ovaries. As regards the *x*-ray treatment, Professor Gauss had stated definitely that the neoplasms disappeared, quite apart from the cessation of haemorrhage.

The PRESIDENT said there could be no doubt that removal by myomectomy or hysterectomy was the correct treatment of fibroids, but he would not go so far as to advise their removal in cases unaccompanied by symptoms. In a young woman who consulted him for sterility, and who had small fibroids without symptoms, he would be disposed to try ordinary dilatation and curetting first before suggesting myomectomy, as pregnancy might occur without dangerous complications. He would also be disposed in a woman of 52, who had only slight symptoms, and who resented operation, to adopt less severe treatment than hysterectomy, so as to tide her over the menopause. In his experience fibromyomata very seldom gave trouble after the menopause; in over 800 cases on which he had operated for fibromyomata, only 12 were after the climacteric, and he knew of many cases of aged women who had fibroids which gave rise to no trouble. He endorsed practically everything Professor Donald had said with regard to the *x*-ray treatment. It merely sterilized the patient in the same way as removal of the ovaries. It was irksome and prolonged, and very slightly influenced the tumour itself. He had a large experience of Apostoli's treatment, which was very successful in many cases, but failed in more.

Professor DONALD, in a brief reply, said he was pleased that *x*-ray treatment had received so little support from the Section, but at the same time regretted that Dr. Gauss was not present in person to uphold his views. With regard to the question of removal of both ovaries, the speaker's practice was based, not on theory, but on practical results.

DISCUSSION ON THE TREATMENT OF CONTRACTED PELVIS IN PREGNANCY AND LABOUR.

OPENING PAPERS.

I.—HENRY JELLETT, M.D.,
Master of the Rotunda Hospital, Dublin.

(Abstract.)

PELVIC contractions may be divided into two main groups—symmetrical contraction and asymmetrical contraction. With the latter of these I do not propose to deal, as time for doing so is not available. There are two main types of symmetrical contraction—simple flat pelvis and generally contracted pelvis. In the former variety the conjugate diameter is principally affected; in the latter variety all the diameters of the pelvis are more or less affected, but still preserve their normal proportions to one another. I have always followed the teaching that divides symmetrical contraction into four degrees, based on the length of the true conjugate. These degrees are not laid down on mere haphazard lines, but are the direct result of what practical working shows to be right.

In the first degree, with a conjugate above 3¼ in., it is usually possible for a full-term child of normal size to be born, provided the uterine contractions are normal in intensity, and that the presentation is normal. In the second degree, with a conjugate between 2¾ and 3¼ in., it is only possible for a living child to be born through the vagina if either the size of the child is below the normal or the size of the pelvis is increased. That is to say, either premature labour must be induced, or pubiotomy or symphysiotomy must be performed. In the third degree, with a conjugate between 2¼ and 2¾ in., it is impossible for a living and viable child to be born through the vagina, and consequently Cæsarean section alone is available. In the fourth degree, with a conjugate below 2¼ in., it is impossible for a child, even though considerably reduced in size by some destructive operation, to be born through the vagina, and consequently, whether the child is alive or dead, Cæsarean section is necessary. In the second degree and in the third degree Cæsarean section can be performed if it is considered advisable, while in any of the first three degrees, if the child is dead perforation or other reducing operation can be performed if necessary.

The treatment of the third and fourth degree of contraction may be regarded as definitely settled. I do not think that in either of these degrees any one will be found to advise any other course than Cæsarean section if the child is alive, unless the circumstances of the case are altogether exceptional. The treatment of the first degree is still open to discussion, and the teaching of obstetricians in general varies to a considerable extent. I do not propose, however, to consider it to-day, but rather to devote

the time at my disposal to the consideration of the treatment of the second degree of pelvic contraction.

In this degree four courses are possible: First, the induction of premature labour in order to get a smaller child; secondly, the enlarging of the pelvis by pubiotomy or symphysiotomy at term; thirdly, Caesarean section at term; and, fourthly, craniotomy. It is unnecessary to refer to the last, because I think modern obstetricians are practically universally agreed that perforation is only permissible in the case of a dead child, except under the most exceptional circumstances.

It may be well if I briefly sum up the different advantages and disadvantages of the three remaining lines of treatment. First comes the induction of premature labour. The advantages of this procedure, in my opinion, are not very numerous, and principally consist in the fact that it is comparatively easily carried out, and that it usually results in the birth of a living child. On the other hand, the arguments against it are, first, that it is extremely easy to infect the patient during the process of induction; secondly, that all methods of induction recommended up to the present are uncertain in their action, and sometimes mean repeated manipulation and considerable delay; and, thirdly, that the premature child is very liable to die in consequence of its feeble condition. I am sure there are many who will consider that I am underestimating the advantages and over-estimating the dangers of this procedure, but still I am inclined to state as my deliberate opinion that the induction of premature labour in the second degree of pelvic contraction is not the treatment of choice, although it sometimes may be the treatment of necessity.

The second possible line of treatment is Caesarean section. In favour of this operation are a considerable number of points. In the first place, it is very simple and easily carried out. If it is done early in labour, or at the beginning of labour, or before labour has begun, it is almost free from risk. There is no such thing as vaginal or perineal laceration; recovery is rapid; there are none of the pains and discomforts of a prolonged labour; and the fetal prognosis is usually entirely good. Lastly, it can be performed in subsequent labours, probably as often as is required, provided no abdominal infection occurs. In fact, it only possesses two disadvantages, but these are serious. If we are to get all the benefits of Caesarean section without the dangers, it must be performed either before labour begins or early in the first stage, and, consequently, it is not possible to give the patient an opportunity of delivering herself. The second disadvantage is the result of this—namely, that when once a Caesarean section is done on a patient on account of contracted pelvis, there is no logical reason why it should not have to be done in every subsequent pregnancy. In short, one may say, once a Caesarean section always a Caesarean section. This is a serious disadvantage, first, because it is not always possible to measure a pelvis so very exactly as to be able to say that it falls positively into a certain degree, and, secondly, even if one can measure it so exactly, one is not able to estimate correctly the actual size of the fetal head. Practical experience shows that in the second degree of pelvic contraction or in border-line cases between the first and second degree it may be entirely impossible to deliver through the vagina a living child at one labour, whereas in the next labour, with stronger uterine contractions and greater moulding of the head, it is possible to effect delivery. If, however, a woman is to be delivered by Caesarean section the operation must be done at an early period of labour, so losing all possibility of spontaneous or instrumental delivery.

The third possible line of treatment of these cases is pubiotomy. In favour of this operation are the facts that it is a smaller procedure than is Caesarean section in a favourable case; that its performance can be postponed till the last possible moment, when a positive indication for delivery on behalf of either the mother or the child arises, and that so every opportunity of spontaneous delivery or of delivery by the forceps is afforded; and that it improves directly the prognosis of subsequent labours, because it causes a permanent increase in size of the pelvis. On the other hand, the operation possesses certain disadvantages. In the first place, the antecedent labour is prolonged and painful, and during it the child may possibly die, owing to compression, even though it is most carefully watched. Further, it is always liable to cause laceration of the vagina and possible injuries to surrounding parts, and, consequently, in unfavourable cases it may prove to be a much more difficult operation than is Caesarean section. One has therefore to consider carefully whether the possible risks of a pubiotomy are or are not counterbalanced by its advantages. I am of opinion that the advantages are considerably in excess of the disadvantages. First, because the fact that the operation can be performed late on in labour gives the patient every opportunity of escaping any operation, and, secondly, on account of the extremely beneficial effects of pubiotomy on subsequent labours.

[The speaker then justified his belief by throwing on the screen lantern-slide tables relating to all cases in which pubiotomy had been performed at the Rotunda Hospital either by his predecessor, Dr. Hastings Tweedy, or himself. The first showed in a general way the essential facts of all the cases. The second showed the nature of the different complications occurring during the performance of pubiotomy or subsequently. Only in 4 out of the 19 cases did anything that could be regarded as a serious complication occur, and in all the 19 cases the ultimate recovery was perfectly satisfactory. Two cases demonstrated that failure of union of the bone at the site of incision in no way interfered with locomotion. The third and fourth tables showed the difference between labours occurring previous to the performance of pubiotomy and labours occurring subsequent thereto. It was seen that whereas in 29 labours previous to pubiotomy only 3 children were delivered alive spontaneously, subsequent to pubiotomy 8 children out of 15 labours were delivered alive spontaneously. In one case three Caesarean sections had been performed after pubiotomy, and the first table showed that this patient's conjugate diameter was less than that recognized as the normal minimum for pubiotomy, namely, 7 cm.]

In conclusion, I would like to offer for discussion the following opinions of my own as to the treatment of the second degree of pelvic contraction:

1. Pubiotomy is the operation of choice, unless there are special circumstances in the case or special complications present.

2. Pubiotomy is specially indicated in the young multipara, because, owing to previous labour, the vaginal canal is dilated and lacerations are unlikely to occur, and because of the effect of the operation on subsequent pregnancies.

3. On the other hand, Caesarean section is more suitable in the elderly primipara, because vaginal laceration is more likely to occur, and because it is unnecessary in her to take account of further pregnancies.

4. Premature labour is only indicated under special conditions which render either of the foregoing operations impossible or inadmissible.

5. Craniotomy is only permissible when the child is dead.

I have deliberately refrained from entering into the methods of performing pubiotomy or into any detail regarding it, as what I want to bring before you for discussion is the broad question of the advisability or otherwise of the operation.

II.—Professor FRANK,
Cologne.
(Abstract.)

PROFESSOR FRANK said that a hundred years ago people tried to prohibit by law the operation of symphysiotomy as if it were an attempt to murder. To-day this is the most successful operation in the whole of midwifery, and it ought to be learnt by every accoucheur, because it is simple and not dangerous. In spite of that, this operation is thought to-day more of historical than of scientific importance. Its disuse is nearly universal. People think the operation dangerous, and therefore cannot find any indication for it. This can be understood if one wants to operate by old methods which are dangerous.

1. In regard to the bleeding. Even masters in their business, like von Rusthorn, could not avoid occasional deaths from haemorrhage.

2. In regard to the haematoma, which easily becomes infected, resulting in sepsis.

3. In regard to the tearing of the soft parts, because one did not know the extent of tearing at the site of

operation, and after division of the pelvic bones, the best way of delivery.

Subcutaneous symphysiotomy is up to now the least dangerous operation for both mother and child. The bleeding is prevented, as the clitoris is pulled down from under the arch by means of the left hand. The second danger, the infection, is prevented by the fact that the operation is completely subcutaneous. The outside wound must not be larger than the breadth of the narrow knife used, which is the only instrument employed. When the knife leaves the wound, the operation must be entirely finished. The operation is finished when a jerk is felt and the pelvis gapes for several centimetres. The opening in the skin is sutured immediately with catgut. The third danger, the haematoma, is prevented if the parts at the site of operation are compressed for some time. The fourth danger—the laceration—is prevented, as one does not operate in cases of too great disproportion between the head and the pelvis, and in primiparae one is particularly careful with regard to the position of the legs before and after the incision. I have performed this operation in my clinic 155 times, and among the cases there were 40 primiparae. None died from operation. The two deaths that occurred had nothing to do with the operation. One was infected with gonorrhoea, and died on the eleventh day. The operation wound was healed, but there was a right pyosalpinx with purulent peritonitis. The gonococci were found in the peritoneal effusion. The other case was brought in with severe nephritis, and died eleven days after from uraemia. One can say quite fairly the operation is simple and not dangerous. It is remarkable that haematoma did not occur. Primiparae were not excluded but carefully chosen.

A contraindication is narrowing in the fourth degree, and of unique value is the subcutaneous symphysiotomy as the last resort when after version the head is retained.

Unless the os is fully dilated one should not operate. That is the rule, but, as shown by my statistics, there are several exceptions. It is desirable, if one can, after operation, to leave the birth to Nature, but this is not always possible, if, for instance, pains become less, or if the operation is done as the last resort.

Rise of temperature is no contraindication to the operation if one is anxious to save the child.

Statistics show that the operation has proved excellent. As regards the saving of the child's life, the statistics taken in the case of mothers who have already borne children without this operation, are interesting. Without operation 23 per cent. were live births, with operation 94 per cent.

My conclusions are as follows:

1. In cases with large disproportion, I advise the classical Caesarean section, if one can guarantee asepsis.

2. If the asepsis is doubtful, delivery by the suprasymphyseal route is advocated.

3. In the middle degrees of narrowing the subcutaneous symphysiotomy is to be preferred in multiparae. In primiparae, with narrow soft parts, the suprasymphyseal delivery is to be preferred if there is suspicion of infection. In clean cases in primiparae classical Caesarean section is advised.

4. In primiparae symphysiotomy is to be considered if there is only slight obstruction to delivery.

DISCUSSION.

Dr. HASTINGS TWEEDY (Dublin) said the Master of the Rotunda had put his facts so clearly that he had left no further excuse for scepticism as to the value of pubiotomy. His indications for this operation and also for Caesarean section were altogether admirable. When once the true measurements of the pelvis had been ascertained, treatment became precise and scientific. The obstetrician must make up his mind that in certain instances he would be called on to perform either symphysiotomy or pubiotomy as an easier and less elaborate operation than Caesarean section. The latter would find greatest favour amongst hospital operators.

Professor MURDOCH CAMERON (Glasgow) stated that his line of practice in cases of contracted pelvis might be placed under three heads: (1) Forceps, (2) induction of labour, (3) Caesarean section. Symphysiotomy had no place in his practice, but he did not object to other specialists in that line performing it. He considered induction of labour had a very important place and preferred it to symphysiotomy. In the hands of a general practitioner, where precautions against sepsis were taken, there was little or no danger. He thought that the relative size of the fetal head and the pelvis was the chief point in deciding the method of delivery. As regards Caesarean section, he objected to cases which should be dealt with by this operation being relegated to craniotomy simply because such patients had been examined outside either by a midwife or practitioner. As regards high forceps cases, he took the opportunity of showing his antero-posterior forceps, which were a vast improvement on the ordinary forceps. Along with them he drew attention also to his axis-traction cephalotribe, crochet, blunt hook, and decapitator.

Professor KYNOCH (Dundee) considered that in minor degrees of pelvic contraction their aim should be to obtain spontaneous non-operative delivery. To achieve this the duration of the second stage of labour should not be decided by the hands of the clock, but by observing the progress of the advance of the head, and the effect the labour was having on the condition of mother and child. In cases where spontaneous delivery was improbable, Walcher's position, with or without help by forceps, generally succeeded. Version should be reserved for special cases, such as malpresentations movable at brim. The rate of infantile mortality with high forceps or version was about the same (40 per cent.). Where the first labour had proved difficult, and the child had died, in future pregnancies they had the choice of inducing premature labour, or an operation involving an increase in size of the pelvis. One of the most important problems for the teacher of obstetrics was to decide whether operations involving the widening of the pelvis were to be chosen in preference to other methods. He thought that the induction of premature labour had been too adversely criticized of late. Its failures were in many cases due, not to the method itself, but to its being carried out is a haphazard way, instead of carefully measuring the pelvis, and watching from week to week the relation of size of the child's head to the pelvic inlet, and endeavouring to postpone the operation if possible till the thirty-fourth week of pregnancy. With these precautions the infantile mortality would not be much higher than the general rate of infantile mortality. In this connexion he would emphasize what had been pointed out to him by Professor Herff, of Basle, namely, the value of the ratio of the greatest diameter of the child's head anteriorly, and the spine of the last lumbar vertebra, the so-called "Rücken Kopf Mass." If equal to, or smaller than, the external conjugate, the head would enter the pelvis easily; if 1 cm. larger, Walcher's position would probably suffice; if 3 cm. larger, the head would not pass and Caesarean section would be necessary. If 2 cm. larger, more care was required in the decision between induction, Caesarean section, or pubiotomy. He advocated, when possible, the induction of labour. With aseptic precautions it was safe; its results were fairly certain, and what was of most importance, it could be undertaken by the general practitioner. It was generally admitted that widening the pelvis was only suitable for hospital practice, which therefore must limit its usefulness. A permanent enlargement of the pelvis after pubiotomy was not to be relied upon, as was proved by the too frequent reports of repeated cases on the same patient. There was also the great drawback of a 50 per cent. morbidity owing to lacerations of the surrounding parts. In contrasting Caesarean section with pubiotomy, he strongly advocated section, because it was a straightforward operation, with good prospects for mother and child, and by it they could if necessary prevent subsequent pregnancies. He believed pubiotomy would always be of very limited advantage. He would reserve widening of the pelvis to cases where forceps in Walcher's position just failed to deliver a living child, and where craniotomy would be the only alternative. The most satisfactory method was subcutaneous symphysiotomy as recommended and practised by Professor Frank, the guest of the Section. Craniotomy should be reserved as far as possible for the delivery of dead children.

Sir JOHN BYERS (Belfast) said he would like to draw attention to the preventive aspect of the treatment of contracted pelvis. All women who were pregnant should be seen before labour and carefully examined, and then a decision should be arrived at as to the proper method of treatment. Further, if rickets were got rid of, many cases of contracted pelvis needing treatment would be prevented. He thought that cases needing special obstetric treatment should be sent into maternity hospitals or special hospitals, where the most modern operative means could be scientifically employed.

Dr. OLIPHANT NICHOLSON (Edinburgh) understood by the second degree of pelvic contraction cases where the pelvis had a true conjugate ranging from 3 to 3½ in. There were several alternative methods of treatment. The recognition of a disproportion between the child's head and the pelvis was of much greater importance than the absolute size of the pelvic cavity itself, which measurement, he believed, it was impossible to accurately determine by any of the methods commonly in use. In each case one really wanted to know exactly how the fetal head fitted into the mother's pelvis—a large head, especially if it was lying with the occiput behind, might fit very badly into a pelvis which had a conjugate of even 4 in., and might give rise to an obstructed labour. So one must always ascertain the size and exact position of the fetal head before assuming that pelvic deformity was the cause of difficulty. Cases sent into the Edinburgh Maternity Hospital for craniotomy had sometimes been successfully delivered of living children by the manual internal rotation of the body and head of a fetus lying persistently occipito-posterior. To gauge the relative size of the pelvic brim and fetal head the manipulative method described by Munro Kerr, if carried out under an anaesthetic, gave a good idea whether or not the head would pass readily through the pelvis. In a primipara, when one made an external examination five or six weeks before the full time—as should always be done—and found that the child's head had not entered the brim, one certainly suspected disproportion, for in normal cases the head should be well down in the pelvis. If this condition of relatively large head, or, it might be, relatively small pelvis, was recognized sufficiently early one had the option of performing induction of premature labour, and, in his opinion, this was the right and proper thing to do. It was quite unscientific and wrong under such circumstances to arrange to do a pubiotomy later on. One must fix upon the date of induction by the ease or difficulty with which the head entered the brim, not by the size and shape of the pelvis. If the induction of labour was selected for those cases of disproportion, the general practitioner could perform the operation—if operation it could be called—as easily and as successfully as the specialist. Nowadays, with the use of antiseptics, one could honestly say that, for the mother, a premature labour was as safe as one at full term; one could offer no other alternative which was nearly so safe. The easiest and most natural way of inducing premature labour—except in a primipara, when induction was seldom performed—was simply to pass a finger through the internal os and detach the membranes from the lower uterine segment as far as one could reach. Then the bag of waters was made capable of protruding through the open os, and labour would generally come on. If, after one or two such detachments, uterine action did not commence, it was the speaker's practice to pack ribbon gauze into the lower segment by means of a cannula packer, which was curved like a sound, and in that way lift the membranes still further off the uterine wall. All this could be done without an anaesthetic with the patient lying in the left lateral position—sometimes, indeed, under the guise of a vaginal examination. If Nature would not then start off labour within two days—which was very unusual in his experience—one could always provoke uterine activity by the insertion of a Champetier de Ribes's bag through the cervical canal. There was certainly no more morbidity from this method than might occur after a normal labour at term. One could employ this method in a primipara by the preliminary use of a laminaria tent, or by opening up the cervix with Fenton's dilators till it would admit the end of the gauze packer. As regards the children born prematurely his results in private practice were quite satisfactory, though in hospital the results were rather disappointing. When disproportion between the head and the pelvis was only detected after labour had started, one was obliged to consider either forceps delivery or pubiotomy. A child of normal weight (7 lb.) might be safely born with the forceps through a conjugate of 3¼ in. if the head was lying in a favourable position, and no definite time limit was fixed for the second stage, so that much moulding could occur. Possibly the Walcher position might assist matters. With a conjugate of 3 in., unless the child was very small the pelvis would have to be enlarged by pubiotomy or symphysiotomy if a living child was to be obtained. When a multipara had lost her first child from disproportion, as frequently happened, he advised that the next labour should be induced, and if the child was again lost he would still advise a second induction, even in preference to Caesarean section. He considered that the mother was subjected to a greater risk from pubiotomy, and in addition, her pelvis sustained a definite injury. If pubiotomy was done at all it should be reserved for some of the cases where prolonged moulding and forceps just failed to get a living child through the pelvis. When the head was caught at the brim, and forceps had absolutely failed, craniotomy on the living child, if necessary, was still the best practice, and in certain cases would always be carried out if one considered what was best for the mother.

Dr. JELLETT, in reply, said that much of the criticism which had been made seemed to be that pubiotomy could not be recommended because it was unsuitable to the general practitioner. He wished emphatically to point out that modern midwifery could not be hampered by restricting it to such measures as could be satisfactorily carried out by the general practitioner alone. If such reasoning was applied to the treatment of any gynaecological condition, such as fibromyoma, for instance, what would our present position be? General practitioners were much hampered in their work by insufficient assistance, unsuitable accommodation, and so forth, and consequently it was impossible to expect that they could carry out, no matter how skilled they were themselves, all modern methods of treating contracted pelvis. In his opinion, both the induction of labour and the treatment of contracted pelvis in general should be carried out in a properly equipped hospital, either public or private. Practically all the speakers had referred to the importance of noticing the relation between the head and the pelvis in cases of contraction. It was for this reason that pubiotomy was so valuable, because it applied the test of labour to the head, and one was able to allow the latter to mould for many hours through the pelvis before resorting to operation. In this way operation was frequently altogether avoided. He laid particular stress on the improvement which occurred in labours subsequent to the performance of pubiotomy, as was very clearly to be seen from the tables he laid before the meeting.

RUPTURE OF UTERUS THROUGH THE SCAR OF AN OLD CAESAREAN SECTION.

BY A. TENNYSON SMITH, M.D.Aberd.,
Orpington.

THE following case seems to present points of sufficient interest to merit its being brought before the notice of this Section:

On August 21st, 1908, I received a message to attend a Mrs. ——, aged 21, in her first confinement. I was told she had been in labour for about eight hours. Examination showed an elongated bag of membranes full of prolapsed cord, protruding through the os, which was about one-fourth dilated. There was a very considerable amount of contraction of the pelvis. General condition good. As I felt certain that delivery of a living child was impossible through the natural channel, I had her removed to the Cray Valley Cottage Hospital, where I immediately performed Caesarean section, making the usual high longitudinal incision. The placental site was cut into, and the placenta had to be separated before delivery of the child. The uterine incision was closed by means of two rows of sutures, one including peritoneum and the whole of the muscle down to the submucous layer, the second taking in peritoneum alone and burying the deeper layer. The woman made an uninterrupted recovery, and took her discharge from the hospital before the end of three weeks. The child, a well developed male, did well.

On August 5th, 1913, at 2 p.m., I received an urgent message to go and see the same woman, who was in labour. I found her in almost moribund condition—face drawn, lips pallid, extremities cold, with a pulse so rapid and feeble that it could scarcely be felt. The history I got was that she had been having labour pains, more or less severe, for over a fortnight, but would not allow her people to send for me as she was sure I would again take her into hospital. I was told that she had a severe pain suddenly on the morning of the 5th, when she sent for a midwife, who informed me that when she arrived she thought the patient was going to die suddenly. She gave her brandy, and applied hot-water bottles to keep her going. On examination the abdomen was big, flabby, with no muscle resistance and well filled up with free fluid. The fetus could be distinctly mapped out, and appeared to be just under the parietal wall. The diagnosis was clearly one of ruptured uterus, with severe internal haemorrhage.

It was quite impossible to do anything in her dirty cottage, and I had her removed to Cray Valley Cottage Hospital for operation, where I saw her in consultation with my partner, Dr. C. S. Battiscombe, and gave her a hypodermic injection of morphine gr. ¼, and atropine gr. $\frac{1}{150}$. She was desperately ill, but he agreed with me that her only possible chance—and that a small one—was by operation. The anaesthetic (A.C.E.) was given by Dr. Bennion, and during the operation she had a continuous saline injection in both axillae, 3 pints of saline being used. A long incision was made ½ in. to the right of her old incision scar. On opening the peritoneum a large quantity of blood escaped when the fetus presented itself—a back presentation with breech downwards and to the right, encased in its membranes. The child, which appeared healthy and only recently dead, was removed at once, and the uterus was pulled up into the wound. From that point there was no further haemorrhage. The abdominal cavity was then cleaned up. The placenta was free in the abdominal cavity and almost entirely surrounded by omentum which was adherent to the parietal peritoneum at the site of the old incision. There were no adhesions to uterine peritoneum. All blood and blood clots were removed as quickly and carefully as possible. On examining the uterus it was seen that a rupture 4 or 5 in. long had taken place along the line of the previous incision. The wall on either side of the tear was thinned out almost to a line to which the peritoneum was closely adherent, so that before the tear took place there must have been quite a deep sulcus. Any attempt to closely approximate the edges of the torn uterus by means of sutures being impossible, I decided to do a hysterectomy. The uterine arteries on both sides were ligatured, and the broad ligament clamped and ligatured close up to the uterus. A posterior flap of peritoneum and as little tissue as possible was made, and the uterus removed as near the cervix as possible. The stump was trimmed with scissors, the cervical canal mopped out with iodine, and a purse-string suture of catgut used to close it up. The stump was then covered by means of the flap which was sutured to the peritoneum in front, and the stump of the broad ligament buried on either side. All blood clot was carefully removed and the abdominal cavity swilled out with a hot saline solution, about a pint being left in. The parietal wound was closed by means of through and through sutures, a tube being left in for drainage. The condition of the patient, which was very critical and caused us great anxiety during the earlier part of the operation, improved somewhat during the later stages, and a little pulse could be felt when the patient was returned to bed, the foot of which was tilted up as high as possible. With the addition of a hypodermic of pituitrin given immediately after the operation, and which seemed to improve her condition, the after treatment was as usually followed out. The tube was removed in twenty-four hours and a stitch which had been inserted and left loose was tied. The woman wanted to leave the hospital at the end of ten days and took her discharge at the end of a fortnight. A month later I went to see her and found she was working in the fields.

The interest in this case lies chiefly in the fact that the woman went on for fourteen days of labour pains, and that, although she was not seen till seven hours after her rupture and not operated on for at least one hour and a half later, during which time she had to undergo a journey of five miles to the hospital, she was still able to rally after her operation. It is of interest to note that the placenta lay in the anterior superior segment of the uterus when the first operation was performed in 1908, and had to be separated from the uterus before delivery of the child. So far as I can gather, about 22 cases of similar accident—that is, rupture of the uterus through a previous Caesarean section scar—have been recorded, 4 in this country (2 by Targett[1] and 2 by Munro Kerr[2] of Glasgow), the rest by German and American writers, and in the majority of those the position of the placenta has been described as underlying the incision.

As Caesarean section is by no means an uncommon operation and secondary rupture comparatively rare, it would almost seem that the placental site in those latter cases may be a predisposing cause, the spongy nature of the tissues preventing firm union through the whole thickness of the uterine wall. It was a matter of regret to me, when I saw my patient in her cottage after her rupture, that I had not sterilized her during her first operation. I have come to the conclusion that one is perfectly justified in doing so. It depends, of course, a good deal on the class of patient one is treating, but, as a rule, I consider that efficient sterilization should be secured.

DISCUSSION.

Dr. RATCLIFF-GAYLARD (Birkenhead) gave details of a case in which Caesarean section had twice previously been performed, which was sent into hospital for uterine haemorrhage at the fifth month. Pelvic contraction was extreme. Her temperature was 100° F. Coeliotomy showed a ragged tear along the line of the old uterine incision, at the junction of the lower and middle thirds. The uterus was moored by adhesions. The rent was repaired with twenty-day catgut, the patient sterilized, and the abdomen closed in tiers. The patient recovered. His personal experience of the security of the uterine scar after Caesarean section was small, but there was no reason to doubt that twenty or thirty-day catgut was quite satisfactory. In the case in question the rupture appeared to have been due to expansion of the uterus limited by strong adhesions.

Other speakers discussed the question of the best suture material for uterine wounds. The meeting largely agreed with Dr. Donald that catgut was the best. Dr. SHANNON (Glasgow) suggested that possibly the rupture took place earlier than the reporter of the case believed.

Dr. TENNYSON SMITH, in reply, stated that catgut was used for suturing the uterine muscle at the time of the first Caesarean section on the case reported. Sepsis as a cause of the rupture could be absolutely excluded. There seemed no doubt that the rupture did take place on the date mentioned. The fetus was unmacerated, and appeared to have very recently died.

FURTHER EXPERIENCES WITH VERATRONE IN THE TREATMENT OF ECLAMPSIA.

By F. W. N. HAULTAIN, M.D., P.R.C.P.Edin.,

Examiner in Midwifery, University of Oxford; Physician, Maternity Hospital, Edinburgh.

A YEAR ago I brought before the Edinburgh Obstetrical Society a short communication on the treatment of eclampsia by means of veratrone, and having had a further satisfactory experience of this drug I again bring it under notice. My new cases are as follows:

CASE I.

Mrs. T., aged 35, primipara, seven months. Complained of headache, blindness, swelling of face and extremities. Urine scanty, solid on boiling. Pulse, 80; blood pressure, 170. 1 c.cm. veratrone injected at 10 p.m. By next morning headache gone. 20 oz. urine passed. Blood pressure, 120; pulse, 64. In spite of complete milk diet the urine continued highly albuminous and tended to diminish in quantity, while the blood pressure continued to rise. When it exceeded 160 headache was always complained of. Veratrone injections were therefore continued, and on every occasion brought down the blood pressure and instantly removed the headache. For over a fortnight this treatment was continued, without any permanent effect on the albuminuria and other symptoms. I therefore induced labour and a living child was born. In all, 7 c.cm. of veratrone were given. The albumin very slowly diminished from the urine, but all other anxious signs rapidly disappeared, except the defective sight, which took over five weeks to be restored.

CASE II.

Mrs. C., 8-para, pregnant seven and a half months. Previous pregnancies normal. Admitted February 12th, having had six fits. Face, arms, and legs markedly oedematous. Blood pressure, 175; pulse, 100. 4 oz. urine drawn off; 12 grains per ounce of albumin, granular casts. 1 c.cm. veratrone injected at 12.30. As the blood pressure continued to rise, and the urine to diminish in amount, I decided to induce labour by the Krause method. This was easily accomplished, and she was delivered of a living child on February 19th. During the pains the blood pressure at times rose to 195. During the puerperium the blood pressure never fell below 150, and the albumin in the urine never fell below 0.05 per ounce, in which condition she left the hospital after three weeks.

CASE III.

Mrs. D., aged 32, 4-para, admitted February 16th, 1914; with first and second child, both dead born, she had fits. In third pregnancy she was carefully dieted, had no fits, and the child was born alive. Since February 13th she had noticed swelling of fingers and face, and commenced to vomit, which continued steadily. On February 15th she had severe headache and dimness of vision. On February 16th she had several (five) convulsive seizures and became unconscious, and in this condition was brought to hospital. Blood pressure, 120; pulse, 70. Her blood pressure rose to 200, when she had another convulsion. 4 oz. urine drawn off; solid on boiling. 1 c.cm. veratrone given at 10 a.m. 11 a.m., blood pressure, 140; pulse, 60. At 5 p.m. the blood pressure rose to 160, when she had another convulsion, and 1 c.cm. veratrone was given. At 6 p.m. blood pressure, 130; pulse, 70; the patient was violently sick. At 6 a.m. 12 oz. urine drawn off. Her blood pressure gradually rose till 12, when 1 c.cm. veratrone was given. At 2 p.m. blood pressure, 110; pulse 55. At 4 p.m. 25 oz. urine drawn off. The patient remained fairly well for the next four days, and passed from 20 to 40 oz. of urine daily; gradually, however, the blood pressure again rose to 180, while the urine diminished in quantity and albumin increased. ½ c.cm. veratrone given at 10 a.m. on February 23rd; 11 o'clock, blood pressure, 140. She now sweated profusely. At 11 o'clock on the 24th blood pressure again rose to 195; ½ c.cm. veratrone given, and labour induced by Krause's method. Labour pains commenced on the 25th, during which the blood pressure rose to 210; 1 c.cm. veratrone given, which reduced blood pressure to 150. Living child born. Blood pressure remained high—150 for the next few days, and she left hospital on March 4th, albumin having disappeared.

CASE IV.

M. C., admitted on January 2nd, 1914. She had noticed much swelling of legs and feet for the last month. On December 30th she had difficulty in seeing and had severe headache, which had lasted till admission. On admission her entire body was swollen; blood pressure, 175; albumin 7 grains per oz. She was put on milk diet for some days, during which time her urine never exceeded 9 oz. in the twenty-four hours, and her blood pressure remained about 160. On January 5th, blood pressure, 180; albumin, 5 grains per oz.; 1 c.cm. veratrone given at 3.15 p.m.; pulse rate, 93. At 3.25, blood pressure, 125; pulse rate, 41. Patient violently sick. At 8 p.m., blood pressure, 110; pulse, 48. She now passed 22 oz. of urine, and her headache had entirely disappeared. January 6th, blood pressure, 160; pulse, 60; no headache; 30 oz. urine. January 7th, blood pressure, 180; headache renewed; 1 c.cm. veratrone at 1.50. At 2.5 a.m., blood pressure, 125; headache gone. January 8th, pains all night; during pains, blood pressure, 180. January 9th, 6 a.m., delivered of twins, alive and healthy. Puerperium uneventful. On dismissal, blood pressure, 130. Urine showed trace of albumin.

CASE V.

Mrs. C., primipara. Shortly after normal labour was seized with convulsions; four fits occurred in the course of two hours; 3 oz. of urine were drawn off, solid on boiling. Blood pressure, 180; pulse, 84. 1 c.cm. veratrone at 7 p.m. 7.30 p.m., blood pressure, 120; pulse, 56. 6 a.m., 20 oz. urine drawn off. No further fits occurred. Albumin rapidly diminished, no trace being found after ten days.

In a general survey of the foregoing cases the outstanding feature is the continuous presence of a raised blood pressure, both in the women in which fits had occurred and in those in which the premonitory symptoms of an imminent convulsion were evident. As this also obtained in all the cases I previously published, one may therefore legitimately reason that a raised blood pressure probably is one of the active factors in the development of convulsions—a contention which is corroborated by the fact that eclamptic convulsions are most prone to occur during labour, when the blood pressure is greatly increased by labour pains.

That a high blood pressure is the only or even the main cause of fits is not for a moment to be contended, as from the cases described it will be noted that, subsequently to the injection of veratrone the blood pressure rose considerably higher than it had previously been, and yet no convulsions occurred. It may be assumed, therefore, that an eclamptic seizure is of a complex nature, initially due to the action on the brain centres of a toxin or a poison, which among other manifestations gives rise to increased blood pressure, which may be considered as a potent factor in the active precipitation of the convulsion. It was with this theory in my mind that I determined to try veratrone, as from a previous use of veratrum viride I had got beneficial results, due I considered to the marked fall in the blood pressure with which its rise was attended.

In this direction the action of veratrone surpassed all expectations. Without exception, after the injection of 1 c.cm. the blood pressure was lowered markedly and rapidly, and almost in every instance with an immediate cessation of fits.

The depressent action is usually only temporary, extending over but a few hours. It is associated with a marked slowing of the pulse rate and increase of the urinary secretions and diaphoresis, and in some instances vomiting, particularly when the pulse rate falls below 55.

Through the kindness of Dr. Cramer, a number of experiments were made on cats, several of which I personally observed. From these the following conclusions were come to:

1. That in small doses it invariably causes marked fall of blood pressure and a slowing of respiration.
2. No effect is produced on either after the vagi have been cut.
3. When the blood pressure has been lowered, adrenalin and pituitrin still cause a marked constriction of the arterioles.

From these facts it may be assumed that veratrone stimulates the afferent fibres of the vagus, so that its effect is produced reflexly through the vasomotor centre and not through the paralysis of the vaso-constrictor nerve endings or the muscular wall of the arterioles. By this means the diaphoresis is secured by the dilatation of the skin arterioles, and the diuresis by the removal of spasm in the renal blood vessels.

It is more than probable, however, that it has a further action as an antidote to the eclamptic toxin, for, as has been shown on subsequent rises of blood pressure, fits seldom occur. This is further supported by the comparative mildness of the action of the drug in eclamptics or pre-eclamptics, when compared with cases of simple increased blood pressure, such as chronic Bright's disease. Here the injection of 1 c.cm. gives rise to extremely anxious symptoms of severe vomiting and syncope, associated with the marked lowering of blood pressure.

In eclamptics, on the other hand, the injection of 1 c.cm. may be repeated frequently without any toxic effects becoming evident. I have now used this drug in the treatment of 17 eclamptic and markedly pre-eclamptic cases, with the inhibition of fits in every instance. One of the cases ended fatally, the woman having been the subject of chronic Bright's disease with oedema for over a year, and had ten fits before the treatment was commenced.

The lines of treatment I have adopted have been the immediate injection of 1 c.cm. veratrone, with the stimulation of diaphoresis by hot packs and, if possible, attempts at free purgation by calomel and jalap. The blood pressure is carefully taken at frequent intervals, and if it rises over 160, ½ c.cm. veratrone at once given. The diet, I need hardly say, is purely milk.

It may be that the good results obtained are the will of Dame Fortune, but they rest on a sufficient physiological therapeutic basis to warrant a continued trial.

DISCUSSION.

Professor KYNOCH (Dundee) recorded two cases where the blood pressure and pulse were rapidly brought down with no recurrence of fits. The treatment was best carried out in hospital on account of the necessity for carefully watching the pulse rate. With the pulse kept constantly under 60 in cases of eclampsia fits would be unlikely to recur. On account of the great depressant action the effect of the veratrone must be most carefully watched, as in treatment by veratrum viride. With those precautions the results of this treatment were worthy of further observation.

Emeritus Professor WM. STEPHENSON (Aberdeen) recorded his experiences with preparations of veratrum viride other than veratrone. He had recommended treatment with this agent for many years, and had been well satisfied with the results. It was necessary for a good effect that the pulse rate should be reduced. Stale preparations would often fail to do this, and it would appear as if veratrone overcame this difficulty.

Dr. JELLETT (Dublin) considered that veratrone should not be considered a treatment, but as an adjunct to a fuller plan of campaign. The plan at the Rotunda Hospital, now in use for several years, had proved eminently satisfactory as statistics and details shortly to be published would show.

SECTION OF MEDICINE.

RAPID RELIEF IN ACUTE LUMBAGO BY MANIPULATION AND ACTIVE MOVEMENT.

By WILLIAM HAIG, M.B., C.M.Edin.,
Crieff.

WHEN we find one authority stating that "lumbago is usually regarded as a manifestation of rheumatism or gout, that it may be due to inflammatory changes in muscles or intermuscular connective tissue, to neuralgic affections of the nerve terminations in the muscles, to actual rupture of muscle fibres at the seat of attachment to the iliac crest, but that, for his own part, he believes it to be a thrombosis of the arterioles and capillaries due to a toxaemia," we may readily agree with his further statement that "in the absence of definite pathological data to go upon we can only theorize." Whitla, with fewer suggestions as to the tissues which may be affected, says: "The invariable absence of a fatal result has prevented any real knowledge being obtained of the actual pathological condition." Osler gives a good description of it; writing of neuralgia or muscular rheumatism, he says: "Lumbago, one of the most common and painful forms, affects the muscles of the loins and their tendinous attachments. It occurs chiefly in working men. It comes on suddenly, and in very severe cases completely incapacitates the patient, who may be unable to turn in bed or to rise from the sitting posture."

The suddenness of onset has made me think that the condition may be, in the first instance at least, a mechanical one, analogous to "crick" in the knee, which (as most of us, I dare say, have experienced) may be so severe that, but for the necessity of moving on and thereby setting in motion again the muscles which have suddenly come into a state of contraction, it would be quite as crippling as an attack of acute lumbago. Again, having heard from medical men of cases of evidently undoubted benefit in other conditions from the manipulation of the osteopath, it occurred to me to wonder whether as a profession we have not hitherto neglected the consideration of the spinal column as a series of individual movable joints. And, being desirous of seeing whether or not there might be some grains of wheat among the osteopathic chaff, I was led to try what amount of movement I could obtain in the various regions of the spinal column, with, in one case, rather remarkable benefit, but that is another story.

And so I come to my method of treatment, which consists of (1) deep thumbing of the lumbar muscles, in process of which a painful area is usually found either in the middle line or to one or other side; (2) fixing the part of the vertebral column below this painful region by firm pressure of the thumb on each side of the spine; and (3) making the patient perform movements of flexion, acute dorsiflexion, lateral flexion, and rotation. The result is cure of the attack of lumbago, inasmuch as the patient is able to at once return to his work, and in no case have I had to repeat the process.

Among the many remedies suggested by authorities on lumbago, remedies so varied as to include purgatives, diuretics, diaphoretics, hot baths, Turkish baths, warm packs, fomentation, hot ironing, iodides, iodine, guaiacum and sulphur, nux vomica in large doses, hypodermics of morphine or cocaine, local applications of A.B.C., counter-irritation by cautery or blisters, electricity with massage, acupuncture and porous plasters, I only find two suggestions as to movements. Romer advocates in traumatic lumbago the stretching of the contracted muscles and rupture of the adhesions by forcible movements executed under chloroform. And Chalmers Watson, in the *Encyclopaedia of Medicine*, says: "To those who cannot readily obtain the requisite amount of active exercise and fresh air desirable it is advisable to recommend the daily performance of two or three studied muscular movements—movements calculated to bring into play those muscles whose function through non-use is being abused." Obviously these writers are referring to chronic cases. My method is, I think, better, inasmuch as it cures the condition in the acute stage, and prevents it from becoming chronic. I mention three cases to illustrate the treatment and its results.

1. N. V., a ploughman on a small farm where his absence brought the work on the harvest field practically to a standstill. Naturally he and his employer were anxious that he should be well as quickly as possible. I found him lying in bed complaining of pain in the back and inability to move, temperature and pulse normal, tongue clean, and evidently in perfect health but for this crippling pain and stiffness in his back. Getting him into a sitting position with his back to the edge of the bed, I sat on a chair, and with my thumbs kneaded the lumbar muscles deeply for a short time; then, fixing the lower part of the spinal column by strong pressure of my thumbs on each side of one of the vertebrae, I made the man (1) bend forward as far as possible, then back as far as possible half a dozen times; (2) sit straight up and fall first to one side and then to the other half a dozen times; (3) still erect, turn his head and shoulders round as far as possible (until he could see with his left eye over his right shoulder and with his right eye over his left shoulder, I told him) half a dozen times in each direction, my thumbs all the while deeply pressed against his spine and my fingers spread out over the buttocks to keep the lower part of the body as rigid as possible. We finished with a few more antero-posterior flexions and extensions. The man returned to his work in the harvest field the same afternoon, and I had no occasion to see him again.

2. A. M., a chauffeur, came to my consulting-room one morning, telling me that while "cranking up" the previous evening he had been suddenly seized with pain in his back, and with difficulty managed to straighten himself sufficiently to walk home. He was now so stiff and sore that it was impossible for him to start up his engine, and he was required for a long journey that day. I made him bare his back, hold up his shirt with a hand over each shoulder, and sit astride a chair, while I knelt on the floor and carried out the operation already described. On finishing, I threw his cap on the floor, told him to pick it up, and asked how he felt. With a delighted smile, he replied, "Thank you, doctor, I am all right now, and able for my work." He went off, and has not required attendance since.

3. The last case I shall refer to is that of J. S., a very stout man, a wood merchant, who the previous day, when going through a wood marking trees for felling, had got thoroughly soaked, and had a long drive home in his wet condition. He was lying in bed, and complained of pain in his back and inability to move, but was otherwise in good health. With my assistance and with evident suffering he got out of bed and sat astride a chair. I carried out my treatment, made him pick up something from the floor, and asked him how he felt. With a surprised look at me through his glasses, he replied, "I am better the noo onywey." I told him to send for me if the pain should return, but no message came and he has remained well.

I mention these three cases as they are typical of what might be called rheumatic as well as traumatic lumbago. I have had many others with equally good results, and I feel sure that any one will have the same good results if he takes the trouble to try the method. It is not easy work, and one's thumb muscles are somewhat painful at the end of it, but the result is well worth the trouble. If you compare these results with a case under the old method, which stands clearly out in my mind because of the loss of time and the expense to a professional man not overburdened with this world's gear,* you will easily see the benefit of this method from the patient's point of view, and, especially if the patient be a panel one, from the doctor's standpoint as well.

THE BABINSKI SIGN IN TRANSIENT FUNCTIONAL DISEASES.

By F. C. EVE, M.D.Cantab., M.R.C.P.Lond.,
Physician, Royal Infirmary, Hull.

(*Abstract.*)

EVER since Babinski first published his valuable method of deducing from an extensor plantar reflex the existence of organic disease in the pyramidal tract I have watched this sign somewhat closely in general hospital and private work.

This experience revealed only one group of exceptions to the rule that the presence of an extensor plantar reflex in conscious adults indicates organic disease in the upper motor neurons. Conversely I have never found it present during or after hysterical paralysis or fits. The one group of exceptions is that, after fits, coma, or paralysis due to epilepsy, uraemia, or eclampsia, I have

*This man, having stooped to pick up a stud while dressing, was suddenly seized with lumbago, and had to remain in his half-dressed condition for a considerable time before help came; he was treated in bed at home for several weeks by the usual remedies, and ultimately was sent to Bath before he was fit to resume his duties.

learnt to expect to find a Babinski sign present for a few hours or even a day or two. Others have found it present also after coma from alcohol, or anaesthetics, or in saturnine encephalopathy. An excellent article by Dr. Hawthorne (published in the *Practitioner* for September, 1914) states that the sign is also sometimes found after diphtheria and other infections, after some drugs, such as strychnine and hyoscine, and with rheumatoid knees.

Let us now see if any useful deductions can be made from the fact that a transient Babinski sign occurs in various transient toxic functional affections of the nervous system. As an illustration we may take an elderly uraemic patient of mine who developed uraemic hemiplegia, and in whom the autopsy showed no gross disease of the brain. He had a well-marked Babinski sign. Contrast this with a case of hemiplegia due to hysteria. In both cases the hemiplegia is due to functional disease; one shows a Babinski sign, the other does not. Since we know that Babinski's sign is due to some blockage in the pyramidal tract, surely the inference is irresistible that hysterical hemiplegia is due, not to any deficiency in the pyramidal tract, but to loss of function in some higher levels of the brain. The only alternative to this conclusion, so far as I can see, is the highly improbable assumption that Babinski's sign in these multifarious toxic diseases is due to a selective action of their toxins for the pyramidal tract.

Although our inference (that hysterical hemiplegia is peculiar in being due to loss of function in levels of the brain above the pyramidal tract) is in keeping with our general notions of the nature of hysteria, yet I do not know of any evidence which in hysterical paralysis so clearly exculpates the upper motor neurons and so neatly incriminates the higher levels of the brain as does this deduction which I have just submitted to you for your criticism. If any one should reply that my thesis is already in a vague way embodied in our current views of hysteria, I would reply by quoting the definition of hysteria in the opening sentence of the chapter on hysteria in the most recent neurological textbook I have (Judson Bury, 1912, p. 716). He says "hysteria is a psychical disorder which often leads to disturbance of the lower centres of the brain and spinal cord and of the sympathetic system. . . . The exact nature of the cortical disturbance is unknown." My thesis asserts that the lower centres of the brain and cord are entirely unaffected in hysteria, and are as innocent as the peripheral nerves.

For the sake of clearness I have so far only spoken of hysterical or uraemic hemiplegia. But obviously my thesis applies equally to hysterical or uraemic paraplegia and monoplegias, or indeed to any hysterical paralysis of a cerebral type. And, after all, every hysterical paralysis is of the cerebral type, and is never ascribable to loss of function in a peripheral muscle or nerve.

But let us concentrate for a moment on hysterical paraplegia. You may object that paraplegia should, at any rate, be considered a disease of the cord rather than of the brain, and that this, therefore, condemns my thesis that hysterical paralysis is always cerebral in origin and superior in level to the pyramidal tract. But surely this habit of thought is only excusable in dealing with organic lesions, in which case one is correctly averse to explaining a paraplegia by two large symmetrical cerebral lesions when a single small lesion in the cord accounts for the paraplegia. Not so, however, in hysterical paralysis, where experience shows that the brain is just as readily affected symmetrically as unilaterally. So that hysterical paraplegia becomes no obstacle to my thesis if it is regarded as a symmetrical cerebral monoplegia of the legs, which I submit is the proper way to regard it.

Next, to speak of Babinski's sign after fits, hysterical and otherwise. A plausible explanation of Babinski's sign is that it is in some way an effect of lessened inhibitory control normally exerted by the upper motor neuron. If this be so, one may reasonably deduce that the transient Babinski sign after fits, etc., is in the same way an expression of diminished inhibitory control, but due in this instance to temporary exhaustion or poisoning of the upper motor neuron. Now, I have never seen Babinski's sign present after a hysterical fit, but I have learnt to expect to find it after fits due to epilepsy, uraemia, or eclampsia. Hence this sign is a useful guide as to whether or no a fit has been hysterical, provided one can observe this sign before it has passed off. This may be turned to practical account, especially in these days of the Workmen's Compensation Act, as a means of showing whether a fit has been genuine epilepsy or has been hysterical or malingered.

Next, as to the occasional presence of this sign in infantile paralysis. This I can bear witness to, and it shows that the myelitic process is not always confined to the anterior horns in this disease, but sometimes invades the white matter of the cord, or at any rate of the pyramidal tract.

Next, I have often noticed an apparent tendency for the flexor and extensor response to occur simultaneously, leading to a rivalry between the flexor and extensor muscles, and hence to a very equivocal Babinski sign. If I can see the tendon of the big toe pulling, even if the stronger flexors do not allow an upward movement of the big toe, I consider that the response is extensor. The distinction is easier when there is a normal flexor response on the other side with which to compare the equivocal response.

For three years I have been watching a very curious case in which I only obtained a Babinski sign twice. On numerous other occasions the soles were cold or unresponsive. She is a middle-aged, very nervous lady, with a doubtful diagnosis of disseminated sclerosis, characterized by a weakness and ataxy of the legs, tachycardia, and distressing "vasomotor storms" in the chest and abdomen. For years she has had to take small doses of bromide. Can any one tell me if the plantar reflex or Babinski's sign can be abolished by habitual bromide? Or could there be, in addition to the sclerosis, some variable spasm in the vessels of the cord which would account for the coming and going of her Babinski sign? It is suggestive of spasm that nitroglycerine and digitalis gave her great relief.

Finally, in a book on massage, Kellgren (*Technic of Ling's System*, 1890, p. 54) says: "In sclerosed conditions of the crossed pyramidal tract frictional massage given on the internal plantar nerve with a moderate amount of energy will, after a latent period of about half a second's duration, cause involuntary extension of the toes; if given more energetically, involuntary flexion of the hips occurs, accompanied, if the patient be in the half-lying position, by passive flexion of the knee-joint." Cyriax asserts that this sign may be present in organic disease when Babinski's sign is absent.

I record this observation because it is practically the same as Babinski's sign, but it was published eight years earlier. And since books on massage are so rarely read by medical men, the observation might probably escape attention.

To sum up my main thesis: We know from dissections of those dying with organic nervous diseases that Babinski's sign is due to a lesion in the pyramidal tract. Babinski's sign also occurs in certain diseases, such as uraemic hemiplegia, which is too transient to be organic; so that in this disease the hemiplegia must be due to a transient functional paralysis of the pyramidal tract. Yet in *functional* hemiplegia due to *hysteria* Babinski's sign is never present.

It follows, therefore, that hemiplegia in hysteria is due to loss of function, not in the pyramidal tract, but in the neurons at some higher level in the brain. And this reasoning as to hysterical hemiplegia can be extended to other hysterical paralyses.

NOTE.

OVER the paper of Mr. E. P. Cathcart, on The Rôle of Carbohydrates in Nutrition, published at page 503 of our issue for September 19th, should have appeared the word "abstract." A similar notification might, in fact, properly have been introduced into the headings of all communications to the Sections at the Aberdeen Meeting hitherto published, for, with the courteous co-operation of their authors, all have been materially abridged.

ERRATUM.

IN the report of the discussion on aneci-association the word "Plymouth" instead of "London" was accidentally inserted after the name of Mr. C. A. Pannett, of the Royal Free Hospital, when recording his remarks on page 353 of our issue for August 22nd.

A PSYCHOPATHIC annexe to the Los Angeles Hospital in California, with accommodation for one hundred patients, has recently been opened. The cost was £35,000.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

ANAESTHETICS IN EYE-WORK.

MR. MAURICE H. WHITING, in his note on this subject in your issue of September 12th, has called attention to the very special and important work of the anaesthetist when called upon to give a general anaesthetic for an ophthalmic case. I look upon this as the most refined and exacting work which he is ever asked to do. I have met with many anaesthetists, specialists and others, who although of good reputation for general surgical cases were nevertheless totally unfitted to give an anaesthetic for an eye case. For this state of affairs the teachers are the most to blame. Students are nearly always taught that the test for anaesthesia is the corneal reflex, consequently nine men out of ten consider it their duty constantly to rub their surgically unclean fingers over the cornea of their patient. It is one of the most annoying things which the ophthalmic surgeon has to put up with. I wonder what the general surgeon would think of a man who professed to be unable to determine the depth of anaesthesia without constantly thrusting his hand into the wound or into the abdomen in, say, an operation for appendicitis. Yet this is exactly similar to what the ophthalmic surgeon is subject to. The eye has to put up with an amount of injury which at least must cause the patient great pain on recovery owing to a large corneal abrasion, and at the worst may give rise to a hypopyon ulcer with loss of vision from anything up to total blindness. If anaesthetists are unable to determine the depth of the anaesthesia without using such a barbarous test they ought never to be allowed to give an anaesthetic at all. The test is always dangerous, always unnecessary, and, to my mind, stamps a man as incompetent if ever he resorts to it. Mr. Whiting, while house-surgeon at Moorfields, has given dozens of anaesthetics for me, and I can fully testify to his ability in this branch of work, and I take the greatest pleasure in being able (though now far removed from London) to say how cordially I agree with all he has said in his communication, which will, I trust, be read and acted upon by every one who is likely to have to give anaesthetics.

H.M.S. *Euryalus*. C. DEVEREUX MARSHALL.

MR. WHITING'S reference, in the JOURNAL of September 12th (p. 471), to the use of chloroform as an anaesthetic in eye-work raises incidentally the whole question of general anaesthesia in ophthalmic surgery.

The question whether chloroform, ether, or a combination of these is the least dangerous may safely be left to the specialists in anaesthetics; at the present time there seems to be a growing tendency in ophthalmology to dispense with general anaesthesia, by whatever agent produced, to a much greater extent than hitherto.

The special conditions of anaesthesia which are desirable in eye surgery are, in nearly all cases, so much more easily and conveniently attainable by local than by general anaesthetics that it may be not without interest to examine closely the residue of cases for which general anaesthesia has until recently been assumed to be necessary.

Such cases may be arranged in three groups:

1. Operations involving the orbital tissues or the back of the eyeball. For example, enucleation of the eyeball, evisceration, exenteration of the orbit, removal of the lacrymal sac, and plastic operations on the lids. Many operators now use only local anaesthesia for these.

2. Cases in which anaesthesia is difficult to produce by "drops" owing to the presence of inflammation or congestion. Under this heading fall operations in acute glaucoma and in cases of inflamed eyes, such as hypopyon ulcer, etc.

3. Cases in which *pain* can be abolished by local anaesthesia, but, owing to youth, old age, insanity, nervousness, or some other cause, the patient cannot be trusted to exercise the necessary control. Here the general anaesthetic is used not so much to prevent pain as to produce a passive patient. The use of sedatives preliminary to operation helps to reduce this class of case to within comparatively small limits.

If, however, a free use is made of the method of injecting anaesthetic solutions subconjunctivally and post-ocularly (intraorbitally) as well as or in place of the usual method of simply dropping such a solution into the conjunctival sac, we find that the only cases requiring a general anaesthetic are those in Group 3, and even here the number will diminish as our skill and experience increases.

To give only one example of the advantages of this method, enucleation of the eyeball, even where it is inflamed and very painful, with chemosed conjunctiva and swollen eyelids so tender that the use of a speculum causes severe pain, needs no assistant, and becomes merely the subject of a few minutes' pleasant chat with the patient.[1]

The decline of general anaesthesia in eye surgery is illustrated by Mr. Whiting's figures. General anaesthesia was used in the hospital to which he refers in 1909 in 803 cases, and in the next four years in 517, 598, 631, and 473 cases respectively. Here we have a sudden drop in 1910, followed by a slow partial recovery, and then a sudden and more decided drop in 1913. An analysis of these figures would be interesting.

Lastly, when general anaesthesia must be used, it is an advantage to use it in addition to adequate local anaesthesia, and to confine the general anaesthetic to its true sphere in ophthalmic surgery—namely, that of providing a passive patient. This disposes of the question of the corneal reflex.

SUBLINGUAL MEDICATION.

IN the interest primarily of our wounded soldiers, I wish to call the attention of army surgeons to the great and obvious advantages of sublingual medication as compared with hypodermic.

It is safer, cleaner, and quicker, because no preparation is required except washing out the mouth with water. Fifty could thus safely be relieved while one was safely injected. The purification of needles being out of the question, under the circumstances, rules the syringe out of court. The awful possibilities of a tainted needle are apparent. Even after removal to hospital, there are many points in favour of the simpler method. Let any one who doubts this look in a mirror at the larger surface (I estimate it as six inches, covered by the thinnest membrane), and compare it with the limited area for absorption of an ordinary hypodermic injection. A lieutenant who once worked for me, and who had gained experience during the last South African war, told me that to drop a tablet under the tongue of a wounded man, grey with shock and drawn with pain, to hurry on to others, and then to return in a few minutes to find the first patient relieved and anxious to point out others needing help, was a constant gratification and surprise.

As far as I know, the method is not taught in hospitals or mentioned in examination papers. Why? Too simple, perhaps; and yet I know numbers of men who never go a round without a small case of tubes in their vest pocket, and use them daily. At the time I mention—about twenty years ago—when this was first advocated, Messrs. Burroughs and Wellcome, with their unique opportunities, were good enough to make wide inquiries, and reported that, as far as they could ascertain, it was an entirely new and successful mode of administering medicine. If the discovery had only been made abroad and taken up as a means of self-advertisement, how different would have been its fate!

Ross-on-Wye. WILLIAM PAULSON, L.R.C.P.Lond.

A STRAW-CHARCOAL ABSORBENT DRESSING.

A CHEAP, absorbent and aseptic dressing for wounds which have much discharge is one used by the Japanese. I have also used it and proved its value. Make charcoal of straw by burning straw in a fireplace where the air can be excluded. This is done by blocking up the fireplace with a sheet of tin or board, after lighting the straw. After the fire has burnt out, the straw is the same in shape, but black. This put into linen bags is very absorbent and a deodorizer.

London, N. E. F. WILLS.

Reviews.

TAYLOR'S "MEDICINE."

A BOOK on any subject that has successfully reached its tenth edition has fulfilled so faithfully its early promise and justified so thoroughly its existence that it is beyond the need of commendation. Dr. FREDERICK TAYLOR'S *Practice of Medicine*[1] has achieved this record within a period of somewhat less than a quarter of a century, and it is safe to assert that its popularity has steadily increased since the first issue saw the light in 1890. The tenth edition follows very much on the lines of its predecessors, but the increasing mass of scientific knowledge and technical achievement has necessitated some increase in the dimensions of the present volume. This increase, though difficult to avoid, is a doubtful advantage, and, if progressive, must make future editions unwieldy. One possible way of escape would be to omit the section on diseases of the skin, which in this edition occupies 74 pages. Dermatology has nowadays become so much a specialized department of practice and has accumulated such an extensive literature of its own that its inclusion in a handbook on general medicine seems no more necessary than would be a section on ophthalmology or gynaecology.

There is in this edition a valuable addition to the illustrations with which Dr. Taylor's book is embellished, and reference is made to several new subjects which have within recent years attracted professional attention and marked the continued progress of medicine both as an art and a science. The diseases of the ductless glands, for instance, are grouped in a section of their own; infectious disorders are rearranged so as to harmonize with modern views as to their etiology; and the chapters on cardiac disease are elaborated by a concise account of such rhythmic irregularities as auricular flutter, auricular fibrillation, and heart-block.

As in former editions, the space devoted to the all-important problems of treatment is, in our opinion, inadequate. The majority of men in general practice find need for guidance about most ailments in the direction of their treatment rather than of their symptomatology, etiology, or pathology; while from the point of view of the patient his requirements are best fulfilled by the doctor who knows how to relieve his discomforts and who is able most speedily to restore him to a condition of health such as will fit him for an early return to the duties of his everyday life.

An example, taken at random from Dr. Taylor's book, will illustrate what is meant. Under "Ulcer of the Duodenum" the treatment is summed up as follows: "The duodenal ulcer may be treated in the same way as the gastric ulcer. It is perhaps less amenable, and may sooner call for surgical methods." Now duodenal ulcer is one of those ailments of which the symptoms, with the one exception of haemorrhage, very closely resemble those met with in certain forms of neurasthenic dyspepsia, and it would have been well to give a warning as to the need for judicious observation before surgical methods are resorted to, and of the means to be adopted by medical and dietetic prescriptions to prove the position and to avoid operative interference, if that be possible.

In discussing the treatment of diabetes the author does not refer to the value of limited periods of starvation as a means towards controlling the output of sugar in a patient whose glycosuria proves not to be entirely dependent upon carbohydrate ingestion.

In connexion with the various forms of pancreatic disturbance, which are becoming nowadays more frequently recognized or suspected than formerly, hardly enough stress is laid on the value of gall-bladder drainage as a means of relief or cure. It seems an undoubted fact that cirrhosis of the pancreas is often directly associated with a chronic cholangitis, and the cure of the latter by cholagogue remedies and suitable dieting, or, that failing, by drainage, will, in many instances, save the pancreas from degenerative changes which must ultimately tend towards disability and death. It is highly desirable, from the patient's point of view, that his doctor should be informed of these facts, and be competent to deal with such an illness in the manner best calculated to avoid the end-results.

These gaps are referred to only to emphasize our view that the weak point, from the practical aspect, in this as in so many treatises on such a vast subject as the practice of medicine, lies in the inadequate amount of detailed instruction which is given to that part of the subject which more than any other fulfils the purpose of the title. In every respect otherwise, Dr. Taylor's new edition is admirable, and will commend itself, we feel sure, to an ever-increasing number of readers. The revision has been thorough; the general arrangement of the subject matter leaves nothing to be desired either in the way of convenience or of grouping; and the pleasure of perusal is much facilitated by the easy and graceful style which characterizes all Dr. Taylor's writings.

EMBRYOLOGY AND ANATOMY.

A Textbook of General Embryology,[2] by Professor KELLICOTT, is a most admirable and thoroughly justifiable addition to the rapidly increasing number of books on embryology in the English language. The book appears to us to be the clearest and most exhaustive account which we have within one volume of the somatic and germinal cell and of the changes which the latter undergoes in the processes of maturation, fertilization, cleavage, and blastula and gastrula formations. These highly interesting phenomena are considered from the widest point of view, and treated with a wealth of illustrations drawn from all branches of the animal kingdom, although naturally the invertebrata are laid under the heaviest contribution. The various means to a common end which Nature so liberally employs in these matters are carefully correlated, and the whole is lightened up by the introduction of suggestive theories as to the meaning of the variations in a manner which makes the book singularly interesting and readable. While the general medical student will find the volume a most useful book of reference, it makes a more direct appeal to students of cytology, biology, protozoology and teratology, and to those engaged in cancer research. A very useful bibliography is given at the end of each chapter, and adds materially to the value of the book, which does distinct credit to American scientific scholarship.

Professor BUCHANAN, in his *Manual of Anatomy*,[3] aims at giving the medical student the essentials of the subject from particularly the very important point of view of the general medical practitioner. He is in consequence enabled to dispense with many unnecessary details which even in the examination room are of doubtful value. Students vary in the way in which they acquire their knowledge. For some a considerable amount of detail seems to facilitate learning and remembering, making for permanency, like the cement between the bricks in a wall; for others, and perhaps these are in the majority, detail has a tendency to obscure the really fundamental facts, and should therefore be kept within strict limits. To such as these latter we think Professor Buchanan's manual is likely to be of distinct help, for it is not more than half the size of the other English textbooks, and yet contains everything that it is necessary to know. Further, its size and character are such that long after his student days the practitioner will find it a ready and satisfactory book of reference. Instructions are given at the end of each section as to the procedure advised in dissection, but, as these are brief to a degree as well as divorced from the description of the parts, we think most students will find it desirable to use a separate practical manual for use in the dissecting room. A similar commentary, we think, applies to the embryological portions, for a student must surely have received instruction in general embryology before he can be expected to follow intelligently the short developmental notes appended to the descriptions of the various viscera. The old anatomical nomenclature has been retained, although the Bâle synonyms are given in an appendix. This feature should make the book popular

[2] *A Textbook of General Embryology.* By Professor W. E. Kellicott. London: Constable and Co., Limited; New York: H. Holt and Co. 1914. (Med. 8vo, pp. 380; 168 figures. 10s. 6d. net.)

[3] *Manual of Anatomy, Systematic and Practical, including Embryology.* By A. M. Buchanan, M.A., M.D., C.M., F.R.F.P.S.Glasg. Second impression. University Series. London: Baillière, Tindall, and Cox. 1914. (Demy 8vo, pp. 1558; 631 figures. 21s. net.)

with many, for there is a lot of life in the old names yet, and we are not at all sure that the more recent have come to stay. The book is excellently printed and illustrated, and has the further advantage of having come from one source, and so escapes the confusion of style and method which is not infrequently apparent in more composite works.

The *Intervertebral Foramen*,[4] by Mr. HAROLD SWANBERG, is a topographical study of the anatomy and contents of the first thoracic intervertebral foramen in the cat as they can be demonstrated by serial microscopical sections. The idea is good, but as we conceive that the justification for a record of minute relationships must be their value in practical application, we cannot but feel that the research should have been undertaken on the human subject, difficult though it might be to obtain the necessary material in a sufficiently fresh condition. The work is illustrated by a number of excellent photomicrographs, but, unfortunately, in the copy under review pages 60–64, and plates 6 and 9, are missing. The author finds that the roots of the spinal nerve, and the spinal nerve itself, are closely surrounded and protected by loose fatty tissue, but that as we approach its primary divisions this is replaced by dense fibrous tissue, which can be shown to have an attachment to the adjacent transverse processes; in this tissue in the neighbourhood of the anterior primary division the rami communicantes of the sympathetic are to be seen. The nerve as it passes through the foramen lies very near to the transverse process of the upper vertebra. At a rough estimate the size of the foramen is three times that of the nerve, so that there is little likelihood of pressure upon the nerve unless much absorption of the intervertebral disc or adjacent body of the vertebra has occurred. The author claims that the book is unique, and to some extent it is; but we imagine he will find many imitators in the future, for serial sections afford undoubtedly the best opportunities for obtaining a knowledge of those minute intimate relationships which are so helpful to the clinician.

SALVARSAN TREATMENT OF SYPHILIS.

THE book by Drs. STOPFORD-TAYLOR and R. W. MACKENNA on *The Salvarsan Treatment of Syphilis in Private Practice*[5] is based on their experience of some 400 cases. Like most other workers in this field, they prefer intravenous injection, and use a full dose of 0.6 gram on each occasion. They report no untoward results, and attribute this absence to careful preparation of the patient before injection and careful watching afterwards. In this connexion, however, must be mentioned a recent work by Schindler,[6] who claims equally good results from intramuscular injection of an oily suspension of salvarsan (Yoha). This author points out that most of the fatalities due to salvarsan have occurred after intravenous injection, and argues that they are due to paralysis of the blood vessels by the direct action of arsenic. Intramuscular injection, in which the absorption of the drug is more gradual, is much less liable to cause this effect. In their preface Messrs. Taylor and MacKenna refer to the unique efficacy of salvarsan in controlling syphilis. Against this optimistic view are the facts that mercury is now universally employed in addition to salvarsan, that Professor Ehrlich has been engaged in making new preparations containing copper, that the French chemists are manufacturing new arsenical preparations which shall be free from the danger of salvarsan, that preparations of antimony made on similar lines are being produced, and that new compounds of mercury, such as merlusan, are being introduced. In fact, it should now be fully recognized that salvarsan, although it removes syphilitic lesions, cannot certainly be depended on to cure the disease, and has toxic properties, the ultimate effect of which yet remains to be ascertained. The authors consider that this danger has been exaggerated, and that the noxious effects are due to overdoses, bad technique and administration in unsuitable cases. It is, however, we believe, now admitted that death after injection of salvarsan may be due to the direct action of arsenic. In his analysis of 274 cases of death after salvarsan, Mentberger attributed thirty-one to this direct action. Ehrlich himself in a letter to this JOURNAL (May 9th, 1914) admitted that an oxidation product of salvarsan was one factor in the fatal cases. The authors attribute the freedom from relapses in their cases to thorough treatment with mercury in addition to salvarsan. This, however, points to the efficacy of mercury rather than to that of salvarsan. We are glad to note that the authors hold that microscopical and biological methods of diagnosis should never be allowed to replace clinical investigation. The book contains some useful information regarding the technique of salvarsan treatment, but takes rather a one-sided view of the subject.

GONORRHOEA AND ITS COMPLICATIONS.

DR. LUYS'S book on gonorrhoea is perhaps the most comprehensive work on this subject which has appeared since Finger's classical treatise. Mr. FOERSTER is therefore to be congratulated upon the production of an English translation, although his statement that "for a number of years no book has been published in the English language on this subject" is hardly correct. The title of the translation is *A Textbook on Gonorrhoea and its Complications*,[7] and as Dr. Luys is a well known advocate of the urethroscope and has done excellent work in this department, it is not surprising to find that much attention is given to urethroscopy. Dr. Luys is evidently an optimist, for he says in his preface that "there is no inflammation of the urethra which cannot be cured completely by appropriate treatment," and that "urethroscopy alone enables us to diagnose the local lesions with accuracy and to apply the sovereign remedy correctly." This statement is somewhat discounted by his remark that urethroscopy is not a "universal panacea for inflamed urethras." With the last sentence we are in entire agreement, and would add that the urethroscope, when used indiscriminately, is a source of danger to the patient. In fact, Dr. Luys warns us against its use in recent or acute inflammations. It is true that in expert hands the instrument is a valuable aid to diagnosis, but it by no means follows that the lesions thus detected can always be cured. Of the various forms of urethroscope Dr. Luys prefers his own, in which direct illumination is supplied by a small lamp on a holder running in a groove in the endoscopic tube. With this instrument applications can be made to the urethra without withdrawing the lamp. In acute gonorrhoea he favours urethro-vesical irrigation in most cases, but advises a large syringe when there is spasm of the sphincter. In chronic gonorrhoea the treatment recommended comprises urethro-vesical irrigations or injections, massage of the prostate, seminal vesicles and Cowper's glands, dilatation by metal sounds, dilatations with Oberlander's four-bladed dilators, combined irrigation and dilatation with Kollman's instrument, and especially urethroscopic treatment, which Luys rightly considers to be far better than instillation of silver nitrate by Guyon's syringe. Other methods mentioned are ionization and electrolysis of the urethral mucous membrane, treatment by thermo-electric bougies, etc. Bier's passive congestive treatment is recommended in cases of gonorrhoeal endometritis. Luys is not much impressed by vaccine treatment. Mention is made of complement fixation in gonorrhoea. A good account is given of the pathology of gonorrhoea and its complications, and Luys thinks that general gonococcal infection often has its origin in seminal vesiculitis. The book is clearly and concisely written and is profusely illustrated, the coloured plates of urethroscopic images being especially good. The English translation has been excellently done by Mr. Foerster, and the book affords one of the best expositions of the subject in the English language.

SPECTRUM ANALYSIS IN BIOLOGY AND MEDICINE.

THE late Dr. C. A. MACMUNN covered a vast amount of ground in the difficult subject of the spectrum analysis of the pigments that colour both animal and vegetable tissues. It is to him more than to any other worker that we owe most of our knowledge of these complex and varied colouring matters, and a posthumous work,[8] edited by Dr. J. H. MILROY, has recently appeared in which an account of his activities in this field is given. Dr. MacMunn was devoted to scientific research, but could find time for it only in the brief intervals of leisure snatched from a busy and fully occupied professional life, and he had no adequate library or laboratory facilities to help him. The work begins with a general account of the spectroscope and the chromatology of plants and animals. Special chapters on chlorophyll, haemoglobin, the histohaematins, and myohaematin follow, and an account of the spectrophotometer employed for quantitative spectrum analysis. The last three chapters deal with fluorescence and phosphorescence, biliary and urinary pigments, and the pigments of invertebrates generally. The book forms stimulating and interesting reading, for its author was a versatile man of wide views, and thoroughly at home in the complications of the apparatus employed by the worker in spectrum analysis. It exhibits a certain incompleteness that is accounted for by the fact that its talented author did not live to see it through the press, yet it is really a valuable contribution to scientific literature. The subject is one that appeals to many besides medical men; the volume is excellently got up and illustrated, and should be in the hands of all who are interested in the study of either pigments or spectroscopy.

NOTES ON BOOKS.

MEDICAL officers of health and students of preventive medicine have of course long been alive to the importance of a knowledge of the methods of constructing and interpreting life tables, while the Insurance Act has made it desirable for other medical men to possess some familiarity with the principles involved in the preparation of morbidity tables. The publication of Messrs. ELDERTON and FIPPARD'S *Construction of Mortality and Sickness Tables*[9] is therefore opportune. The authors have brought within the compass of 120 small pages a great deal of information and have avoided the introduction of any mathematical formulae which, in this branch of statistics, are apt to be of a kind particularly unpalatable to the ordinary reader. Any one who takes the trouble to read this book through should have no difficulty in following the actuarial discussions provoked by the Insurance Act, or, indeed, the reports of life assurance valuations. On the other hand, the medical officer of health who seeks a guide in the actual work of constructing a life table will not find this book sufficient, and must still refer to such sources of information as the papers of Hayward, Newsholme, and Stevenson in the *Journal of Hygiene*. We think the primer will be of use to many readers and serve as a good introduction to more technical works.

The health and comfort of the infant has been Miss WILENA HITCHING'S first consideration in compiling her book on *Baby-Clothing*,[10] and she has succeeded in designing a layette which should meet the requirements not only of the baby itself but of the most fastidious and exacting mother. Her patterns have the crowning merit of simplicity; and even the least expert of needlewomen should find little difficulty in following her clear and explicit instructions. A large packet of well-cut paper patterns accompanies the volume, which is illustrated with numerous diagrams, and contains a short introduction by Sir James Crichton-Browne.

MOTOR AMBULANCES IN WAR SERVICE.

By H. MASSAC BUIST.

ALIKE at home and abroad there has arisen a sudden demand for motor ambulances for service with the British forces. The call has come so suddenly that the first method of procedure has been to improvise a number of motor ambulances by adapting various types of pleasure car chassis to the needs of the field, sometimes with the happiest results, at others with anything but a successful issue. The widespread nature of the need was sufficiently illustrated quite early in the war, when some of the wounded from the *Amphion* were taken from the dock to the hospital in the neighbourhood of Chatham in a lorry on a London General Omnibus chassis, a thing by no means suitable for ambulance work of any sort, despite the fact that in this country we have roads that foreigners tell us have surfaces of the billiard table variety. At the other extreme, one has seen examples of light car chassis transformed into ambulances, in which connexion it can only be said that those who have to travel on stretchers in them are to be pitied. Fortunately, whatever may have been left to desire in the necessarily hurried arrangements made at the very outset of war, there are sound grounds for believing that considerable discretion is being displayed in the further orders that are being placed for motor ambulances. Nevertheless, there may continue to be improvised from privately owned vehicles, or what not, various sorts of motor ambulances; therefore, in face of the fact that medical men all over the country may be called on at any time to advise in this capacity, it may be as well to draw attention to one or two points learned already as the result of the war, and to give a few general hints on the principles of constructing ambulances on motor chassis.

POINTS TO BE NOTED.

Among vehicles I have noticed that have gone to the front are sundry ambulances for the Australian contingent. One of these impressed me as being on chassis of too small and weak a character, comparatively ill-sprung, while at the other extreme there is what I consider to be the most intelligent improvisation of a motor ambulance that the campaign has so far afforded. An undertaker had a grey hearse on a Rolls-Royce chassis, so arranged that the back opened to take the coffin in and out. With a minimum of change in the interior arrangements, this has been made into a most perfect ambulance, and is deservedly the pride of the Australian outfit.

We have to remember that, important as it is that cars used for ambulance work at home should be well sprung, since they have to carry men suffering from all sorts of wounds, the issue of life or death from which may depend entirely on the amount of oscillation experienced, that point becomes of double importance on the Continent, where the average of roads to be traversed were, even before they were cut up by supply traffic, of very indifferent surface when compared with our own. It has therefore been recognized on all hands that smoothness of suspension is a very important factor. A mistake has been made in some examples that have come under my notice, however, through ensuring what is a plangent suspension by the use of various auxiliary devices called shock absorbers. Ideal suspension does not consist in supplying a plangent vehicle, because when indifferent road surfaces are traversed that plunges vastly too much.

What is wanted is a suspension that depends as little on auxiliary action as possible, and which itself has a certain amount of stability or stiffness. Therefore, if there is any choice of chassis that are being taken from among vehicles offered or commandeered, it is as well to look for springs having comparatively long leaves, for as broad a track and as long a wheel base as possible, and for large wheel diameter. If the springs prove particularly good, the size of the wheels matters the less. Thus, many large and powerful chassis have proportionately small wheels to give a low centre of gravity; but such wheels will be furnished with very deep section tyres. These, in combination with the springs, will give the necessary softness of action. A point particularly to be looked for in the chassis, especially in face of the fact that the number of really powerful ones available of a refined character will generally be found

comparatively few, is that the wheel base should be proportionately long.

Overhang to be Avoided.

The importance of avoiding overhang has been brought to mind from observing various old-fashioned chassis of short wheel base and of comparatively small size, say, the 16–20 h.p. size of three or four years ago—and limousine motor cars, also a little out-dated, wherein the rear part of the body projects a considerable distance behind the back axle. This is eminently undesirable for ambulance work, because the stretcher is being accommodated in that part of the vehicle which makes the maximum movement in response to the road shocks to which the machine is subjected in the course of travel. This is incidentally one grave disadvantage attending the system of transforming ordinary touring cars with Cape-cart hoods, as they are called, into ambulances by cutting out the back panel in hinged fashion. To overcome this by fitting extremely plangent springs, possibly supplemented by shock absorbers, may do reasonably well so long as the machine has to travel over the very best of our highways at a comparatively slow speed. Even so, however, when the stretcher is thus accommodated so that its mid-length about corresponds with the back axle, an unnecessary amount of side-swaying is occasioned when turnings are negotiated. Therefore, despite the good intentions that have promoted many endeavours in this connexion, all such practices should, if possible, be avoided, and the whole length of the stretcher accommodated forward of the back axle—that is to say, anywhere between the two axles, so that there is no overhang of any sort whereby all shocks, whether lateral or in a vertical direction, are reduced to the minimum.

In orders that have been placed for new vehicles, the authorities have shown an apt appreciation of these points by selecting chassis the springs of which are good as originally designed. It is as grave a fault to have a spring that is too plangent as one that is too stiff. Incidentally, medical men whose opinion is asked about ambulances for foreign service would do well to remember that at least an extra leaf to each spring is needed to achieve equivalent effects of suspension on the Continent to what will be obtained in this country without the use of such extra leaf; in other words, springs must be stiffer.

British Red Cross Society's Scheme.

The British Red Cross Society asked *Cooper's Vehicle Journal*, the recognized organ of the coach-building industry, to design a temporary ambulance body for fitting to various sorts of chassis. The working drawings were issued by that journal in August, and may be recommended to the notice of medical men who desire that the approved design should be followed. One of the difficulties was to scheme the body so that it could be built quickly and cheaply, as well as to enable a common scheme to be suitable for fitting to any substantial touring car chassis that might be requisitioned. Nothing would have been easier than to fall into the error of building a top-heavy ambulance. This, however, has been skilfully avoided by providing the body with a well covered by substantial floor-boards which can be hinged back so as to leave an open space along both sides on which men are able to travel in a sitting position. All that is necessary to apply this standard form of ambulance body to various sorts of chassis is the insertion of suitably cut packing pieces.

In my humble judgement, the weak point of the design is that a rather long tail is rendered inevitable by its application to most chassis, for room has necessarily to be provided for stretchers of about 8 ft. in length, slipped in from the back, which is consequently left open save for a waterproofed storm curtain. By reason of adopting this mode of construction the ambulance body is cross-braced at the front. Whatever adaptation of existing body work is made, care should be taken always to ensure that the necessary reinforcement by cross-bracing should be employed to make up for cutting open the back to form doors or hinged flaps. Extended eaves provide ventilation, which can further be furnished at option at the front and sides, which are merely covered over with waterproofed material, such as unbleached calico treated with boiled linseed oil, quite a cheap, yet eminently a satisfactory and durable job.

The coach-making industry of the country has entered fully into the spirit of the hour. A very considerable number of members of the industry, as well as of motor manufacturers, offered to construct ambulance bodies for the British Red Cross Society free of charge, and the work was put in hand some time ago.

Possibilities of Lengthening Chassis Frames.

As previously pointed out, this matter of overhang is really the weak point of nearly all motor ambulances, save those that are constructed on chassis of exceptionally long wheel base. Most of these ambulances are needed quickly. But if a few weeks are provided for the work of adaptation, and only a small chassis or one of comparatively short wheel base is available among either commandeered machines, second-hand or privately owned ones given for the cause, very useful work may be done at comparatively small cost by submitting the chassis to the treatment of such firms as make a practice of adapting old chassis. At a comparatively cheap cost these concerns can lengthen the frame in a manner which would nevertheless be quite a substantial job. This question of carrying the stretcher between the axles, and of therefore having comparatively a long wheel base, is of even greater importance to ensure the maximum comfort than any mere manipulation of springs and spring gear.

Sphere of the Light Car Ambulance.

In a large number of cases it is not necessary for the patient to be at full length, therefore it is not necessary always to have an overhang. This point comes out particularly when considering the many quite interesting schemes that have been brought forward for equipping light car chassis as ambulances. It is always best to secure those with comparatively long wheel base. Some light cars as standardized have come out really quite well under this head. Not much, however, has been done in this direction, and that little is almost entirely intended for home service, where, indeed, it is much more suitable than abroad, for these light car ambulances are primarily and essentially suitable for carrying men in a seated position. They usually have a flap, however, that can be let down into the form of a stretcher, quite two-thirds of which, and in some cases nearly three-quarters, then projects behind the back axle; but to mention this fact is alone sufficient to indicate the unsatisfactory nature of attempted adaptations of this sort.

A much more clever idea on a comparatively small car, and one which for that matter could be adapted to light car chassis, is one I have seen fitted to the smallest Fiat ambulance. In this the necessary length for two stretchers, with scarcely any portion projecting behind the line of the back axle, is ingeniously obtained by having them superposed and at the side of the driver, behind whom sits the attendant, who is therefore beside the heads of his patients as the vehicle travels forward. Like most of the ambulance schemes brought forward, this has canvas side curtains and hood, so that the vehicle can be used either as a wholly open, partially closed, or entirely closed ambulance, according to the condition of the weather.

For the most part, however, the fact that the light car chassis makes quite a good tradesman's delivery van, and that the exterior lines of a delivery van and of an ambulance body may bear a considerable likeness one to another, must not be taken as affording any indication of the suitability of the light car chassis to ambulance work. There is a vast difference between transporting mere goods and human beings who have been injured in battle, generally after experiencing days, if not weeks, of overstrain, often with the most irregular feeding, so that the system is not in the most favourable condition to withstand shocks in any case. The light car chassis should therefore be used only when it is a question of taking that or of having to give up all idea of providing a motor ambulance chassis. These vehicles are extremely valuable accessories to saving life, especially in cases where time is of the utmost moment, therefore a certain amount of evil can be put up with to ensure that end, when it may be a case of improvised motor ambulance of too small a chassis or none at all.

ADAPTING MOTOR CAR BODIES.

There have been sundry examples of adapting covered motor car bodies of middle and large sized chassis to motor ambulances carrying three and sometimes four stretchers. In all cases such instances, however, if the chassis is not a powerful one the body projects considerably behind the back axle line. Owing to the accommodation for the driver's seat, the forward part of the stretcher is only 2 ft. to 2½ ft. in front of the back wheel. When adapting a totally enclosed limousine body, this difficulty does not occur, because two stretchers can be carried, one above the other, quite along beside the driver, as in the case of adapting the small car type of chassis previously described.

It is possible to adapt the ordinary limousine bodies, wherein the drivers' seats are quite separate and are exposed at the sides, by cutting away the seat beside the driver, enclosing the two sides in front by putting up a glass window, and thereby moving forward the two superposed stretchers, care being had to cross-brace the body specially to accommodate the redistribution of load and stresses. This method is infinitely preferable to using the ordinary interior of the limousine or covered coachwork for the stretchers, even though in this, as in most cases we have been considering, we are to assume that sufficient sense is displayed to place the head of the patient in that position which will bring head and body as near as possible between the axles, so that if there is any overhang at all behind the back axle it will be from the waist line downwards.

This method, of course, has to be used in those cases in which ordinary four-seated touring cars with Cape-cart hoods are transformed into ambulances by making the back panel of the body collapsible to afford the necessary length for the stretcher. The patient's head, therefore, lies practically against the back of the front seats. A slight and simple extension of the ordinary rainproof motor car hood to take the place of the back panel when collapsed is easily effected.

THE EMERGENCY AMBULANCE SCHEME OF THE BRITISH RED CROSS SOCIETY.

It may be as well for medical men to be reminded that the British Red Cross Society is engaged in organizing an extensive emergency service of motor ambulances, all offers in connexion with which should be addressed to Department 8 of the Society at 83, Pall Mall, S.W. The work is being further aided by the Imperial Motor Transport Council; while members of the Royal Automobile Club and of the Automobile Association have come forward in the most generous fashion with offers of vehicles. Any motor owners who discuss with medical men the question of lending cars for this work should be made clearly to understand that the Society only wants vehicles which are unconditionally offered for the whole period during which emergency motor ambulance service may be rendered necessary by the war. The motor owner must therefore be prepared for anything that is considered necessary to be done to his chassis, no matter how that may mutilate it from the point of view of the vehicle as a privately owned motor carriage. Of course, when cars are no longer needed they will be returned to their respective owners, while those owners may further be assured that during use every effort will be made to ensure that the cars will not be abused in any way, but will be submitted only to such legitimate wear and tear as is essential in carrying out the good purpose which can be the sole aim in lending them. The Society is, of course, not responsible in any way for deterioration, or even for the total loss of the car. Loss, however, is extremely improbable in view of the fact that the vehicles are needed only for service in this country. Motorists desirous of offering their cars may communicate direct with the Honorary Secretary, Imperial Transport Council, 173, Fleet Street, London, which, as already stated, is working in co-operation with the Society.

Though the members of the Automobile Association have already lent over 19,000 motor cars and motor cycles for war services, the names of other volunteers are still being taken, so that this organization itself may assist the Imperial Motor Council and the Red Cross Society by classifying the cars that it raises. It is therefore well to note that the make, horse power, date of manufacture, type of body, and seating capacity should be mentioned, as well as whether the owner or his motor man drives the vehicle, the owner's telephone number, and his telegraphic address. Red Cross work under this head embraces the conveyance of officials to various dépôts, attending ports and railway stations to convey wounded on arrivial to hospitals, and removing wounded from London to various convalescent centres. Of course cars with motor ambulance bodies for lying-down patients are in greatest demand. To assist members willing to have their vehicles so converted, the association itself has a variety of designs and estimates to enable such conversion to be achieved with the most moderate outlay, with, nevertheless, quite satisfactory results. Of course, comfortable landaulette, limousine, or cabriolet cars are also needed in numbers for carrying patients who are able to sit up.

A last point worth noting on this subject concerns the Scottish Branch of the British Red Cross Society, which has sanctioned an appeal made by the *Motor World* to open a fund the proceeds of which are being devoted to defraying the expenses of the motor transport work of this branch. Vehicles that have been offered to the Society are being converted into ambulances and all other necessary work carried out to provide a really adequate supply of motor ambulances. Mr. Robert J. Smith, Secretary of the Scottish Automobile Club, has been appointed convener of the Transport Committee. Individual subscriptions, limited to £1, may be sent to the fund being raised by the *Motor World*, 73, Dunlop Street, Glasgow, which has raised several hundred pounds in the course of the first ten days during which the appeal has been made. This is therefore a note for medical men in Scotland who may be asked what those can do to assist motor ambulance work who nevertheless have not cars to give or lend.

SCIENCE NOTES.

IN a communication published in the *Röntgen Society's Journal* for July Mr. Lawrence Bragg points out that not only does the analysis of x rays by crystals yield interesting results, but also the analysis of crystals by x rays. In using various crystals as diffraction gratings in the path of an x-ray beam, many types of spectra have been found, and in almost all cases it has been possible to assign them to corresponding peculiarities of crystal structure. As an instance of the connexion between the character of the spectra and the crystal structure, he refers more particularly to the case of the diamond. The octahedron face—denoted by crystallographers as the index (111)—of this cubic crystal yields a set of spectra which are peculiar in that, while the first, third, fourth, and fifth orders are well marked, the second is missing. If we look at the diamond structure we see that the planes parallel to the face are arranged in pairs in such a way that the distance between the planes of a pair is one-quarter that between successive pairs. In yielding the first spectrum the two planes of a pair do not act exactly in concert, but they do so sufficiently to give a good reflection. In yielding the second spectrum, however, the waves from two planes of a pair fit together crest to trough, and exactly annul each other, thus destroying entirely this reflection. For the third, fourth, and fifth spectra again the reflection is good. It is thus possible to find from the peculiarities of the spectra this paired arrangement of (111) planes, and so arrive at the structure of the diamond. Among other crystals whose structure has been found in this way are the rock-salt series, the calcite series, aragonite, zinc-blende, pyrites, galena, fluor, cuprite, and zincite. In the case of rock-salt structure, when x rays are reflected from a (111) face, the spectra are peculiar in that the first is weaker than the second, instead of the first, second, and third decreasing regularly in intensity as is normal, and this peculiarity is to be traced to the alternate arrangement of the planes of Na and Cl parallel to that face.

MESSRS. LONGMANS, GREEN, AND CO. will issue shortly a new part of *Quain's Anatomy* (eleventh edition, edited by Sir Edward Schäfer, Dr. Johnson Symington, and Dr. T. H. Bryce). This is the second part, vol. ii, and will deal with splanchnology, the author being Dr. Johnson Symington. There are 349 illustrations, many of which are in colour.

British Medical Association.

The Treasurer would especially appeal to those who have not yet paid their Annual Subscription for the current year to forward £2 2s. without further delay. Cheques should be made payable to the British Medical Association.

EDWIN RAYNER,
Treasurer.

British Medical Journal.

SATURDAY, SEPTEMBER 26TH, 1914.

EXCESSIVE PRESCRIBING UNDER THE INSURANCE ACTS.

THE Memorandum of the Insurance Commissioners to Insurance Committees on the Supply of Drugs and Appliances, which appears on page 180 of the SUPPLEMENT, should receive the earnest attention of every practitioner who is under agreement to give medical attendance to insured persons. It contains certain specific indications as to articles which are not to be ordered as drugs or appliances, which will, we believe, be welcomed by both doctors and pharmacists, and in addition deals with the general question of over-prescribing in a way which demands the serious consideration of all concerned.

The Memorandum is, however, as important because of what it implies as because of what it actually says. It has always been apparent to those who have studied the question that the panel system as it now exists must stand or fall by the success or otherwise of the method of providing drugs and appliances. If pharmacists as a body found they could not profitably continue the present system, the alternative would probably be the establishment of State dispensaries, and this would give a great impetus to the movement for employment of salaried whole-time medical practitioners. Under the present system, in which the 9s. allowed for medical attendance and drugs is divided into a medical fund and a drug fund, the demands on the latter are to a considerable extent within the control of the medical profession. By carelessness or extravagance on the part of doctors the drug fund can be made bankrupt, and the pharmacist can under his present agreement with an Insurance Committee be compelled to accept only a portion of the money for which he has worked, and part of which is actually out-of-pocket expenses. It is obvious that pharmacists are not likely to stand such a loss for long, though in any given area they might for a time consent to have their bills discounted; the Scottish panel chemists are reported[1] to have threatened to cancel their agreements with Insurance Committees unless, amongst other things, they are secured against the discounting of their bills and guaranteed the prompt and full payment of their accounts and the abolition of the "floating sixpence." It is only when this dependence of the pharmacist on the carefulness of the panel doctor is fully realized that the great importance of the circular now under consideration can be estimated. In several places it is hinted, not obscurely, that if the present machinery for the control of the cost of drugs and appliances is not effective, some other device will have to be found, and it is an open secret that the Commissioners have been hard pressed to abolish the distinction between the medical fund and the drug fund, and throw the cost of the drugs on the whole 9s., guaranteeing the pharmacist the payment of his bills in full. If this were done, and the cost of drugs in any area exceeded 2s. per head, the doctors would be penalized for this excess, and not the pharmacists as at present. The circular of the Commissioners is evidently intended to foreshadow some such change as this if the present machinery, which the Insurance, Panel, and Pharmaceutical Committees are urged to utilize to the utmost, is found to be inadequate.

The check on excessive prescribing which at present exists lies practically entirely in the hands of the Panel Committees, who are entitled, after examination of the prescriptions, to recommend Insurance Committees to surcharge those practitioners proved to have been extravagant. To make these surcharges is, of course, an unpleasant task from which many Panel Committees have up to the present shrunk, but the existing method of financing the drug fund can only be preserved if this duty is carried out consistently and fearlessly. The circular points out to the Insurance Committees that it is sometimes a very difficult thing to ascertain whether any given instance is one of excessive prescribing, and the Committees are reminded that on this they must be guided by the advice of their expert advisers—namely, the Panel Committees. The Commissioners evidently realize that a high cost of drugs in any area may be due not to careless prescribing but to excessive sickness, and that this latter may be the reason why some areas have exceeded the rate of 2s. a head per insured person for drugs and appliances, while in others not only have the chemists been paid in full, but the doctors have secured the "floating sixpence." But excessive sickness will not explain the differences which the Commissioners state have been found to exist in the cost of prescribing as between individual practitioners on the same panel.

The causes of the differing demands on the drug fund are complex. We have little doubt that some of the excess is due to the inexperience in prescription writing of many practitioners, at any rate in England and Wales where they have mainly been accustomed to dispense their own medicines. Whatever the reasons for it, the continuance of widely spread excessive demands on the drug fund would have such serious and far-reaching results that the advice given by the Commissioners to the Insurance, Panel, and Pharmaceutical Committees to keep up a continuous check on the prescriptions and chemists' accounts is sound and timely. Such a continuous check will not only act as a deterrent on careless members of the profession, but will enable the profession in any area to satisfy itself whether any excess in the cost of drugs and appliances is due to extravagant prescribing or to a genuinely high rate of sickness which would justify the high cost.

An allusion is made in paragraph 6 of the circular to a point which is already receiving close attention at the hands of the medical profession—namely, the question whether the tariff of charges at present in force is suitable. Investigations which the Association has already carried out seem to prove that there are many points at which the tariff could usefully be revised, and that many of the charges

[1] *National Insurance Gazette*, September 19th, 1914.

could not be justified on a purely commercial basis. It is, however, difficult to insist on the adoption of a scale of charges which would be quite proper if the payment of all accounts could be guaranteed, at a time when pharmacists in many parts of the country are having to submit to the discounting of their bills by considerable percentages. If the Panel Committees give this matter the attention it deserves and use with judgement and determination the machinery which the Regulations provide for the checking of over-prescribing in every insurance area, we believe that the average cost of drugs and appliances in a normal year would be found to be well under 2s. a head, without any detriment to the insured persons. An irresistible case could then be made out for a revision of the tariff on a strictly commercial basis. We sincerely trust that members of the profession, and particularly members of Panel Committees, will give the circular of the Commissioners and these comments their most careful consideration. The result of action taken on the lines of the Memorandum would inevitably be either that the cost of medicines and appliances would fall below the 2s. limit, or the Panel Committee would be able to demonstrate that the financial provision which has been made under the Insurance Act for drugs and appliances is inadequate. In view, however, of the experience of a considerable number of areas which have shown that the cost can, apparently without any detriment to the insured population, be kept below 2s. and even below 1s. 6d., the conclusion that the 2s. is insufficient can only be reached after each Panel Committee has carried out the checks which are provided in the Regulations.

PROPRIETARY MEDICINES AND THE LAW.

IMMEDIATELY upon the publication of the Report of the Select Committee on Patent Medicines, its findings and recommendations were reproduced in full, and in a subsequent issue we directed the attention of our readers to the "obsolete and chaotic" condition of the statute law in regard to the sale of drugs and poisons as revealed by that report and to the urgent necessity for "radical review and drastic amendment" of our pharmacy legislation. We briefly referred to some of the principles which have been regarded as underlying the restriction by law of the sale of medicines—proprietary, patent, and other—and we did not underestimate the formidable nature of the opposition with which huge vested interests would be ready to confront the pathway of the reformer.

The British Medical Association may congratulate itself on a striking success. But for its persistent efforts, continued through many years, it is exceedingly unlikely that the Select Committee would ever have been appointed. The statements with regard to the quack medicine trade made by the Association and in the BRITISH MEDICAL JOURNAL have been fully borne out, and a most important part of the inquiry and report of the Committee followed the line indicated by the articles on secret remedies published in the BRITISH MEDICAL JOURNAL, and subsequently collected into the two volumes, *Secret Remedies* and *More Secret Remedies*, published by the Association, many issues of which were quickly exhausted.

A comparison of British law with that of our allies on the Continent made by the Committee is illuminated by a striking instance: The Committee states of the American Macaura, who is alleged to have made £60,000 by his recent campaign in England, on behalf of an alleged vibratory cure for innumerable ailments, that "for the same procedure in Paris he has just been sentenced to three years' imprisonment and a fine of £120."

The Committee is convinced that the proprietors of the better-class newspapers would welcome a drastic suppression of suggestive or improper advertisements, but as regards "advertisements of swindlers like Macaura, the 'eye quacks,' the 'deaf quacks,' the cancer curers, the consumption curers, the electric belt makers, the curers of rupture without operation, or 'fakirs' generally," it finds that most newspaper proprietors do not regard it as incumbent upon them to inquire into the good faith of those who puff their wares, and, indeed, believes that the valuable consideration received in some cases leads to newspaper proprietors excluding from their columns criticisms or discussions of secret remedies. On this point the Committee says: "When the British Medical Association, for example, issued their volume, entitled *Secret Remedies*, containing analyses, costs, etc., of a large number of proprietary medicines, not only was the volume not noticed editorially by most papers, but even an advertisement of it was declined by many journals, some of them of the highest class." The Committee prognosticated that in obedience to the same tenderness towards advertising quackery its own findings would not be likely to enjoy what is commonly known as a good press. Even apart from any such motive, we fear that the preoccupation of journalism by the war will preclude that publicity which the labours of the Committee in the public interest alike merit and demand. In commenting further upon analyses in *Secret Remedies* issued by the British Medical Association, the Committee says that "it is asserted by expert analysts representing the proprietary medicine trade that no known methods of analysis will enable the composition of many secret remedies to be accurately determined. Consequently, it was claimed, the analyses published in *Secret Remedies* are incorrect in many cases. In one or two instances the makers informed us in confidence of ingredients which the British Medical Association analyst or the Government Chemist had failed to identify. Where there is an undiscovered ingredient, the maker claimed special virtues for it, which he would possibly not do, as one witness suggested, if it were named." The Committee goes on to state that "a large proportion of drugs consists of inorganic substances, or compounds of inorganic with organic substances. Practically all of these are recognizable, and so far as concerns the inorganic substances themselves, determinable—that is, not only the substance recognized but also its quantity determined—by competent analysis. A further group consists of manufactured compounds, and these are practically all recognizable by analysis, even in somewhat complex mixtures. There remains a group of vegetable extracts, of which dandelion and gentian are familiar examples. But even simple vegetable extracts are really highly complex bodies, and the exact composition of these is still unknown to chemistry. Unless one of these, therefore, possesses a marked smell or taste, or if, possessing such, its smell or taste is masked by the greater smell or taste of some other similar substance, it cannot in many cases be specifically identified. The difficulty of identification, moreover, increases rapidly in proportion to the number of such extracts in a mixture, and when a large number, say eight or ten, are mixed together, even separate detection is impossible, and accurate

determination out of the question. What is relied upon, however, in vegetable extracts for medicinal effect is often an alkaloid or mineral constituent, and these can be accurately discovered and determined. Further, sub-groups of this group possess in common an active principle which can be recognized, and which serves to identify the substances of the particular sub-group. For example, emodin is said to be the active principle of rhubarb and half a dozen other vegetable extracts."

The Committee draws from these considerations the general conclusion that "any maker of a secret remedy, by mixing together, whether with or without scientific or therapeutical knowledge, a number of vegetable extracts, can truthfully state that the composition of his remedy cannot be discovered by analysis. A mixture of tinctures, infusions, decoctions, or extracts of such familiar yet complex bodies as treacle, honey, aloes, cinnamon, liquorice, linseed, coltsfoot, cubebs, pepper, horehound, ginger, gentian, dandelion, rhubarb, saffron, etc., may defy all chemical, microscopic, spectroscopic, olfactory, or physiological analysis. While a mixture, therefore, may have a therapeutical value, it may also be made to defy the analytical exposure of a fraudulent claim of therapeutical value. There are thus distinct limits to analysis, but in practice these limits are narrower than would appear, for in a large majority of cases the essential nature of the principal constituents of any medicine can be detected with almost perfect certainty, and determined with reasonable accuracy, given skill, time, and a sufficient quantity of material."

Even where scientific analysis has done its best, it is undoubtedly the case that many organic compounds, especially the admixture of vegetable extracts, defy identification and isolation by the chemist, and it is not always possible to assert with accuracy the precise constituents of some much vaunted specific; moreover, these secret remedies have a knack of changing their names while maintaining their composition, or of changing their composition while maintaining their names. Thus the Committee states that "Acetanilide is sold as 'antikamnia,' 'ammonol,' 'antitoxine,' and 'phenalgin.'" The Committee goes on to state: "'Powell's Balsam of Aniseed' was repeatedly proved in courts of law to contain morphine. It now contains none. The same is true of 'Mrs. Winslow's Soothing Syrup.' The formula of 'Pond's Arthriticus' was said to be altered by the addition of potassium bromide and salicylic acid. The powders in one packet of 'Steedman's Powders' varied in weight from 1.9 to 4.5 grains. Sir Joseph Beecham informed us that 'Beecham's Cough Pills' at one time contained morphia, as that was considered to be a necessary medicinal ingredient; that when the law compelled the word 'Poison' to be put on the wrapper of preparations containing morphia, the morphia was taken out of the pills; then so small a quantity was put in again that it was 'comparatively innocuous or perfectly innocuous,' and therefore did not need to be labelled poison. That is, a potent drug was put in this remedy, taken out, and put in again, without regard to its medicinal effect, but solely because of the legal conditions under which it could or could not be sold."

It will probably be a revelation to many members of the public, though not to our readers, that several of the much advertised medicated wines are as rich in alcohol as are port and sherry. The Committee states that "the recommended dose of 'Wincarnis' equals one wineglassful of whisky per day." The Committee is satisfied that "there can be no doubt that many persons acquire the 'drink habit' by taking these wines and preparations, either knowing that they are alcoholic—since they can be purchased and consumed without giving rise to the charge of 'drinking'—or in ignorance that they are highly intoxicating liquors." Some years ago a Parliamentary Committee, considering legislation in regard to inebriety, secured an enlargement of its reference in order to report upon the nature and composition of the much-vaunted secret remedies for inebriety and drug addiction. The Committee, however, instead of exhausting its extended reference, appears to have been exhausted by it, and to have given up the attempt to handle this very delicate question in any effective way. That such remedies should have been patronized and puffed by some whose smug propriety would be scandalized by the mere suggestion of transgression of the canons of orthodoxy, bears testimony to the fact that the fascination of the unknown lies at the bottom of the success of the empiric.

Sir Henry Norman's Committee very properly dilates upon the folly and danger incident to the treatment of symptoms rather than of causes, and gives a short list of examples of "Fraudulent Claims" to cure diseases such as Bright's disease, cancer, syphilis, and consumption. One of the Committee's recommendations is that the advertisement and sale of medicines purporting to cure such diseases should be prohibited.

We would urge all those who at the proper psychological moment are ready to bring the necessary pressure to bear upon the appropriate Government departments with whom the initiation of such legislation will rest, to study attentively the valuable report of the Committee on Patent Medicines* and the conclusions at which it has arrived as the result of some two years' study of the question and the examination of witnesses, representatives of all the rival interests concerned.

A SANITARY ORGANIZATION IN BEING.

In an article published on September 12th, briefly discussing the steps which could be taken to guard the health of the Territorial and new forces, we commented on the circular of the medical officer of the Local Government Board, which did not seem to us specially well calculated to have the effect so ardently desired by all who are acquainted with the history of our previous warlike operations. A week later we again dwelt on the great need for prompt concerted action to safeguard the health of the many thousands of the Territorial Force who have been mobilized and the very large number of recruits who are enlisting in the regular army. Already, according to the recent statement of the Under-Secretary of State for War in the House of Commons, there are 200,000 men being drilled—100,000 at Aldershot, where, as we have been able to note, careful precautions are being taken under the direction of experienced officers of the Royal Army Medical Corps, and another 100,000 distributed in ten camps in various parts of the country. Very shortly these numbers will be doubled or trebled. The importance of the subject compels us to deal with it once more and to state in more detail the measures which we believe to be necessary.

So far as the regular army is concerned the services of the Royal Army Medical Corps suffice to provide

* Report from the Select Committee on Patent Medicines. London, Wyman and Sons; Edinburgh, H. M. Stationery Office; Dublin, E. Ponsonby. 1914. 3d.

the advice to commanding officers which is needed for the army which has gone abroad. The same to a very considerable degree may be said of the sanitary staff of the Territorial Force employed on foreign service. This is the best that can be done. The Royal Army Medical Corps is well trained in hygiene and will make the best of conditions which exist, wherever they may be serving. The sanitary officers of the divisions of the Territorial Force are for the most part experienced medical officers of health and will without doubt be able to render most valuable service. We stated, however, that when the military sanitary service (Territorial Force) was instituted the original idea was that the sanitary officers whose services would be available on mobilization would each be able to advise and direct in his own locality. This expectation has not been realized. Only exceptionally would the sanitary officers have the local knowledge required for the divisions which to a large extent would be operating outside the areas known to them. What is undoubtedly wanted is an organization which would make the local knowledge of medical officers of health available for military purposes.

Upon investigation of the sanitary conditions in London, we have ascertained that a very complete organization exists for the supervision of the health of the troops and of the localities occupied by them. This organization, we gather, is headed by the late medical officer for the county of London, who has the willing assistance of the medical officers of health of the various metropolitan boroughs, each of whom is responsible for the supervision of the general sanitary arrangements for the troops within the area with which he is familiar in ordinary times. We understand that these medical officers are in immediate communication with the commanding officers of the various bodies of troops scattered in each area, and communicate to these officers any suggestions or recommendations which their sanitary training tells them to be necessary. In addition, according to the information at our disposal, they report at regular intervals to the head quarters of the district upon matters which come to their notice from time to time. With regard to the nature of their investigations and of the duties they have accepted, it would appear that they inquire into the accommodation provided, the supply of food, its cooking, and the feeding arrangements generally, and as to latrines, urinals, means of ablution, and the removal of refuse.

The duty of giving effect to the recommendations of the medical officers serving in any capacity with military forces should be impressed on commanding officers. The duty is clearly laid down in the King's Regulations for the army; and, as regards the Territorial Forces, the paragraph in the Regulations is as follows, that: "Medical officers are charged with advising general and other officers commanding, who will incur grave responsibility if such advice is neglected without adequate reason." We believe that commanding officers are, as a rule, very ready to remedy defects brought to their notice; and every soldier, whatever his rank, from the private upwards, must be taught his individual obligation in sanitary matters. But in a large organization like an army individuals cannot think and act independently for themselves; they must be told what to do and how to do it, and constant vigilance must be exercised by officers of all grades and branches of the service to see that there are no breaches of discipline in this respect. But a special responsibility rests on medical officers, and in the existing crisis it is shared by the medical officers of the civilian public health service.

It seems to us that the sanitary organization which we learn exists in London for safeguarding the health of the Territorial and new forces within the area meets the requirements of the present situation. It is one which we may hope to see extended in principle throughout the whole country. While saying this we quite recognize that the conditions in London are special, and particularly favourable to the success of such a co-ordinated scheme. The civil sanitary service is highly organized, and its officers have had long experience in dealing with large agglomerations of population, and adequate staff and machinery for meeting the difficulties by which such agglomerations must always be attended. In rural districts it may not be easy to establish with the necessary speed a system for safeguarding the health of large bodies of recruits. It has been suggested to us by an eminent member of the public health service that the counties should be the units for the organization of an efficient working scheme of co-operation between the existing civil public health officers and the home military forces. In some instances, we understand, lord-lieutenants have felt it incumbent on them, as the local representatives of the Crown, to take up the task of guiding into useful channels the boundless good-will displayed by people of all ranks and callings in this day of trial. The organization of efficient sanitary control of recruiting centres and camps of training will, we trust, not fail to command their attention.

ENGLISH UNIVERSITIES AND LOUVAIN.

For the time Louvain has virtually ceased to exist as a university. It is a noble testimony to the solidarity of letters—at least as far as places of learning outside the sphere of German culture are concerned—that the great universities of England have come to the help of their afflicted Belgian sister. It was announced in the *Times* of September 12th that a committee of ladies and gentlemen connected with the University of Oxford had been formed, with the approval of the Belgian Minister, for the purpose of offering hospitality to professors of the University of Louvain and their families. The committee consists of the Vice-Chancellor (Dean of Christ Church), the Principal of Brasenose College, Sir William Osler, Mrs. W. Max Müller, and Miss Price. Through the American Minister at the Hague the Professors of Oxford University have offered a home for the winter to the young children of the professors of Louvain. Cambridge for its part has offered itself as a temporary substitute for their *alma mater* to the students of the wrecked university. It has placed at the disposal of the teachers and students who are in an academic sense left homeless, the use of its libraries, laboratories and teaching equipment, so that the continuity of their work may be maintained. In fact it has invited the University of Louvain to migrate to Cambridge and there carry on its own separate studies granting its own degrees, and generally continuing its activities as if its own buildings had not been destroyed. Efforts are being made to arrange hospitality, in the way of living accommodation and so forth, by the individual colleges and by private persons. The academic staff of University College, University of London, are prepared to receive as guests about seventy members of French and Belgian universities, whether professors, teachers, or students, men or women, who may be driven to take refuge in this country. Special arrangements will be made for students of these two nationalities to continue their work in London.

A FAMOUS LOUVAIN STUDENT.

ANDREAS VESALIUS, the most famous of the many famous students and teachers of Louvain, was born at Brussels on the last day of 1514. It had been arranged that an official celebration of the quatercentenary of his birth should be held in the city of Brussels in December next, and a committee, appointed by the University and presided over by the Burgomaster, had decided that one part of the commemoration should be the publication of a *Liber Memorialis*. The first part of this, extending to about two hundred pages small quarto, was to be devoted to the iconography of Vesalius. His features have been reproduced by a great number of painters, sculptors, and medallionists—several of them illustrious artists. As in the case of other celebrities—notably Shakespeare and Queen Mary of Scots—the portraits differ so greatly that they can hardly be accepted as representing the same person. In the Basel portrait, for instance, the great anatomist is represented with fair hair; in the one at Munich with black hair: in that at Glasgow with dark-brown locks, while in the Padua portrait the hair is red. There is one portrait of Vesalius which is generally regarded as authentic; it forms the frontispiece of his great work *De Humani Corporis Fabrica*, published in 1543. In the *Liber Memoriatis* all the portraits and likenesses that could be obtained from Louvain, Brussels, Basel, Padua, Amsterdam, Munich, Florence, Glasgow, London, Paris, Oxford, Vienna, Marseilles and other universities and museums, are reproduced in phototype. Each portrait is accompanied by a note giving all information about it and critically studying its origin and history. The author is Mr. M. H. Spielmann, of London, the well-known art critic who has made a special study of the portraits of Shakespeare. The second part of the book is devoted to the biography of Vesalius; all the legends that have gathered about his name are related and their sources critically examined. M. Paul Failer, professor at the Athénée of Mons, has translated the introduction written by Vesalius himself for his book; Professor Desmarez, archivist to the city of Brussels, has made researches on the authentic documents possessed by the library, in which he has found interesting information regarding the youth of Vesalius and the part played by him at the Court of Charles V, to whom he was physician-in-chief, and whom he accompanied on some of his campaigns. Professors Paul Héger, H. Leboucq, and A. Brachet have dealt with the scientific work of Vesalius. The *Liber Memorialis* will thus constitute a magnificent homage to the memory and work of the Luther of anatomy. According to the *Journal Médicale de Bruxelles* of July 23rd, it was then in the press, and was to be published in December. But how much has happened since then! *Inter arma silent leges*, and still more is this the case in regard to literature. We fear it is not likely that the *Liber Memorialis*, even if it has escaped destruction at the hands of the modern apostles of culture, will see the light at the appointed time.

PASTEUR AND HIS GERMAN HONOURS.

A NUMBER of German professors, out of hatred for this country, are giving up honorary degrees received from British universities, though there seems to be some difference of opinion among these great exemplars of culture as to the propriety of this particular way of expressing patriotic indignation. This recalls the fact that Pasteur, who was the son of one of Napoleon's veterans, resigned a German honorary degree in January, 1871, when the Paris Museum of Natural History, which till then had been respected by "all parties and all powers, national or foreign," was bombarded by the Prussians. In 1868 the University of Bonn had conferred on Pasteur the degree of Doctor of Medicine on the ground that "by his very penetrating experiments he had much contributed to the knowledge of the generation of micro-organisms, and had happily advanced the progress of the science of fermentations." He was very proud of this degree till the act of vandalism directed against the museum stirred him to fierce indignation, not only as a patriot, but as a man of science. On January 18th, 1871, he wrote to the Rector of the University, and after recalling his former sentiments he went on: "Now the sight of that parchment is odious to me, and I feel offended at seeing my name, with the qualification of *Virum clarissimum* that you have given it, placed under a name which is henceforth an object of execration to my country—that of *Rex Gulielmus*. While highly asseverating my profound respect for you, Sir, and for the celebrated professors who have affixed their signatures to the decision of the members of your Order, I am called upon by my conscience to ask you to efface my name from the archives of your Faculty, and to take back that diploma, as a sign of the indignation inspired in a French scientist by the barbarity and hypocrisy of him who, in order to satisfy his criminal pride, persists in the massacre of two great nations." Pasteur's protest ended with these words: "Written at Arbois (Jura) on January 18th, 1871, after reading the mark of infamy inscribed on the forehead of your King by the illustrious director of the Museum of Natural History, M. Chevreul." "This letter will not have much weight with a people whose principles differ so totally from those that inspire us," said Pasteur (quoted in his *Life* by Vallery-Radot), "but it will at least echo the indignation of French scientists." The reply was so characteristic that we think it interesting to quote at the present time: "Sir, the undersigned, now Principal of the Faculty of Medicine of Bonn, is requested to answer the insult which you have dared to offer to the German nation in the sacred person of its august Emperor, King Wilhelm of Prussia, by sending you the expression of its *entire contempt*.—Dr. Maurice Naumann. P.S.—Desiring to keep its papers *free from taint*, the Faculty herewith returns your screed." In acknowledging this courteous communication, Pasteur said: "I have the honour of informing you, Mr. Principal, that there are times when the expression of contempt in a Prussian mouth is equivalent for a true Frenchman to that of *Virum clarissimum* which you once publicly conferred upon me." After invoking in favour of Alsace-Lorraine, Truth, Justice, and the laws of humanity, Pasteur added in a postscript: "And now, Mr. Principal, after reading over both your letter and mine, I sorrow in my heart to think that men who like yourself and myself have spent a lifetime in the pursuit of truth and progress, should address each other in such a fashion, founded on my part on such actions. This is but one of the results of the character your Emperor has given to this war. You speak to me of *taint*. Mr. Principal, taint will rest, you may be assured, until far-distant ages, on the memory of those who began the bombardment of Paris when capitulation by famine was inevitable, and who continued this act of savagery after it had become evident to all men that it would not advance by one hour the surrender of the heroic city." These words remain as true as they were when they were written. The temper and manners of the German professor and the brutality of the German soldier have not been softened by nearly half a century of further culture.

QUACKS AND THE WAR.

THE war seems to have stimulated quack medicine vendors to make special efforts to attract public attention by way of advertisement. An attempt is made to give a warlike tinge to the customary nonsensical claims, and the testimonials seem to be doubly prized if they have a military air. It might have been thought that at this great crisis in our history newspaper proprietors would have been chary of devoting columns to blazoning forth the impossible claims of some panacea of the same class, if not of the

same name, as those exploded with a pungency which a mere journalist can only envy and admire, by the Select Committee on Patent Medicines. But advertisements these times are hard to come by, and what is a newspaper manager to do if butcher, baker, and candlestick maker, and even Edwin and Angelina fail him? Paper is dear, editions many, and the moratorium is not an unmixed blessing. But even the harassed manager ought to draw the line somewhere, and we venture to suggest that he should draw it on the hither side of advertisements which may injure not merely the individual soldier, but the army of which he is a member. To advise a soldier to doctor himself is something worse than commercial recklessness, and when it comes to recommending him to drug himself for diarrhœa it is much worse, for typhoid fever, dysentery, and other diseases which first manifest themselves by this symptom are the scourges of armies. Any man so affected should be encouraged to go at once to his medical officer and not privately to take some sedative that will merely suppress the symptom for a time, during which the infection may be disseminated among his comrades. Men who at this time, for the sake of a few sovereigns in hand, spread such pernicious doctrine broadcast should realize that an appeal made later to the benevolent public for a fund to treat and nurse sick soldiers who have been rendered useless to their country by disease will not undo the mischief or redress the balance against them.

AN AMBULANCE COLLEGE.

A LARGE gathering held at the Polytechnic, Regent Street, on September 9th, for the purpose of making a presentation to Mr. James Cantlie, ended in the foundation of a new institute. Dr. George Catheart said that he had been approached by a number of those attending classes at the Polytechnic in regard to the presentation to Mr. James Cantlie of a suitable testimonial in acknowledgement of the enormous amount he had done, and was still doing, in connexion with ambulance work. He had been the embodiment of ambulance work in this country for well-nigh forty years. He had raised by his own initiative and exertions the Volunteer Medical Staff Corps, which had afterwards developed into the magnificent ambulance department possessed by the Territorial army. Both in connexion with the St. John Ambulance Association and with Red Cross work as a whole his exertions had been titanic. Dr. Cathcart was followed by Mr. T. H. Stanley, who, after further allusion to Mr. Cantlie's work and his capacity for infecting others with his own enthusiasm, said that their appreciation of his labours on behalf of the sick and suffering could not be better shown than by falling in with his wishes that any testimonial presented him should take the form of the foundation of an institution that he had at heart. The character of the proposed new institution was subsequently explained by Mr. James Cantlie himself. From what he said, the plan would appear to be that the new institution shall be a school or college for the study and teaching of ambulance work in its more scientific phases; that it shall be possessed of working models of every kind of appliance used in ambulance and first-aid work, both in war operations and in civil life; that it shall hold classes of instruction for medical men in ambulance work, drill, and the improvisation of appliances, as also classes for the officers of Voluntary Aid Detachments, and place its resources at the disposition of those who wish to study the general subject thoroughly; that it shall issue a diploma representing really advanced knowledge, crediting those already holding certificates in first-aid work from other bodies with a certain number of marks at the examinations to be held for the diploma. Apart from its educational work, the college will serve as the head quarters of a new body bearing the name Humanitarian Corps; the aim of this body will be to afford first aid not merely to those suffering from street accidents, or bullets of an enemy, but to any and every one standing in need of instantaneous help, whether physical or moral. On conclusion of Mr. Cantlie's address it was unanimously resolved that the testimonial to him, in recognition of his lifelong devotion to ambulance work, should take the form of a sum of money towards the foundation of the College of Ambulance and the Humanitarian Corps to render "First Aid to the Needy." Before the gathering separated Mr. Cantlie stated that Mr. Boyton, M.P. for Marylebone, had generously placed Nos. 3 and 4, Vere Street, at the disposal of the institution, free of rent for twelve months. The secretary of the new institution is Mrs. Colin Macdonald.

A TROPICAL INSTITUTE OF MICROBIOLOGY.

AN institute of microbiology has recently been established in New Caledonia. It is intended for research work on the prophylaxis of infectious and parasitic diseases, endemic or epidemic, which might attack the colony. Among the duties specified by the Governor in the regulations for its working are the preparation of small-pox vaccine, of the antiplague vaccine, and of antimurin, and other viruses for the destruction of rats and mice. The institute will also study the special prophylaxis of leprosy, and supply such serums as may be needed in medical practice. It will also make all analyses connected with the health of the troops asked for by the military authorities.

WE have on several previous occasions mentioned that the Library of the British Medical Association did not possess a set of the *Transactions* of the Seventeenth International Congress of Medicine held in London last year. In response to these notifications several volumes were presented, and the Librarian now has pleasure in acknowledging the gift from Dr. John Patrick of Glasgow of the records of the Section of Medicine, vols. i and ii complete. The Library has now received nine volumes in all—namely, those dealing with Sections VI, VII, VIIa, part ii, XIII and XXIII, and the General volume. The Librarian will be grateful for any of the remaining volumes.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Separation Allowances to Soldiers and Sailors.—On September 17th the Prime Minister announced that with regard to separation allowances for the army it had been decided for the period of the war to adopt a scale based on a minimum, inclusive of compulsory allotment, of 12s. 6d. a week with consequential increases. He said that the new scale would compare with the old as follows:

Wife, 12s. 6d., as compared to the present scale of 11s. 1d.

Wife with one child, 15s., as compared to the present scale of 12s. 10d.

Wife with two children, 17s. 6d., as compared to the present scale of 14s. 7d.

Wife with three children, 20s., as compared to the present scale of 16s. 4d.

Wife with four children, 22s., as compared to the present scale of 17s. 6d.

The London allowance of 3s. 6d. remained unaltered subject to the present condition.

The machinery of the Old Age Pensions Committees would be utilized for the purpose. The scale would apply to all men, Territorials and new recruits, directly they were embodied and separated from their wives. It had been decided to grant separation allowances to wives and children of men serving in the navy, conditional on the minimum allotment being made. The allowances would be paid weekly through the post-office, and would date from October 1st, but, owing to administrative difficulties, it might not be possible to make payments on the new scale until October 12th. The Prime Minister promised that the details of the scheme would be announced as soon as possible.

A Parliamentary White Paper issued on September 22nd gives particulars of the new separation allowances for the dependants of seamen, marines, and reservists. No separation allowance will be paid unless the seaman makes an allotment of 20s. a month to his wife out of his pay. Subject to this proviso the following scale has been approved:

In the case of an ordinary seaman the wife will receive 6s. per week, with 2s. a week for the first child, 2s. for the second child, and 1s. each for other children. Motherless children will receive 3s. a week each. This is the scale for privates, corporals, and sergeants. In Class II, colour-sergeants' wives will get 7s. a week. In Class III, the wives of quartermaster-sergeants and staff sergeants will receive 8s., while in Class IV the wives of warrant officers will receive 9s. The allowances for children are the same in all cases. The term "children" includes boys under 14 and girls under 16. Families now residing within the London postal area will receive an additional allowance of 3s. 6d. a week.

Hospital Accommodation. — Sir Charles Henry asked whether, in order that the accommodation of hospitals and infirmaries might be available as far as possible for the reception of civilian patients, the War Office, before sending wounded soldiers to these hospitals and infirmaries, would avail themselves of those hospitals which had been specially equipped and were ready for the reception of the military patients.—The Under-Secretary of State for War said that the War Office was making every effort to prevent military exigencies from interfering with the needs and comfort of the civil population. No institutions under the control of the Local Government Board had been utilized for the accommodation of military patients, and none would be used to the detriment of the poor of the districts. Beds in civil hospitals used for the sick and wounded from overseas had been voluntarily placed at the disposal of the War Office by the authorities of the hospitals, and no demand had been made for the use of beds which might possibly be required for the civilian population. The War Office was availing itself of specially equipped hospitals provided by the generosity of private individuals; altogether about 12,000 beds had been offered.

New Camps for Recruits.—On September 17th, Sir Ivor Herbert, immediately before the adjournment of the House, asked for some statement to relieve the public anxiety with regard to the treatment of recruits. Briefly stated the complaints were, he said, that there was no proper feeding, no accommodation, leading to overcrowding, no sufficient sanitary arrangements, no means of washing, no clothing, and no other necessaries. Finally, as there was no pay, a man had no means to provide these things for himself. Mr. Arthur Henderson associated himself with Sir Ivor Herbert in the complaint, and while making the fullest allowance for the strain which had been placed on the War Office, he asked that the organization should be such that great groups of men should not be placed at Aldershot, and there exposed to inconvenience and annoyance to themselves, and to the pain of having to carry in their memories the sufferings imposed upon those left at home.—Mr. Tennant said that the War Office had opened ten large new camps at Salisbury, Ottery St. Mary, Tring, Shoreham, Shorncliffe, Lulworth, Wool, Wareham, Bulford, and Grantham. All were equipped with tents and a blanket was served out to each man. It was hoped soon to give another, and in the winter possibly three. The ten camps would accommodate approximately 100,000 men, and there were 100,000 at Aldershot. Most of the tents were now supplied with boards below and others had waterproof sheets. There was, he said, no difficulty about food; there was a plentiful supply of the best food.

Hutting for Troops.—In reply to Mr. C. Bathurst, who asked whether huts were being constructed for the use of troops now under canvas in Great Britain, the Under-Secretary for War said that hutting for some 490,000 men in addition to many Territorial troops had been ordered. The numbers required for the Territorials would depend upon the possibilities in each place of utilizing available public buildings. The first lot of huts at Belton Park would be ready for occupation by September 25th; it was unlikely that all would be ready before the end of November.

THE WAR.

MEDICAL ADMINISTRATION IN THE TERRITORIALS.

BACTERIOLOGICAL DIAGNOSIS: ANTITYPHOID INOCULATION.

IT is one of the merits of the scheme of the Territorial Medical Service that medical men engaged in all departments of practice hold commissions in it. The system, no doubt, has certain drawbacks, but it has compensating advantages, and by making judicious use of the special aptitudes and training of the various officers much good may be done. We understand that the principal medical officers of some of the larger bodies in which the Territorial Forces are assembled have found it advisable to make arrangements to take advantage of special knowledge possessed by regimental medical officers for the advantage of the whole command. We know of at least one instance in which the principal medical officer has found among the officers in his command juniors trained in modern methods of bacteriological diagnosis, and has seen the wisdom of arranging that their services should be available in the diagnosis of doubtful cases occurring in any unit in the force. The importance and value of such specialist assistance are well recognized in civil life, and they are, if possible, even more important under military conditions. It is very satisfactory to know that the situation has been grasped at an early stage by senior Territorial medical officers, whose responsibilities for the health of these troops are so serious.

With regard to typhoid inoculation, we understand that in some instances a similar system has been introduced, and special inoculators have been selected from among the medical officers available in the command. In other instances this has not been found necessary, or indeed, for reasons indicated by a correspondent in our last issue (p. 517), always desirable.

It appears from the statements of Ministers in the House of Commons, and from the letter of Sir William Leishman, published last week, that it has been finally decided not to make antityphoid inoculation compulsory in the British forces; but from the information which reaches us it is to be gathered that the men generally understand the value of the protection the process confers and are readily taking advantage of the offer made to them. In some commands we understand that over 90 per cent. have already been inoculated or are awaiting their turn, and Sir William Leishman, indeed, anticipates that the voluntary response will be almost universal. This has been brought about through the influence of regimental medical officers, helped by the example set by the other regimental officers.

THE HOSPITALS AND THE WAR.

A NOTE ON THE CONDITION OF THE WOUNDED FROM THE FRONT AT THE 2ND EASTERN GENERAL HOSPITAL (BRIGHTON).

OF the 300 cases admitted on September 1st from France about 250 were of a surgical nature. The men, the great majority of whom were wounded at the battle of Mons, had come down to Rouen by road, and were there transferred to boat, which took them to Southampton; they had been brought on by train from the latter place. In spite of this rather trying journey, most of them were in very good condition when they arrived.

Of the medical cases very few were serious. Most of them were quite simple, the patients suffering from such affections as "rheumatism," bronchitis, pleurisy, or diarrhœa. Of the cases of "rheumatism," the greater number were in the feet, and occurred in reservists. Probably the heavy marching undergone by men unaccustomed to it, in combination with the dampness of the ground over which they passed, is accountable for this. There is also the probability that in many of these cases there was a gonorrhœal element.

Among the surgical cases wounds were most numerous. Those sent on to Brighton were the least serious, the very severely wounded men being detained at Netley or some hospital close to the port of landing. The wounds were

much more commonly caused by shrapnel or shell than by rifle bullets. Many more occurred in the legs than in other parts of the body.

In those examples in which the embedded bullet was causing no symptoms, the patient was not operated on, but if symptoms were being caused, such as pain, swelling, suppurating sinuses, etc., operation was undertaken for their removal. Before operation x rays were used to locate the bullet exactly, and usually this made its ready removal possible. In some cases, however, even after the location by means of x rays, operation failed to find the piece of lead, an experience which has unfortunately happened to most surgeons.

The following are some typical examples of bullet wounds:

Shrapnel Wound of the Thigh.—It was decided to remove the piece of shrapnel left in the thigh because it was causing a good deal of boggy indurated swelling in the upper part of the front of the thigh. A good-sized round bullet was seen in an x-ray plate, close to the great trochanter. This was cut down on, but after a careful exploration the bullet could not be found. The man was very muscular and the bullet was deeply seated. Probably the incision into the indurated swelling (there was no pus) will relieve the condition, and nothing further will require to be done.

Bullet Wound of Lung.—This patient was shot in the back, the bullet passing right through the lung, and remaining in the front part of the chest, just over the ribs. Haemorrhage from the lung occurred just after the wound was received. When the patient was admitted his condition was as follows: His general tone was good, appetite healthy, but his temperature kept at about 100° F. There was a piece of shrapnel to be felt on the third rib in front; it was contained in a small superficial suppurating cavity. There was also a large empyema in the left pleura. The bullet was extracted, and the superficial abscess drained. A little later it is intended to treat the empyema by drainage and resection of rib.

Wound of Lower Part of Thigh: Secondary Haemorrhage.—This patient was hit by a bullet which passed right through the lower part of his thigh. All went well till about a fortnight later, when he had been in the hospital four days. After some slight exertion blood poured very freely and rapidly from the wound of exit. This was temporarily stopped by pressure on the main artery. The wound was opened up and, with a good deal of difficulty, the bleeding end of the vessel (the anastomotica magna) found and tied. This is the only case, so far, of secondary haemorrhage.

Bullet Wound of both Upper Jaws.—This man was hit by a rifle bullet, which passed through one cheek and upper jaw and then through the other upper jaw and cheek. When admitted he had two large foul ulcerating cavities in the mouth, one in each upper jaw. Several teeth were extracted, and his mouth kept clean with peroxide lotion. He is rapidly getting well. Several small pieces of dead bone have come away.

Fracture of Larynx.—A man fell 60 ft. over a cliff, bruised himself all over, but broke no bones. His neck swelled very considerably, and he had respiratory trouble. The swelling was caused by surgical emphysema. With simple treatment he is improving considerably.

Acute Mastoiditis: Meningitis: Death.—The man was admitted with a temperature of 103° F. and rheumatic pains in the wrist and ankles, and he was at first supposed to be suffering from acute rheumatic fever. He was found to be suffering from discharge from one ear. As the ear symptoms increased, the mastoid was explored and cleared; the lateral sinus was opened, but found quite patent. He died quite shortly afterwards with signs of meningitis.

Up to the present the operations performed are as follows: 2 for appendicitis; 2 for removal of cartilage of knee; 12 for extraction of bullets, in all of which, except one, the bullet was found; 1 for radical cure of hernia; 1 for pyelitis—20 in all. Several cases are still waiting, many of them for removal of bullets, several of varicose veins.

It is surprising how few of the bullet wounds were septic. Most of them had either quite healed or were well on the way to it, before admission.

The general impression given from a survey of the whole cases is that a very large proportion, about 30 per cent., were really quite trivial cases, which required no treatment, and which need never have been sent to this hospital at all, had any means existed by which they could have been sent straight to their own homes on furlough, before rejoining their regiments.

Manchester and Salford.

No fewer than fourteen members of the staff of the Manchester Royal Infirmary have either been called up or have volunteered for active service in the war, and, though some difficulty was experienced at first in filling their places, the board has been able to take advantage of the fact that the infirmary is a large medical school, and a number of senior men have been obtained to undertake the duties of the absentees. The offer of the board to set aside 50 beds immediately, to be increased to 200 if necessary, for the treatment of wounded soldiers and sailors, has been gladly accepted by the army and navy authorities. The first contingent of wounded from the front, numbering 125 men, arrived in Manchester last Sunday. They had crossed from France to Southampton by the hospital ship *Asturia*, and were met at London Road Station by a numerous staff of doctors and nurses, who supplied them with tea, soda water, and light refreshments. A number of Red Cross vans, police ambulances, and motor cars were in waiting, and they were all quickly removed to the Whitworth Street Military Hospital.

At the Salford Royal Hospital the vacancies caused by members of the staff who have volunteered for active service have been filled up, and the ordinary work of the hospital is now going on as usual. The board offered to provide from 60 to 100 beds for the wounded, and this has been accepted, while a further number of beds is kept in reserve to be used if necessary.

From both hospitals a considerable number of nurses have been accepted for service. Fifteen of the infirmary nurses were sent to military hospitals soon after war was declared, and since then two others have gone to Chatham and two to hospital ships, while five who went to the front were last heard from at Rouen. Several others are still awaiting orders. From the Salford Hospital four nurses volunteered, and two of them are now at the front, while two are on duty at the Whitworth Street Military Hospital. The boards of both hospitals have recently received a letter from Queen Alexandra thanking the matrons for the response made to the appeal for nurses, and expressing grateful appreciation of the prompt and untiring trouble taken in selecting them and sending them out with the shortest possible delay to the seat of war.

Charing Cross.

Considerable numbers of sick and wounded soldiers have been sent this week to various hospitals throughout the country. Charing Cross Hospital now flies the Red Cross flag, and a banner across the street appeals for "Quiet for the Wounded." Here 16 lying-down cases and 20 ambulant cases have been received, and more are expected shortly. Most of the 36 cases are serious, and include some sufferers from rheumatism and pleurisy—an indication of the severity of recent weather conditions at the front. Certain wards at Charing Cross Hospital which have been unused for some years are being thoroughly renovated, and will soon provide beds for 250.

THE BRITISH RED CROSS SOCIETY.

The Society's Organization.

The British Red Cross Society has moved from Devonshire House to new quarters adjoining the Royal Automobile Club at 83, Pall Mall, S.W. Several floors have been placed at the disposal of the Society, and the extensive accommodation greatly facilitates the work, which is proceeding quite smoothly. The Society is meeting all requirements, and grants of stores have been made to 26 hospitals in Great Britain in which sick and wounded soldiers have been already received. The stores are now very large; up to the middle of September 15,000 pieces of bedding, etc., and over 62,000 garments had been received. Although these numbers may appear large, stocks are becoming rapidly depleted. Sir Alfred Keogh, the Society's Chief Commissioner in France, has telegraphed from Rouen making an urgent appeal for shirts, pyjamas, sheets, pillow-slips, mackintosh sheets, slippers and socks.

Although not connected directly with the work of the Red Cross Society, it may be noted here that the Queen, at the request of Lord Kitchener, has made an appeal to women to supply 300,000 belts, knitted or woven, and 300,000 pairs of socks early in November. The articles or gifts of money should be sent to the Lady-in-Waiting to Her Majesty, and addressed to Devonshire House, London, which the Duke of Devonshire has placed at the disposal of the Queen for the purpose of these gifts. Written instructions can be obtained from the Lady-in-Waiting at Devonshire House.

Search for the "Missing."

The British Red Cross unit at Boulogne is doing admirable work, and has covered nearly the whole of the ground traversed by the British in their retreat towards Paris. This unit has been reinforced by a large number of orderlies and nurses: it employs many motor cars, by means of which practically all the travelling is done. The Society already has 30 motor ambulances on the Continent and hopes to send out 50 more almost directly. With a fleet of 80 vehicles much service can be rendered. In connexion with the work of searching for the "missing," the Society has the advantage of the services of the yacht *Miranda*, lent by Lord Leith of Fyvie.

Hospital at Rouen.

A hospital of from 300 to 500 beds is being established at Rouen and all the personnel has been sent out. The commandant of the hospital is Surgeon-General Kenny, the chief surgeon is Mr. Percy Sargent of St. Thomas's Hospital, the radiographer is Dr. Gouldesborough, and the matron is Mrs. Ludlow, R.R.C., who is well known as the matron of the British hospital camp at Ladysmith.

Rest Stations and Base Hospital.

Rest stations are being established on the lines of communication. The British Red Cross base hospital at Netley will be ready to receive patients at the beginning of October. The commandant is Colonel Sir Warren Crooke Lawless, K.C.B.; the senior surgeon, Mr. Cuthbert Wallace, of St. Thomas's Hospital; and the senior physician, Dr. Miller, of the London Hospital. In connexion with this hospital Lord Brassey has very generously placed the *Sunbeam* at the disposal of the Society.

The Professional Staff.

The Society (Sir Frederick Treves informed a representative of the JOURNAL) is much impressed with the generosity and self-sacrifice of the medical profession in its desire to be of use in the campaign. Many practitioners have given up important appointments and have left lucrative practices in order to help in the care of the sick and wounded. The oldest volunteer who has presented himself at the Society's offices was a hale and vigorous old gentleman of 71, who said he was prepared to work anywhere. Many of the younger surgeons, when they found there was no prospect of immediate employment, enlisted. No women have been sent out (added Sir Frederick) except fully trained hospital nurses. Statements in the lay press that there is a shortage of nurses for Red Cross work are absolutely unfounded, and the proposal that domestic servants out of work should be rapidly trained to nurse the sick is ridiculous. The Society has on its list at this moment 1,500 fully trained hospital nurses.

British Hospital for the French Red Cross.

A hospital unit composed of four women doctors and eight English trained nurses left for Paris on September 15th. It was organized with the approval of the French Red Cross Society, and has had placed at its disposition the Claridge Hotel in Paris. The initial expenditure was provided by private subscription, but all maintenance expenses are to be met by the French War Office. The intention is to provide 80 beds, and to supplement the work of the English staff by a few male orderlies. The surgeon in charge is Dr. Louisa Garrett Anderson, the other members of the staff being Drs. Louisa Woodcock, Flora Murray, and Hazel Cuthbert.

THE DISPOSAL OF SEWAGE IN THE FIELD.

As a result of the collaboration between Mr. James Menzies and Dr. Myer Coplans, Beit Memorial Fellow, working at the Lister Institute, on the problem of the effective disposal of sewage in the field by means of a self-supporting system of destructive distillation, an apparatus has been devised whereby the gases and oils evolved, together with the residual charcoal, are utilized as fuel for the maintenance of the process, which is thus rendered entirely independent of extraneous fuel supply; all problems of fuel transport are thus automatically eliminated. The ammoniacal liquor evolved, which contains organic bases of marked bactericidal and insecticidal value—as tested against flies and *B. typhosus* in the presence of faeces—would seem capable of replacing the coal-tar disinfectants hitherto used in camp sanitation, more particularly for the purpose of maintaining hygienic conditions in field and camp latrines.

The practicability of the apparatus has recently been demonstrated to military and naval representatives in a series of tests conducted on a large scale at Wimbledon Sewage Works, and, as an outcome, the War Office has sanctioned the immediate construction of a suitable apparatus capable of dealing with the needs of 12,000 men in camp.

NOTES.

THE OVERSEAS DOMINIONS.

Canada.

As was briefly stated in the JOURNAL of September 12th, the Toronto Academy of Medicine, at a special meeting held on August 27th, unanimously decided to undertake without charge the medical care of needy dependants of the volunteers. A sum of £200 has been voted from the funds to the Toronto Patriotic Fund to provide for the dependants of those who have gone to the front. A committee of past presidents will arrange to look after the practices of the professional members who have left with their regiments.

From the *Journal of the American Medical Association* we learn that there are about 350 medical officers in the Canadian Militia. Many of these will probably be called on for active duty in the field. Dr. Wallace A. Scott will be in charge of the Army Medical Service of the Toronto branch of the first Canadian contingent. Dr. Irving Howard Cameron, professor of surgery in the University of Toronto, has offered his services to the British Government in connexion with base hospital work.

SORE FEET.

Major J. B. SIMPSON, R.A.M.C.(T.) (attached 5th Seaforths), writes from Golspie, on September 21st, as follows:

Mr. Basil Hughes's thoroughly practical article ("Examination of Recruits of the Territorial Force and their Early Training") in the BRITISH MEDICAL JOURNAL of September 19th, p. 496, deserves to be widely read by all regimental medical officers at present on service. The question of the prevention of sore feet is of extreme importance.

Might I venture to suggest a method for hardening the feet adopted by deer-stalkers and shepherds in the Highlands—that is, take a hot saturated solution of alum in a basin or pail, soak the feet in this for ten minutes, preferably at night? Next morning smear the socks with soft soap. The alum bath need not be repeated more than once or twice. The result is a foot which does not blister readily.

Of course, the provision of properly fitting boots is a *sine qua non*. In some Territorial regiments no service boots are supplied, or at least they have not been supplied up to date. Many men mobilized in August were wearing not their ordinary working boots, but either their "Sunday" boots or new boots; shod in this way, blisters and sore toes were inevitable.

If some of the money which is at present being spent in preparing and equipping private houses as hospitals—we have already, I believe, ample hospital provision without private houses—was given to county Territorial Associations to form a fund for the provision of suitable boots for our Territorials during the coming winter, I am sure a great service would thereby be rendered to the country.

VACANCIES FOR MEDICAL OFFICERS.

Lieutenant-Colonel W. CAMPBELL HYSLOP (Secretary) writes under date September 22nd: In accordance with the orders of the Secretary of State for War, it has been decided to raise reserve units of the Territorial Force. Consequently there are vacancies for a number of medical officers in the Royal Army Medical Corps units of the 1st London Division. These are the 1st, 2nd, and 3rd Field Ambulances, and a sanitary company. Gentlemen who desire commissions should apply by letter, in the first instance, to the Secretary of the City of London Territorial Force Association, Friars House, New Broad Street, E.C.

Dr. JOSIAH OLDFIELD, Major, R.A.M.C.(T.), commanding the 3rd Reserve East Anglian Field Ambulance, states that there are still vacancies for medical men who want R.A.M.C.(T.) commissions, both in the service unit and the field ambulances. He will be glad to receive at the Drill Hall, Walthamstow, applica-

tions from medical men wishing for a commission in the Reserve unit of the 3rd East Anglian Field Ambulance.

National Volunteer Reserve.

We have received the following communication, dated September 22nd:

Sir,—The above Volunteer Reserve has been formed to enable men to be trained as soldiers who through business or family ties are absolutely unable to join the regular forces of the Crown, and it is hoped at no very distant date that the Army Council will recognize this new force as a military organization for home defence. In the meantime it is proposed to proceed with drill, etc.

It is, of course, obvious that to be efficient the force must consist of men who are physically fit and who have passed a medical examination.

The members will give their time and energies for the good of the country, and it is only right that they should not be put to expense as well; indeed, many, of course, will be working men earning small salaries. I am therefore writing to you to ask if any patriotic medical men in London and suburbs who will undertake to examine, free of charge, recruits for the National Volunteer Reserve, will kindly send their names, with qualifications and addresses, to me at Trafalgar House, Waterloo Place, W., in order that a printed list may be given to each candidate for enrolment.—I am, etc.,

Arthur Todd-White,
Medical Referee, National Volunteer Reserve Committee.

FURTHER CASUALTIES IN THE MEDICAL SERVICE.

Army.

Killed.

Armstrong, Lieutenant A. K., R.A.M.C.
Forrest, Captain Frank, R.A.M.C.
Scatchard, Captain T., R.A.M.C.

Captain Forrest was reported on September 20th as killed in action during the previous week, presumably in the battle of the Aisne. He was educated at Owens College, Manchester, took the diplomas of M.R.C.S. and L.R.C.P. Lond. in 1904, and, after serving as assistant house-surgeon of the North Staffordshire Royal Infirmary and Eye Hospital, entered the army as lieutenant on January 30th, 1906, becoming captain on July 30th, 1909. He had no previous war service.

Wounded.

Dalton, Lieutenant-Colonel Charles, R.A.M.C.
Wyler, Lieutenant E. J., R.A.M.C.

Lieutenant-Colonel Dalton was educated at the Carmichael College, Dublin, took the diplomas of L.R.C.S.I. and L.R.C.P.I. in 1888, and entered the army as surgeon on January 31st, 1891, becoming major on January 31st, 1903, and lieutenant-colonel on May 7th, 1913. His station, previous to going to the front, was Dublin, where he held the post of deputy assistant director of medical services. He has a very long list of war service, namely: Burma, 1893, in the Kachin Hills, medal with clasp; North-West Frontier of India, 1897–8, on the Malakand, and action at Landakai, medal with clasp; Sierra Leone, 1898–9, the Karene expedition, mentioned in dispatches, medal with clasp; and South Africa, 1899–1900, as special service officer. Here he took part in the operations in Natal in 1899, in the relief of Ladysmith, including the operations of January 17th to 24th, 1900, being severely wounded on January 23rd; in the Orange Free State from February to May, 1900, including the actions at Hontnek (Thoba Mountain), Vet River, and Zand River; and in Cape Colony. He was mentioned in dispatches, and received the Queen's medal with three clasps. He also holds the Albert medal and the Royal Humane Society's medal for saving life.

Captain Leckie, R.A.M.C., previously reported wounded, is now reported wounded and missing.

Officers Reported as Prisoners of War.

Beaman, Captain W. K., R.A.M.C.
Berry, Captain H. M. J., R.A.M.C.
Butler, Lieutenant P. P., R.A.M.C.
Davy, Captain P. C. T., R.A.M.C.
Egan, Captain W., R.A.M.C.
Fry, Major W. B., R.A.M.C.
Furness, Major J. C., R.A.M.C.
Hamilton, Captain E. S. B., R.A.M.C.
Hattersley, Lieutenant S. M., R.A.M.C.
Lander, Lieutenant J. L., R.A.M.C.
Lynch, Captain J. P., R.A.M.C.
Mitchell, Captain W., R.A.M.C.
Priestly, Captain H. E., R.A.M.C.
Routh, Lieutenant L. M., R.A.M.C.
Sutcliff, Captain A. A., R.A.M.C.
Vidal, Captain A. C., R.A.M.C.
Williams, Captain A. S., R.A.M.C. (previously reported killed).

Captain Hamilton before the war was in practice in Manchester.

Missing.

Danks, Lieutenant W. S., R.A.M.C.
Kempthorne, Captain G. A., R.A.M.C.
Middleton, Captain E. M., R.A.M.C.
Thompson, Captain W. I., R.A.M.C.

Officers Reported Missing who have now Reported Themselves.

Dwyer, Captain P., R.A.M.C.
Irvine, Major F. S., R.A.M.C.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

Lunacy in Ireland.

According to the sixty-third annual report of the inspectors of lunatics in the district criminal and private lunatic asylums of Ireland, just issued, there were 25,009 insane in establishments on January 1st, 1914. There was a total increase of 170 during the year, the corresponding increase for the previous year having been 184. The increase for 1913 was 100 less than the average increases for the last ten years. Since 1880 an increase of 12,027 has taken place in the total, but there has been a decrease in the number of pauper lunatics in workhouses of 1,019. These figures do not, of course, include all the insane in the country, as a number reside in their own homes or with relatives, or are wandering at large. The number of the latter classes in the last census amounted to approximately 14 per cent. of the total. The report further states that the order of the provinces of Ireland as regards the prevalence of mental disease is found to be—Leinster, Munster, Connaught, Ulster; and the proportion of the population in these provinces under 20 years of age as follows: Leinster 37.4 per cent., Munster 39.5, Ulster 39.6, and Connaught 41.4. The order, therefore, differs from what might have been expected only as between Ulster and Connaught. Continuing, the report says: It appears clear that the tendency to mental abnormality is becoming less amongst the young, which must mean a reduction in the number of congenital cases. The number of insane and idiots in the earlier twenty-five years of adult life, though increasing as compared with the general population at the same age, is growing at a rate slightly slower than the general increase of mental abnormality at all ages, and actually forms a steadily diminishing percentage of the insane. The number in the later twenty years of adult life shows a comparative increase, in fact the highest of all, and forms a less rapidly growing percentage of the total insane; while the number of senile cases shows a comparative growth somewhat above the average, and the proportion of the mentally affected at that age has considerably more than doubled in the fifty years under review. All this at least strongly supports the suggestion of the influence of the former larger population, and, it may be, of a legacy of mental weakness dating from the sufferings of the awful famine years. It holds out a hope that as time goes on, and these influences exhaust themselves, there may be seen, if not a diminution in the numbers of the insane, an arrest, or at least a greatly lessened velocity of increase.

Appointment of Relieving Officer.

In the King's Bench Division recently an application was made on behalf of the Local Government Board for a conditional order for a writ of mandamus, addressed to the guardians of the Killbala Union, County Mayo, directing them to appoint a relieving officer in accordance with the instructions already issued by the Local Government Board.

It appeared that on June 14th, 1914, the guardians appointed a Mr. Thomas Loughney as relieving officer. The Local Government Board directed its inspector to inquire into and report as to the fitness or otherwise of that gentleman. The result of the inquiry was a suggestion that Mr. Loughney should be given two months on probation. At the end of that time he was granted another month of probation, but the Local Government Board eventually refused to sanction the appointment and directed the guardians to re-advertise. This they at first refused to do, but afterwards they advertised, and promptly re-elected Mr. Loughney, the voting being 13 to 6. A long and animated correspondence ensued between the guardians and the Local Government Board. Counsel asked that a special note should be inserted in the order, making the thirteen members of the board of guardians who had voted for the resolution responsible for the costs. The Lord Chief Justice granted the conditional order.

The Babies of the Soldiers and Sailors.

The executive committee of the Belfast branch of the Women's National Health Association of Ireland decided unanimously, at its meeting on September 12th, to give permission to Lady Byers (President) and Mrs. Robert Campbell (Secretary), of the Infantile Mortality Section, to open a special department at the Babies' Club, Divis

Street, Belfast, to look after the babies and children of the wives residing in Belfast of the soldiers and sailors at the war, in connexion with the Belfast branch of the Soldiers' and Sailors' Families Association. Work began on September 16th, when a number of soldiers' wives brought their infants to the club. The object is to allow any of the soldiers' or sailors' wives—who are specially recommended by the local branch of the Soldiers' and Sailors' Families Association, or any of the other charitable agencies—to bring their children for advice.

India.

[FROM OUR SPECIAL CORRESPONDENT.]

EASTERN MEDICAL SCIENCE.

AT the annual general meeting of the Anjuman-i-Tibbia, Delhi, an institution for teaching Indian methods of medical treatment, the Chief Commissioner made a short speech in which he declared that he always regarded it a pleasure to attend such meetings, particularly one convened in connexion with the Madrassa-i-Tibbia. Personally he differed from those who did not consider it worth while to devote their attention to the indigenous system of medicine when they fully believed in the efficiency of the European methods of treatment. He was prepared to say that no system could claim perfection. The West owed a great deal in its advance in medical science to the medical skill of the East, and there was every reason for the advocates of the Eastern medical science to make steady efforts for the revival of their system and to combine with the Western science in the cause of humanity. There was nothing final, even in the most advanced European systems, and changes were of frequent occurrence. He was much interested in the cause of the Madrassa-i-Tibbia and in the efforts of its promoters who were strenuously endeavouring to raise it to the status of a college. Such endeavours were the only means to secure the revival of their past medical science, but he would point out that in their progress towards revival the promoters and students of the Eastern medical science would fully realize what they had to learn from the advanced Western system in anatomy, surgery, bacteriology, etc. But he hoped that steady application to real work and perseverance in undertakings like the one initiated by Haziqul Mulk, who had devoted an enormous amount of time and labour to the cause of the regeneration of the indigenous medical science of India, might achieve the object in view, and that the proposed college might take a prominent place among those institutions which stand for the relief of human suffering.

Correspondence.

NUTRITION AND MEAT EXTRACTS.

SIR,—In Mr. Sohn's book on *Nutrition* (p. 79), recently reviewed in the BRITISH MEDICAL JOURNAL, I am given credit for an economical dietary to which I cannot properly lay claim. It is one of four such dietaries issued by the Women's National Health Association of Ireland, and may be had on application to the Literature Secretary, Viceregal Lodge, Dublin. A footnote to the printed sheet containing this dietary says that it was drawn up and cooked by Miss Angela Mahalm, to whom therefore the credit is due. It is possible, however, that Mr. Sohn may have got his information second-hand. He gives as one of the items 15½ lb. "Standard" flour, whereas the original gives 15½ lb. flour.

In another part of the same book (pp. 116 and 117) reference is made to investigations carried out in my laboratory on the nutritive effects of beef extracts. The results of these were published, first as a "preliminary communication," in the *Proceedings* of the British Association, 1910, and later as a complete paper in the BRITISH MEDICAL JOURNAL, September 16th, 1911. Mr. Sohn's criticism refers to the former only, and he does not seem to know of the latter, as he speaks of three experiments with dogs, whereas in the full paper the details of four more are given; two with dogs and two with human subjects.

In these investigations I was assisted by several colleagues, and the conclusions drawn from our results are given in the following quotations. The first is taken from the preliminary communication mentioned and reads:

> The general conclusions seem to be that the beef extract used has both a direct and an indirect nutritive value, apart from any effect it may have as a vascular stimulant. The former leads to relatively large increase of weight in proportion to the amount of foodstuff given. The latter is manifested by a fuller utilisation of the other food constituents to which the extract is added, and is in accordance with Pavlov's observations, to the effect that meat extracts promote an increased flow of active digestive juices.

The second is taken from the article in the BRITISH MEDICAL JOURNAL already mentioned. The conclusions are stated as follows:

> 1. The addition to the diet of the beef extracts used (commercial and self-made) led to an increase of body weight both in the case of animals and man.
> 2. Accompanying this increase there was a retention of a considerable proportion of the nitrogen given in the extracts.
> 3. The extracts also caused a reduction in the output of nitrogen in the faeces, this no doubt being due to a better digestion and absorption of food of the ordinary diet.
> 4. The extracts may therefore be accredited with both a direct and an indirect nutritive value.
> 5. During the feeding with the extracts there was also a retention of water in the body.

These conclusions, I venture to say, will appear moderate and unstrained to any one who studies our data. Nothing has happened since they were published to nullify or weaken them. On the contrary, a great deal has been discovered which supports and corroborates them.

Mr. Sohn goes on to offer two explanations for the increase of weight, which we do not consider the most important effect. The first is somewhat involved, and is not physiologically sound. It is, that "Since the biscuit was apparently properly digested by the animal when it had no meat extract, an increase in weight out of all proportion with the augmentation of ingested material means that metabolism is retarded."* The other suggests that the increase in weight is due to retention of inorganic salts, the salts in turn necessitating a retention of water.

We state that there is a retention of water, but, since animal tissues contain 75 to 80 per cent. of water, there can be no increase of weight, except as stored up fat, without such retention. We also show in one of the protocols in the full paper the effect of adding daily, 5 grams of inorganic salts obtained from commercial meat extract, to the diet. This amount is five times that contained in the ordinary quantity of meat extract we used, yet it produced but a slight increase of weight—nothing equal to the effect of the whole extract. Further, in all our experiments sixteen to eighteen hours elapsed each day between the last feeding and the weighing next morning. In this period all but a trace of the inorganic salts was excreted. This slight trace probably accounts for a small part of the increase in weight, but it is certainly not the main cause; nor is the increase in itself the most important result.

We are now familiar with the fact that traces of certain substances (vitamines) produce nutritive effects out of all proportion to their fuel value. It is not improbable that the nutritive effects of meat extracts pointed out by us may prove to be due to one or more of these substances of a thermostable nature. Eykman has shown that in muscle there is a vitamine which cures polyneuritis.—I am, etc.,

Dublin, Sept. 19th. W. H. THOMPSON.

INDIAN SANITATION.

SIR,—In your issue of September 12th (p. 477) an able review of my paper on "The Position of Sanitation in the Administration of India" practically accepts my arguments, with one exception. In the interest of sanitary advance in the tropics generally, and of India in particular, I should like to encompass the conversion of your reviewer; and this I have every reason to hope for, as his conception

* There are numerous mistakes in the physiology of the book which have been generously overlooked by your reviewer. But even its chemistry is not free from them. I shall only mention two. On page 23 nucleo-proteins are said to be free from purin bases, whereas the presence of these bodies is the characteristic feature of their composition. On page 28 inosite is described as a sugar and a carbohydrate; it is neither.—W. H. T.

is founded upon a misapprehension. He suggests that I have referred to sanitation as a "different profession" to that dealing with the cure of disease. I have, however, nowhere made such a suggestion. The duties connected with the health of the individual and of the community, respectively, are undertaken by markedly specialized branches of the medical profession. Their co-operation in certain aspects of their work is desirable. But this co-operation is not of a nature to demand that the administrative care of sanitation (in India extending over an area of 1,093,000 square miles, possessed of a population of 244 millions) shall be in the hands of that branch of the medical profession which is specialized for cure, and it is in this sense that I treat the question in my paper.

It will be remembered that in 1911 the Government of India attempted, on the death of Lieutenant-Colonel Leslie, C.I.E., to get rid for the future of their separate and independent Sanitary Commissioner; but, on failing to persuade the Secretary of State for India to that effect, they secured the compromise of subordinating that officer in all administrative functions to the Director-General, Indian Medical Service—an officer selected direct from the rank of Lieutenant-Colonel for promotion to that of Surgeon-General for ability in curative medicine. Although this retrograde step was contrary to a ruling on the same subject by the Secretary of State when Lieutenant-Colonel Leslie was first appointed, as well as to existing conditions in the chief local Governments, in accordance with orders issued by the Government of India, and to precedents extending back to 1863, the Government of India defended their action by asserting that it was impossible to divorce the sanitary from the medical service in India. It is to their policy in this respect that the Hon. Mr. Sarma referred when he stated the prevalent opinion in India was that "the Medical and Sanitary Departments must be divorced from each other." That opinion professional journals would have heard more of, were it not that officers on the active list of the Indian Medical Service specially interested in sanitation are, for reasons which require no explanation, dumb on this subject.

Were the policy now pursued by the Government of India adopted in Great Britain, the Medical Officer of the Local Government Board of England would not be a specialist in sanitation, but would be selected from the physicians of our hospitals, and that selection would be confined to a limited number, by the vested rights of hospitals, to those of a single county, say, Middlesex.[1] Dr. Newsholme as a technical assistant (staff officer) would then be required to submit his administrative policy for the approval of this physician, before he dare submit it for sanction of the Local Government Board. If he wished research to be pursued in sanitary interests in a direction that appealed to him, all action would be subject to approval and sanction by the physician!

In a paper kindly read for me by Mr. Cantlie at the recent Aberdeen meeting[2] I advocated earlier specialization by medical students for the position of whole-time sanitarians serving in the tropics. In its resolution on the subject, that view was rejected by the Tropical Section of the meeting, although I venture to prophesy, in the light of present-day sanitary evolution in the tropics, it will prevail ten years hence; but what is of importance in this connexion is that this Section unanimously approved of my suggested type scheme for public health administration in our tropical possessions, requiring that under a "Ministry of Public Health and Economics" the heads of the medical and sanitary departments should control their respective charges, and, in the matter of research, arrange for co-operation—without subordinating either officer to the other. It will therefore be seen that, if I claim that the whole-time sanitarian in the tropics should not be trammelled in making recommendations to the Government, or other authority, paying him, by the overlordship of the curative branch of medicine, I have no desire to claim the "strange doctrine" that the sanitarian is a creation apart from the profession which begat him. In short, I agree with your reviewer that, under a Ministry of Health, the services destined for the cure and the prevention of disease should constitute "two phases"; but, whilst arranging for cordial co-operation, I would, for administrative purposes, emphasize that word *two* from top to bottom of both departments concerned.—I am, etc.,

W. G. KING,
Colonel, I.M.S. (ret.).

Hatch End, Sept. 16th.

[1] The officers in the Bengal establishment are alone eligible for the appointment of Director-General of the Indian Medical Service.

[2] BRITISH MEDICAL JOURNAL, August 8th, 1914, p. 303.

LICE.

SIR,—With reference to Dr. Shipley's article on lice, in the JOURNAL of September 19th, will you appeal to medical officers of health who have troops in their districts to offer to disinfect blankets for the troops. The military are very diffident about asking for civilian help but will accept it when offered. The York authorities have been "stoving" blankets for ten days. The fear of lice keeps many men from enlisting.—I am, etc.,

FREDERIC P. HEARDER.

Whixley, Nr. York, Sept. 23rd.

Medico-Legal.

GERMAN PATENTS AND TRADE MARKS.

MR. W. TEMPLE FRANKS, Comptroller-General of Patents, has been sitting with Sir Cornelius Dalton, his predecessor in that office, to consider applications to avoid or suspend German patents under the legislation passed since the outbreak of the war.

Early in the proceedings the Comptroller said that the general principle by which the court would be guided was that, unless it were proved to be in the public interest, it would not recommend the Board of Trade to transfer to other businesses device trade marks which were known to be associated with foreign firms. Those cases, in his opinion, were not contemplated by the Act. The object was not to confiscate any one's property, but to enable business in this country to go on, which would not be always possible without the suspension of patents or trade marks. Although we might wish to supplant the Germans, no civilized country had at present gone so far as to take bank balances.

Among the applications heard on September 17th was one from Messrs. Burroughs, Wellcome and Co. for the transfer to them of the patent of Messrs. Meister, Lucius, and Bruning, of Frankfort, for the manufacture and sale of salvarsan in this country. Counsel in support of the application said that it was necessary in the interests of the community that there should be a supply of this drug in this country, and that as it was unobtainable from Germany it should be manufactured here. The applicants desired the transfer of the licence for the total period of the patent, as otherwise they might not see their way to set up the machinery necessary for manufacturing the drug. Evidence was given by a representative of the applicants to the effect that the firm was capable of carrying out the manufacture of salvarsan. In cross-examination, he said, it would be possible to sell at the same price as now, but that he could not say whether the firm would be able to pay a royalty to the German firm, as he had not gone fully into the particulars of manufacture. Evidence was given on behalf of Messrs. Meister, Lucius, and Bruning, by their manager in this country, Mr. E. H. Scholl, who said that he was a British-born subject, and that the salvarsan he was now selling was manufactured at Ellesmere Port, Cheshire. He believed the firm could supply all the drug that was necessary. The Comptroller stated that the court would report to the Board of Trade, which would give its decision in due course.

Messrs. Burroughs, Wellcome and Co. also made an application on September 18th for an order enabling them to supply hexamethylenetetramine by the title and trade mark "Urotropine." Counsel on behalf of Mr. August Zimmerman, a naturalized British subject trading in this country, opposed the application, on the ground that his client had a stock of the original drug, which, in ordinary circumstances, would meet the demand for six months. Counsel for the applicants said that his clients desired to keep the name of the article alive, and after the war would resume their former relations with the producer. They also agreed to take a supply from Messrs. Zimmerman at the usual prices as long as that firm was in a position to supply them, and on this understanding the application was postponed for three months.

On September 22nd an application by Messrs. Charles Zimmerman, of St. Mary-at-Hill, E.C., that an exclusive licence should be given to them to manufacture and sell the disinfectant "Lysol," the trade mark of which was held by Messrs. Schulke and Mayr of Hamburg, led to a long argument, in the course of which counsel for the applicants said that Messrs. Zimmerman was an absolutely English firm. Several firms of chemists asked that the right to manufacture and sell "Lysol" should be extended to them equally with Messrs. Zimmerman. The court stated that it would make a recommendation to the Board of Trade.

THE Paris Académie des Sciences has awarded the La Caze prize of £400 to Professor Gley of the Collège de France for his works on physiology.

Obituary.

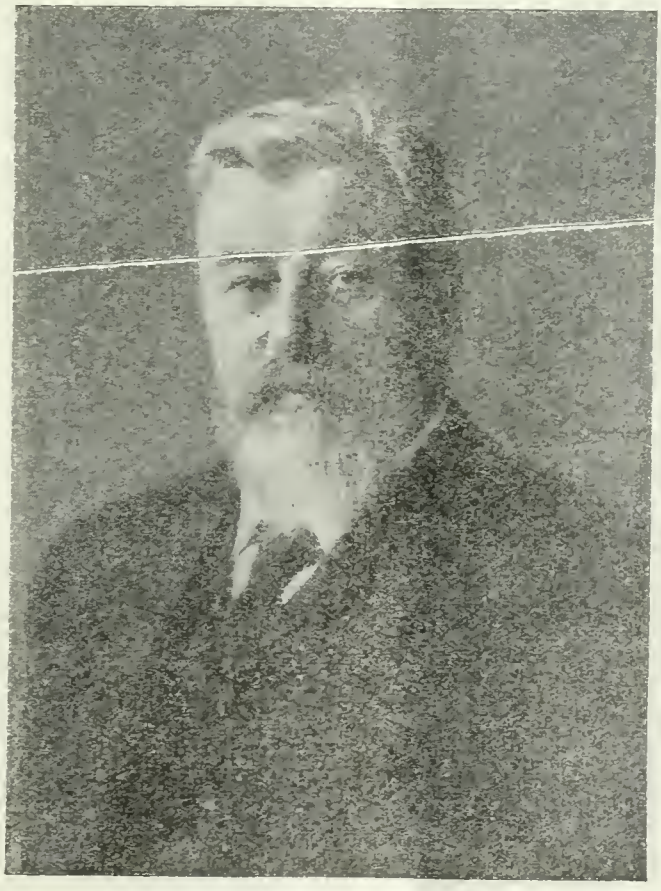
WALTER HOLBROOK GASKELL, M.D., F.R.S.,

HON. LL.D.EDIN. AND McGILL,

FELLOW OF TRINITY HALL AND UNIVERSITY LECTURER IN PHYSIOLOGY, CAMBRIDGE.

THE death of Walter Holbrook Gaskell, which took place, after a very brief illness, on September 7th at his home near Cambridge, marks the close of a distinguished career. He was born at Naples on November 1st, 1847, the son of Mr. John Dakin Gaskell, barrister, and Anne his wife. He received his early education at Sir Roger Cholmeley's School, Highgate, and entered Trinity College, Cambridge, in 1865. In 1870 he proceeded to University College to study medicine, and took his M.D. degree in 1878.

When in the early Seventies Michael Foster, then praelector of physiology at Trinity College, began his great work for the biological school at Cambridge, he gathered about himself a small group of brilliant workers. Of these Gaskell was one of the very few survivors. In those days the science school was small, and to get his men Foster was compelled to recruit from other studies. Balfour had no intention of pursuing science till he came under Foster's influence. Lea was a classical scholar, and Gaskell a mathematician—he was a wrangler in 1869.



WALTER HOLBROOK GASKELL.
(Photograph by Elliott and Fry.)

At Foster's advice, Gaskell went to Leipzig in 1874, to Ludwig's Laboratory, with the intention of working at problems connected with the sympathetic nervous system, and from that time until his death he was in the main occupied with the meaning of this system and with problems, such as the function of the cardiac nerves, which arose from its study. The years 1874 to 1889 were years of crowded and amazingly successful work. To appreciate the extent to which Gaskell then made our knowledge of the relations of nerve fibre, nerve cell and muscle fibre, it is necessary briefly to glance at views prevalent at the time. Physiologists were then obsessed (no other word is strong enough) with the belief that the nerve cell was the sole cause of muscular movement; the tone and the beat of the heart, and the contraction of the muscle fibres of arteries were supposed to be caused by nervous impulses sent out by the nerve cells of peripheral ganglia. It is hardly necessary to point out how opposed this is to modern clinical teaching, and the change of view is due to Gaskell.

He was able to prove by experiments, which are a model of neatness and finality, that the muscle fibre, instead of being merely the passive agent of the nerve cell, is itself endowed with the property of rhythmical contraction. The contraction wave which sweeps over the cardiac muscle from the great veins to the aorta progresses continously from muscle fibre to muscle fibre, and suffers a retardation in slowly conducting tissue at the junction of auricles and ventricles which provides the necessary pause between the systole of the auricle and that of the ventricle. Our knowledge of the function of the cardiac nerves, which before this time was obscured by the conflict between Weber's discovery of the inhibitory influence of the vagus and Schiff's later discovery that stimulation of this nerve is sometimes followed by augmented beats, was brought by Gaskell practically to the point at which it now stands. Some of his results are even now only finding their place. Within the last few years it has been found possible to dissociate experimentally the excitation process and the contraction process of muscle: indeed, the complete electro-cardiagram has been obtained from the quiescent heart. Thirty years earlier Gaskell showed the electrical event to be independent of contraction when he found that stimulation of the vagus and the sympathetic would evoke a normal electrical response from the quiescent heart. The fundamental significance of this fact was pointed out by him in a passage too long to quote.

The work of this period was made the subject of the Croonian Lecture of 1881, and the pathology of the heart must for all time find its assured basis in this great classic. In 1882 Gaskell took up the study of the sympathetic nervous system in general, the starting-point being an investigation of the anatomy and histology of the cardiac nerves. Various small papers appeared in the *Journal of Physiology*, leading up to the great paper of 1886—great in every sense of the word, for surely no problem ever received more ample breadth of treatment. The facts of anatomy, of histology, and of function were brought into relationship, and the framework of our knowledge of the sympathetic system was put together once and for all. It was as definite and conclusive an achievement as was Pflüger's analysis of the phenomena of electrotonus.

An attempt on similar lines to unravel the underlying scheme of the cranial nerves—a problem which had tasked the skill of such masters as Huxley, Gegenbauer, and Balfour—led him in 1889 to formulate a theory of the origin of the central nervous system of vertebrates, according to which the central canal is the lumen of a primitive gut. This theory has not won general acceptance, but it led to much fruitful work on the nervous system and other organs, especially of the lamprey and of *Limulus*.

About this time Gaskell, at the request of the Hyderabad Commission, undertook the investigation of the action of chloroform. The work, which was done in conjunction with Dr. L. E. Shore, is memorable owing to the bold experimental method adopted. In order to discriminate between the effects produced on the respiratory centre and on the heart, cross-circulation experiments were made, the brain of one dog being fed by the carotid arteries of another. In this way, by limiting the action of the drug to the heart, it was conclusively proved that chloroform produces a fall of blood pressure by acting on the heart, and not on the vasomotor centre.

Gaskell's character was of the simplest. He was a good straight fighter when he had to fight, and a most faithful friend. One of the most approachable of men, he had the faculty in a supreme degree of acquiring a sympathetic knowledge of men younger than himself. It is no exaggeration to say that every physiologist who has worked in the laboratory at Cambridge since its start has

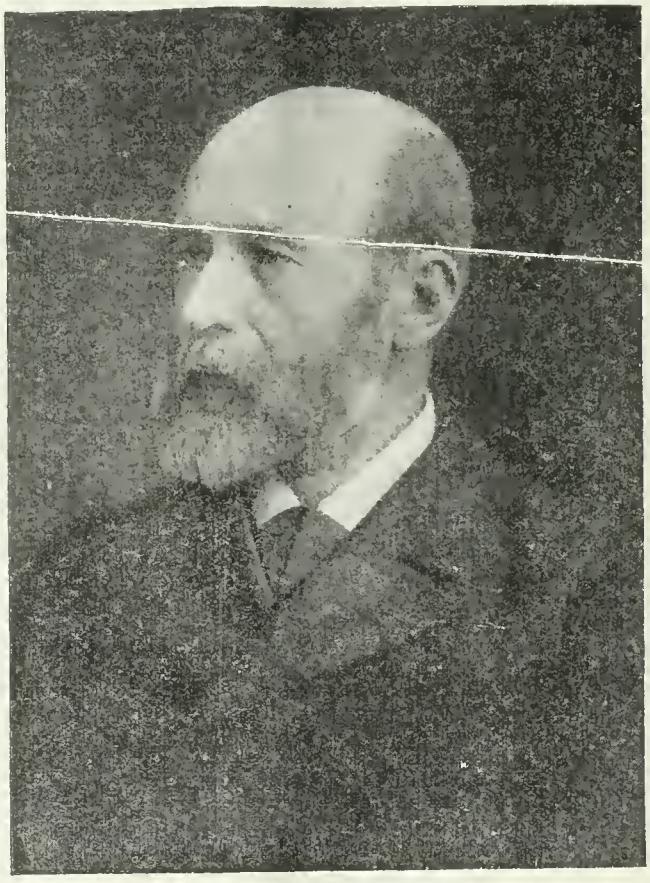
been his personal friend. Dr. Gaskell was an honorary LL.D. of Edinburgh and McGill Universities, and Marshall Hall prizeman. He was awarded a medal by the Royal Society, and the Baly medal. He served on the Moseley Commission and on the Vivisection Commission.

SIR HENRY GREENWAY HOWSE, M.S., F.R.C.S.,

CONSULTING SURGEON TO GUY'S HOSPITAL.

FEW men have left so many evidences of their work in a quiet way than Sir Henry Greenway Howse, whose death was briefly mentioned in our last issue.

A mere record of what he did to improve surgical methods, to advance surgical practice, to promote the efficiency of the medical school at Guy's, to serve the College of Surgeons, the University of London, and the higher education of women, would alone make a list of formidable length. That his work and his worth were not more widely known was due to his natural dislike of publicity. He was content to apply the results of his investigations for the benefit of those he had undertaken to teach and to help.



SIR HENRY GREENWAY HOWSE
(Photograph by Lafayette.)

Howse was born at Lyncombe Hall, Bath, on December 21st, 1841, the second son of Henry Edward and Isabella Howse. He entered Guy's after two years' apprenticeship under Mr. Workman, of Reading, when about 20 years old. After a successful career at the London University, where, as well as at his own school, he gained many distinctions, he was admitted M.R.C.S. in 1865; three years later he became a Fellow of the College and also Master in Surgery at the University, where he divided the only distinction with one who was later to share with him the honour of introducing Lister's antiseptic methods into London—the late Mr. Marcus Beck. While preparing for these higher examinations he visited Paris, where he spent some time studying operative surgery. In 1868 he made, in association, we believe, with Marcus Beck, the memorable visit to Lister's clinic. Returning to London, he was appointed demonstrator of anatomy in his old school.

In 1870 he was appointed assistant surgeon on the retirement of Mr. John Hilton, and five years later he became a full surgeon when Mr. John Birkett retired. This position he resigned in March, 1902, his appointment having been extended three months beyond the retiring age of 60, to enable the hospital to secure his services as their representative at an important public meeting.

Howse thus, it will be seen, served the hospital and school for some thirty-four years. On his retirement he was placed on the consulting staff.

In the medical school he lectured on anatomy for some years, his colleague being first Arthur Durham, and later Davies-Colley. When he became lecturer on surgery he had again for many years the same junior colleague, with whom a long and lasting friendship existed, only broken by death in 1902.

The services he rendered to Guy's Hospital and to its Medical School were such as few could have given. The paucity of subjects for dissection led him, when demonstrator of anatomy, to introduce a method for the preservation of the bodies. This enabled the school to start in October with an ample supply. The method was published in the *Guy's Hospital Reports*, and was, we believe, widely adopted. As a lecturer on anatomy he was accurate and painstaking, and by admirable diagrams and blackboard notes cleared up many difficulties. His own knowledge had been gained by abundant dissections, and by several years' service as a demonstrator. He was not a brilliant lecturer on surgery; indeed, in no sense could this epithet be applied to him. He would have been the last to lay claim to such a description. He was essentially a teacher and set himself to help the students where the books were particularly wanting. In surgery his classifications were valuable and his directions as to treatment sound and wise, and while giving full credit to the work of others, he was able, by drawing from a large experience, to lay down methods of his own derived from a long practice of antiseptic surgery.

In addition to his lectures he instituted a voluntary course of morbid histology somewhere about 1867 or 1868, cutting all the sections himself with a razor. We believe this was the first course of its kind to be established in London, and existed many years before it became a compulsory part of the curriculum. This is only one example of his many efforts to improve the knowledge of the student without waiting for the action of authorities.

As a clinical teacher Howse attracted in his day all the best men. He was exact, taught by asking questions, answering himself when no reply was forthcoming. A generation of students owed much of their sound knowledge to his excellent teaching. It was to Howse the student went to see the triumphs and learn the methods of Listerism, and he never tired in giving instruction.

In all the relations between the hospital and the school Howse was a trusted adviser. In the building of the resident college, in all financial concerns, in all committees, he took a leading part. To mark their appreciation of his services, rendered throughout with unflagging interest and unfailing courtesy, the governors of the hospital and his colleagues presented him with his portrait. This shows Howse in a characteristic attitude, clad in the presidential robes of the College of Surgeons. It is an admirable work, executed by Lance Calkin, and hangs in the entrance hall to the Governors' Court Room at Guy's Hospital.

On his appointment in 1870, Howse at once began to apply Lister's methods, and as for five years he shared the whole of the work with Davies-Colley, the opportunities for testing the value of the new surgery, even if injuries alone be considered, were unlimited. The effect was immediate. Those who can recall the state of the wards in the Seventies—the frequent deaths from septic infection, the delayed union, the erysipelas—well know what a change can be wrought by the work of one man. So confident had Howse become that within four years he did not hesitate to amputate the thigh and return the patient to the erysipelas ward. When he became full surgeon his wards were soon purged of septic

infection. While others lost cases from this cause, it was extremely rare to find such a complication arising in any case operated upon by Howse. He was admirably supported by his colleague Davies-Colley, who himself made many cautious advances. He affixed to the old operating table—a relic of Astley Cooper's time—a support to hold the receptacle from which the carbolic lotion dripped upon the wound, and used the putty dressing and the carbolic gauze. Then followed the hand spray, and later the steam spray. Howse was one of the last, if not the very last, to abandon this Listerian apparatus, with which he had obtained so many triumphs. Gradually he advanced in the application of antiseptic surgery to new fields, more particularly to diseases of joints. In the excision of the knee his success became widely known. When others were losing their cases from sepsis, and others amputating. Howse secured almost uniform success. In 1874 the writer of this brief and all too imperfect sketch had the advantage of serving as his clerk, and later as dresser. It was common to have as many as four, and even six, cases of excision of the knee under our care at one time. Howse superintended the dressing of every case, and must have spent the greater part of the five years of his assistant surgeoncy in the hospital. Failure in recovery was very rare indeed, and the large proportion of the knee cases had excellent and useful limbs. Had he published the results of this operation even in 1880, Howse must have taken a premier position amongst the surgeons of Europe at that time. No one could show so splendid a series of cases, not only from the point of view of mortality, but of usefulness of the limb. His work in this field of surgery was not given to the profession till 1893, when—with the help and at the urgent desire of one of his old dressers, Dr. Newton Pitt—he published a paper in the *Guy's Hospital Reports*. By that time success had become general, his methods had become well known, and the place of excision of the knee for tuberculous disease had become established.

Gastrostomy was another operation to which he gave attention, and he soon placed it upon a successful basis. The mortality was somewhere about 90 per cent., partly due, as he says in the article in *Heath's Dictionary*, to the exhausted condition of the patients as well as to faulty technique. The modification Howse introduced consisted in securing adhesion of the stomach to the abdominal walls before opening the viscus. Writing in 1886 he said that the operation was then only attended by a very small mortality, and even this was due to the late period at which the operation was done. In this operation use was made for the first time of the rectus muscle as a sphincter, as will be found set forth in the article referred to. His success in this operation attracted many visitors, and inspired more than one article on the subject and at least one book. The method of operating in two stages has had a wide application. The only article Howse wrote on this subject was the brief account in *Heath's Dictionary of Surgery*.

Another great advance in surgical practice—the excision of varicose veins—must be set down to his credit. His paper on this subject was published in the *Guy's Hospital Reports* for 1877. The first operation, an excision of a large varix from the leg, was performed on December 4th, 1873, and was successful. It was not till September 10th, 1874, that he succeeded in persuading a second patient to submit to operation. This was for varicocele. His colleague, Mr. Davies-Colley, had been more successful, and recorded some cases in the same reports for 1875. To appreciate the importance of this procedure Howse's account must be read wherein he refers to the dangers attending the then existing methods. So far as the surgery at Guy's is concerned, it was Davies-Colley who first operated for varicocele. Annandale's first operation was performed on November 7th, 1874.

These three examples fairly well illustrate the progressive nature of his work. He never rested content with the progress he had made, and was constantly breaking new ground under the security of Listerian methods.

In his breast operations he invariably cleared the axilla, while widely removing the skin with the whole gland. This was his practice in 1874, and before that, and the success was uniformly good. This is worth recording when one recalls the protest made by Mitchell Banks of Liverpool. Howse was the first to record a successful operation for intussusception in an adult, and this leads one to refer to the marked success he obtained in ovariotomy, and later in other abdominal operations. He had satisfied himself as early as 1873 that trephining could safely be undertaken without setting up meningitis as a direct result of the operation. This led to his operating with benefit in many doubtful head injuries.

His surgery at the Evelina Hospital for Children was again of a high and progressive order. His excisions here did well, and young as were the children—all under 10—one cannot recall an example in which the growth of the bones was impaired from epiphyseal injury. He was for many years associated in his work at this hospital with Morrant Baker; and here it may be mentioned that another exponent of Listerism, Sir Thomas Smith, was a close friend.

Though Howse did not write any treatise on surgery, he contributed several articles to *Heath's Dictionary*, and wrote many papers in the *Guy's Hospital Reports*, of which he was for many years co editor with Dr. Frederick Taylor. Many valuable papers by him will be found in the *Transactions* of the Pathological and other societies. If he did not publish his successes, nevertheless the value of his work became known, and many visitors resorted to Guy's Hospital to see his practice. To all he gave freely and generously of what he possessed. He never claimed to have made great advances, putting everything down to the accurate carrying out of Lister's directions. In many ways Howse made additions to Lister's work, and it was the personal supervision of the dressing of the cases that determined his almost uniform success.

Howse was a man who made few intimate friends, and yet was always courteous and ready to give friendly advice, and pleased whenever it lay in his power to do another a good turn. His holiday for many years was spent in Alpine climbing, chiefly with his two colleagues, Frederick Taylor and Savage. In this pastime he was an adept, and accomplished many difficult passes without guides. He had a strong mechanical bent, worked a lathe, did turning in metal, and when he retired took charge of his own electric installation.

For twenty-two years he took an active part in the work of the College of Surgeons. He was appointed examiner in anatomy and physiology under the old system in 1883. In the same year he was appointed examiner in the same subjects for the Fellowship—a position he held till 1887. With the establishment of the Conjoint Board in 1884 he became an examiner in anatomy. These appointments came to an end in 1887, when he passed to the Court of Examiners, of which he remained a member until 1897. He was a member of the Council from 1889 to 1905, Vice-President 1897 to 1900, and President from 1901 to 1903. At the coronation of Edward VII he received the honour of knighthood.

Sir Henry Howse, though of a quiet disposition, was a man of exceptionally strong character. He thought out every question for himself, and gave his own opinion without in any way attempting to influence the views of others by manner or persuasion. He had the faculty of seeing all sides of a question, and was able to examine calmly and give full value to the opinions of others even where much controversial warmth existed. These exceptional qualities, coupled with a wide knowledge of the various questions connected with the management of a medical school, made him a most valuable member of committees. Howse was always listened to, for he never spoke without knowledge of the subject—a knowlege the outcome of personal investigation. In this respect his services were of special value to the council of the College and to his own medical school, and always to the London University, in the work of which he took a keen interest for many years. He was examiner in anatomy and later in surgery, served on the Committee of Convocation for many years, associating with those endeavouring to broaden the basis of the university, and, lastly, was for some years on the senate. He also became secretary to the University Dining Club, in the hope of promoting a closer personal association between members of the various faculties. Those with whom he worked in these more public capacities recognized the worth of Howse's opinions equally with those

more closely associated with him. When he was elected President of the College, and later honoured by his King, it was generally allowed that no man ever sought such distinction less or deserved it more. Sir Henry married, in 1881, Miss Marshall, daughter of the Rev. T. Lethbridge Marshall, and leaves two daughters and one son.

Soon after the conclusion of his term of office as member of Council of the Royal College of Surgeons of England he retired to the neighbourhood of Sevenoaks, and seldom visited London. Of late he suffered from a return of a painful sciatica and became very much crippled. An aggravated form of this trouble, causing many weeks of suffering borne with philosophical resignation, gradually exhausted his strength, and he died on September 15th.

We are indebted to Dr. FREDERICK TAYLOR for the following tribute to the memory of his friend:

When I entered at Guy's Hospital, Henry Greenway Howse was already a distinguished student. He had obtained the second prize for general proficiency in his first year, and the first prize for the same in his second year. In his third year he also gained the first prize, and at the London University First M.B. Examination took the exhibition and gold medal for physiology, histology, and comparative anatomy, and honours in anatomy. At the Final M.B. Examination two years later he obtained the gold medal in midwifery, with marks qualifying for the scholarship, and honours in medicine; and in the following year at the examination for the Bachelor of Surgery he obtained the scholarship and gold medal. A year later he took the degree of M.S. Having held the usual hospital appointments, including that of house-surgeon, he was appointed demonstrator of anatomy in October, 1868, and gave demonstrations on the use of the microscope in the succeeding summer session. Howse threw himself wholeheartedly into everything with which he was associated. In the three years he spent as a demonstrator of anatomy he devoted himself to the question of the preservation of the subjects for dissection, and, after making numerous experiments, he perfected the method of thoroughly injecting the bodies with glycerine containing a small quantity of arsenic, the glycerine infiltrating the tissues from the arteries, and thus preserving the whole for an almost unlimited time. I was a demonstrator at the time the method was introduced, and can vouch for the extraordinary difference which the dissecting-room presented from its malodorous state previously. It was characteristic of Howse that the method was not introduced into the room until he had thoroughly proved its efficacy by testing it for months upon separate portions of a subject. For several years he was editor of the *Guy's Hospital Reports*, and there again he made his mark, introducing order into the financial business at a time when the scientific aspects of the publication had been allowed to overshadow the commercial. I was for some years his colleague in the editorship, and know well the immense trouble he took to develop this work in every detail. In his early days also he contributed liberally to its pages, though not so much after he became full surgeon; but he broke silence in 1893 with his valuable paper on "The results of 130 cases of excision of the knee." It is to be regretted that he did not give to the profession something more of his experience in his later years. As a member of the medical school he fulfilled his duties most thoroughly; a most useful member of committees and councils, giving the most careful consideration to every matter before him, and exhibiting great judgement in his decisions, upon which his colleagues could almost absolutely depend. As to his merits as a surgeon I am, perhaps, not in such a position to judge as my surgical colleagues; but there is no doubt that he was an exceedingly able surgeon—cautious, deliberate, even slow, but not wanting in boldness where that was necessary. If I remember rightly, when he had been appointed assistant surgeon, his first operation in the theatre—and a theatre *was* a theatre then—was an amputation at the hip-joint; this he carried out most successfully—of course, under the eyes of many of his seniors. It is to his lasting credit that he was one of the first surgeons in London to obtain first-hand knowledge of Lister's methods and to apply them in his practice. He went himself to Edinburgh and saw the method adopted there, and at once brought it into use in his wards at Guy's Hospital. With it he had extraordinary success in excisions of the knee and of other joints, of which operation he was one of the staunchest advocates. In connexion with the germ theory of disease, the following is interesting: At an early meeting of the Clinical Society he made the observation that he was convinced, from his experience of cases of tetanus, that it was in some way dependent upon the soiling of wounds with London mud. The suggestion was received with a smile, but we know now that the inference was practically correct. I need hardly say what a pleasure it was to his friends and colleagues when he was elected President of the College of Surgeons, and when subsequently he received the honour of knighthood. For a number of years Howse's recreation during holiday times was mountain climbing, and I had the pleasure of accompanying him in many of these excursions in Switzerland. He was one of the early climbers to go without guides, and was naturally reproached with the unwisdom of such a course. But I can testify that there was nothing reckless or careless about his proceedings. He neglected nothing in his preparations, took every precaution against failure, and had the valuable faculty of recognizing when Nature was too strong for him, and failure had to be admitted.

I knew that he always had it in his mind to retire into the country at a suitable time after giving up his active service on the hospital staff, but when that time arrived he had not completed his Presidency of the College of Surgeons. He had first practised in St. Thomas's Street, near Guy's Hospital; in 1887 he moved to 59, Brook Street, and since the termination of his presidency he had lived at Cudham in Kent, keeping, for a short time only, consulting-rooms in Grosvenor Street.

Mr. C. H. GOLDING-BIRD writes:

The present generation of Guy's men can, I think, hardly estimate how much they owe to the late Sir Henry Greenway Howse, whose recent death we all deeply deplore. He was not only a great teacher and surgeon, but a pioneer to whom the hospital owes the introduction from Edinburgh, in the early Seventies, of Listerism as it then was.

Howse in all that he did was Teutonic in his minute accuracy; and I remember as a student being much impressed by the precise exactitude of his methods and teaching in the dissecting-room; and subsequently by the way in which he started and maintained the first histological class. Those were the days before microtomes—at least as we knew them now—and every specimen was hand-cut by himself and mounted in glycerine, requiring an attention to detail in manipulation, to be successful, that only his patient instruction ever enabled the raw student to master. Every one in his class received his personal attention, and each man felt he must work with a master who was himself so assiduous.

The same characteristics were exhibited in his work in the wards, and he was afraid of trying nothing that might help to banish sepsis in its many forms and the curse of all surgical cases. Early antisepsis failing to make much impression on old and chronic ulcers, for instance, he exercised his ingenuity—albeit without success—upon them; and I well recollect his employing dried earth in one case as a purifying application, and in another his attempts to stay suppuration by a dressing of peptones, conceiving, as he explained, that if he could feed the granulations they would not waste their energy in the loss of such valuable protoplasmic matter as pus. To men of these times such experiments read as childish, but, in our then state of pathological and physiological knowledge, nothing, however unlikely or empirical, was unworthy of a trial; and Howse, at least, had always a sound reason to give for what he attempted.

In the wards he will always be remembered by his great work on the resection of joints. The introduction of the spray gave a power over local sepsis that opened up a new realm to surgery, and to it Howse adhered for long after others had abandoned it. By its aid serous cavities could be opened with comparative impunity, and so he did not hesitate to tackle the hitherto almost fatal practice of operation upon joints. His records in the Guy's *Reports* show what extensive and valuable work he did in this direction, and his Tuesday and Friday operations were

largely attended, and not by Guy's men only, for his repute in this then experimental branch of surgery was widespread. His success—especially in cases of tuberculous knees in children—made a great impression on those whose hitherto experience had been of the purely temporary relief afforded by Scott's dressing and the back splint, and he quickly had followers without as well as within the walls of Guy's.

Quiet almost to reticence, his manner totally changed when teaching or when answering the inquiries of the student; his face would then brighten with the light of the enthusiast and his speech would become energetic and rapid, and his remarks were always to the point and conveyed in a phraseology almost as dogmatic as it was convincing.

As a counsellor in the affairs of the hospital and its school his advice was of the greatest value, for he never spoke without purpose, and his great experience in academic matters and his profound knowledge of students requirements guided every meeting in a sound direction. To this aspect of his character Guy's owes a great debt of gratitude to Sir Henry Howse.

Beyond his annual summer holiday, which was for the most part spent in mountaineering, I cannot bring to mind his ever having any relaxation. Bank holidays or other reasonable excuses for a slight slackening in official duties were unknown to him, and even on Sunday mornings Howse was most likely to be found in the wards of Guy's; and a visit of an evening to his rooms would generally find him immersed in some subject with a view to subsequent teaching.

He was no great writer, but a great thinker, researcher, and teacher, and I have no hesitation in asserting that the standard to which the school at Guy's has reached is largely owing to the strict attention to duty and to the surrender of all private calls to academic and professional requirements that he inculcated—an example followed to the letter at the present time.

The memory of Sir Henry Greenway Howse will ever keep green among Guy's men.

RICHARD VERNON, M.D.,

AUDLEY, STAFFORDSHIRE.

THE oldest practitioner in North Staffordshire, and one of the oldest in the country, has been removed by the death of Dr. Richard Vernon of Audley and of Audlem, who was born in 1817, and died on September 15th, in his 98th year.

Dr. Vernon received his medical education at Birmingham and at the University of Glasgow, and graduated M.D.Glasg. in 1846 and C.M. in 1856. Except for a brief period at Filey in Yorkshire, the whole of his professional work had been done in and around Audley, where he settled some sixty-eight years ago. He was a man of strong will and vigorous personality, and in spite of his slight build had an abounding physical energy. His rounds used to be performed for the most part on horseback, but in his prime he would frequently walk twenty or even thirty miles in the day. Indeed, within the last two years he has been known to walk back from his birthplace at Audlem, where he had considerable property, to his home at Audley, twelve miles away.

For over forty years he worked almost incessantly, with scarcely an interval for holidays; and during this time he was probably the best known and most notable figure in the district. Since his retirement a quarter of a century ago he had become quite an institution in the village, his erect carriage and quaint, old-fashioned professional garb attracting attention and respect wherever he went. The son of a farmer and the owner of several farms himself, his greatest interests outside of his work were always agricultural.

Dr. Vernon lost his wife several years ago, and leaves two children, a son and a daughter, the former, Dr. J. Vernon, J.P., having succeeded him in the practice when he retired. Amid many tokens of affection and respect from friends and tenants, his remains were laid to rest at Audlem on September 19th. J. F. B.

WE regret to record the death, on September 16th, after a very short illness, of Dr. George Gresswell of Louth. He, the fifth member of a large family of brothers and sisters, of whom nine survive, received his general education at the Grammar School of the town in which the later part of his life was spent, and went up to Oxford as the winner of an open exhibition at Christ Church. There he graduated B.A. with honours in physical science in 1880, and a year or two later went to South Africa as lecturer in this subject in one of the constituent colleges of the University of Capetown. After a few years' tenure of this office he returned to England and commenced the study of medicine, working in turns at several medical schools, including the Westminster, St. Bartholomew's, and St. Thomas's. It was with the first named that he was longest connected. He entered it as winner of a scholarship in classics and mathematics, and later on served as demonstrator in the physiological department. He was also resident medical officer at Ockley Sanatorium. Meantime he had become a Licentiate of the royal colleges at Edinburgh, and in 1893 proceeded to the M.A. both of the University of Oxford and of Capetown. Subsequently he settled down in practice at Grimsby, but about 1902 joined his brother, Dr. Albert Gresswell, at Louth. It was not their first partnership, for the two brothers had as young men written conjointly a book entitled the *Wonderland of Evolution*. While still in South Africa, and before he joined the medical profession, Dr. George Gresswell published an essay containing a considerable number of interesting facts on the subject of snake poisoning in South Africa, and some ten years later issued several books dealing with the disorders of animals. One of them, entitled the *Veterinary Pharmacopœia and a Manual of Comparative Therapy*, reached a second edition in 1903. He was also, in 1909, the joint author of *Health, Morals, and Longevity*, and early in the current year of the *Vital Balance*. A man of cultivated mind, wide experience, and lovable character, Dr. George Gresswell will be much missed.

ON August 24th Dr. CHARLES A. HILL, of Liverpool, died at his residence in Hoylake, after a long and distressing illness borne with characteristic fortitude. Dr. Hill spent all his professional life in Liverpool. He was educated at Rugby School, Trinity College, Cambridge, and St. George's Hospital, and devoted himself during the earlier years of his career to laboratory work under Sir Rubert Boyce. One of his first appointments was that of assistant bacteriologist to the Royal Commission on Sewage Disposal, and, although later his interests became chiefly clinical, he continued his laboratory studies as bacteriologist to the Northern Hospital, where his services were much valued by his colleagues. Through his appointment as physician to the Hospital for Diseases of the Chest, his name became chiefly associated with the subject of tuberculosis, and the soundness of his opinion on this condition was widely recognized. Charles Hill's interests, however, extended beyond his professional work. For many years he was a member of the City Council, and he did valuable service as a member of the Port Sanitary and Hospitals Committee and the Water Committee. He took an active part in the political life of the city as a Conservative. As a Freemason he held high offices in the district. Although in failing health during the last year, he assiduously attended to his duties in spite of the protests of his friends, and refused to admit an exhaustion of strength which was only too evident to them. His chief recreation was climbing. He was an active member of the Wayfarers' Club of Liverpool and of the Yorkshire Ramblers' Club, and his imperturbable temperament and fine physique made him an ideal companion on a climbing expedition. He was a past-president of the Wayfarers' Club, and none of his friends will miss him more than those who in the Lake country and in Wales and on the Yorkshire moors enjoyed the privilege of his companionship. Much sympathy is felt by his many friends for his widow and young family.

SURGEON-MAJOR ALEXANDER CHARLES MACLEOD, Madras Medical Service (retired), died on August 20th. He took the diploma of M.R.C.S. in 1840, and those of M.R.C.P.Lond. and L.K.Q.C.P.Irel. in 1861, and the F.R.C.S.Eng. in 1865. Entering the Indian Medical Service as assistant surgeon on March 8th, 1841, he became surgeon on October 26th, 1859, and surgeon-major on March 8th, 1861, retiring on February 26th,

1874. He served in the Mutiny campaign of 1857–8, and spent his whole service in military employment. For many years he had been the senior officer on the Madras retired list; the next man now on the list, Surgeon-Major W. H. Harris, was twelve years his junior. There is, however, one man senior to him still on the Bengal list—the centenarian, H. B. Hinton.

Universities and Colleges.

UNIVERSITY OF GLASGOW.

DR. WALTER JAMES DILLING, Lecturer in Pharmacology at the University of Aberdeen, has been appointed to the newly established "Robert Pollok" Lectureship in Materia Medica and Pharmacology at the University of Glasgow. Dr. Dilling was formerly Professor Kobert's assistant at Rostock; and he revised Dr. Mitchell Bruce's *Materia Medica and Therapeutics*, ninth edition, 1912. He is the author of many memoirs on pharmacological subjects.

AN APPEAL TO EXAMINING BODIES.

The Higher Diplomas.

ANOTHER VOLUNTEER writes: One of your correspondents suggests that the higher examinations be stopped for the time being, or allowed only to those over military age. May I remind him that the reasons for a man being at home at the present time may be many and various? If for some reason he is not at the front, that should not debar him from proceeding with his examinations. Whilst on the subject of examinations, I should like to ask why the authorities of the University of London cannot follow the example set by the Conjoint Board, and hold a special final examination, say, in January. For this special examination, and indeed for future examinations, I would suggest that the university adapt itself to circumstances a little more. Why should it be necessary to enter and deposit a fee a whole month in advance? Many candidates do not know where they will be a month hence. The whole procedure with regard to the M.B., B.S., is unwieldy. Surely if one examining body can accept fees three days only in advance, and take the provincial candidates first, another can.

Medical News.

SEVEN fresh cases of plague and seven deaths were reported at Hong Kong in the fortnight ending September 19th.

THE session of the South-West London Medical Society will be opened on October 14th, when Dr. Arthur Whitfield will give a lantern demonstration on lichen planus.

THE West London Medico-Chirurgical Society is to hold the opening meeting of its thirty-third session at 8.30 p.m. on October 2nd. Its rooms are at the West London Hospital.

IT has been decided to cancel the old students' dinner of St. Bartholomew's Medical School, which was arranged for October 1st. The medical school will reopen as usual for the winter session on October 1st. The same observation applies also to the London Hospital.

THE next session of the North-East London Clinical Society will commence on October 1st, at 4 p.m., at the Prince of Wales's General Hospital, Tottenham.

DURING the past few weeks our contemporary the *Nursing Times* has devoted most of its space to notes on war topics. Though written mainly from the point of view of nurses, a good deal of the information published has been of general interest.

IT is stated that Dr. August Bier, Professor of Surgery in the University of Berlin, is Surgeon-in-Chief of the German army, and that Baron von Eiselsberg, Professor of Surgery in the University of Vienna, holds the same office in the Austrian army.

THE Medical Committee of the Queen's Hospital for Children, Hackney Road, has found it necessary to cancel the arrangements that had been made for the usual course of post-graduate lectures to take place during the ensuing three months, owing to uncertainty whether many members of the staff will be able to keep their engagements to lecture in present circumstances.

MESSRS. NEALE AND WILKINSON, 32, St. Mary Axe, London, and 60, Hanover Street, Liverpool, are prepared to receive and forward free of all charge, packages for soldiers on active service. They must contain no wine, spirits, or matches, or any article of a perishable nature likely to cause damage to other packages, and must weigh not less than 11 lb., and not more than 56 lb. Further particulars, if required, can be obtained on application to either of the addresses named.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS *forwarded for publication are understood to be offered to the* BRITISH MEDICAL JOURNAL *alone unless the contrary be stated.*

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Aitiology, Westrand, London.* The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London.*

TELEPHONE (National):—

LETTERS, NOTES, ETC.

THE Royal Sanitary Institute, 90, Buckingham Palace Road, is compiling a list of members and associates willing to help in carrying on sanitary administration, and of assisting local authorities whose staffs may have been depleted owing to the war.

DR. A. J. MANASSEH (Friends' Hospital, Brumana, near Beyrout, Syria) writes: With reference to fresh air and pneumonia I read with much interest the letters of Drs. A. Stevenson and John Bain (BRITISH MEDICAL JOURNAL, June 13th, p. 1336). They will be interested to know that although I did not mention the unlimited supply of fresh air enjoyed by every one of my cases of pneumonia, I agree fully with their remarks on this subject. I always made it a first and strong point to attend to the due ventilation of the sick-room. On several occasions I refused to go in and see the patient unless I had all the windows and the door opened. In some cases the hygienic and sanitary arrangements were far from satisfactory, but I arranged for the patient to occupy the best ventilated corner of the large common room which was sometimes shared by a whole family, an even temperature being maintained by means of either an open wood or charcoal fire.

A CLINICAL TEST FOR THE ESTIMATION OF GLUCOSE.

MR. G. C. PARNELL writes: I am much obliged to Dr. Barker Smith for his remarks in your issue of August 1st upon my paper of July 4th, 1914, "A Clinical Test for the Estimation of Glucose." So far as I am concerned, it is of no importance if the investigation of glucose in urine by coloured glasses, after caramelization of glucose by liquor potassæ, had been previously made and published, although had I known of such I might have been deterred from submitting my article. My aim is simply to obtain in a practical and portable form a means of estimating the percentage of glucose at the bedside or in the consulting-room, and I hope no objection will be raised on the ground that a pocket case containing a few coloured microscopic slides is needed. With regard to the phrase "thoroughly boiled," to which exception has been taken, the meaning was obvious, although it might have been better to have substituted "boiling from ten to fifteen seconds." My consulting-room carpet unfortunately bears much evidence of this mistake, but who ever boiled a sample of urine with liquor potassæ "*for over a minute*" when using Moore's test? When I mentioned the exact sizes of the test tubes it was only to emphasize the importance of careful details as against haphazard methods. Since writing the article I have found that four glasses are sufficient for all estimations, and if the colour produced at the first boiling is deeper than the 3 per cent. glass, it is better to make another analysis with urine diluted than trust to the difference of the tints of the 3 per cent. and 4 per cent. glasses, as they are not of sufficiently definite contrast to give an accurate reading. I take the opportunity of thanking the many who have written to me privately upon the subject.

THE SURGICAL TREATMENT OF NEPHROPTOSIS BY OCCLUSION OF THE PERINEPHRIC FASCIAL SAC (CAPSULAR OCCLUSION).

BY

C. B. LOCKWOOD, F.R.C.S.Eng.,

CONSULTING SURGEON TO ST. BARTHOLOMEW'S HOSPITAL, ETC.

During the recent discussion on nephropexy and its results[1] the speakers laid special stress upon fixation by suturing, and no other method of curing a loose kidney seems to have been contemplated by any of them. "A successful operation was one which efficiently and permanently anchored the kidneys *in their normal position*, and was free from unpleasant sequelae such as pain, weakness of the scar, persistent sinus," etc. But a movable organ like the kidney is not in its normal position when it has been immovably fixed to the abdominal wall, and it is certain that a large proportion of the kidneys which have been fixed regain their mobility.

In 9 out of 14 St. Bartholomew's Hospital cases* seen by Mr. Blakeway the kidney had become loose again. But the following suggests that even 9 out of 14 was not a large enough proportion.

On clinical grounds, a woman, aged 59 and moderately fat, was supposed to have a stone in the right ureter. A skiagram showed the stone at about the level of the umbilicus, which strengthened the belief that it was in the ureter. Then Mr. Reid made a new and admirable skiagram, in which is seen the outline of the kidney, its hilum and ureter, and the stone in the upper part of the pelvis of the ureter. But this skiagram also revealed the fact, hitherto unsuspected, that the whole of the kidney was below the level of the twelfth rib. When I performed nephrolithotomy the kidney was well below the twelfth rib and not easy to secure, because it slipped about so freely. So that scientific *x*-ray investigation might show that the percentage of kidneys which become loose again after they have been fixed high up has been underestimated.

It would be interesting if an *x*-ray investigation of cases of nephropexy could be carried out so as to give scientific evidence of the position of the kidneys, and also whether they had begun to move again.

Dr. Harrison Orton took an *x*-ray photograph of a patient upon whom, eleven years before, I had performed nephropexy on both sides for Dietl's crises. The photograph was taken with the patient lying upon her abdomen, and shows both kidneys "in correct position," but the question of movement of the kidneys was not raised, because I was not then aware that after nephropexy the kidney might remain high up, but nevertheless move again with respiration.

The St. George's cases when seen gave no better results than the St. Bartholomew's ones; out of 8 cases of nephropexy the kidney had remained "absolutely fixed" in one.[2]

Mr. Mills,[3] who examined 30 Birmingham cases of nephropexy, and who gives such a clear and judicial account of them, says significantly "that most of these kidneys that are fixed high up still move normally in respiration." Incidentally, speaking of low fixation, he says, "A kidney fixed in this position is rarely associated with a cure of the symptoms." I infer that in some of those in which the kidney was high up and moved, a cure of the symptoms had ensued.

Sometimes the kidney may regain its mobility although more than one attempt has been made to fix it. Two attempts had been made to fix the right kidney of a nurse, but in the end it was still loose, slipped about in the abdomen, and entered a ventral hernia. The kidney, too, had probably been damaged, for separation showed that it secreted only a quarter as much urine as the left, and that of poor quality. I found a small kidney with the remains of some silk sutures at its lower end. The kidney was removed, the gap in the abdominal wall closed, and a cure ensued. It would be instructive to separate the urine in most cases of nephropexy. I surmise that the kidney which had had sutures put into it would not always function properly.

Although so many nephropexies have failed to immobilize the kidney, yet there is evidence that fixation is well within the range of surgery. But there is also evidence that the fixation may inflict grave injury upon the kidney. I have already mentioned a case in which two attempts had left the kidney small and inadequate, and two other cases of injury have fallen within my own experience. The right kidney of a woman had been partially decapsulated and sutured to the abdominal wall.† The pain and discomfort persisted and the patient became a chronic invalid. I found the kidney firmly fixed to the posterior abdominal wall, and partially embedded in inflamed tissues, much engorged, and its cortex inflamed. It was removed, and the pain cured. I took this step most reluctantly. The loss of a kidney is a severe penalty to pay for a nephropexy which had been a mechanical success but a clinical failure. The inflamed condition of the kidney seemed at the time to preclude any other course. An operation which relieved the symptoms without any risk to the integrity of the kidney would have been much better. On consideration it seems possible that the kidney might have been set loose, and an attempt made to perform the operation which I am about to describe.

The third case was that of a married woman who came under my care for an injury. After a sharp attack of appendicitis the appendix was removed. A year afterwards nephropexy was performed for right nephroptosis. For a year the result was all that could be desired. Then the kidney was loose again, with an aggravation of the former symptoms. The kidney was explored with the view of fixing it again, but had been damaged so much by the first attempt that it had to be excised. Mr. Ernest Shaw reported that "the kidney weighed 3 oz.; surface red, torn, and rough in parts. Lining of pelvis ecchymosed (?) from trauma at operation . . . apparently slight chronic interstitial nephritis."

It is probable that some kidneys loosen after nephropexy because their true capsule is too delicate and their tissues too soft to hold sutures, rather than from want of a firm fixation to the twelfth rib, arcuate ligament, diaphragm, or contiguous parts. Once, in attempting nephropexy, I encountered this condition of the kidney. On another occasion after a stone had been removed from a loose kidney it was so soft that sutures would not hold. Attempts to fix kidneys such as these are not only likely to fail, but must be fraught with danger to the integrity of the organ.

But can it be physiologically correct to immobilize a mobile organ? One would surmise that the movements of the kidneys are beneficial in promoting the secretion and flow of the urine, the circulation of blood and of the lymph. It is not to be supposed that the movements of the kidney are a mere accident. Presumably they fulfil some useful purpose. The mobility which kidneys regain after they have been fixed is a significant fact: on reflection that is what might be expected to happen when an attempt is made to immobilize organs which are naturally mobile.

It is probable that the continuous movements of the diaphragm loosen the kidneys after nephropexy, and the general movements and joltings of the body would assist. Mr. Mills found that most of the kidneys which had been fixed high up still moved normally with respiration, and that those fixed low down did not move on inspiration. Clearly the latter would be much less influenced by the movements of the diaphragm. Mr. Mills says that fixation low down is rarely associated with a cure of the symptoms.[4]

When the kidney moves with respiration it moves within the perinephric sheath or capsule. I am indebted to the admirable essay of Wilson and Howell[5] for a clear and correct account of this structure, and one which accords with my own dissections and operations. Briefly, the perinephric fascia is a sac containing the kidney. "It forms a complete investment for the kidney except at its hilum and lower pole." At the lower pole the

* Two of the 64 St. Bartholomew's operations were done by me after the method described by the late Stanmore Bishop, and which I found unsatisfactory. (Mobile Kidney, with a Description of an Operation for Anterior Nephropexy, *British Gynaecological Journal*, 1907.)

† I was told after the method described by Sir W. Watson Cheyne. (Movable Kidney, with Details of an Operation for Fixing the Kidney, *Lancet*, April 24th, 1909, p. 1155 et seq.)

perinephric sheath is, those authors say,[6] continued downwards and inwards, as a funnel-shaped prolongation, which was just exterior to the sacro-iliac joint. "Here there is a weakness in the perinephric sheath, and it is down this channel that the kidney prolapses, and, guided by the direction of the funnel, the organ soon assumes a position with its long axis directed downwards and slightly inwards." The lower part of the perinephric sac may contain fat, and if that departs the sac becomes too big for the kidney. It is generally believed that loss of weight may loosen the kidney and that the trouble may cease when the sufferer gets fat again.

The perinephric sheath does not move because it is continuous with the diaphragmatic fascia, the crus of the diaphragm, and is attached to the vertebral bodies. At its upper and inner part, where some of it passes behind the suprarenal body, the perinephric fascia is thick and strong. Here it is reinforced by a strong fibrous band, the true "suspensory ligament" of Wilson and Howell. To perform nephrectomy the kidney has to be withdrawn from its perinephric fascial sheath. In those who are strong and athletic the kidney is firmly upheld by the perinephric fascia. When performing nephrolithotomy on a muscular young man the left kidney was in a thick and tough fascial sheath, and when it had been freed from that it was still strongly held there—the twelfth rib had to be excised for the removal of the stone.

My own observations confirm the accounts given by Wilson and Howell, except that I do not think the downward prolongation is as constant as they imply.

The perinephric sheath is also held firm by its continuity with the transversalis fascia, with the sheaths of the quadratus lumborum and psoas muscles, and by its attachments to the vertebral column.[7]

The perinephric fascia supports the kidney and restrains its movements during respiration and during the movements of the body. Although the average weight of the kidney is only five or six ounces, nevertheless this small weight is not to be ignored. When the kidney is loose in its sheath it can be felt moving about according to the position of the body. Standing up it falls towards the pelvis; lying on one side it falls to the other.

So the perinephric fascia not only restrains the movements of the kidneys during ordinary respiration but also during respiratory efforts and during joltings and shakings of the body. When the kidney becomes loose the perinephric fascia does not yield at its attachments. Its sac becomes too capacious, and then the kidney begins to have a wide range of movement within it.

This was clearly seen during an operation which I performed in December, 1896. A woman aged 42 suffered from intermittent hydronephrosis. The right kidney was loose, with a considerable range of movement. It felt enlarged, and was very tender. Inasmuch as the woman looked ill, and had become thinner, Mr. A. W. Lemarchand felt suspicious lest the kidney had a growth in it. The kidney was exposed by an incision through the right semilunar line. The hepatic flexure of the colon was at the iliac crest. The right lobe of the liver was 2 in. below the costal margin. The kidney was normal, but moved about freely within the perinephric fascia. It was easily pushed up, and kept in a high position by two silk sutures, which closed the opening which had been made in the perinephric fascia, and which also fastened it to the abdominal wall. My note says that those sutures seemed to fix the kidney, but clearly they did not fix the kidney, but only prevented it from falling again, its former receptacle having been obliterated. It was still a movable organ, but not a loose one. During this operation I found the liver much in the way; the incision would not have been made through the semilunar line had there not been reason to suspect a growth in the kidney.

Mr. A. W. Lemarchand reports that after this operation the symptoms disappeared, and the patient was well in June, 1902, five and a half years after the operation.

Later (December, 1906), after exploring the left kidney, which was very loose, the usual fixation was made by stripping its capsule and fastening it to the diaphragm and arcuate ligament. In addition, two stout silk sutures were inserted through the perinephric capsule at the lower end of the kidney and fastened to the abdominal wall. After this the kidney was 2 in. above the iliac crest and very strongly held. I now think the sutures which held the perinephric sheath would have sufficed. That would have obviated the risk of damaging the kidney by stripping its true capsule.

After these experiences, I began to treat loose kidneys by occluding the loose and too capacious perinephric sac or bag.

The Operation Recommended.

The steps of the operation have been as follows: The patient is placed in the usual position for nephrotomy with a sandbag or an inflatable air cushion between the table and the flank. An oblique incision is made about an inch below the twelfth rib, not quite parallel to it, but more in the direction of the fibres of the external oblique. The incision begins behind at the outer border of the erector spinae, and is carried forward for four or five inches. The length of the incision depends upon the thickness of the abdominal wall. The muscles are split in the direction of their fibres. No nerves are divided, and the bleeding is trifling. The fascia transversalis having been opened the kidney is sought for. I have found this step, usually a troublesome one, made quite easy by rolling the patient over until the wound faces the table. Then the finger is passed over the kidney to separate the perinephric fascia from the colon and peritoneum, and the perinephric fascia is taken between the finger and thumb at the lower end of the kidney, which is squeezed upwards within its sac. When the kidney has gone up as high as is judged necessary, the perinephric fascia is clamped at its lower end with pressure forceps, and ligatures of No. 2 or 3 twisted silk are passed round it with a curved needle. I have passed two and sometimes three of these silk sutures about half an inch apart. The ends of these ligatures are left long and used to fix the perinephric fascia to the abdominal wall. Before applying the pressure forceps the perinephric fascia is felt between the finger and thumb to make sure that the ureter is not being taken in. When the perinephric fascia has been ligatured the lower end of the kidney is at about the level of the twelfth rib and moving a little with respiration.

Unless it is necessary to explore the kidney it is better not to open the sac of the perinephric fascia. A case has been mentioned of a rather stout, elderly woman in which a stone was situated in the hilum of a loose and prolapsed kidney. The perinephric fascial sac had to be opened for the extrusion of the kidney. The opening was rather troublesome to close, especially as the perinephric fascia was thin and loose and had much fat about it. On the other hand, no difficulty whatever was met with in closing the opening after removing a stone from the pelvis of the kidney of a young woman with well developed muscles and firm tissues. Three chromic gut sutures were used to close the hole in the perinephric fascia and to obliterate the lower part of its sac. The kidney, which had been unusually loose, was then supported with its lower end just below the level of the twelfth rib, and four years afterwards was judged on clinical grounds to have remained there. During the four years the patient had led a very active life, her chief amusement being lawn tennis. I regret to have been unable to get an *x*-ray photograph taken.

The operation is completed by bringing the abdominal muscles together with chromic gut sutures, and suturing the skin with silkworm gut.

This operation hardly takes more than half an hour, and is followed by very little shock, pain, or vomiting, and in these respects contrasts favourably with the operations which I have done to fix the kidney. The patients have hardly suffered more than they would have done after radical cure of hernia. After the operation I follow my usual routine after abdominal operations—namely, three weeks in bed, three weeks on a couch, six weeks' gentle exercise.

Although I have not been able to learn that a similar operation has been performed by others, yet it is difficult to suppose that a proceeding which seems to fulfil the pathological conditions so well can have been overlooked.

Surgeons have, doubtless, been deterred from dealing with the perinephric capsule by the emphatic condemnation which has been meted out to that course. For instance, Sir Henry Morris in his admirable work[8] writes:

> In one particular, however, all operators are now agreed, namely, that the original plan of Hahn, and every modification

of it, whereby only the perinephric tissue—the fibro-fatty investment of the kidney—is shortened and fastened to the parietes, is useless or at any rate uncertain, and therefore unsatisfactory.

But Hahn,[9] in the two operation cases which he described, did certainly not aim at the occlusion of the perinephric fascial sac. As I read his account, it appears that, after the kidney had been approached through an oblique lumbar incision, the "capsula adiposa" was pulled backwards into the wound and fastened there with six or eight catgut sutures, and the wound packed with carbolic gauze. It is difficult to see how this proceeding could adequately and permanently diminish the size of the too capacious perinephric capsule, and it is not surprising that it was abandoned.

Nephropexy has been sparingly performed in London hospitals—on an average, ten per annum in each of four large London hospitals (St. Bartholomew's, St. Thomas's, Guy's, St. George's)—because it is looked upon as a serious operation, which for a time makes the patient very ill, which may not cure the symptoms, and which may damage the kidney and weaken the abdominal wall.

Occlusion of the perinephric fascial sac is not a severe operation, does not injure the kidney in the least, and, as the abdominal wall is split and brought together again, it is not likely to be followed by ventral hernia.

I now give some of the results of the few operations which I have done.

Four years ago I performed nephrolithotomy upon a young married woman. Her right kidney, besides having a stone in its pelvis, descended below the level of the umbilicus and slipped about very freely, so that after the abdomen had been entered as far as the peritoneum by splitting the muscles in the flank it was exceedingly difficult to secure. After the removal of the stone the perinephric fascial sac was occluded with three chromic gut sutures. Four years after this operation the right kidney could not be felt, although in the meantime the patient had been leading a rather strenuous life—lawn-tennis being her chief amusement. So, then, occlusion of the perinephric fascial sac suffices to keep the kidney up.

A neurasthenic patient who was operated upon more than a year ago has been seen. The right kidney cannot now be felt. The patient says that she has had great benefit from the operation. "The backache and dragging are gone, and I can now walk about again and ride in trains and buses." In addition to the pain of backache this patient had symptoms pointing to intermittent hydronephrosis. She had had other operations done before, and says she suffered much less from the kidney operation than from any of them.

Another patient with backache, dragging, and symptoms pointing to intermittent hydronephrosis has been entirely freed from these symptoms, but only three months have elapsed since the operation.

A children's nurse, aged 38, was operated upon in April, 1909. I have been unable to see her, but in December, 1913, she wrote: "I am most grateful to be able to write you that I have now no trouble whatever from the kidney which was operated on. I rapidly recovered my strength, went back to my usual work, and have gone on ever since without a rest." Before the operation she had had severe crises with pain, vomiting, and blood in the urine. The presence of a calculus was suspected, but none could be found, although the kidney was explored.

As regards intermittent hydronephrosis, a remark made by Wilson and Howell[10] is to be noted. "The portion of the ureter (about two inches) within the perinephric sheath is free to follow the kidney in all its movements, and thus a kink may be produced at its point of exit from the perinephric sheath," which does not yield. Mr. Alfred Johnson[11] has conclusively shown the truth of this.

So occlusion of the perinephric fascial sac in cases of nephroptosis cures the symptoms caused by the dragging upon the renal plexus, the obstruction of the renal veins, and the kinking of the ureter. A kidney which had been loose and prolapsed had, owing to kinking of the ureter, become a thin-walled cyst, distended with urine, and it had to be removed.

Calculi seem rather common in loose and prolapsed kidneys. I have met with this association in 5 cases of nephrolithotomy. It is, however, difficult to know whether the presence of the stone causes the looseness of the kidney or whether the looseness of the kidney causes the stone. I suspect the latter is usually the case, but clearly it is desirable, after removing a stone from a loose kidney, to complete the operation by occlusion of the perinephric fascial sheath.

There are grounds for suspecting that loose kidneys are more liable to infection, either through the blood stream or by way of the ureter. Clinical histories are not very reliable, but I have removed a tuberculous kidney which had been loose for many years. Ascending colon bacillus pyelonephritis was severe and persistent in the case of a female with nephroptosis on the right side. The left kidney was in normal position, and did not suffer. Such considerations as these suggest a wider field for the treatment of nephroptosis by an operation which seems to be efficacious, is not severe, and does not endanger the kidney.

THE USE OF AN APERIENT BEFORE X-RAY EXAMINATION OF THE INTESTINE IN CHRONIC CONSTIPATION.

BY

RICHARD GOMPERTZ, M.B., AND MAITLAND SCOTT, M.R.C.S., L.R.C.P.

From the X-ray Department, Duff House.

IT does not appear to be certainly known to radiographers whether or not the presence of faecal accumulations in the last portions of the large gut influences the rate of passage of the mixture of bismuth and food in any constant manner.

If there be such an influence, it would seem that the gut should always be emptied by an aperient before an *x*-ray examination is made, in order to obtain comparable results in different cases. Some writers advise an aperient, whilst others do not mention it. Search in those books and journals to which we have had access has not afforded any definite evidence on the point; as it seems to be of some moment we have, therefore, at the suggestion of Dr. Spriggs, endeavoured to investigate it.

Four adult men, who had all suffered for many years from chronic constipation, for which there did not appear to be any cause in the nature of mechanical obstruction, were observed, the same procedure being employed in all.

Two series of photographs were taken in each case; the first series was not preceded by an aperient; in the second the bowel was emptied by a dose of castor oil on the night before the bismuth meals. Observations were made immediately at 4, 6, 12, 24, 36, and 48 hours after the bismuth breakfast, and at other times when necessary.

The following is a summary of the findings in the 4 cases:

1. The first case was one of delay in the stomach and colon. In the first series of skiagrams, before which no purgative was taken, the stomach emptied in about nine hours, and the transverse colon, which was reached in seven hours, not till 100 hours.

In the second series (after castor oil) the stomach emptied about one hour earlier, but the delay in the colon was not appreciably affected.

2. The second case was one of spastic constipation of the descending colon, the passage through the stomach and small intestine being normal. The stomach was emptied in four and a half hours and the caecum reached in four hours. The stasis in the large bowel was especially marked in the caecum.

On comparing the two series of skiagrams, it was found that the bismuth passed rather more rapidly in the first series than in the second one (after castor oil).

3. In the third case also the delay was in the large intestine, but here we found that the second series (after castor oil) showed a slightly more rapid passage of the bismuth.

4. The fourth case was one of moderate delay in the caecum, but the total time which the bismuth took to traverse the entire bowel was not abnormally long; the caecum was not quite emptied in thirty hours, while the bismuth had entirely left the rectum in forty-eight hours.

In this instance there was practically no difference to be noted between the two series of skiagrams.

Conclusion.

So far as the evidence in these cases goes, the conclusion may be drawn that, in cases of chronic constipation, the variations between the rates of passage of the bismuth along the intestine were but small, whether the bowel had been emptied by a preliminary aperient or not; at the most the differences were not greater than can be said to be within the normal limits.

Further, where differences were noted in the two series, they were not constant, being in one case in the direction of greater rapidity after an aperient, in another of less, and in a third varying at different times in the same patient.

It is, however, undoubtedly wise in most cases to give a purge before making an *x*-ray examination, on account, first, of the greater clearness of the skiagrams obtained when the intestine is empty; and secondly, of the discomfort which the patient, deprived of his usual aids to defaecation, may experience in the two or three days occupied by the *x*-ray observations, during which, of course, no aperient must be given.

The result of these trials appears to show, nevertheless, that in cases in which time does not permit of a preliminary purge, or in which it is undesirable for any other reason to give it, the conclusions reached may be accepted without the fear that they have been materially vitiated by the omission.

INSECTS AND WAR:

III.—*FLEAS.*

By A. E. SHIPLEY, Sc.D., F.R.S.,
MASTER OF CHRIST'S COLLEGE, CAMBRIDGE.

Marke but this flea, and marke in this,
How little that which deny'st me is;
It sucked me first, and now sucks thee.
And in this flea our two bloods mingled bee.
Dr. DONNE.

THE fact, now fully established, that the bubonic plague is conveyed to man from infected rats or from infected men by fleas has taken that wingless insect out of the category of those animals which it is indelicate to discuss.

No doubt, as Mr. Dombey says, "Nature is on the whole a very respectable institution"; but there were times when she presented herself in a form not to be talked about, and until a few years ago the flea was such a form. Hence few but specialists have any clear idea either of the structure or of the life-history or of the habits—save one—of the flea.

Fleas are temporarily parasitic on many mammals and birds, but some mammals and some birds are much freer

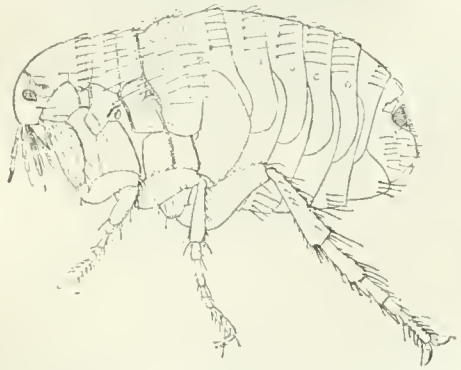

Fig. 1.—*Pulex irritans*, female. The legs of the left side only are shown. (After a drawing by A. Dampf.) Enlarged.

from fleas than others. As the flea is only on its host for part of the time, it has to put in the rest of its existence in some other place, and this in the case of the human flea is usually the floor, and in the case of bird-fleas the nest; from these habitats they can easily regain their hosts when they retire to rest. But large numbers of ruminants—deer, cattle, antelopes, goats, wild boars—sleep in different places each night, and to this is probably due the fact that, with the exception of two rare species, one taken in Northern China and the other in Transcaucasia, the ruminants have furnished descriptive science with no fleas. Both of these ruminant fleas are allied to the burrowing fleas or "chigoes."

I know I shall not be believed when I say that the same is true of monkeys, but I do this on the undoubted authority of Mr. Harold Russell, who has recently published a charming little monograph on these lively little creatures. Monkeys in nature are cleanly in their habits, and although in confinement occasionally a human flea attacks them, and although occasionally a chigo bores into the toes of a gorilla or chimpanzee, "speaking generally, it may be said that no fleas have been found truly parasitic on monkeys." Whatever the monkeys are looking for, it is not fleas. What they seek and find is in effect little scabs of scurf, which are made palatable to their taste by a certain sour sweat.

As a rule, each host has its own species; but though for the most part *Pulex irritans* is confined to man, it is occasionally found on cats and dogs, whilst conversely the cat and dog fleas (*Ctenocephalus felis* and *Ct. canis*) may attack man. The bite of the flea is accompanied by the injection of the secretions of the so-called salivary glands of the insect, and this secretion retards the coagulation of the victim's blood and stimulates irritation.

It is only a few years ago that the spread of plague was associated first with rats, and then with rat-fleas; and it became at once of enormous importance to know which of the very numerous species of rat-flea would attack human beings. The Hon. Charles Rothschild, who has accumulated a most splendid collection of preserved fleas in the museum at Tring, had some years ago differentiated from an undifferentiated assemblage of fleas a species first collected in Egypt, but now known to be the commonest rat-flea in all tropical and subtropical countries. This species (*Xenopsylla cheopis*)—and to a lesser extent *Ceratophyllus fasciatus*—unfortunately readily bites man, and if they should last have fed upon a plague-infected rat, their bites will communicate bubonic plague to human beings. Plague—the old English "Black Death"—is a very real peril in armies operating in Asia and in certain parts of Africa.

Just as some fleas attack one species of mammal or bird and avoid closely allied species, so the human flea has its favourites and its aversions. There is a Turkish proverb which says "An Englishman will burn a bed to catch a flea," and those who suffer severely from flea-bites would certainly do so; but there are persons even a flea will not bite. Mr. Russell has reminded us in his Preface of the distinguished French lady who remarked, "Quant à moi ce n'est pas la morsure, c'est la promenade!"

There are one or two structural features in a flea which are peculiar, the most remarkable being that, unlike other insects, it is much taller than it is broad. As a rule insects, such as a cockroach, the bed-bug, or a stag-beetle, are like skates—broader than they are thick; but the flea has a laterally compressed shape, like a mackerel or herring. Then the three segments or rings which come after the head are not fused into a solid cuirass as they are in the fly or the bee, but are movable one on the other. It is usual in insects for the first joint of the leg to be pressed up against and fused with the segments of the body that bear them, but in the flea not only is this joint quite free, but the body-segment gives off a projection which stretches out to bear the leg. Thus the legs seem, unless carefully studied, to have an extra joint and to be of unusual length. They certainly possess unusual powers of jumping. As Gascoigne, a sixteenth century poet (1540–78), writes, "The hungry fleas which frisk so fresh." The male, as is so often the case amongst the invertebrata, is much smaller than the female. The latter lays at a time from one to five minute, sticky, white eggs, one-fortieth of an inch long by one-sixtieth broad. They are not laid on the host, but in crevices

Fig. 2.—Larva of *Pulex irritans*. *Cf*, frontal horn; *d*, antenna. Enlarged.

between boards on the floor, or at the bottom of a dog kennel or bird's nest. Mr. Butler recalls the case of a gentleman who collected on four successive mornings 62, 78, 67, and 77 cat-fleas' eggs from the cloth his cat had slept upon. Altogether 280 eggs in four nights! The date of hatching varies very much with the temperature. *Pulex irritans* takes half as long again—six weeks instead of four—to become an adult imago in winter as in summer, but in India the dog-flea will complete its cycle in a fortnight.

When it emerges the larva is seen to be a whitish segmented little grub without any limbs, but with plenty of bristles which help it to move about; this it does very actively. There are two small antennae and a pair of powerful jaws, for the larva does not take liquid food, but eats any scraps of solid organic matter which it comes across; dead flies and gnats are readily devoured. The larva casts its skin several times, though exactly how often it moults seems still uncertain.

After about twelve days of larval existence it spins itself a little cocoon in some sheltered crevice, and turns into a whitish inert chrysalis or pupa. During its pupal existence it takes, of course, no food, but it grows gradually darker, and after undergoing a tremendous internal change, breaking down its tissues and building up new ones, the chrysalis case cracks and the adult flea jumps out into the world.

Fig. 3.—Pupa of flea. (After Westwood.)

There are many superstitions about fleas. March 1st is in some way connected with them, and in the south of England the house doors are in some places closed on that day under the belief that this will render the building immune for the following twelve months. The most successful insecticide is said to be prepared from *Pyrethrum*, which is grown in the near East in large quantities for this purpose. Wormwood (*Artemisia*) is also recommended.

> While wormwood hath seed, get a handfull or twaine,
> To save against March, to make flea to refraine:
> When chambere is swept and wormwood is strowne,
> No flea for his life dare abide to be known.
>
> TUSSER.

The author of *A Thousand Notable Things* suggests the following plan, but, so far, I have not met any one who has tried it: "If you mark where your right foot doth stand at the first time that you do hear the cuckow, and then grave or take up the earth under the same; wheresoever the same is sprinkled about, there will no fleas breed. I know it hath proved true."

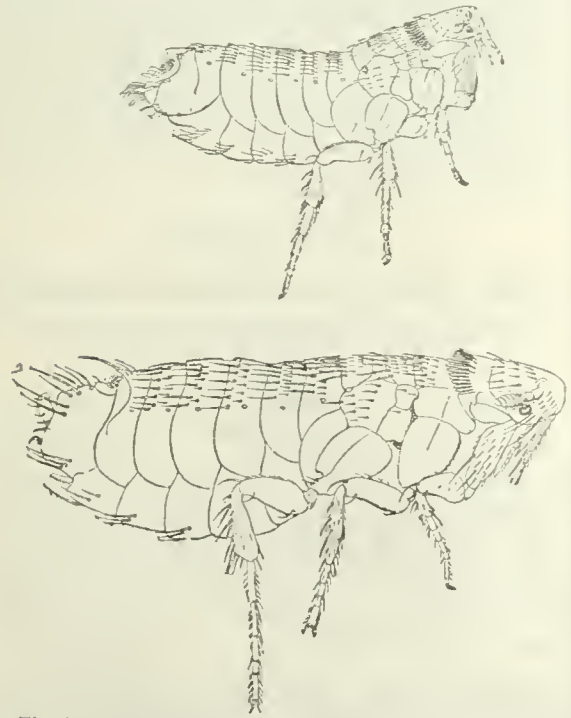

Fig. 4.—*Ceratophyllus gallinulae*. Male (above) and female (below). Drawn to scale and both highly magnified. These specimens taken from a grouse are of the same genus as one of the plague-conveying fleas.

Plastering a floor with cow-dung, which is a common practice in South Africa, is said to be a very efficacious means of keeping down fleas.

But we must, in the long run, treat fleas seriously. Although the *Pulex irritans* is a very common insect, the greatest living authority on fleas tells me it has never been accurately drawn. We have Blake's "ghost of a flea," but what did Blake know of entomology? In distinguishing one flea from another—fleas which may attack man and fleas which have hitherto declined to do so—every hair, every bristle counts (Fig. 4). Hence I illustrate this article with accurate outlines of certain fleas found on the grouse, and for whose accuracy I can vouch. As I have said above, a certain rat-flea (*Xenopsylla cheopis*) and another (*Ceratophyllus fasciatus*) undoubtedly conveyed the bacillus of plague from rats and other Murinae to man and vice versa. The *Bacillus pestis* is unlikely to establish itself in the present war, but *quien sabe?* The Black Death of 1349-51 was conveyed by fleas, and so was Pepys's plague of 1665. Plague—flea-borne, we must remember—is still endemic in places as near Europe as Tripoli, and in numerous centres in Asia. Not a disease altogether to be neglected, but still not a very threatening one in Europe in the twentieth century.

BACILLI AND BULLETS.

AN ADDRESS TO THE OFFICERS AND MEN IN THE CAMPS AT CHURN.*

BY SIR WILLIAM OSLER,

REGIUS PROFESSOR OF MEDICINE, OXFORD.

I HAVE been asked to say a few words on the question of health in war time, that you may realize its importance. Formerly an army marched on its belly; now it marches on its brain. Only by utilizing existing knowledge, in all grades from commander-in-chief to private, is the maximum of success available. To put the largest number of the enemy out of action with a minimum of loss to his own men is the aim of every general. While in one way modern war merges the individual in a great machine, on the other hand the intelligent action of the unit has never been so important a factor in making the machine work smoothly and efficiently. After all, it is the man behind the gun who wins the victory.

What I wish to urge is a true knowledge of your foes, not simply of the bullets, but of the much more important enemy—the bacilli. In the wars of the world they have been as Saul and David—the one slaying thousands, the other tens of thousands. I can never see a group of recruits marching to the dépôt without mentally asking what percentage of these fine fellows will die legitimate and honourable deaths from wounds, what percentage will perish miserably from neglect of ordinary sanitary precautions? It is bitter enough to lose thousands of the best of our young men in a hideous war, but it adds terribly to the tragedy to think that more than one-half of the losses may be due to preventable disease. Typhus fever, malaria, cholera, enteric, and dysentery have won more victories than powder and shot. Some of the diseases I mention need no longer be dreaded. Typhus, and malaria, which one hundred years ago routed a great English army in the Walcheren expedition against Antwerp, are no longer formidable foes. But enough remain, as we found by sad experience in South Africa. Of the 22,000 lives lost in that war—can you believe it?—the bullets accounted for only 8,000, the bacilli for 14,000! In the long arduous campaign before us more men will go into the field than ever before in the history of the Empire. Before it is too late, let us take every possible precaution to guard against a repetition of such disasters. I am here to warn you soldiers against enemies more subtle, more dangerous, and more fatal than the Germans—enemies against which no successful battle can be fought without your intelligent co-operation. So far the world has only seen one great war waged

* Copies of this address in pamphlet form can be obtained from the Oxford University Press, London, Edinburgh, Glasgow, New York, Toronto, Melbourne, and Bombay, price one penny net.

with the weapons of science against these foes. Our allies, the Japanese, went into the Russian campaign prepared as fully against bacilli as against bullets, with the result that the percentage of deaths from disease was the lowest that has ever been attained in a great war. Which lesson shall we learn? Which example shall we follow—Japan, or South Africa with its sad memories?

We are not likely to have to fight three of the greatest former scourges—typhus, malaria, and cholera—though the possibility of the last has to be considered. But there remain dysentery, pneumonia, and enteric, against two of which we should be able to bring to bear successfully resources of modern science.

Dysentery, an inflammation of the large bowel, has been for centuries one of the most terrible of camp diseases, killing thousands, and, in its prolonged damage to health, one of the most fatal of foes to armies. So far as we know, it is conveyed by water, and only by carrying out strictly, under all circumstances, the directions about boiling water can it be prevented. It is a disease which, even under the best of circumstances, cannot always be prevented; but with care the incidence should be reduced to a minimum, and there should never again be widespread outbreaks in the camps themselves.

Pneumonia is a much more difficult disease to prevent. Many of us, unfortunately, carry the germ with us. In these bright days all goes well in a holiday camp like this; but when the cold and the rain come, and the long marches, the resisting forces of the body are lowered, the enemy, always on the watch, overpowers the guards, rushes the defences, and attacks the lungs. Be careful not to neglect coughs and colds. A man in good condition should be able to withstand the wettings and exposures that lower the system, but in a winter campaign pneumonia causes a large amount of sickness, and is one of the serious enemies of the soldier.

Above all others one disease has proved most fatal in modern warefare—enteric or typhoid fever. Over and over again it has killed thousands before they ever reached the fighting line. The United States troops had a terrible experience in the Spanish-American war. In six months, between June and November inclusive, among 107,973 officers and men in ninety-two volunteer regiments, 20,738—practically one-fifth of the entire number—had typhoid fever, and 1,580 died. Fortunately, in this country typhoid fever is not prevalent in the districts in which camps are placed. The danger is chiefly from persons who have already had the disease, and who carry the germs in their intestines, harmless messmates in them, but capable of infecting barracks or camps. You can easily understand how flies lighting on the discharges of such typhoid carriers could convey the germs far and wide. It was in this way probably, and by dust, that the bacilli were so fatal in South Africa. Take to heart these figures: There were 57,684 cases of typhoid fever, of which 19,454 were invalided, and 8,022 died. More died from the bacilli of this disease than from the bullets of the Boers. Do let this terrible record impress upon you the importance of carrying out with religious care the sanitary regulations.

One great advance in connexion with typhoid fever has been made of late years, and of this I am come specially to ask you to take advantage. An attack of an infectious disease so alters the body that it is no longer susceptible to another attack of the same disease; once a person has had scarlet fever, small-pox, or chicken-pox, he is not likely to have a second attack. He is immune, or has what is called immunity. When you expose a solution of sugar to the air, or if you add to it a pinch of yeast, a process goes on which we call fermentation, accompanied by a growth of little germs of the yeast in the fluid, and by an increase in temperature (in fact the solution has a fever), and the composition of the fluid alters, so much so, that you can inoculate it afterwards again and again with the same germ, but no further change takes place. Now this is what happens to us when bacilli make a successful entry into our bodies. They overcome the forces that naturally protect the system, and grow just as the yeast does in the sugar solution; but the body puts up a strong fight, all sorts of antibodies are formed in the blood, and if recovery takes place, the patient afterwards has immunity, for a time at least, from subsequent attacks. The body has mobilized its forces, and is safe for a few years at least against that disease. It was an Englishman, Jenner, in 1798, who found that it was possible to confer this immunity by giving a person a mild attack of a disease, or of one very like it. Against small-pox all of you have been vaccinated—a harmless, safe, and effective measure. Let me give you a war illustration. General Wood, of the United States Army, told me that, when he was at Santiago, reports came that in villages not far distant small-pox was raging and the people without help of any kind. He called for volunteers, all men who showed scars of satisfactory vaccination. Groups of these soldiers went into the villages, took care of the small-pox patients, cleaned up the houses, stayed there until the epidemic was over, and not one of them took the disease. Had not those men been vaccinated, at least 99 per cent. of them would have taken small-pox. Now, what I wish to ask you is to take advantage of the knowledge that the human body can be protected by vaccination against typhoid fever. Discovered through the researches of Sir Almroth Wright, this measure has been introduced successfully into our own regular army, into the armies of France, the United States, Japan, and Germany. I told you a few minutes ago about the appalling incidence of typhoid fever in the volunteer troops in America during the Spanish-American war. That resulted largely from the wide prevalence of the disease in country districts, so that the camps became infected; and we did not then know the importance of the fly as a carrier, and other points of great moment. But in the regular army in the United States, in which inoculation has been practised now for several years, the number of cases has fallen from 3.53 per thousand men to practically nil. In a strength of 90,646 there were in 1913 only three cases of typhoid fever. In France the enteric rate among the unvaccinated was 168.44 per thousand, and among the vaccinated 0.18 per thousand. In India, where the disease has been very prevalent, the success of the measure has been remarkable. In the United States, and in France, and in some other countries this vaccination against the disease is compulsory. It is not a serious procedure; you may feel badly for twenty-four hours, and the site of inoculation will be tender, but I hope I have said enough to convince you that, in the interests of the cause, you should gladly put up with this temporary inconvenience. If the lessons of past experience count, any expeditionary force on the Continent has much more to fear from the bacillus of typhoid fever than from bullets and bayonets. Think again of South Africa with its 57,000 cases of typhoid fever! With a million of men in the field, their efficiency will be increased one-third if we can prevent enteric. It can be prevented, *it must be prevented*; but, meanwhile, the decision is in your hands, and I know it will be in favour of your King and country.

A CASE OF RUPTURED ECTOPIC GESTATION COMPLICATED BY SPLENO-MEDULLARY LEUKAEMIA.

By LIONEL E. SUTCLIFFE, M.B., CH.B. SHEFFIELD,
CHESTERFIELD.

THE combination present in the following case of spleno-medullary leukaemia with pyrexia of such a marked character and for so prolonged a period, together with the fact that it was complicated with ruptured ectopic gestation, that there was shrinkage of the spleen coincident with the haemorrhage, and that it enlarged markedly and rapidly during the reactionary stage, are features of great interest.

S. A., aged 21, was admitted to the Lowestoft Hospital at 5 p.m. on January 10th. On January 8th, at 1.30 a.m., she had been seized with acute abdominal pain accompanied by vomiting. Three weeks previously she had menstruated normally, and had never missed a period since her marriage, twelve months earlier. The abdomen was distended, motionless, and universally tender. Rigidity was most marked on the right side, and the patient localized her most acute pain in the right iliac fossa. The temperature was 101.4° F., and the pulse 135.

Vaginal examination elicited the fact that there was a large, soft, fluctuant mass in the pouch of Douglas. The diagnosis of ruptured ectopic gestation was made, and the patient operated upon at 7 p.m. The abdomen was full of blood and clots; the ruptured gestation sac, which was in the right broad ligament, was removed, the stump ligatured, and the abdomen closed after being cleansed.

The temperature rose on the following day to 102.6° F., at which point it remained practically stationary until the sixth day after operation, when it rose to 103.2° F.; it remained almost constantly at 103° F. or 103.2 F. for six days—that is, to the twelfth day after operation. It fell steadily during the next two days to 101° F. as maximum, at which it remained practically stationary until the eighteenth day after operation, when it rose gradually during the day to a maximum of 105 F. once more in the evening.

This date marked a new era in the disease. Nothing could be found to account for this pyrexia; there was no suppuration in the wound, no pain or tenderness in the abdomen, no complication in the heart or lungs, and nothing abnormal to be felt in the abdomen. There was slight albuminuria. There was, however, one positive fact—namely, that in spite of her general improvement, apart from the raised temperature, the patient showed extreme blanching; she said, however, that she was usually very pale. On January 28th, when the further sudden rise of temperature occurred, the spleen was found to be easily palpable. The blood examined that day was found to contain large quantities of myelocytes, nucleated red cells (both megaloblasts and normoblasts), mast cells, and polymorphonuclear leucocytes in every condition. The temperature fell in the course of two days to 100° F., between which and 99° F. it oscillated for a fortnight more. The spleen continued steadily to enlarge until it reached to a finger-breadth below the umbilical level and extended considerably into the right hypochondrium.

One additional feature throws some light on the condition of the blood. On the tenth day after operation the stitches were removed, and it was seen that there had been no attempt at healing. The edges of the wound were scraped and it was again united by sutures, but once more failed to heal. After being dressed with lotio rubra and after further scraping, it was again sutured.

It seems certain that for some considerable time the patient had been the subject of this form of leukaemia—she had experienced fits of giddiness and breathlessness on going about, and had recently consulted a medical man for obstinate epistaxis.

It appears, therefore, I suggest, that the spleen was enlarged previously to the occurrence of the abdominal catastrophe, that it shrank with the progress of the haemorrhage, and with the onset of the reaction therefrom it again began to enlarge.

I find Sir William Osler quotes several cases which have come under his notice in which this occurred in the presence of a severe haemorrhage. The woman has now made a complete recovery, the spleen and blood both having become normal.

I am indebted to Dr. Bell, senior surgeon to the Lowestoft Hospital, under whose care the patient was admitted for operation, for permission to publish this case.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

SUBLINGUAL MEDICATION.

SIR,—I heartily endorse what Dr. William Paulson says (p. 541), as to the simplicity, cleanliness, and efficacy of sublingual medication, and have for many years used it daily in my practice. In 1885 I was returning to medical duties in Japan after furlough. The passage was exceedingly rough, I was weak from effects of malaria and dysentery, and so sick that I could take no kind of food, while brandy returned immediately. Happening to notice, however, that when a few drops of brandy rested under the tongue some internal glow was felt, I began to use that well-known remedy in this way with the best effects. I cannot remember having seen any notice of this method in print, but from that time I have used the ordinary subcutaneous tabloids in everyday practice, and have never known any inconvenience arise from placing them under the tongue. The results are very quick and sure, and I but rarely resort to hypodermic injections now. For this purpose the tablets might be made more palatable with advantage, but that is a small matter.

Stoke-on-Trent. HENRY FAULDS, L.R.F.P. and S.

TREATMENT OF ACUTE GONORRHOEA IN THE MALE.

I HAVE read with interest the articles on this subject lately appearing in the BRITISH MEDICAL JOURNAL.

Thirty years ago, working in Canada with surgeons of that country, I adopted their method for acute cases seen early—that is to say, I ordered the usual rest, diet, diluents, etc., but began injections of a 2-grain solution of zinc sulphate on the first or earliest possible day of the disease, with instruction to the patient "to inject always after passing urine, and never to inject unless urine had just been passed." The patient was given the usual syringe in a bottle, the cork (rubber) of which makes the handle of the syringe, and told to always carry it and always use it immediately after passing urine. With this treatment the discharge usually ceases about the fourth day. The patient should continue the injections as directed for three or four days after its disappearance, and then gradually lessen the number; there should be complete cure in from eight to ten days. Latterly I have used zinc permanganate instead of sulphate, and have given also hexamethylenetetramine (which I prefer to cystopurin) by the mouth. The results have been the same.

EIGHTY-SECOND ANNUAL MEETING

OF THE

British Medical Association.

Held in Aberdeen on July 29th, 30th, and 31st.

PROCEEDINGS OF SECTIONS.

SECTION OF DISEASES OF CHILDREN.

Dr. JOHN THOMSON, President.

A DISCUSSION ON THE THYMUS GLAND IN ITS CLINICAL ASPECTS.

OPENING PAPERS.

I.—A. E. GARROD, D.M., M.A., F.R.C.P., F.R.S.,

Physician to St. Bartholomew's Hospital; Consulting Physician to the Hospital for Sick Children, Great Ormond Street.

DURING active adult life the vital processes are in a condition of more or less stable equilibrium, and, unless disease intervene, the regulator mechanisms are so accurately balanced that there is little disturbance of the normal standards from year to year.

In childhood different conditions prevail. This is a period of active growth and development. The regulater mechanisms are not yet balanced; income is in excess of expenditure, and, as puberty is approached, the organism takes upon itself new functions in the interest of the race rather than of the individual.

We are learning how large a part is played in the regulation of the vital processes by internal secretions of glands, such as the thyroid, pituitary, and adrenals; and it is a reasonable hypothesis that the special features of childhood are due, at least in part, to the functional activities of certain glands of which the influence passes into abeyance when childhood is past. It is probable that the pineal is such a gland, but the glandular organ of childhood *par excellence* is the thymus, the clinical aspects of which, as yet so shadowy and ill-defined, form the subject of discussion to-day.

It is now generally conceded that the thymus is a gland of internal secretion, despite the resemblance in its structure to that of the lymphatic organs, and its enlargement in association with these in the victims of status lymphaticus. But the methods which have thrown so much light upon the functions of the thyroid have, in the case of the thymus, yielded far less definite results.

The more recent experiments upon removal of the thymus in young animals carried out by Basch,[1] Klose and Vogt,[2] and Matti[3] have yielded results sufficiently uniform to carry conviction. This is doubtless due to improvements of technique, which allow of more complete removal, and to the early age at which the operation was performed, for it must be remembered that in dogs and rodents the period of childhood, the interval between birth and puberty, is far shorter than in man.

In puppies experimented upon a period of latency of several weeks was followed by a stage of adiposity, and later by cachexia and wasting, and eventually by death in coma. Growth was arrested and the animals developed a cretinoid condition. But the most striking and characteristic effect of thymectomy is the supervention of changes in the bones so like those of human rickets as to be practically indistinguishable therefrom. Lastly, changes occur in other glands of internal secretion, such as increase of the adrenal medulla and enlargement of the thyroid, pancreas, and testes.

Of recent years the operation of thymectomy has been repeatedly performed upon children for the relief of dyspnoea, but although the mortality has been high, the effects observed in animals have not been seen. In a single case, recorded by König,[4] severe rickets followed the operation, which was, however, limited to removal of the left lobe of the thymus. Complete thymectomy, followed by recovery, has been recorded in children of 6 and 9 months, but it is unlikely that the removal was so complete as in the animal experiments.

Of the converse effects of over-activity, or perverted activity, of the thymus we know almost nothing. Svehla's[5] observation of a depressor action of thymus extracts loses all importance from the fact that such depressor action is common to extracts of most animal organs and tissues. Attempts to counteract the effects of thymectomy in animals by thymus feeding have seemed only to aggravate the symptoms, but reference may be made to some suggestive experiments by E. E. Hewer[6] upon the effect of thymus feeding upon the activity of the reproductive organs in rats.

Tumours of the thymus produce pressure symptoms but no characteristic signs, and other gross diseases of the gland, such as syphilitic and tuberculous lesions, are equally devoid of clinical interest.

It may be that, at some future time, the thymus may be shown to play a much more prominent part in connexion with diseases of children than it is yet known to do, and it is a tempting hypothesis that derangements of the functions of this gland have an important share in the causation of rickets.[7] We know that in young animals thymectomy induces the rachitic changes in bones, but the converse evidence, that in human rickets the functions of the thymus are impaired, is not as yet forthcoming. Again, it is suggested that a form of cretinoid idiocy in children may be due to thymic defect. Thus Klose[8] describes the case of a twin boy whose twin brother had died suddenly with asphyxia, whose epiphyses were thickened and his bones bent. He was fat and idiotic, and an operation performed when he was 5 years old revealed complete absence of the thymus.

I do not propose to discuss the interesting question of the correlation of the thymus with other glands of internal secretion and especially with the genital glands; for the remainder of the time at my disposal must be devoted to the association of hyperplasia of the thymus with sudden death in children and in adults.

The subject is usually discussed under three heads—namely, thymic death, the sudden death of infants apparently healthy, apart from any antecedent signs of pressure upon the trachea; secondly, thymic asthma, a condition which may assume a more or less chronic form, or may manifest itself in paroxysms of stridulous dyspnoea; and thirdly, the condition known as status thymico-lymphaticus or status lymphaticus.

It is an undoubted fact that many infants who die suddenly possess unduly large thymus glands, but it is difficult to assert with confidence that the gland is of abnormal size, save in cases in which its size is such that no doubt is possible.

The limits of normality are somewhat wide, and very competent observers have arrived at estimates of the average weight of the thymus in a child of some 2 years which differ as widely as from 9 to 10 grams to 25 or 30 grams. Moreover, when the question of pressure is under consideration it is obvious that the form of the gland, whether it be of the flat or plump variety, has to be taken into count.

Those who have seen thymus deaths of infants describe a sudden throwing back of the head, a gasping breath, rolling up of the eyes, dilatation of the pupils and pallor or cyanosis. Other symptoms are swelling of the tongue, clenching of the hands and extension of the legs.

I imagine that thymic asthma must be a rare phenomenon. I cannot recall having seen a case in which the diagnosis was made and confirmed, and some colleagues with wider experience of sick children tell me that they can say the same. In most instances the symptoms suggest pressure upon the trachea, and cases are recorded in which the tracheas have shown signs of compression *post mortem*, and some in which the compression has been seen with the bronchoscope during life. However, it should be mentioned that some modern anatomists hold that the trachea of a normal infant is of oval shape.

Caution is needed in making the diagnosis of thymic asthma, and in some cases such a diagnosis made during life is shown to be incorrect *post mortem*. What is thought to be an enlarged thymus may prove to be an abscess around mediastinal glands, as in a case which Thursfield has described. Nor must it be forgotten that stridulous dyspnoea in infants has several causes, such as enlargement of bronchial or tracheal glands, retropharyngeal abscess, membranous laryngitis, laryngeal spasm, and the abnormality of the larynx causing congenital stridor, which you, Mr. President, have taught us to recognize. Lastly, there is evidence that not a few cases of supposed thymic death have actually been due to suffocative bronchopneumonia.

Around the question whether thymic asthma and thymic death in infants are due to pressure of the enlarged gland upon the trachea, blood vessels or nerves, there has centred no little controversy. The advocates of the pressure theory may claim that their opponents have no alternative explanation to offer which rests upon physiological or other experimental evidence; but, on the other hand, sudden deaths in status lymphaticus, whatever the mechanism of their causation be, certainly cannot be ascribed to a mechanical cause.

Undoubtedly, the upper thoracic orifice of an infant is very small, and we may readily suppose that a large thymus may exert considerable pressure upon the surrounding structures. Tumours of the gland undoubtedly exert such pressure. On the other hand, the beneficial effect of removal of the thymus in some cases of thymic asthma are not so conclusive as they appear at first sight, for they may be equally well explained upon a theory of hypersecretion.

It is difficult to doubt that, in some cases at least, thymic asthma is due to pressure, but in others the stridor appears to be due to laryngeal spasm rather than to narrowing of the trachea. However, when we attempt so to extend the pressure theory as to explain thymic death, apart from obvious dyspnoea, by pressure upon blood vessels and nerves we venture upon less firm ground.

The publication of Paltauf's well-known paper,[9] in 1889-90, opened a new chapter in the study of thymic deaths, and placed the subject upon a broader basis. Although others before him had suggested similar ideas, the credit is rightly assigned to Paltauf of having brought the subject of status lymphaticus into the field of practical medicine and surgery. He presented the picture of a general constitutional state which predisposes to sudden death from causes apparently inadequate, and in which hyperplasia of the thymus is no longer the dominant feature, but only one of a group of deviations from the normal. Nowadays the name "status lymphaticus" is widely used—to the medical man a name of dread, to the layman a term of mystery. Hardly a week passes in which it is not heard in coroners' courts, in connexion with deaths under anaesthetics, or after slight injuries or shocks.

It is not necessary to dwell here upon the details of the classical description, the pale pasty skin—no constant feature, by the way—the hyperplasia of the lymphatic structures of naso-pharynx and alimentary canal, the

somewhat enlarged spleen and thymus gland. Later observers have added fresh items to the list, some of which are of great importance, but the fundamental features remain unchanged.

Doubt has been thrown upon the very existence of status lymphaticus as a definite morbid state. In children it is often difficult to determine whether the diagnosis be justifiable in a particular case, for thymus and lymphatic structures alike are naturally conspicuous in children, and the latter readily become enlarged in response to various infections. He who seeks to be convinced should study cases of adults and older children, upon which Paltauf's description was chiefly based. The features which might be normal in a child are obviously abnormal when met with in an adult.

The liability of so many young people to sudden death from slight causes is obviously a matter of urgent practical importance, and few problems can make a stronger appeal to the clinical worker than that of the diagnosis of status lymphaticus, with reasonable certainty, during life.

It is obvious that not a few of the factors which go to make up the clinical picture are such as cannot be detected in the living patient. Such are the general enlargement of the intestinal follicles, the unduly small aorta, and the diminution of the chromaffin tissue, which may be the most important of all. Of the accessible signs, special stress may be laid upon the hyperplasia of the lymphatic tissues at the root of the tongue, which may be seen with the laryngoscope, and which is regarded by good observers as specially characteristic. Enlargement of the tonsils and adenoid vegetations are so common apart from status lymphaticus as to have little diagnostic value, and the same is true of slight enlargement of the lymphatic glands in the neck, axilla, and groins. But these conditions may help to strengthen a diagnosis based upon other signs. An increase of lymphocytes in the blood is of similar service, and if it can be shown that the thymus is abnormally large this affords evidence of considerable value.

The minor signs, which are described in detail by Wiesel,[10] and are discussed by Emerson[11] in a recent paper, are such as afford comparatively little help in children, however much they may facilitate the diagnosis in adult cases. Some, it is true, are of the nature of congenital malformations, but others are concerned with secondary sexual characters, such as scantiness of hair in various situations, feminine distribution of the pubic hair in males: and vice versa, feminine contours in the male, and genital hypoplasia—such anomalies, indeed, as we are learning to connect with lesions of glands of internal secretion.

The detection of thymic hyperplasia is no easy matter, especially in its minor degrees. Only when greatly enlarged will the gland present as a palpable tumour above the manubrium sterni. Percussion may reveal a much more extensive dullness than the normal triangle of which the base connects the sterno-clavicular joints, and of which the apex reaches downwards to the level of the third costal cartilages. Probably the most valuable indicator of hyperplasia is the thymic shadow thrown by the *x* rays, which rests upon the shadow of the heart. Mr. R. E. Humphry[12] regards as an additional sign, valuable in diagnosis, a lowering of the upper limit of the superficial cardiac dullness, in the absence of emphysema or other changes in the lungs which may account for it.

Careful descriptions of fatal cases, such as that given by Mr. Bellamy Gardner[13] a few years ago, of the death of a boy under an anaesthetic, should help materially towards the solution of the difficult problem of the reason why individuals with status lymphaticus are so liable to die suddenly.

In many cases death is so rapid and unexpected that time for observation is lacking. Often no medical man is present, and in the anaesthetic cases he is so fully occupied in the attempt to restore life that he has neither time nor equanimity for minute observation of the sequence of events.

It would appear that in some cases, such as have recently been recorded by Dr. Emrys Roberts,[14] breathing ceases whereas the heart continues to beat, but in others it seems clear that arrest of the heart beat is the initial event.

Wiesel, who first observed the reduction of chromaffin tissue in status lymphaticus, inclines to the view that a sudden fall of blood pressure, due to adrenalin defect, is the fatal condition. In cases with marked hyperplasia of the thymus, but no other signs, the loss of substance of the adrenal medulla is not observed, and Wiesel suggests that subdivision is needed into cases of status thymicus, thymo-lymphaticus and lymphaticus. He has also shown that status lymphaticus is usually present in Addison's disease, and not only in the primary, non-tuberculous cases. It may be that the condition of the adrenal medulla renders it an easy prey to the tubercle bacillus.

In exophthalmic goitre, too, status lymphaticus appears to play a part. That the thymus is often large is well-known, and an associated lymphatic state may explain the sudden deaths of patients with Graves's disease during and apart from the administration of anaesthetics.

The drift of opinion at the present day is towards regarding the abnormal constitutional state as a widespread defect of the organs of internal secretion, and there is much to be said for this view, but whereas some hold that the condition is inborn, others believe that it is also capable of being acquired. That status lymphaticus may be inherited some family histories show clearly.

In the cases in which the lymphatic structures are widely involved the enlargement of the thymus appears to be mainly due to increase of its leucocytic elements, and Wiesel makes the interesting suggestion that the hyperplasia of the lymphatic structures may represent an attempt to protect the weakened tissues from the infective agents to which they so readily fall victims.

The treatment of diseases of the thymus has hitherto been almost entirely directed to the relief of pressure caused by the enlarged gland. It is to be hoped that some who take part in the discussion will be able to speak of the methods and results of thymectomy and of the effects of irradiation by the *x* rays upon the enlarged gland. That the size of the thymus can be readily reduced by irradiation appears to be beyond doubt, and caution has been enjoined in exposing the thorax of a young infant to the *x* rays on this account. It is difficult to suppose that any treatment can be of avail for status lymphaticus as such, but if the fatalities which it entails are due to failure of internal secretions we may hope to do something to reduce its fatalities by the administration of adrenalin, pituitrin, or the active principles of other secretions. Perhaps some who are present will be able to relate experience of their use in threatened death under anaesthetics.

I am very conscious of the shortcomings of the sketch which I have attempted to give of the clinical aspects of the thymus gland. Although my time is exhausted, it has not been possible even to touch on many points, such as the rôle of the thymus in connexion with myasthenia gravis.

The whole subject is obscure, and paucity of facts does not always conduce to brevity of statement.

II.—ALEX. MACLENNAN, M.B., C.M.,

Visiting Surgeon, Royal Hospital for Sick Children; Assistant Surgeon, Western Infirmary, Glasgow.

THE TECHNIQUE OF THYMECTOMY, WITH REPORT OF EIGHT CASES.

SEVERAL facts as to thymectomy seem now clear:

1. As to the operation. Although when the gland is normal in size the removal of the thymus is a comparatively trivial operation easily and rapidly performed, yet when the gland is so enlarged as to occupy a considerable section of the anterior mediastinum, to cover part of the heart, and to overlap the pleurae, its successful removal becomes an operation of great difficulty and, indeed, often of impossibility. If the operation were persisted in its mortality might, indeed, exceed that of the disease.

2. As to the cases where the operation is advisable

considerable diversity of opinion still exists, because of the vagueness of our knowledge of the maladies known or supposed to be connected with the thymus. It has consequently not been possible to fix the indications for thymectomy with precision. But I may here remark that symptoms may be caused by a thymus normal in size.

In August, 1908, I described in the *Glasgow Medical Journal* an experimental investigation into the function of the thymus gland, and arrived at the following, among other, conclusions:

1. The gland is not essential to life or health.
2. The function of the gland is temporary.
3. The association between it and the thyroid is close, each tending to atrophy on the removal of the other.
4. In certain cases of exophthalmic goitre it was advised that the thymus should be removed before the thyroid.
5. The action of the enlarged thymus is not mechanical but physiological.

This investigation was begun in 1898, but the thymectomies about to be reported were mostly carried out in 1908. My search through the literature of the subject at the latter date failed to disclose the report of a case where the entire thymus had been removed in the human subject. At that date only incomplete removal or displacement of the gland (thymopexy) had been carried out by anyone. As a result of my experimental research several thymectomies were performed for a number of diseased conditions in children, and the technique employed by me was in large measure a result of the investigation I had carried on in removing the glands of animals. Indeed, without it, and in the absence of all records of the experience of others, the operation would not have been attempted at all. Chloroform was the anaesthetic used, and in only one case were difficulties experienced with the patient on this account. The steps of the operation for the removal of the thymus when normal in size or only moderately enlarged, are the following:

1. A short incision is made through the skin and subcutaneous tissue of the suprasternal fossa after the skin has been drawn downwards over the sternum; the incision should extend about 1 in., and have its lower end placed just over the upper part of the sternum.
2. The deep fascia, the sterno-hyoids, and the sterno-thyroids are raked apart by a pair of blunt, double-hooked retractors.
3. The cervical horns of the thymus will then appear under the sterno-thyroids. The loose capsule of the gland should be cleared from that part of the gland exposed. The left lobe should be picked up with dissecting forceps (sharp-pointed should not be used) and drawn out from beneath the sternum; a second pair of forceps grips the gland lower down as it becomes exposed, and by a hand-over-hand movement the left lobe is withdrawn from the capsule. It is occasionally necessary to free the capsule by a blunt-pointed instrument.
4. The right lobe is removed by the same manœuvre. It is my experience that when the left lobe is removed first there is more likelihood of the gland being got out entire.

The left pleura may be opened during the removal of the corresponding lobe, but the puncture of one cavity does not interfere unduly with the respiration.

Haemorrhage should not be troublesome, and indeed it is seldom that any vessels require ligation. Any large vessels appearing during the extraction of the gland should be ligatured at once while on the stretch and should not be allowed to retract within the thorax.

The operation is therefore an intracapsular enucleation.

5. Immediately the extirpation is completed the deep structures are sutured with fine catgut; before the last suture is tied the thorax should be compressed so as to expel as much air from the pleura or mediastinum as possible.
6. The skin is united by a few silkworm sutures.
7. A small pad of sterile gauze is then sealed in by rubber adhesive plaster.

Such, then, is the ordinary operation, which is trivial and safe, entailing practically no risks and causing no morbidity; the after-treatment is nil, so far as the wound is concerned. After the operation the patient should be put upon a mixture containing strophanthus and atropine, and the nurses or guardians be told to watch the child carefully for any recurrence of spasms. If a recurrence of the "fits" takes place, the patient should immediately be placed in the upright position. The neck should be free from clothing; bandages are of course absolutely contra-indicated.

Unfortunately every case is not so easily and safely managed. In some the gland is either too large or too adherent for removal by this method. Those who have conducted or been present at necropsies of cases dying of "status lymphaticus" may have observed that sometimes the association of the thymus with the great vessels and the serous coverings of the heart and lungs has been close so that it was difficult to strip the gland free from these structures without injuring them. In such cases better access to the gland is only possible if part of the sternum be divided or removed; the upper part of the sternum may be safely excised.*

If, in cases where the simple plan fails, the surgeon be not prepared for section of the sternum an incomplete extirpation results, and such an operation is bad practice. As there is no certain sign whereby such a condition of the thymus as has been mentioned can be diagnosed before operation the procedure should not be undertaken unless its completion is intended, and obviously a thymectomy ought not to be undertaken in the case of an outdoor patient. The cases operated upon may be briefly reported. All were carried out among out-patients by the method described without section of the sternum. The results were not favourable, so the operation was abandoned.

1. A. R., male, aged 16 months, was brought to the dispensary on account of crowing respiration, called "false croup." The thymus was removed entire (weight not noted) in January, 1908. The child gave trouble during the operation, and required artificial respiration, inflation of the lungs, etc. Three or four days after the operation the crowing ceased and it has never returned. The child, now 7½ years of age, was seen last month. During these years he had been in perfect health with the exception of the usual children's complaints. There was no sign of rickets; the spleen was not enlarged, nor was there any evidence of glandular enlargement. The scar was visible, having stretched with the general growth; it was quite movable.

2. D. M., male, aged 6 years, was brought to the dispensary on account of tibial curvature, shortness of stature, thickening of the joint ends of the bones, etc. The case was considered one of achondroplasia, though not a marked case. The child's mother was also stunted in appearance but not markedly so. The thymus was removed entire in March, 1908; it weighed 131 grains; microscopic examination did not reveal any abnormality. Recovery was uninterrupted but no effect followed the thymectomy. The child was frequently at the dispensary during the succeeding years on account of suppurating cervical glands, etc. Last month he was 4 ft. 1 in. in height. The legs were short and the arms long, reaching to within 1½ to 2½ in. from the upper edge of the patellae. His intelligence was normal. *X*-ray plates of the humerus and the leg bones did not show any special abnormality other than the curvature with expansion of the ends.

3. J. F., male, aged 10 months, attended the dispensary of the Western Infirmary on account of cyanosis and "fits," which were marked by the infant becoming black in the face and stiff, with more or less complete loss of consciousness. The diagnosis arrived at was that the child presented the condition of status lymphaticus. The child was still being breast-fed; during the examination he had a slight fit. In March, 1908, the thymus was removed entire, its weight being 105 grains; microscopic examination showed normal histology. The anaesthetic was well borne though he became slightly dusky; the child was not upset by the operation. After it the fits continued as before, there being no effect from the removal of the gland. About one week later the child died in one of its seizures. No *post-mortem* examination was allowed. The wound did not show any sign of sepsis.

4. M. K., female, aged 1 month, was brought to the dispensary on account of having "kinks" since birth. The condition was one of laryngismus stridulus. On March 31st an attempt was made to remove the thymus. The left lobe could not be found. Part of the right lobe only was removed, it weighed 21 grains. On April 5th the child had a "temper" fit, and did not come out of it. On the 6th a *post-mortem* examination was made. The wound was healthy; there was no haematoma. The thymus left was removed: it weighed 96 grains, and was spread out in the lower anterior mediastinum. It was only accessible after removal of a large part of the sternum. The gland was adherent to the innominate vein, and was very red and turgid. The left heart was normal, the right flabby. There was neither stenosis nor flattening of the trachea. The thyroid was normal.

5. W. M., male, aged 7 months, was brought to the dispensary on account of his having "kinks." On October 3rd, 1908, an attempt to remove the thymus was made; 23½ grains were removed from the left lobe, which was all that could be induced to come from the thorax; microscopic examination demonstrated a normal structure. On the 13th the fits were distinctly less in number and severity. On November 26th they were on the increase, and on December 1st the child died while in one of them. On December 2nd a *post-mortem* examination was made. The remaining thymus weighed 218 grains; it extended over both pleurae and pericardium, being somewhat adherent to the great vessels. The thyroid was normal, so were the lungs. The left heart was hypertrophied; the right

* In a recent case of attempted excision of a cancer of the gullet I removed part of the involuted thymus (which sections showed to consist principally of fat). The sternum had been removed by disarticulating the clavicles and dividing the costal cartilages of the first ribs. The left pleura was accidentally opened. No objectionable symptoms followed the operation.

was thin, pale, and flabby. The spleen was enlarged; the bowels were distended. The head of the pancreas was hard and dense. The adenoid tissue was increased about the glottis.

6. A. H., male, aged 15 months, was brought to the dispensary on account of crowing respirations of three months' duration. During an attack he became almost unconscious; cyanosis was not present, but the child became rather white about the lips. About twenty to forty fits occurred daily; he was never a day without one. On February 16th, 1909, 90 grains of a very firm thymus were removed. Ten days later the fits were reported more frequent and severe. On March 2nd a well marked tetany was present. The child was lost sight of, but on inquiry was found to have died shortly after being last seen at the clinic.

7. J. E., male, aged 10 months, had 61 grains of the thymus removed on account of the failure of medical treatment to alleviate "kinks." The child recovered, but has not been traced. The left pleura was opened during the extraction.

8. Another case of well marked laryngismus stridulus was operated upon with success, but all notes of the case have disappeared.

The following cases might be referred to shortly:

B. B., female, aged 12 months, was brought to the dispensary on account of "spasm of the windpipe," or "false croup," since birth. The child if "crossed," and if allowed to cry much, became cyanosed and semi-conscious. No operation was done. Six months later she took measles and whooping-cough; the spasms ceased from this time. When 3 years of age the child died with symptoms of tuberculous meningitis.

Another similar case was examined with the intratracheal speculum; the trachea was neither stenosed nor flattened. The patient died next day in a "kink."

From these cases, though few in number, the bad results of incomplete removal of the gland are very apparent. Further, the impossibility of removing the whole gland in some cases without a big and risky operation is demonstrated. No case died on account of the operation, though 4 of the 8 did in spite of it.

Since these operations were done many cases suggesting a thymic origin have been seen by me, but in none has it been deemed necessary to operate.

Assistant Surgeon, Edinburgh Royal Infirmary; Assistant Surgeon, Leith Hospital.

APPENDICITIS AND STATUS LYMPHATICUS.

The constitutional condition known as status lymphaticus and characterized by a persistent or enlarged thymus gland and hyperplasia of the lymphoid tissue throughout the body is of supreme interest to surgeons in that it predisposes to sudden death during anaesthesia, particularly chloroform anaesthesia. That the subjects of status lymphaticus may show a peculiar susceptibility to fulminant acute infections has been suggested by McNeil and McGowan[1] as a result of their observations on cases of fulminant pneumonia occurring in an industrial school. Dauf[3] also has noted the association of status lymphaticus with rapidly fatal diphtheria in young children, and Emerson,[4] in a series of necropsies on adult males, was struck by the frequency of milder degrees of status lymphaticus associated with death from various infective conditions.

In fulminant abdominal infections it has been customary to regard the rapidly fatal issue as being due to a peculiar virulence in the invading bacteria, and less regard has been had to a possible constitutional susceptibility in the host. I would submit that an acute infective abdominal condition supervening in a subject of status lymphaticus entails two special risks—first, that of an abnormally low resistance to the infection, and secondly, the liability to sudden death under the anaesthetic should surgical intervention be required. The following three fatal cases of acute abdominal disease met with in the Edinburgh Royal Infirmary, which I had the opportunity to investigate *post mortem*, illustrate, I believe, the reality of the risks referred to. The first case was under my own care, the remaining two under that of two other members of the surgical staff, to whom my thanks are due for permission to use their notes.

Case I.

Janet H., aged 7, had been in good health except for occasional incontinence of urine, for which she had received medical treatment. On November 17th, 1913, she went to bed at 9 p.m. apparently in the best of health, having eaten a good supper. At 1 a.m. on November 18th she was wakened with acute pain in the lower part of the abdomen, and vomited. Heat was applied, but as the pain continued the doctor was sent for. At 4 a.m. the doctor found her looking ill and suffering acute abdominal pain. Her temperature was 100° F., pulse 100, and there was marked tenderness and rigidity in the lower part of the abdomen. Diagnosing appendicitis, he made arrangements for her immediate removal to hospital.

State on Admission.—The patient was admitted to the Edinburgh Royal Infirmary at 6 a.m. on November 18th. It was noted that she was a stout, well-nourished child, particularly well developed for her age. Her face was pale and drawn, and she was evidently in acute pain; temperature 100.5°, pulse 120. The abdomen was tender and rigid all over, but especially so in the right lower quadrant.

Progress.—Operation was decided on, and was carried out at 7 a.m.—that is, six hours after the onset of the first symptoms. On opening the peritoneum under ethyl chloride and ether some very slightly turbid serous fluid escaped, some of which was kept for microscopic examination. The appendix was found slightly swollen and much congested, and in its middle third there was a purplish area covered with recent lymph. It was removed, and the abdomen was closed without drainage. On slitting open the appendix the mucosa was seen to be swollen and oedematous, and a small ulcer was found at the point where the lymph and purplish discoloration was seen from the outside. There was no gangrene or perforation.

Result.—On examining a film of the peritoneal fluid the grave nature of the case was at once realized, for it was seen that the fluid was swarming with diplococci, and there was little if any cellular reaction. It was obvious that the child could only last for a matter of hours. In spite of saline infusions and stimulants the pulse rose rapidly, and by 2 p.m. the child appeared moribund, being of an ashen hue and semi-conscious. She never rallied, and died shortly after midnight, that is, within twenty-four hours of the onset of symptoms.

Post mortem it was again noted that the child was plump and unusually well developed for 7 years. The abdomen contained turbid serous fluid and flakes of lymph; films of the fluid showed few cells and swarms of diplococci. On culture the organism was somewhat difficult to identify. One film from the peritoneal fluid showed the diplococcus was encapsuled. Injection into a mouse was negative. The organism was probably the pneumococcus. There was general enlargement of the mesenteric lymph glands. The thymus was very large, extending down in front of the pericardium and measuring 4 in. by 2½ in. The tonsils were large, there were marked adenoids, the lymphatic tissue at the base of the tongue stood out prominently. The lymph follicles in the pyloric end of the stomach and first part of the duodenum were of remarkable size and in the ileum the Peyer's patches and solitary glands were enlarged. The Malpighian corpuscles in the spleen stood out from the pulp, which was semi-diffluent. The lungs were acutely congested, and the kidneys and liver showed cloudy swelling.

Case II.

Marion S., aged 13, a boarder in an orphan school, was suddenly seized with abdominal pain at 8 a.m. on January 30th, 1914. She vomited several times after the onset of pain, which continued severe in spite of hot applications. She was seen by a doctor at 8.30 a.m., and again two hours later in consultation with a surgeon. Appendicitis was diagnosed, and she was admitted to the Edinburgh Royal Infirmary at 2.30 p.m.

State on Admission.—It was noted that she was a pale, plump, and unusually well-developed girl for her age. She looked ill, evidently suffering severe pain, temperature 100° F., pulse 118. There was rigidity and tenderness over both lower quadrants of the abdomen, particularly over the right.

Progress.—An operation was undertaken at 4 p.m., eight hours after the onset of symptoms. On opening the peritoneum under ether anaesthesia some slightly turbid serous fluid escaped and the appendix presented at once. It was congested and distended in its distal two-thirds beyond a constriction in the proximal third. There was no evidence of gangrene, however, and no perforation. The appendix was removed and, more as a precaution than because it was deemed necessary, a pelvic drain was inserted. From the findings at operation it was thought that the progress of the case would be altogether favourable. The child became progressively worse, however, the pulse rate rising steadily, the temperature keeping over 100°, and she gradually sank and died with all the signs of profound septic poisoning thirty-four hours after the operation and forty-two hours after the onset of symptoms.

Necropsy.—A well nourished and remarkably well developed child for her age. There was a generalized plastic peritonitis and in the pelvis a small amount of sero-purulent fluid but no abscess anywhere. The mesenteric glands were all enlarged and stood out prominently, the lymph follicles in the pyloric end of the stomach and first part of the duodenum were very prominent, as also were the Peyer's patches and solitary glands at the lower end of the ileum. The liver showed well marked cloudy swelling. The spleen was enlarged and soft and on section the pulp was diffluent, and the Malpighian corpuscles were large and swollen. The kidneys showed marked cloudy swelling. The thymus gland was abnormally large, 3½ in. in length by 2½ in. in breadth, and extended downwards over the pericardium. The right side of the heart was slightly dilated, and the cardiac muscle soft and friable. The bronchial glands were enlarged, the lungs acutely congested. Tonsils were large and the lymph papillae at the base of the tongue stood out clearly. Films from the peritoneal exudate showed numerous Gram-positive cocci in short chains and cultures gave pure growth of streptococcus.

These two cases illustrate a type of acute appendicular disease fortunately rare, where early operation with removal of the inflamed appendix, before gross changes had occurred, failed to influence to any degree the progress of the infection. Either the bacteria in each case must have been of greatly exalted virulence or the resistance of the patient must have been abnormally low. Of the virulence of the organism it is impossible to judge, as experimental injection into animals gives no reliable index. The one feature common to both cases was that both children were the subjects of status lymphaticus, and I believe that the lowered resistance to infection associated with this morbid diathesis was the most potent factor in determining the fulminant nature of the disease in each case.

The third case illustrates the other risk associated with the development of an acute abdominal condition in a subject of status lymphaticus.

CASE III.

Peter F., aged 13, was admitted to the Edinburgh Royal Infirmary on November 8th, 1913, suffering from pain in the lower part of the abdomen and vomiting. The pain had commenced two days previously, and though never very severe, had continued with slight intermissions until his removal to hospital, when it had to some extent subsided. The child had vomited on several occasions on both days previous to admission.

State on Examination.—He was seen to be a well nourished and well developed boy and was not looking seriously ill; pulse 68, temperature 98.4° F. The abdomen was not distended, moved with respiration, and there was very little rigidity in any part, but very definite pain and tenderness in the right iliac region.

Progress.—On opening the peritoneum under chloroform, followed by "open ether," through a gridiron incision some clear serous fluid escaped, and a slightly congested and swollen appendix was removed. The lymphatic glands in the ileo-caecal angle were seen to be considerably enlarged, and from one of them an adhesion extended across the last coil of ileum, slightly constricting it. This adhesion was divided and the abdominal wound was closed without drainage. As the skin suture was being inserted the boy stopped breathing. No anaesthetic was being given at the time, as the ether had been stopped two minutes before. The boy had a nasty grey colour, but the heart continued beating for a few minutes after the respirations had ceased. The head was lowered, artificial respiration carried out, and stimulants administered hypodermically, but without avail. Cardiac massage through an abdominal incision was also fruitless.

Post mortem there were found all the evidences of a pronounced case of status lymphaticus. The thymus was very large, measuring 4 in. vertically and 2½ in. transversely. The tonsils were large, the lymphoid tissue at the base of the tongue greatly increased in amount. In the stomach the lymph follicles stood out prominently, as also in the first part of the duodenum. There was a chronic duodenal ulcer on the anterior wall ½ in. from the pylorus and the scar of a healed ulcer on the posterior wall just opposite. The mesenteric glands were all enlarged, the Peyer's patches and solitary follicles in the ileum very prominent, and the Malpighian corpuscles in the spleen were of abnormal size. The other organs appeared healthy.

This case illustrated the immediate risk which operation under general anaesthesia entails in such cases, and especially one of the dangers associated with the use of chloroform in acute abdominal cases in children. Although during the greater part of the anaesthesia ether had been used, the chloroform given to induce anaesthesia cannot, in determining the cause of the fatal issue, be exculpated in the light of experience with other cases.

CONCLUSIONS.

1. The subjects of status lymphaticus would appear to have abnormally low resistance to acute abdominal infections.

2. Chloroform should never be used to induce anaesthesia in acute abdominal infections in children.

Extra Physician, Sick Children's Hospital, Edinburgh.

(Abridged.)

ASSOCIATION OF FULMINANT PNEUMONIA AND SCROFULA WITH STATUS LYMPHATICUS.

IT need not be asserted that all cases of sudden death in young children are cases of status lymphaticus: but it is probable that the majority are. In Paltauf's 127 cases of sudden death out of 225 autopsies on children aged from 0 to 4 years, the thymus was stated to be enlarged in every one of them (the weight was not given), and the important observation was also made that capillary bronchitis or commencing bronchopneumonia was also present in every case. We may, therefore, describe these cases of sudden death in infants as cases of fulminant bronchitis and bronchopneumonia associated with thymo-lymphatic hyperplasia. Paltauf himself refused to describe these as cases of status lymphaticus, and he is followed in this excision by very many subsequent writers—Hart, Kolisko, Wiesel. I would submit, however, that not only are these cases of sudden death in infants examples of fulminant bronchitis, fulminant gastro-enteritis or bronchopneumonia, but that their fulminant character is due to the presence of abnormal constitution one of the marks of which is thymo-lymphatic hyperplasia. Lately I had the opportunity of examining tissues from 13 infants who had died suddenly (11 of them being found dead in bed). The lungs were examined microscopically in 8, and all showed unmistakable signs of bronchitis and commencing bronchopneumonia. There was also evidence of thymo-lymphatic hyperplasia in a large proportion of the cases.

Fulminant Bronchopneumonia.

Cases of fulminant pneumonia in older children are comparatively rare. In certain industrial schools throughout Great Britain cases of acutely fatal illness, accompanied by others non-fatal but of similar clinical type, have occurred from time to time, and one such outbreak was investigated by Dr. J. P. McGowan and myself. It is reported at length in a Blue Book published by the Scottish Office, but our conclusions may be briefly indicated. All the cases were examples of peculiar distorted pneumonia, assuming three clinical types—fulminant in the acutely fatal group; irregular, and apparently lobular in a non-fatal group labelled "pneumonia" because of the presence of physical signs of consolidation of the lung; and latent or abortive in a third large group, in which the physical signs of pneumonia were absent but in which the clinical symptoms closely resembled those of the other two groups. In the group of fatal cases not only did the *post-mortem* examinations show that pneumonia, commencing or established, was present, and that the pneumonia was pneumococcal (by bacteriological tests); they also showed in most of the cases the classical marks of status lymphaticus. We concluded that the fulminant pneumonias owed their rapidly fatal character to the coexistence of this condition, and that the irregular features of the non-fatal pneumonias were likewise due to its presence but in lesser degree. A few notes of these remarkable cases of acutely fatal illness may be given.

J. M., aged 14 years, was found dead in bed on the morning of June 18th, 1901, with froth and blood about the mouth and nostrils. He went to bed the night before apparently well. From the fact that this case of sudden death occurred among other cases of fulminant pneumonia, there seems little doubt that it was also a case of fulminant pneumonia, death occurring during sleep, as in the group of little infants already referred to. Another case of the same kind occurred in this school, and in the records of other industrial schools subject to these outbreaks of illness a few more cases of boys found dead in bed are recorded. Apart from these institutions, I have not been able to find records of similar cases in medical literature.

The following case is of the more usual type of acutely fatal illness in these schools:

J. W., aged 11½ years, seemed a strong healthy boy, and was of good colour. On April 29th, 1913, he rose at 6 a.m., feeling quite well. At 7.40 a.m. he complained of headache and vomited; but, on getting some bread and butter, recovered and joined his companions at play. Shortly after 9 a.m., headache and nausea returned, and, on being put to bed, his temperature was 102° F. He vomited "some yellow and green stuff." He was in a half-stupid condition, and, though he answered questions, he did so slowly and with effort; he seemed as if he wanted to sleep. This sleepy condition gradually deepened into unconsciousness, and he died at 11 a.m., only three hours after the first onset of his symptoms.

The *post-mortem* examination may be summarized as follows: Lungs: Intense congestion, but no definite palpable consolidation; yet microscopically, marked bronchiolitis and pulmonary catarrh and congestion, and in one area definite pulmonary consolidation. Extreme hyperplasia of the lymphoid tissues at the base of the tongue, stomach, duodenum, and lower end of ileum. Thymus, not enlarged (weight 11 grams). Pneumococci were cultivated from the lungs. Bacteriological examination of the brain and cerebro-spinal fluid showed in this case, as in others similar in which this examination was made, an absence of the specific organisms of acute meningitis.

From the medical record of the school in which this case occurred it appeared that between 1900 and 1911 there occurred 20 cases of fulminant fatal pneumonia, 51 of irregular pneumonia, and 175 of abortive pneumonia. These illnesses took place in outbreaks or epidemics. No evidence was obtained of their being contagious. Our explanation of the problem presented by these outbreaks was twofold: First, that the boys of this school had acquired through some unhealthy condition of environment the morbid constitution, status lymphaticus. Secondly, that when attacked by pneumonia—and they were probably predisposed to it—they took the disease in these irregular distorted forms, a few succumbing quickly to the fulminant type.

The interest of these fulminant institutional pneumonias is that they seem to reproduce in boys long past the age of infancy the peculiar features of fulminant bronchopneumonia in infants: the rapidity of the fatal issue—in a few deaths occurring during the night, as in infants—the pathological character of a bronchopneumonia peculiarly common and characteristic in infants and young children, and the association of thymo-lymphatic hyperplasia.

Scrofula and Status Lymphaticus.

The term "scrofula" or "struma," as applied to a peculiar type of tuberculous infection, was almost submerged for a number of years following the discovery of the tubercle bacillus, but has lately received attention as denoting a separate clinical entity.

The condition of scrofula may be summarized as follows: It is a constitutional disorder, incident to childhood, and manifests itself in one, several, or all of the following characters: Glandular swellings of the neck (nearly always tuberculous); tuberculous disease of bones and joints; peculiar eruptions of the skin (the tuberculides); obstinate and relapsing catarrhs of the eyes, nose, mouth, throat, lungs, and intestines; weeping eczema of the skin and scalp. There is generally a definite configuration or habit of body, characterized by stunted growth of the trunk and limbs producing a relatively large size of head; a fair amount of superficial fat; overgrowth of the hair as seen in the thickly pencilled eyebrows, the long eyelashes, and the increase of the downy hair (lanugo) on the general skin surface, but especially on the cheeks and between the shoulder-blades.

Modern writers (Escherich, Moro, Heubner, Cornet) have revived the old doctrines of a morbid constitution or diathesis in connexion with scrofula. And under various terms this constitutional soil on which scrofulous lesions grow is that of status lymphaticus as defined by Paltauf. Escherich has also noted that in scrofula the local cutaneous reactions to tuberculin are unusually severe. This is an important observation, and has been confirmed by other writers. It means that in scrofula the local reactions to tuberculin artificially applied, and also the reactions of the tissues at the various tuberculous foci, are abnormally intense.

This intensity is illustrated by the following case of scrofulodermia:

> The patient was a little girl, aged 2 years and 3 months. The skin of the scalp, face, legs, and lower part of abdomen was covered with pustules and the livid scars of pustules—a tuberculide of unusually severe character. There was severe blepharitis, conjunctivitis, and keratitis of both eyes, with extreme photophobia; profuse rhinorrhoea; an angry catarrh of the mucous membrane of the mouth, the lips being deeply fissured by raw sores. There was tuberculous dactylitis of the left median finger, but no other evident tuberculous lesion.
>
> The cutaneous tuberculin reaction, both to human and bovine tuberculin, was of acutely necrotic character, the whole thickness of skin rapidly sloughing through.

We have just seen that both in ancient and modern writings upon scrofula great importance is attributed to the part played by status lymphaticus. But status lymphaticus as described by Paltauf is extremely difficult to recognize during life, and, in fact, can only be established by a *post-mortem* examination. Now scrofula, although often a serious and prolonged disease, is not often a fatal one, and therefore the *post-mortem* evidence which is essential to prove the association of status lymphaticus with scrofula is lacking; and this connexion, which is so frequently alleged by writers on scrofula, is too often a mere statement unsupported by evidence. I wish to submit some observations which I hope will be considered to supply this necessary evidence.

In the industrial school already mentioned, the cutaneous tuberculin reaction, tested on every boy, was found positive in 59 per cent. That is perhaps not a remarkable percentage, but what was notable was the unusual severity of the reactions. We have seen that Escherich and others have remarked upon the severity of the tuberculin reactions in scrofula. Now in the five boys showing the highest degree of reaction, two showed large masses of swollen glands in the neck and the scars of old sinuses, two showed chronic blepharitis and conjunctivitis of strumous or scrofulous type, while the fifth showed nothing more than a chronic nasal discharge and a slightly injected conjunctiva. But, in addition, chronic inflammatory conditions of the conjunctiva and chronic nasal discharge were very prevalent throughout the school. That is to say, scrofula of a mild type was prevalent. Finally, in the bodies of the boys dying of fulminant pneumonia, the anatomical marks of status lymphaticus were clearly shown. In this school, therefore, there seems to be direct evidence of this often stated connexion between scrofula and the morbid constitution, status lymphaticus. There was clinical evidence of scrofula, there was *post-mortem* evidence of status lymphaticus, and there was experimental evidence by the cutaneous test of intense tuberculin reactions.

This one school, therefore, furnished examples of abnormal reactions of the body to the two common bacterial infections of pneumonia and tuberculosis. In both cases the abnormal character of the reaction was in the direction of increased intensity; or if a current phrase may be used, there was hypersensitiveness of reaction.

The further remarkable circumstance that these abnormal intensified types of illness were both epidemic and endemic in their character need not be dwelt upon. It does not seem to affect the main point that in childhood and infancy fulminant types of pneumonia, and fulminant types of tuberculosis (scrofula), whether sporadic or endemic, are associated with, and seem to depend upon, the presence of the abnormal constitution, status lymphaticus.

Fulminant Types of Other Illnesses.

It seems probable that fulminant types of other bacterial infection may be explained in the same way. Thus McGowan and I found an enlarged thymus in a case of fulminant or toxic scarlet fever, the patient, a boy aged 10 years, dying in twenty-four hours from the onset of symptoms. Dauf, in a series of cases of rapidly fatal diphtheria, has noted on *post-mortem* examination a high degree of status lymphaticus. The same association of conditions may very well be found in fulminant types of measles, small-pox, and other bacterial infections. But the subject has a wider scope than that of bacterial infections, and seems to include the abnormal reactions that follow the parenteral introduction into the body of a great variety of non-bacterial protein substances. The violent reactions produced in certain individuals by insect stings, pollen grains, various food substances, animal serums, and known as anaphylactic phenomena, are connected in some way with this same mysterious perversion of the constitution, status lymphaticus. The evidence of that is that in some of the rare fatal cases of clinical anaphylaxis, the condition of status lymphaticus has been found on *post-mortem* examination.

[Dr. McNeil devoted the remainder of his paper to a consideration of the probable nature of "status lymphaticus."]

DISCUSSION.

Dr. Hugh Thursfield (London) said that after careful consideration of the results of thymectomy for thymic asthma tabulated by Parker and others, he had been driven to conclude that they contraindicated operation. The mortality was high. From an experience of his own the speaker was inclined to attribute thymic dyspnoea rather to coexistence of enlargement of the neck glands than to the enlargement of the thymus. Furthermore, thymectomy had quite often failed to relieve the dyspnoea. In diagnosis he attached importance to careful percussion over the manubrium, and to a history of sudden pallor.

Dr. D. B. Lees (London) thought that what was most urgently required was a careful histological examination

of the cardiac muscular fibre, such as had been carried out in the rheumatic heart by Dr. Carey Coombs of Bristol. In every case of sudden death, both in adults and in children, a minute and detailed examination of the cardiac muscular fibre by the most recent methods was imperatively necessary. The frequency of occurrence of these distressing cases of sudden death in young children after operations might, he thought, be materially diminished if the precise size of the left ventricle and the amount of dullness over the uppermost part of the sternum were carefully determined by accurate percussion. The interesting cases of appendicitis which had been mentioned as indicating that one cause of death in the "status lymphaticus" was a toxaemic infection led him to draw attention to the very important observations of Drs. Poynton and Paine, who experimentally had obtained ulceration of the appendix by intravenous injection of a culture of a diplococcus obtained from a case of tonsillitis. They had also obtained a pure culture of a diplococcus by allowing slowly to drain an appendix removed by operation.

Dr. FREDERICK LANGMEAD said that he was sceptical as to the presence of any abnormal condition in a very large proportion of the cases which had been recorded as examples of status lymphaticus. His scepticism arose in great part from the frequency with which he had found all the phenomena from which a diagnosis of status lymphaticus was usually made, in children who had died suddenly for sufficient reasons—such as accidents. If observations were made on the amount of lymphatic tissue and on the size of the thymus in a sufficient number of cases of accountable deaths in children previously in good health and taking an ample diet almost to the moment of death, it would be found, he thought, that the amount of lymphatic tissue, which led so often to the diagnosis of lymphatism, was really the normal. He did not refer, of course, to those rare instances in which the thymus was of quite unusual size, perhaps equalling in dimensions the heart. It would be well, perhaps, to mark time, awaiting a fuller knowledge of the normal lymphatic tissue before multiplying the recorded instances of this condition. The matter had become a very serious and important one, because the term was being used daily to explain unexpected deaths, and was also playing a considerable part in medico-legal work. Adopting this attitude, he could not but look with critical eyes on the observations of some of those who had taken part in the discussion. The cases which Dr. McNeil had described were those of children who had died from a very fatal form of bronchopneumonia. It might be that the state of the lymphatic tissue which he found was the normal one, for death had occurred for quite sufficient reason. It was well known that epidemic pneumonia was a fulminating and very fatal disease. The frequency with which Dr. McNeil had found evidence of lymphatism among the children of the school which he had investigated was itself either an indication that it was a very common condition, and scarcely to be avoided in deciding upon operations or other procedures, or that such evidences were not signs of an abnormal condition. The same argument might be applied to the cases of fatal appendicitis described by Mr. Wilkie. It was going too far to say because an unusual amount of lymphatic tissue was found *post mortem* that therein lay the explanation of the virulence of the infection, or the rapidity with which the patients succumbed to it. In those cases also death occurred rapidly in patients previously well, and it might be that the lymphatic tissue seen *post mortem* was nearer the normal amount than one usually had an opportunity of finding. If the pathological diagnosis of lymphatism were accepted too readily, the real but less obvious cause of death in many fatal cases might be overlooked.

Dr. LEONARD FINDLAY (Glasgow) thought it too soon to say that disease of the thymus gland was responsible for spontaneous rickets. Nordmann held that so long as the thymectomized animals received a sufficiency of exercise and a suitable diet, no osseous changes resulted, and the speaker had been successful in inducing changes in the bones identical, both macroscopically and microscopically, with those found in human rickets simply by depriving animals of exercise. It should be remembered, too, that in human rickets the thymus gland was usually found hypertrophied, and in the speaker's own experimental animals the average weight of the thymus was 6.05 grams in comparison with 6.5 grams in the control animals. Again, it had been shown from metabolism experiments that in thymectomy there was, as in rickets, an increased calcium output. This, however, occurred through the urine, as in starvation and diabetes; whereas in rickets less calcium than normal was excreted by the urine, but an excess by the faeces.

SECTION OF MEDICINE.

F. J. SMITH, M.D., F.R.C.P., President.

DISCUSSION ON HEADACHE, ITS CAUSES AND TREATMENT.

OPENING PAPER.

By HARRY CAMPBELL, M.D., F.R.C.P.Lond.

THE term "headache" is used somewhat vaguely to indicate pain, for the most part diffused, felt somewhere in the region of the brain-case (cranium).* There is some difficulty in defining the lower boundary of the headache area. Are we to make it correspond to the shell of bone immediately underlying the basal dura, or shall the entire thickness of basal bone, with the contained ethmoidal, sphenoidal, and auditory cavities be embraced in the headache area? (Figs. 1 and 2.) If the frontal sinuses are to be included in it, why not, it may be asked, these other cavities? To me it seems they ought to be included. I shall accordingly define headache as pain felt anywhere in the region within or above the cranial base, including the cavities contained within the latter. This region I shall speak of as the "cephalic region," and the structures which it comprises as the "cephalic structures."

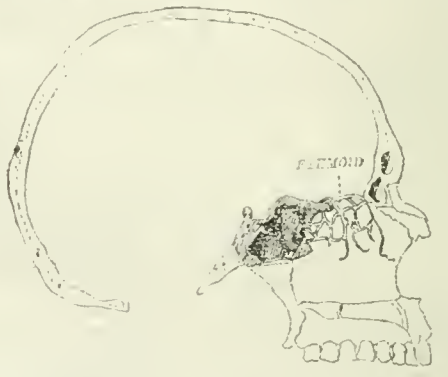

Fig. 1.—Shows the close relation of the frontal, ethmoidal, and sphenoidal sinuses to the cerebral membranes. The ethmoidal sinuses are diagrammatically represented.

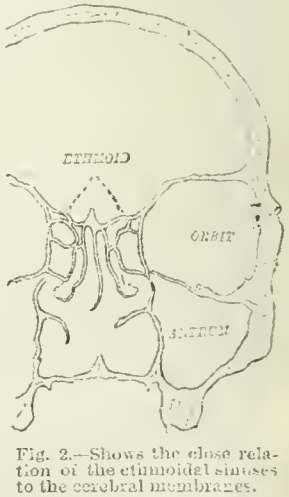

Fig. 2.—Shows the close relation of the ethmoidal sinuses to the cerebral membranes.

The cephalic structures comprise:

(*a*) The cranial contents, consisting of the brain, its membranes, and the intracranial vessels and nerves at the base of the brain.

(*b*) The bony brain-case, with its contained cavities—frontal, ethmoidal, sphenoidal, auditory.

(*c*) The soft structures enveloping the cranial vault,† and that part of the occipital base which is posterior to the foramen magnum—that is, the pericranium, the frontalis, occipitalis,

* In modern anatomical language the term "cranium" signifies the brain-case, the term "skull" signifying the cranium together with the facial bones.

† By "cranial vault" I understand the roof and lateral walls of the cranium.

and the intervening "cranial aponeurosis" (roughly corresponding to the vertex); the temporal muscles and their fasciae, the thick mass of muscles and fasciae in the occipital region; and, finally, the skin and subcutaneous tissues constituting the frontal and the hairy scalp.

All these tissues, save the brain tissue proper, are supplied with sensory nerves, and, with this exception, are therefore all endowed with sensibility; but while the brain tissue is insensitive, the fact that sympathetic nerves accompany the arteries of the brain suggests that these vessels are capable of being painfully affected.

It is noteworthy that the dura mater, which is richly supplied with nerves, gives off extensive processes (falx cerebri, etc.), into the cranial cavity, and also that the pia penetrates into the brain in the form of the vela interposita and choroid plexuses. Hence deep-seated intracranial disease (for example, tumour) may give rise to headache by directly implicating the meninges.

The Varieties of Cephalic Sensibility.

The sensitive cephalic structures are endowed with the same kind of sensibility as similar structures—serous membranes, bone, muscle, aponeurosis, skin, and subcutaneous tissues—in other regions. As in the case of bone in general, the cranium is insensitive to the trephine.

The pain of headache may affect any or all of the sensitive cephalic structures, though it is rarely possible to locate it definitely in any one of them. It may display all the variations of quality characterizing pain felt elsewhere. Headache does not, however, always consist of pain pure and simple. It is often associated with other morbid sensations—dysaesthesiae, as we may call them—so intimately, indeed, that it may not be possible for the patient to say how much of what he calls his head *ache* is genuine pain and how much is dysaesthesia.

The cephalic dysaesthesiae occur quite commonly independently of actual headache, and may cause as much distress as or even greater distress than it. Their favourite seat is the vertex. As in the case of headache, it is only exceptionally that the dysaesthesia can be referred to any definite cephalic structure.

Sensations of Pressure.—These are very common. They probably pertain to the pressure sensibility of the scalp and the underlying tissues. Most frequently a feeling of weight on the vertex is complained of; or there may be a sensation as of a cord or "iron band" round the head, or as if "the head were encased in a tight-fitting cap."

Heaviness of the Head.—The entire head may feel heavy, the patient complaining, for example, that he feels "top-heavy." This is probably in the main a muscular sensation. Less frequently the head feels unduly light—"as light as a cork," as one patient put it. Possibly there may be a vestibular element in this sensation.

Sensations of Heat.—Sensations of heat (for example, burning, scalding), doubtless in the main cutaneous, are quite common.

Sensations of Cold.—These are less common.

Pruritus.—Sensations of "crawling," "creeping," in the scalp, or "itching," occur independently of any disease of the scalp or external irritation. They are manifestly cutaneous sensations. They are sometimes so severe as to make the patient feel he could "tear his head to pieces." These violent forms are most frequently observed in patients who are much run down in health.

Sensations of Numbness.—This sensation, and those of "pins and needles," are mainly cutaneous and quite common in their occurrence.

Sensations of Bursting.—It is not uncommon for a patient to complain of a bursting sensation, "as if the head were going to burst." Doubtless this is very largely an extracranial sensation due to vascular turgescence.

Giddiness and Allied Sensations.—Headache is often associated with giddiness, not only with definite vertigo, which is a vestibular sensation, but with allied sensations of a less definite character expressed by such terms as "dizziness," "mental confusion," "bewilderment," a feeling as if the sufferer were "going out of his mind." It is not at present possible to make a satisfactory classification of these morbid sensations, nor to say to what structures they more particularly pertain. Probably many of them contain a vestibular element.

Tenderness of the Scalp.—This is so frequent an accompaniment of headache as to require some mention in this place. It occasionally happens that a local tenderness of the scalp marks the site of an intracranial lesion—for example, tumour—but much more frequently it is either a transient reflex phenomenon similar to that observed on the body wall in visceral disease, or the result of effusion into the extracranial tissues (as happens in "rheumatic" headache). In either case it may recur independently of headache. It is very common in women at the climacteric, when the tenderness is often extreme, the patient complaining, for example, that "the slightest contact of the hairpin causes pain," that "the head feels as if it had been bruised," or as "if the hair had been pulled out."

The Cortical Centres of Cephalic Sensibility.

The cephalic structures are represented, as regards their sensibility, in a limited portion of the cerebral cortex, situated at the inferior extremity of the posterior central gyrus (Fig. 3). All the cephalic sensations, normal and morbid (except the vestibular), rise into being in connexion with this centre, on one or other side. The vestibular centre has not yet been located with certainty. One would expect it to be in close association with the auditory centre.

Fig. 3.—The shaded area marks the region of the centre for cephalic sensibility.

Why Headache is so Common.

Of all the pains from which man suffers, the *dolor capitis* is the most common, the next most common being, perhaps, *dolor dorsi* of women. How are we to explain this so frequent painful excitation of the cephalic sensory centres? There are, I suggest, four main reasons for it.

1. Certain of the cephalic structures are exposed with unusual frequency to painful stimuli. Thus, among the poor, *Pediculi capitis* are a common cause of headache. In women the mere weight of the hair, or wearing it in a way which leads to undue traction upon the scalp, may help to cause headache. A heavy hard-rimmed hat, by compressing the nerves of the scalp against the rigid cranium, may have the same effect. Then, again, the scalp and the underlying muscles and fasciae—notably the large fibro-muscular mass in the occipital region—are frequently the seat of effusions which may give rise to soreness and pain. In this connexion the structure of the cranial aponeurosis occupying the crown of the head is of interest. This dense membrane, closely adherent to the overlying hairy scalp, is pierced by minute apertures, traversed by nerve filaments, and these are thus subjected to considerable pressure when local effusion takes place. It is noteworthy that the vertex—the region, that is, of the cranial aponeurosis—is the seat *par excellence* of morbid cephalic sensations, such as those of pressure, burning, coldness, irritation, and that it is in this region that tenderness is most frequently and most severely experienced. As regards the cranium, the frontal and basal sinuses and the middle ear, lined as they are with mucous membrane continuous with that of the nose and throat, are peculiarly liable to catarrh, and such catarrh is a common cause of headache. Concerning the intracranial structures, though they do not display any special liability to painful affections, disease of them helps to increase the frequency of headache.

2. That portion of the trigeminal area which lies below the cephalic area, including as it does the eyes, teeth, nasal passages, and maxillary antra, is in neo-civilized man peculiarly apt to be subjected to painful stimulation as the result of eye-strain, dental disease, and naso-antral affections. Now, the sensory centres, both subcortical and cortical, pertaining to this area are contiguous with the corresponding centres of cephalic sensibility—those, that is, which are responsible for headache. Indeed, the latter are chiefly constituted of trigeminal centres. Hence the cortical irritation which among the neo-civilized is so frequently started by eye-strain, dental and nasal disease,

is apt to spread to the continuous cephalic sensory centres, and thus to set up headache.

3. Not only is headache liable to be set up by irritation in the extracephalic region just referred to, but also by irritation in more remote parts of the body. Thus, Head has shown that disease of the thoracico-abdominal viscera receiving sensory branches from the vagus is apt to give rise to referred tenderness and pain in what he terms the "dorsal area of the head," owing, it is supposed, to the existence of a peculiarly close connexion between the centres of the vagi and the fifth nerves. This dorsal area (Fig. 4) is bounded on either side by a line which, starting from the nose, follows the lower line of the bony orbit to the upper part of the insertion of the ear, thence dipping down in a curved line to the occipital protuberance. It is subdivided into the fronto-nasal, fronto-temporal, temporal, vertical, parietal, and occipital areas (see diagram).

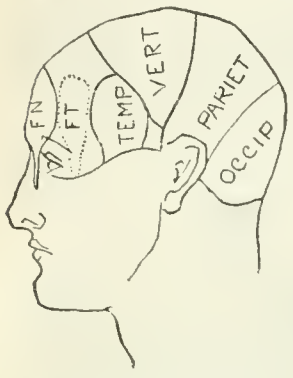

Fig. 4.—Diagram showing Head's "dorsal area of the head," mapped out into sub-areas. FN = fronto-nasal. FT—fronto-temporal.

Affections of the thoracico-abdominal viscera may, it is well known, cause reflex tenderness and pain in correlated areas of the body wall. Now, when the tenderness and pain in any of these areas reach a certain intensity, similar tenderness and pain tend to appear in a correlated portion of the dorsal area of the head, the relation, broadly speaking, being such that the higher the area in the trunk, the more forward is the correlated area on the head (H. Head). Thus, the upper thoracic areas are associated with areas over the nose and forehead; the seventh, eighth, and ninth thoracic with the temporal, vertical, and parietal regions respectively, and the tenth thoracic with the occipital region. One of the most frequent of these associations is that between the seventh thoracic and the temporal area. Thus, disease of the upper part of the stomach, the base of the lung, or the mitral valve, tends to give rise to pain and tenderness not only in the seventh thoracic area on the trunk, but in the temporal area also.*

4. Lastly, in explanation of the frequency of headache, account has to be taken of the close connexion between the centres, subcortical and cortical, of cephalic sensibility and of the special senses—sight, hearing, and smell. Not only is this shown by a variety of clinical facts, it is further suggested by phylogenetic considerations. It has to be remembered that the special senses have evolved from common sensibility. Thus, the retina and organs of Corti may be regarded as systems of "glorified touch spots" which have become differentiated from the sensory organs of the neighbouring body surface. We should therefore expect the visual and auditory centres to be closely connected with the sensory centres pertaining to the skin of the head, especially with the cutaneous areas in which the eyes and ears are situated. The same argument applies to the olfactory centres.

These considerations help to explain why bright lights, loud noises, and powerful odours are apt to set up headache. The violent commotion started in the special sense centres tends to spread to the closely connected centres of cephalic sensibility. Both clinical and phylogenetic evidence points to a similar close connexion between the higher psychic centres and the centres of cephalic sensibility. Hence the tendency for psychic processes to affect cephalic sensibility, and hence the occasional occurrence of headache as a result of intellectual effort.

THE CLASSIFICATION OF HEADACHES.

Some physicians have attempted the impossible task of making a clinical classification of headaches—that is, one founded upon their symptomatology. The symptoms of each supposed variety are set forth with great nicety, and from them the reader is supposed to be able to diagnose each case of headache that comes before him, and to prescribe the appropriate treatment for it. It is, however, only exceptionally (as in migraine) that headache constitutes the obtrusive symptom of a well-defined and easily recognizable symptom-complex. Far better is it to regard headache as a symptom, and to base our classification of headaches upon causation. Having discovered the causative factors we must then endeavour to remove them. I say causative *factors* because in headache, as in other disorders, we often find many causes at work, and we may sometimes be able to effect a cure by removing any one of them.

The following classification, though not conforming to the strict requirements of logic, will be found a convenient one for practical purposes:

1. Organic disease of the cephalic structures—for example, meningitis, "rheumatic" effusion into the scalp.
2. External irritation of the cephalic structures—for example, pediculi, traction on the hair.
3. Irritation in areas other than the cephalic—for example, eye-strain.
4. Circulatory disturbances in the cephalic structures, and morbid states of the blood, causing functional headache.
5. Causes not included under the previous headings—for example, mental causes, physical exercise, atmospheric conditions.

1. The first class includes meningitis, intracranial tumour, gumma, disease of the various cranial sinuses, and of the middle and internal ear, rheumatic effusion into the extracranial soft tissues. I shall limit my remarks to two forms of organic headache—the syphilitic and the rheumatic or "nodular" headache.

The syphilitic headache. Inasmuch as syphilitic headache may herald a serious outbreak of incurable cerebral syphilis (for example, hemiplegia), it demands prompt treatment. Perhaps the best plan in most of these cases is to administer a full dose of salvarsan (or neo-salvarsan) intravenously. Short of this potassium iodide should be given in drachm doses four times daily, together with mercury.

Rheumatic or "nodular headache" has of recent years attracted a good deal of attention on the Continent, where it is regarded as quite a common form of headache. It occurs most frequently in middle-aged or elderly women, and is liable to be brought on by a chill, as by sitting in a draught after washing the hair. The pain is continuous, and may last for years. It is apt to get worse at night, and to be aggravated by the recumbent posture. Cold applications tend to increase, warm applications to relieve it. Careful palpation discloses within the subcutaneous tissues of the scalp and neck, in the substance of the cervical, occipital, and temporal muscles, or along the tendinous insertions into the occiput of the cervico-occipital muscles, circumscribed indurations, very tender to the touch. These consist of nodules varying in size from a millet seed to a bean. Along the tendinous insertion of the occipital muscles they usually form flattened masses. The nodules within the muscles are most easily felt when the latter are relaxed.

The treatment of this form of headache is general and local. The digestive system should be carefully attended to; alcohol should be avoided; the hair should not be washed, but cleansed by means of spirituous lotions, and care should be taken to avoid chills. Among drugs, potassium iodide, sodium salicylate, and potassium bromide are the best. Local treatment is all-important. It consists of massage of the head and neck, preceded by a two hours' application of hot poultices. Each manipulation lasts from fifteen to twenty-five minutes, and the entire course from one to three months. The first eight to ten manipulations generally cause considerable pain, and make the headache worse, so that it may be necessary at this time to give anodynes such as codeine and antipyrin. Improvement begins from the third to the sixth week. The manipulations should be carried out daily until decided improvement occurs, when they should be limited to alternate days, and should be persevered with until all the indurations have disappeared. Some practice is needed in order to acquire the necessary skill in manipulation. The patient assumes the sitting posture, resting the chin on both hands so as to steady the head. The operator begins by making downward strokes with the palms of the hands

* It is probable that reflex headache may be occasionally set up by irritation in still more remote regions—for example, from uterine and ovarian disease.

along the sides and back of the neck (effleurage). The underlying muscles are then vigorously kneaded with both hands (pétrissage), the deep muscles being as far as possible plucked up from their supports in the process. The indurations — subcutaneous, intramuscular, and intratendinous—are then individually kneaded for about half a minute, by means of three or four finger-tips closely approximated, the movement adopted being a circular one from the shoulder-joint. Then follows a repetition of the effleurage. The same routine is gone through in the case of the scalp, and the sitting is terminated by a general effleurage of the entire head.

2. External irritation of the cephalic structures. Reference has already been made to the influence of pediculi, undue traction upon the hair, and the wearing of unsuitable headgear in causing headache.

3. Irritation in areas other than the cephalic causing reflex headache. Headache may be reflexly induced by irritation of any part of the extracephalic region. The most important sources of reflex headache are to be sought for in the eyes, the teeth, the nasal cavities, the maxillary antra, the throat, and in the thoracic and abdominal viscera. I invite discussion on these sources of headache, merely remarking in this connexion upon the importance, in cases of headache from eye-strain, of securing the fullest possible correction of any error of refraction that may exist, and of insisting, where this is necessary, that the patient shall wear glasses for distance as well as for near work.

4. Circulatory disturbances in the cephalic structures causing functional headache. Such disturbances occurring as the result of heart disease, violent exercise, exercise involving stooping such as gardening, or of wearing tight collars or corsets, may cause headache. It is probable that vasomotor disturbances of the cephalic circulation enter largely into the pathological mechanism of some headaches.

Morbid blood states causing functional headaches. Functional headaches thus arising—haemic headaches as we may term them—constitute much the largest class of headaches. Indeed, functional headache rarely occurs when the blood is in a healthy state.

In this connexion we must bear in mind that the blood-plasma is the most complex fluid in nature, and may thus depart from the normal in an infinite variety of ways. In the present state of our knowledge, it is only in a limited number of cases that we are able to indicate the exact nature of the defect.

As to the manner in which morbid blood states induce functional headache we are still largely ignorant. What, for example, is the mechanism of the toxic headache which occurs during the first week of enteric fever? The mechanism of these haemic headaches doubtless differs in different cases. The morbid blood may set up headache (*a*) by its direct effect upon the cephalic structures, by producing local vasomotor disturbances,* or conceivably, by augmenting the irritability of the cephalic sensory centres; or (*b*) indirectly, by acting upon structures outside the cephalic area—for example, by heightening the irritability of the retina, by weakening the mechanism of accommodation and thus predisposing to eye-strain, or by causing disturbance in the dental area.

It is impossible to do more than touch very briefly on the morbid blood states which give rise to functional "haemic" headache. They include the toxaemias of the infectious fevers, uraemia, the toxaemias produced by drugs, alcohol, and tobacco, deficient coagulability of the blood, anaemia, plethora, and the condition I shall term "alimentary toxaemia." I shall only be able to discuss, and that very briefly, the last four of these.

But first a word on the subject of blood pressure in its relation to headache. Arterial blood pressure is chiefly interesting in this connexion in so far as it indicates an abnormal state of the blood. High arterial pressure is often associated with headache. It generally indicates a toxaemia which we should seek to diagnose and to correct. Low blood pressure occurring as a result of a morbid blood state is sometimes a feature of intractable headache. In some of these cases digitalis has seemed to me to do good. Adrenalin might be helpful in some.

* Sir Lauder Brunton has attributed the pain of migraine—unmistakably of haemic origin—to the violent hammering of the blood against a localized constriction of a cranial artery—for example, the temporal.

Deficient coagulability of the blood. Dr. George W. Ross has described a headache which is associated with this condition. "The subjects of this form of headache are usually of the lymphatic type. The expression is heavy and listless. The face is full and the eyes are often puffy. Some anaemia is the rule. . . The whole bearing exhibits mental and physical lassitude."[1] For this "lymphatic type of headache" he recommends 15 grains of calcium lactate, m ½ of tincture of capsicum, to 1 oz. of chloroform water, before meals. The patient is not allowed to eat oysters, crabs, strawberries, which seem to contain lymphagogic agents.

Anaemia. Headache is a common accompaniment of anaemia in its many forms. It is probable that the headache thus arising is due as much to an associated toxaemia as to an impoverished state of the blood. The so-called anaemic headache has, according to my experience, no special clinical features beyond its tendency to be neuralgic in character.

Plethora, such as is met with in stout, overfed, middle-aged and elderly people, and in amenorrhoeic women at the climacteric. The blood mass is not necessarily increased in these cases, but there is an increased quantity of blood in the superficial vessels of the head and neck, and the patient is apt to complain of flushings, buzzings, and giddiness. Among the overfed of this class the face often assumes a blue tint (as the result, I believe, of contraction of the venules), the eyes tend to bulge, and the patient pants from want of breath. This type of person is a familiar figure in our large hotels. The phenomena just referred to are the expression not of a superabundance of blood (which may or may not exist), but of some defect as regards the *constitution* of the blood. The treatment consists in reducing the diet, insisting on a due amount of exercise, and in administering mercurials and salines.

Alimentary toxaemia. By this term we may conveniently connote blood poisoning from defective digestion in stomach, liver, or bowel (including, as this does, the toxaemia of gout, biliousness, and constipation). This is of all causes of headache the most common. It is often brought on by obscure forms of hepatic and intestinal indigestion, and it is probable that migraine and many of the headaches associated with menstrual disturbance arise in this way. Hence the importance of attending to the digestive system in all sufferers from headache. The diet needs careful regulation. For most the golden rule applies—to eat simple food, in moderate quantity, and to chew it thoroughly, especially the farinaceous portion of it. We must not bind ourselves to any one system of diet, but consider each case on its own merits, our object being to secure normal digestion in stomach, liver, and bowel. If we succeed in this, it matters little what kinds of food we permit. Sometimes, especially in migraine, good may be effected by curtailing the animal food, especially butcher's meat; but in most cases the better plan is to reduce the carbohydrate input, especially starch and sugar.

Some are obsessed with an altogether groundless fear as regards the influence of animal food on the human organism. The endeavour to subsist on a dietary which shall not necessitate the taking of life is a commendable ideal, and one, perhaps, which man may one day realize—approximately, at least; but the view that man is by nature a purely vegetable feeder and that animal food has necessarily an injurious effect upon him is wholly fallacious. The fact is, as I have elsewhere sought to show, man owes his present exalted position in the animal scale to his carnivorism. This truth may not be palatable to the sentimentalists, but it is one which must be fairly and squarely faced. It was the search after animal food which led man's arboreal ancestors to change an arboreal for a terrestrial life, and it was, I am convinced, the conditions entailed by a hunting career which brought about the evolution of the human. For observe the curious situation of the pre-human anthropoid when he took to hunting—assuredly one of the most eventful and dramatic in the whole history of organic evolution. Here was a being lacking the stereotyped equipment for slaughter, instinctive and anatomical, of the carnivora, but gifted with an intelligence surpassing that of any other creature, and endowed with prehensile hands capable of giving effect to that intelligence. It was a situation in which intelligence counted in the life-struggle as it had never counted

before, and it inevitably led to the evolution of man. This agile, intelligent, hand-endowed percursor of man was compelled to rely upon his *intelligence* in hunting his prey; for blind instinct he had to substitute strategy; for natural weapons, weapons made by hand. Once the prehuman ape started on his career of intelligent, as against instinctive, hunter, he began a struggle in which it was inevitable that a higher and ever higher grade of intelligence should continue to evolve, until sufficient mental capacity had been attained to render its possessor supreme as a primitive hunter—a grade of intelligence little short, I imagine, of that of the Australian aboriginal.

I venture to submit that we as physicians will get far more help by studying man's diet from the standpoint of evolution than from laboratory experiments—certainly as regards the main truths, useful as such experiments doubtless are. Such a study shows us that the diet of neo-civilized man differs from that of early man mainly as regards sugar and soft starchy foods. Primitive man consumed an abundance of animal food; his supply of sugar was limited to wild honey, his starchy food to what he could obtain from the uncultivated animal kingdom; and observe that before the discovery of cookery all this had to be masticated laboriously. Hence it was that primitive man consumed comparatively little starch, and such as he did consume was so thoroughly masticated that it was to a large extent predigested in the mouth. In the case of neo-civilized man, on the other hand, not only is sugar abundantly consumed, but the stomach (especially during the first years of life) is literally deluged with undigested starch.

Such considerations surely suggest that, as regards the diet of our neo-civilized patients, we have more to apprehend from an excess of starch and sugar than from excess of animal food.

CAUSES NOT INCLUDED UNDER THE PREVIOUS HEADINGS.

Mental.—Hard thinking may cause headache, but the headache of intellectual workers is more frequently due to eye-strain. Strong emotion, such as anger, worry, and suspense, is a powerful exciting cause.

Atmospheric Conditions.—Thundery weather is a well-known cause of headache; also the stuffy atmosphere of ill-ventilated rooms.

DISCUSSION.

Dr. C. O. HAWTHORNE (London) thought it a somewhat speculative proceeding to use such terms as toxaemic and rheumatic headache or headache due to high blood pressure. It was, of course, well known that patients with high sphygmomanometer records, or with disturbances of the digestive functions, might have headache, but was there sufficient warrant for saying that in the one case this is due to excessive pressure in the intracranial arteries, in the other to poisons absorbed from the alimentary canal? The same thing might be said of the term "rheumatic headache," which suggested, without warrant so far as the speaker knew, that the headache depended on the same agency as that which produced rheumatic fever. On the practical side he thought Dr. Campbell's survey might have emphasized more strongly the necessity for an ophthalmoscopic examination in all cases of headache. There could be no doubt that headache might be the one and only symptom of serious intracranial disease, and it was not always the case that the headache was very severe or persistent. Now and again a child was found to have post-neuritic optic atrophy and the only history was of headache, with or without vomiting and often limited to the early hours of the morning. Whether the underlying cause were tumour or some other form of intracranial disease, the early diagnosis in such cases obviously depended on the use of the ophthalmoscope. Another form of examination to be remembered in cases of persistent headache of obscure causation was examination of the cerebro-spinal fluid. A headache quite unaccompanied by any other evidence of disease might in this way be shown conclusively to be due to specific disease. The examination of the fundus oculi, of the cerebro-spinal fluid, and of the state of the refraction ought be kept in the forefront in the investigation of cases of headache.

Dr. PEGLER (London), speaking as a rhinologist, said that some headaches were certainly of nasal origin, but in their form and locality they possessed no special characteristics. When headache accompanied nasal lesions the patients were probably predisposed towards headaches, since the same lesions might at times be found without any accompanying headache whatever. The nasal lesions commonly associated with headache fell into three groups—non-inflammatory, chronic inflammatory, and acute inflammatory causes. Combinations of these sometimes occurred, and a thickened or deflected septum might complicate any one of them. Cases in the first group were due to pressure somewhere within the nasal chambers of some one more or less rigid body against another, the richly innervated nasal mucous membrane intervening. The pressure of a septal spine against a middle or inferior turbinate was a case in point. Such causes of headache gained increased importance from the fact that quite often they could not be detected until careful search by expert means had been made. The commoner lesions in the second group were conditions such as masses of polypi. The primary effects were stagnations of secretions, accompanied at times by toxic absorption. Should pus be imprisoned in a nasal cavity, headache was liable to be especially severe, but was relieved as soon as drainage was re-established even though the suppuration continued. The third group of lesions was formed of rhinitis in various forms, and was typified by acute coryza. Dry forms of rhinitis, however, were also liable to occasion headache, which could usually be dissipated by free lavage. Other occasional causes were the formation of fibrous adhesions across fossae, these by their traction inducing headache, which disappeared when the bands were destroyed. The speaker then discussed the nervous mechanism of nasal headache and its diagnosis, which, he said, could not be established from the character of the situation of the pain, for this, owing to anatomical misreferences, might be experienced in any part of the head. The commonest location was across the brow, below the hair line. In one particular case, a highly intelligent schoolmistress described to the author three kinds of headache, each with a separate location. She was astigmatic and asthenopic, but could get no benefit from the lenses prescribed for her, nor from a long spell of rest until partial resection of an inferior turbinal, following some time after an adenoid operation, had been carried out. All three forms of headache then entirely ceased. In degree a nasal headache might be anything from an occasional dull pressing pain to a fulminating seizure radiating along all the branches of the fifth nerve. The extreme forms of headache were sometimes accompanied by photophobia and cardiac depression, and were generally due to the first class of causes. A sense of compression or tightness at the root of the nose as a starting-point of the headache often served as a useful guide to latent pressure as a cause; in some cases there was slight swelling with a bluish tint of the skin over the painful spot. Unilateral distribution of the pain was very common in nasal headache, but absence of the classical signs of megrim should serve to prevent a wrong diagnosis of the latter disorder being made. The final diagnosis in any kind of nasal headache must often depend on the results of treatment; this treatment was merely that ordinarily required for the concurrent nasal ailment found to exist, the pain vanishing as soon as this had been removed. In exceptional cases the headache only gradually disappeared after surgical treatment of its underlying nasal cause, and in these the speaker had often found a course of bromides very helpful.

Dr. FRANK EVE (Hull) said the experimental method was too seldom applicable in clinical medicine, but in connexion with the question of headaches was often possible. For instance, one of the regular sequelae of tuberculin injections was a headache lasting perhaps a day, and might also be either relieved by lumbar puncture or induced thereby, unless the patient were kept in bed for a day. It was important not to mistake neuritis for headache, for in this event the patient would not be cured. A case in point was a youngish man who had been infected six months previously with syphilis and for a few

months had had agonizing "headaches." He had been treated by several physicians with mercury and salvarsan, etc. The latter produced some temporary relief, but nevertheless the headaches continued for months. On examination the speaker noted that the trunk of the great occipital was tender and that there were areas of anaesthesia over its distribution. Two or three applications of salicylic ionization produced a rapid and permanent cure of the "headache." In such cases a precise diagnosis was not only essential but equivalent to a cure.

The PRESIDENT, speaking of syphilitic headaches, said that in his opinion the inunction of mercurial ointment was still the most satisfactory treatment, when combined with moderate doses—say, 20 grains three times a day—of potassium iodide.

Dr. CAMPBELL, in his reply, agreed with Dr. Hawthorne as to the necessity of examining the cerebro-spinal fluid in all cases of headache in which there was a suspicion of syphilis; but he pointed out that in cerebral syphilis the cerebro-spinal fluid obtained by lumbar puncture might give no evidence of syphilis. This had been shown by careful investigations made at the London Hospital. As regards errors of refraction, he insisted upon the importance of providing the sufferer from headache with the best possible correction, both for near work and for distance.

ACUTE ATROPHY OF THE THYROID GLAND.

By F. C. EVE, M.D.Cantab., M.R.C.P.Lond.,
Hull.

(*Abridged.*)

THE case of exophthalmic goitre I am about to describe showed complete disappearance of a rather large goitre during the two days preceding death. That is to say, no trace of it could be detected by the eye or fingers. A *post-mortem* dissection was unfortunately out of the question. I cannot find a record of a similar occurrence, though, of course, it is well known that an exophthalmic goitre is subject to fluctuations in size.

The patient was a woman, aged 40, whom I had treated for Graves's disease for five years, and who had suffered from it for six and a half years. Her illness ran the usual course for a few years, with a conspicuous goitre about 4 in. in width, but subject to variations in size.

Looking back on her long illness, one is chiefly impressed by the remarkable instability and variability in the action of her organs. The bowels varied from attacks of diarrhoea to constipation; the blood pressure from about normal to 240 mm., when its measurement became painful and caused petechial escape of blood from the tissues of the forearm. The pulse varied from 100 to 200. The weight was never constant, the catamenia irregular, the eyes varied much in their protrusion, and were often normal for long periods. Her headaches, sleep, strength, and the darkness of her complexion were all very variable.

In the fourth year of her illness she had influenza, the fever of which was succeeded by an alarming and exhausting week or two of high fever. Some people seem to term this thyroid fever, as it seems due rather to poisons and hypersecretions from an angry gland than to bacteria. Thereafter every spring an attack of influenza or tonsillitis brought her near to death by this subsequent sustained thyroid fever.

Her last illness started with frank follicular tonsillitis, followed by her usual thyroid fever, with erythema nodosum on the arms and legs on the twelfth day. On the fifteenth day the thyroid was first noted as having become very small, and diarrhoea had started. On the sixteenth day the thyroid was scarcely palpable, and only half the 160 heart beats were reaching the wrist. The seventeenth day was her last, and no trace of the thyroid gland could be seen or felt before or after death. Her rapid breathing, chest pain, and rusty sputum showed that a few hours of pneumonia had been the final cause of death.

In a patient of 40, with six years of Graves's disease, one would expect the thyroid to contain a good deal of secretion, but the atrophy was so complete that I was compelled to think that there had also been a rapid and extensive cytolysis of the secreting cells, analogous to that occurring in acute yellow atrophy of the liver.

It is important to get information on this point, because we have in normal horse serum an agent which is very potent to arrest such uncontrolled cytolysis, as I showed very clearly by some cases published in the BRITISH MEDICAL JOURNAL in October, 1910. It may be found advisable to inject horse serum in the hope of checking this alarming atrophy of the thyroid, or possibly even the thyroid fever. I did try it in 1911 in a child moribund with acute yellow atrophy, but I saw the child too late to give any remedy a chance. I see that horse serum is now recommended in this disease, but I do not know with what success.

In 1913, in a very young child with acute febrile lymphadenoma, the enlarged subclavicular glands started to atrophy rapidly, and, as the child's general condition was getting worse, I thought it advisable to try to put the brake on the acuteness of the cytolytic process by injections of horse serum. However, the enlarged glands wasted almost entirely away, and after a week or two the child died. Possibly to inject the serum locally would be better. These instances show that acute atrophy of pathologically hypertrophied tissues may be of the gravest import, and (probably) that an attempt to arrest the process should be attempted by horse serum, unless better means be known.*

A medical friend allows me to quote another case illustrating thyroid atrophy preceding death. It was a woman who had Graves's disease for five years but was able to do her house work. Then she had an attack of diarrhoea, fever and loss of flesh, and her goitre entirely vanished. Within two months she was dead.

Another case, which I saw once only in consultation, was a big elderly woman who had had a large simple goitre for several years, with stertor as the only symptom. After six months of dyspepsia, she started with persistent obscure fever and general wasting of remarkable rapidity. Her goitre showed rapid atrophy during the week preceding death.

The histology of these changes requires working out, but clearly it renders the goitre from the *post-mortem* room very likely to be misleading from the histological point of view. So that thyroids removed *in vivo* by the surgeon should alone be relied upon to give a reliable picture of the true state of a goitre.

A CASE OF ANAEMIA WITH ENLARGEMENT OF THE SPLEEN: SPLENECTOMY: CURE.

By J. SOUTTAR MCKENDRICK, M.D., F.R.F.P.S.G.,
Assistant Physician to Glasgow Western Infirmary.

(*Abstract.*)

THE treatment by splenectomy of cases of anaemia associated with splenomegaly until recent times has been comparatively rare. This has depended on two factors: (1) The imperfect knowledge of the function of the spleen, and (2) the danger attending the surgical technique.

Regarding the first factor, the researches of Noel Paton, Goodall, Gulland, and Fowler have shown us that the spleen may be removed without causing death to the animal, either at the time or afterwards. They have shown that whatever function the spleen may have, the lymphatic glands and haemolymph glands may take up this function.

Regarding the second factor, the death-rate from splenectomy in the human subject until recently has been very high. Sepsis, shock, and profuse haemorrhage have been the chief causes of death.

Mr. Spanton tells us that from 1866 to 1875 the death-rate after splenectomy reached 75 per cent. From 1886 to 1895 it fell to 16 per cent., and in the most recent series of cases reported by Giffen from the Mayo clinic it fell to 7.4 per cent.

The operation must not be delayed too long, for in Banti's disease, where the liver is cirrhosed and ascites occurs, the mortality from splenectomy may be higher.

In certain blood diseases the spleen becomes enlarged. The enlargement may be primary, such as is probably the case in splenic anaemia; or secondary, in general infections, toxaemic states, rickets, syphilis, etc. Many

* *Coagulose*, a new and stable preparation of horse serum in powder form (Parke, Davis and Co.), may prove worthy of trial.

such anaemic conditions with splenomegaly have wholly recovered after splenectomy.

S. R., aged 8, was admitted to the Western Infirmary on July 26th, 1912, complaining of great weakness, breathlessness, and loss of appetite.

History of Present Illness.—Up till four years ago her health had always been good. At that time she had frequent attacks of diarrhoea, and following this she gradually became more and more anaemic. During the last year the anaemia deepened despite all usual medical treatment. About six months ago she developed haemorrhagic patches in the skin, and her eyesight was not so good. She at no time had haematemesis or melaena.

Family History.—Nothing noteworthy.

Present Condition.—Intense pallor of skin and mucous membranes. Some icteric tinge of skin and conjunctivae. Haemorrhagic patches on chest and arms. Some evidences of haemorrhagic retinitis. Heart not enlarged, but functional v.s. murmur over pulmonic area. Blood pressure 92 mm. Hg (systolic). Lungs normal. Digestive system: Furred tongue; teeth not good. Liver palpable below the costal margin. Spleen enlarged, passing downwards almost to the umbilicus. No ascites. No enlargement of the stomach. Nothing else noteworthy in the abdomen. No enlargement of lymphatic glands. Urine: No bile or other abnormality.

Blood:

Red cells	2,550,000
White cells	7,800
Haemoglobin	25 per cent.
Colour index	0.5
Polymorphs	56 per cent.
Small lymphocytes	36 ,,
Large lymphocytes	2 ,,
Large mononuclears	3.6 ,,
Mast cells	1 ,,
Eosinophiles	1.4 ,,

Anisocytosis, poikilocytosis, ghost cells, slight polychromatophilia, a few normoblasts, one questionable megaloblast. Wassermann reaction negative.

On August 16th a portion of the ninth rib was excised and bone marrow examined by Dr. Shaw Dunn. This showed a somewhat hyperplastic condition of the blood-forming tissues.

Dr. Alex. MacLennan removed the spleen on August 28th. The spleen was non-adherent. It was of firm consistence, weighing about twice its normal weight, and the lymph nodes were slightly enlarged and prominent. The main departure histologically from the normal splenic appearance was the presence of normoblasts and myelocytes and the unusual number of polymorphs and eosinophile leucocytes. Bacteriological examination for organisms was made with negative results.

On August 29th, the day after operation, the blood had altered materially from the last examination. There was a large increase in red and white blood corpuscles, a very marked polymorphonuclear leucocytosis, and a rush of nucleated red cells (normoblasts).

Red cells	4,650,000
White cells	34,800
Haemoglobin	35 per cent.
Colour index	0.38
Polymorphs	94 per cent.
Lymphocytes	5.6 ,,
Eosinophiles	0.4 ,,
Nucleated red cells	1,800 per c.mm.

Digestive leucocytosis experiments were performed, and were found to react normally. The red cells gradually increased to normal, at one time there being a polycythaemia, while the white cells steadily fell to 9,000. The haemoglobin did not increase so rapidly as was expected. As there was some oral sepsis, a few teeth were extracted.

On November 15th the blood examination was:

Red cells	4,890,000
White cells...	12,000
Haemoglobin	75 per cent.
Colour index	0.8
Polymorphs	62 per cent.
Lymphocytes	27 ,,
Large mononuclears	5 ,,
Myelocytes...	6 ,,

No nucleated red cells.

The patient left the hospital well. On April 26th, 1914, Dr. Hastings, of Skye, writes: "S. R. has grown and is in good condition. She has a good colour, with no trace of anaemia, and is in fact a normal healthy child of her age, not in the least like the poor anaemic child she was. You may safely describe the case as being a complete success so far."

[The author went on to make remarks on the immediate effect of splenectomy in this case, and laid especial emphasis on the importance of examining the bone marrow in the cases of severe anaemia with splenomegaly, before splenectomy is advised, in case there is an aplastic instead of a hyperplastic condition of the bone marrow.

He then discussed the differential diagnosis between cases of splenic anaemia (so-called) and cases of pseudo-leukaemia infantum (von Jaksch), myelogenous leukaemia, pernicious anaemia, and acholaric jaundice with splenomegaly.]

The treatment of cases of anaemia with splenomegaly by splenectomy is still in its infancy, as far as one can gather from the general literature. A new classification of these obscure cases is wanted. Fresh pathological investigation into the causation is needed, and, above all, a further knowledge of the true function of the spleen is required.

THE URINARY DIASTASE TEST IN A CASE OF RUPTURED DUODENUM.

By ARTHUR H. LISTER, M.D.,
Physician to the Aberdeen Royal Infirmary.

(*Abstract.*)

LAURENCE HUMPHRY'S recent communication,[1] with his reference to Dudley Corbett's paper,[2] disposes of the necessity for any preface to the following note:

A healthy man, aged 25, was riding, when his horse reared and fell backwards, crushing the rider. He was sent into my ward on April 17th, but as signs of an intra-abdominal injury were present I asked Professor Marnoch to see him immediately. He was operated on forthwith.

Some free blood-stained fluid was present in the abdominal cavity, and there were subperitoneal haemorrhages in the mesenteries and omentum. There were no haemorrhages in the lesser sac. There was a large retroperitoneal haematoma at the back of the abdominal cavity. This was opened, a semifluid blood clot was removed and a drainage tube was inserted connecting the haematoma with the surface, otherwise the abdomen was closed.

On removal of the dressings, faecal matter was found to have escaped through the tube; vomiting was troublesome, and it was noticed by the house-surgeon that the matter which was vomited was similar in character to that which escaped from the tube. The patient died on April 22nd.

On the 23rd the *post-mortem* examination revealed a transverse rupture of the duodenum close to its junction with the jejunum. At the inner end of the drainage tube was a collection of faecal matter, with retroperitoneal cellulitis. The pancreas was normal, and there was no evidence of any disease of the kidneys.

On April 21st I examined the diastase reaction of the urine on the chance of finding some abnormality in its amount which might point to a lesion of the pancreas. Instead of finding any increase, I found that the diastase, when tested for in the ordinary way as described by Corbett (loc. cit.), was practically absent, though there was a faintly redder violet tinge in the tube containing 0.6 c.cm. as compared with the blue colour in the lower tubes of the series. The control used was a urine showing a normal coefficient ($d = 10$).

The fact which appears to me to justify the publication of this case is that I know of the report of no other in which the diastase test has been applied where the pancreatic secretions have been short-circuited. The case is not complete, as it is conceivable, though improbable, that the pancreas was not secreting. This could have been determined by taking the diastase reaction of the fluid discharged from the drainage tube, but the patient died so soon after I had obtained my results that I did not get the opportunity of making this estimation.

Apart from this possible fallacy, the almost complete absence of diastase from the urine would suggest that the usual source of urinary diastase in healthy conditions of the pancreas is the amylopsin of the pancreatic juice absorbed from some part of the bowel lower than the duodenum. That the ptyalin of the saliva has any definite share in producing it would seem improbable. It is commonly held that ptyalin is destroyed in the stomach,[3] and were it to be absorbed in any large quantity from the stomach wall one might have expected to have found it in the urine of this patient, but no stress can be laid upon this point as vomiting was frequent.

The fact that normally diastase passes apparently with ease into the circulation and on through the renal epithelium, makes its almost complete absence from ascitic fluid, at any rate in some cases, a matter of interest.

A case of ascites in my ward whose peritoneal sac has been tapped some eighty times, to the extent of about

1½ gallons at intervals of about ten days to three weeks, for nearly three years, shows a normal diastase content in her urine ($d = 10$). The ascitic fluid, which at first was clear, is now milky and contains only a very small quantity of diastase ($d = 1.6$ approximately). Dr. Edie, lecturer on biochemistry, Aberdeen University, from a careful analysis is inclined to consider the fluid pseudochylous in its character.

An absence of diastase from chyliform ascitic fluid has been commonly noted.[4] Whether by examining the reaction of fluids removed from the serous cavities any difference may be generally found in the diastase content of inflammatory exudates as distinguished from that of transudates, is still, I believe, a matter for investigation. In view of the considerable quantity of diastase normally present in the blood one would expect to find a higher diastase coefficient in inflammatory effusions, but I have no sufficient facts bearing on the matter to justify any statement.

I have to express my gratitude to Professor Marnoch and to his house-surgeon, Dr. Brand, for the information which they gave me regarding the first case noted.

MEDICAL AND SURGICAL PRACTICE IN HOSPITALS AND ASYLUMS.

GENERAL INFIRMARY, LEEDS.

A CASE ILLUSTRATING THE SURGERY OF THE PUERPERAL UTERUS: HYSTERECTOMY FOR MYOMA SUPPURATING AFTER LABOUR.

(By John Benjamin Hellier, M.D.Lond., Honorary Obstetric Physician to the General Infirmary at Leeds; Professor of Obstetrics, Leeds University, etc.)

Mrs. C. W., a Jewess, was admitted into the Leeds Infirmary on December 8th, 1913, with acute abdominal symptoms, five weeks after her first confinement.

Previous History.—She had been married seven years without becoming pregnant, but had always had good health. Menstruation had been scanty, with rather long irregular intervals, and there had been no reason to suspect any uterine growth. In the early part of 1913 she became pregnant. She had some slight haemorrhage in early pregnancy which lasted two weeks and then ceased, after which the pregnancy ran a normal course. She was confined in the Leeds Maternity Hospital on November 2nd. Before labour external palpation suggested a transverse lie, but at the time of labour the breech presented, and delivery was easy and uncomplicated. After delivery the presence of a moderate-sized myoma in the corpus uteri was easily recognized. She was discharged on November 20th without having developed any morbid symptom.

On December 5th she was admitted to this infirmary at the request of Dr. Umanski of Leeds, who had been called to see her, and had found her with abdominal pain and tenderness, distension, vomiting, and high temperature. On admission a uterine tumour could be felt corresponding to the size and position of a four and a half months pregnancy but lying more to the right than the left of the middle line. It was rather tender. The patient was a well-developed woman, not looking very ill, and the principal organs outside the pelvis were normal. There was no vaginal discharge, no indication of any tissue retained in the uterus, and no sign of cellulitis or phlebitis. There seemed to be no general peritonitis. The diagnosis of infected myoma was at once considered, but it seemed best to observe the case further lest any other complication were developing. Two days after admission the vomiting had ceased, and the patient seemed much better. On the evening of December 10th she had a severe rigor, the temperature reaching 105.8° F. Next day she seemed better, but on December 12th she had a second rigor. Again she seemed to be improving, but on the 17th a third rigor occurred. It was then determined to explore the abdomen, and this was done on December 18th. There was no general peritonitis, but the uterus presented a round fluctuating swelling in the anterior wall. There were no adhesions and no affection of the tubes. It was very easy to draw the uterus upwards and perform supravaginal hysterectomy, the cervix being long and thin. The appendages were removed on both sides with a good length of the ovarian vessels. The patient bore the operation very well, and the wound healed without any suppuration.

There was some herpes on the lips and face before operation, and on the 23rd there was a slight attack of facial erysipelas, spreading in butterfly shape over the nose, cheeks, and forehead. The patient was transferred to the isolation wards, but the erysipelas rapidly subsided. It produced very little disturbance of temperature and had no effect at all upon the abdominal incision.

A, Abscess cavity; B, central necrotic myoma; C, cervix; D, uterine cavity; E, abscess cavity.

On January 2nd, 1914, she was transferred to our semi-convalescent hospital, five miles distant in the country, whence she was discharged cured on January 24th.

Report on Parts Removed.

The uterus after removal measured 5½ in. in length and 5 in. in breadth. The uterine cavity lay posteriorly, and the anterior uterine wall was occupied by an interstitial tumour situated well above the cervix. Well marked fluctuation was perceptible in the tumour, and an exploring syringe withdrew pus. From this no bacterial growth was obtained on cultivation. The specimen was hardened in formalin for two or three days and then a sagittal section was made. The appearance of the specimen on section is represented in the accompanying drawing. The stretched-out uterine cavity is seen lying behind with a greatly thinned posterior wall. The endometrium is normal and the uterine cavity empty. The anterior uterine wall is occupied by a spherical cavity 4½ in. in diameter. Lying loose in this cavity, and occupying not more than about half the space, is a necrotic myoma, dirty greenish-red in colour, but showing the usual fibrous structure of a myoma. The rest of the space was occupied by dirty-looking pus with offensive odour. Anteriorly the

wall of the abscess cavity is very much thinned and in parts does not exceed 1 millimetre in thickness. The tubes and ovaries appeared to be normal.

Histological Appearances.—A section through the wall of the abscess cavity shows a narrow lining of necrotic tissue, much infiltrated by pus in its inner layers. Outside this is a fairly broad zone of fibrous tissue characterized by the presence of many inflammatory cells, polymorphs, lymphocytes, and especially plasma cells. A few tissue mast cells are also seen. Here and there amongst the fibrous tissue one can detect small islets of unstriped muscle, more or less completely necrosed. Outside this again is the muscular wall of the uterus, which is the seat of well-marked interstitial fibrosis and plasma cell infiltration. A few polymorphs and an occasional lymphocyte are also present. The inflammatory cells tend to occur in small clumps in the midst of the fibrous tissue, while tissue mast cells, which are present in considerable numbers, tend to be more uniformly distributed. The myometrium in this situation contains numerous wide, thin-walled blood vessels, the contents of which include many leucocytes. There is no evidence of tumour in the wall of the abscess cavity at any part; the sloughing process appears to have implicated the growth in its entirety.

A section through the solid central slough shows the typical structure of a fibromyoma uteri. The superficial portion is completely necrosed and is slightly invaded by pus cells, but in the deeper parts some nuclear staining still persists.

Sections stained with Pappenheim's pyronin-methyl-green mixture fail to show the presence of organisms, either in the pus or in the wall of the abscess cavity.

REMARKS.

This was a typical case for surgical intervention in uterine infection following delivery. The lesion was strictly limited to the uterus, and though it was causing severe symptoms there were no visceral lesions outside the uterus. There was no peritonitis. The disease was easily and completely removable, and the cellular tissue and the vessels were not involved.

When one sees cases of pelvic infection lasting for weeks after labour, the temptation to treat them by removing the uterus and infected appendages is very strong, but if the mischief has spread beyond these parts, and if the pelvic veins and lymphatics are widely involved the result is doubtful. In acute purulent general peritonitis the results of surgical treatment are very disappointing. I have tried the ligature of ovarian veins for thrombosis with very little success.

I never saw a more marked case of uterine abscess than the present. It seems clear that the hysterectomy saved her life.

I am indebted to Dr. M. J. Stewart, clinical pathologist to the infirmary, for his report on the tumour; to my house-surgeon, Mr. J. B. Wilman, M.R.C.S., L.R.C.P., for his careful observation of the case, and to Miss Ethel Wright for her excellent drawing.

DR. KENRICK S. WISE, Government Medical Officer, British Guiana, has been appointed a member of the Executive Council of British Guiana.

THE *Journal of the American Medical Association* for August 22nd contains statistics of medical colleges, students and graduates in the United States for the year ending June 30th, 1914. The total number of students was 16,502, being 513 less than in 1913. Of these, 794 were in the homœopathic colleges, and 270 in the eclectic colleges. There were 3,594 medical graduates, 387 less than in 1913, and 889 less than the number who graduated in 1912. This is the lowest number of medical graduates in the States since 1890. The total number of medical colleges is now 101, of which 10 are homœopathic and 4 eclectic. Of these 101 colleges, 84 now require one or more years of work in a college of liberal arts for admission, and several others have announced the higher requirement to take effect in 1915. Of the 3,594 medical graduates in 1914, 807, or 22.5 per cent., were also graduates of colleges of liberal arts, as compared with 19 per cent. last year. Women students constituted 3.8 per cent. of all students, and of all graduates 3.4 per cent. were women.

Reviews.

PHYSIOLOGY.

THE fifth edition of HOWELL'S *Physiology*[1] has been issued two years after the fourth. The continued popularity of this textbook is well deserved, for Professor Howell is a master of the art of exposition, and keeps the representation of his subject fresh and up to date. In this edition, in particular, he has incorporated some of the new and far-reaching results obtained in regard to the details of intermediary metabolism in the body, such as the indication that the animal body, under certain conditions, may obtain some of its necessary nitrogen for the synthesis of protein from inorganic sources. The specific function of the different proteins in growth and in maintenance is another field of investigation of fundamental importance which he touches upon. The author still upholds the mechanical view that the aqueous humour filters into the eye through the vessels in the ciliary processes, in place of the more reasonable hypothesis that the cells of the ciliary processes, by their secretory activity, regulate the intraocular tension. In regard to blood platelets, he says: "It has been shown that they are formed elements and not simply precipitates from the plasma." This is far too strong a statement, for in the light of Buckmaster's careful work on this subject the evidence seems to be all the other way. On page 433 Professor Howell has added a curve, taken from a recent paper by Miss Fitzgerald, showing the relationship between the altitude and the percentage of haemoglobin in the blood—a relationship worked out by her in the lofty regions of California. On page 525 he includes a coloured diagram, taken from a paper by Mall, showing the course of the superficial and deep fibres of the bulbo-spiral and sino-spiral systems of the musculature of the heart; and on page 530 a photograph, from a model constructed by Miss De Witt, of the auriculo-ventricular bundle and its ramifications in the interior of the ventricles. On page 794 we note a well-considered and balanced judgement concerning bacterial action in the gastro-intestinal tract. Professor Howell concludes "that while the presence of the bacteria confers no positive benefit, the organism has adapted itself under usual conditions to neutralize their injurious action."

In treating of the function of the interstitial cells in the testis, Professor Howell cites recent experiments of Steinach, who in very young animals transplanted the testes from their normal to other regions. Such animals developed normally, showed all the usual secondary sexual characters, and manifested full sexual desire and potency at the proper period. When the transplanted glands were examined it was found that the sexual elements were lacking, but the interstitial cells were increased in amount. These cells are called by Steinach the "puberty glands." In regard to alcohol, the author takes the well-reasoned view that while it may act as a true foodstuff, its expensiveness and dangers prevent us from regarding it as a practical food. On account of its ready absorption and palatableness, it may form a useful substitute for the solid, non-nitrogenous foodstuffs in sickness. Benedict and Török have obtained results upon diabetic patients which indicate that in this condition alcohol, used as a food, diminishes the production of acetone bodies, and protects the protein.

The author cites the suggestion of Rubner that the power to grow possessed by the cells of the young organism depends upon some special mechanisms of a chemical nature—that is, probably certain special chemical complexes which are responsible for the growth tendency. The thymus and pituitary glands form apparently an internal secretion which stimulates growth, mainly that of the skeleton. Young growing dogs, according to Aron, if given a diet insufficient to maintain their weight, still grow, since the skeleton increases in size at the expense of the other tissues, particularly of the muscular tissues. In the medusa, when unfed, Stechard reports, a regenerating tissue may grow rapidly by feeding on the old body tissues. The same tendency finds an illustration in

[1] *A Textbook of Physiology, for Medical Students and Physicians.* By Wm. H. Howell, Ph.D., M.D., Sc.D., LL.D. Fifth edition, thoroughly revised. Philadelphia and London: W. B. Saunders Co. 1913. (Med. 8vo, pp. 1020; 306 figures. 18s. net.)

malignant growths, and we must look in future to the discovery of the growth complexes and the obtaining of some control over them. Rubner suggests that the growth complexes are given up to the reproduction cells; the individual organism after reaching puberty is thus depleted of the power of growth, and sentence of death becomes inevitable.

DIETETICS.

Dr. Tibbles, the author of *Dietetics; or, Food in Health and Disease*,[2] has had a good deal of experience in writing upon allied subjects, and in the present volume he has produced a useful and comprehensive manual which deserves to be widely read by the medical profession. He complains of the general neglect shown to this subject by the medical profession and urges the need for a professor of dietetics. We believe, however, that this subject is taught now in most medical schools and forms a part of the course of therapeutics, but undoubtedly the arrangement of the course is left more or less to the discretion of individual teachers. We doubt whether there is sufficient material to justify a complete course, and still more whether there is time in the already overcrowded curriculum for more lectures than those already allotted to the subject of therapeutics. Undoubtedly a great change has taken place during the past thirty or forty years in the attention given to the dieting of patients in hospitals, and although the improvement may be slow it is certain that the necessity for arranging suitable dietaries is becoming widely recognized, and the public by their attitude upon this question are creating a demand for an adequate knowledge of the subject, which the profession must be prepared to supply. Those who desire to fill up the gaps in the knowledge they acquired before graduation can find no better guide than the book before us, which gives not only a fair and lucid summary of the scientific principles upon which the science of dietetics is based, but discusses, under the heading of various diseases, the appropriate regimen for each. We especially commend the tables on food values, the want of which has been a frequent subject of complaint with us. The attitude taken by the author on the question of the quantity of food, especially as to protein, is judicious. In his description of various dietaries we think it better that milk diet should consist of milk only, and that the kind of diet the author calls "milk" should be called "low." In his account of gall stones he seems to have overlooked the more recent work of Aschoff and Bacmeister, and we fail to notice any reference to the generally accepted relation of infection of the gall bladder by the typhoid bacillus to the formation of gall stones; the practical value of this observation is obvious. Further, we doubt the propriety of including peniosuria and lactosuria under the heading of diabetes mellitus, but it is possible that this was not the author's intention. The description of Dr. Pavy's theory is not to our mind quite satisfactory, and the date given to Rollo, who was the first to introduce meat diet in the treatment of diabetes, as 1830, is a mistake, as his book was published in 1797.

The genial little book containing the *Lectures on Dietetics*[3] Professor Max Einhorn has been in the habit of delivering to the New York Post-Graduate Medical School contains comparatively little in a systematic form, but there are useful tables of articles of food giving their constituents in protein, fat and carbohydrates and caloric value. The lecturer has omitted to give any table of alcoholic drinks, although he apparently has no objection to the use of alcohol in various forms, in several instances permitting it by name, so that his readers would find it an assistance to have such a table for their guidance. Although the style is easy to follow, it seems to us that occasionally he is speaking in a foreign tongue, and so expresses himself ambiguously; thus on page 20 he says, "The way foods should represent each other is by their calorific value except that we cannot eliminate protein"—a sentence which apparently means that the various kinds of food may more or less replace one another according to their calorific value, but that neither carbohydrate nor fat can take the place of protein. On page 32 he says, "Connective tissue is one of the substances that are absorbed in the stomach"—a statement that completely puzzles us, as it is certainly not true in its obvious meaning. Nor do we understand the story on page 39 about the lady who took half an hour to drink a glass of milk and in consequence suffered from headaches. Professor Einhorn is tolerant with regard to habits. The American habit of two large meals, morning and evening, and a small mid-day meal, is all right, but he approves equally of the German plan of eating six times a day. He says: "Do not try to do better than others; go along with them and you will be all right"—a very comfortable doctrine, but one which is hardly satisfactory to those who are looking for guidance, and he admits that the German plan tends to corpulency. He refers to the possibility of being able to go without solid food so long as abundant liquids are allowed, but he nowhere mentions the fasting methods of which such remarkable accounts reach us from the United States. He talks about "Graves of Great Britain," meaning the late Dr. Graves, of Dublin, but Ireland, even under the Act of Union, has not been thought to be part of Great Britain; further, he misrepresents Dr. Graves in suggesting that his practice of feeding fevers applied to typhoid fever, as at that time the fever prevalent in Dublin was maculated typhus. Nor did Graves introduce the use of milk diet in fever, for he recommended almost every kind of liquid except milk, and, rightly or wrongly, Murchison credited Sir William Gairdner with the introduction of milk. Professor Einhorn's dietaries, like so many constructed by Germans, are unsuitable to English palates. For example, on p. 115 he suggests a meal of "four scrambled eggs with 120 grams of ham," without any bread or bread substitute or vegetables; and on p. 126 he prescribes the following meal: "Three fried eggs with bacon or fried fish with hard boiled eggs or a portion of cold meat 5 oz." He devotes a chapter to reprinting the regimens of Ebstein-Banting, Oertel, Schroth and others, and in the last chapter he describes his method of duodenal feeding, illustrating it by several figures. Without pretending to cover a great deal of ground these lectures convey much useful information.

THE THYMO-THYROID APPARATUS.

Dr. Launoy is convinced that there is a close connexion between the thyroid and parathyroid glands on the one hand and the thymus on the other. He groups them together under the title "The Thymo-Thyroid Apparatus," and has collected in a recent volume[4] a large amount of information about them from the literature of the subject, besides adding accounts of his own experimental researches. From the embryological point of view, the three all arise from the epithelium of the branchial clefts in mammals, or, to speak more precisely, from the epithelium of the branchial intestine. The parathyroids are organs indispensable to life, while the thyroid gland is not; the removal of the thymus from young animals slowly causes death. Both thymus and parathyroids seem to be involved in the production of tetany and in the regulation of calcium metabolism, which is upset by the acid intoxication that follows their removal. Launoy observes that the thyroids and parathyroids have diverse functions, and cannot replace each other in the animal economy. He argues also that while thyroidectomy undoubtedly leads to myxoedema, there is nothing to prove that exophthalmic goitre is the result of hyperactivity of the thyroid gland. He finds that practically all mammals develop tetany after parathyroidectomy, and that this tetany is generally fatal. As for the thymus, he states that its removal determines a slowly fatal cachexia thymopriva in young mammals. The functions of the thymus are still obscure, and he suggests that it may be the seat of synthesis of the nucleins; it begins to undergo involution at puberty, and is found to be enlarged in four-fifths of the patients with exophthalmic goitre. The author naturally raises a great

many more questions than he is able to answer, as is to be expected in any book dealing with ductless glands. He writes clearly, and deals fairly with the authors he quotes. His volume should be read by all medical men and physiologists who are interested in the subject with which it deals.

THE GENTLE ART OF GROWING OLD.

THE attainment of longevity is only desirable so long as sound health is maintained in the process. Long-drawn-out years of invalidism carry but little pleasure to the patient and none at all to those about him. In too many cases the fault is with the patient himself. He has not taken the trouble to learn how to grow old and maintain health at the same time. By many people, and especially by those who have denied themselves nothing during the vigorous years of middle age, the necessity for modifying indulgence as they grow older is ignored. The increasing girth is made the subject of mild jokes, and comes to be regarded as due to advancing years and therefore inevitable. The ever-ready motor car is always at hand, and the brisk walk of twenty minutes to the office or the station, as the case may be, is entirely omitted from the daily round. As years advance health becomes gradually impaired, and in the vast majority of cases imperfect metabolism is the cause. The body is overloaded with material and insufficiently exercised to get rid of the surplus. Many octogenarians have offered advice founded on personal experience, and the well-known work of Sir HERMANN WEBER has reached its fourth edition,[5] showing the means by which healthy life may be prolonged. Self-indulgence must give place to hygienic rule. Regulated exercise, moderation in bodily enjoyments, the counteraction of evil hereditary tendencies, cleanliness, and general mental control must each and all be observed, but many difficulties present themselves in the endeavour to live the strictly hygienic life. Himself a living example of the possibility of maintaining sound health into the ninth decade, Sir Hermann Weber is able to place these various considerations in their true perspective, and the latest edition of his work will be found to contain reference to the newest as well as to the most ancient views on the subject.

THE VISCOSITY OF LIQUIDS.

AMONG the monographs on inorganic and physical chemistry published by Longmans is one on the *Viscosity of Liquids*,[6] by A. E. DUNSTAN and F. B. THOLE—a subject of no small interest to biological chemists. The authors say: "Whereas the viscosity of a molecular solution is defined completely by the concentration and the temperature, that of a colloid presents an entirely different problem." There must be taken into account: (1) Solvate solution—the viscosity increases with the amount of dispersion medium taken up by the disperse phase. (2) Electric charge—ionized particles which move in the electric field impart to the system a materially greater viscosity than uncharged particles. (3) Previous thermal treatment—a gelatine solution which has been repeatedly warmed and cooled has, at first, a lower viscosity. (4) Previous mechanical treatment—a decrease in the viscosity of gelatine solutions can be produced by repeatedly forcing them through the viscometer. (5) Inoculation with small quantities of more viscous colloids. (6) Time—hydrated colloids yield different viscosity readings according to the age of the solution and the viscosity with which the temperature is being altered. (7) Addition of electrolytes and non-electrolytes.

Relatively enormous changes of viscosity occur within very narrow limits of temperature and concentration; a gelatine solution may, by merely altering these variables, or even by mere ageing, pass through all values of viscosity from that of water to that of a solid. Soap solutions can attain the viscosities of solids at concentrations less than 1 per cent.

If it is desired to follow quantitatively the alterations of dispersity or of solvate formation, such as coagulation, peptonization, gelatinization, and so on, any physico-chemical property of the system may be used as an indication of such changes. In practice that property will be chosen which shows the largest possible variation with small changes in the colloidal condition and lends itself to convenient measurement. These requirements are eminently fulfilled by viscosity.

In the case of aqueous soap solutions, the viscosity, on the addition of electrolytes such as caustic soda, first falls and then increases rapidly as the electrolytic concentration rises.

The initial diminution of viscosity may be due to the abstraction of water from the disperse phase, with a consequent diminution in the bulk of the latter; the rapid increase in viscosity above a certain electrolytic concentration is due probably to the formation of colloidal aggregates, the size of which may increase with increasing concentration.

These quotations will be enough to show the interest of this little monograph to those engaged in problems of biological chemistry.

NOTES ON BOOKS.

IN *Some Minute Animal Parasites*[7] Drs. FANTHAM and PORTER have accomplished a difficult task with a considerable measure of success. Their book does not claim to be a treatise on the pathogenic protozoa of man and animals; it gives a popular but, above all, scientifically accurate account of their principal protozoal diseases, which will form attractive reading both to the student and the lay public interested in tropical diseases. Full justice is done to the more important protozoal diseases of man; while "tsetse-fly" disease and "red-water" in cattle, coccidiosis in domestic poultry and game birds, fish and bee disease, and many other protozoal diseases of the lower animals are considered in detail. Apart from the direct effect of disease-producing protozoa on the human race itself, it is necessary, as the authors point out, to consider the question from the point of view of food supply and transport. Red-water fever in the United States, for example, costs that country over £8,000,000 annually, due to deaths of cattle from piroplasmosis. Such facts should bring home even to the most sceptical the enormous economic importance of these questions, which so profoundly affect the health and prosperity of mankind.

The astrologer no longer inspires awe; he is a jest; and it was not worth while to devote to his "science" a solemn course of FitzPatrick lectures before the Royal College of Physicians of London. Yet Dr. MERCIER did this last year, and has now published them in a volume entitled *Astrology in Medicine*.[8] If it is intended to be taken as a joke, as may be concluded from a chapter on saints and signs added to the lectures, it is too laboured. The book, we fear, is an addition to library lumber.

MEDICAL AND SURGICAL APPLIANCES.

Urethral and Urethro-Vesical Irrigations.

MR. FREDERICK H. PICKIN, M.R.C.S., L.R.C.P. (Westminster), writes: When attempted with obsolete implements, urethral irrigation is liable, in spite of a liberal supply of mackintosh sheeting, to make a great deal of mess. With the improvement made possible by the apparatus about to be described, the surgeon can practise irrigation in his consulting room without spilling a drop of lotion, and can dispense with the use of mackintoshes and gloves; all that is required is a small towel spread across the patient's thighs. The apparatus consists of a metal pipe (similar to that sometimes used for irrigating wounds) with a thumb-push stopcock (E) for turning on and off, and regulating the flow of the irrigating fluid. The pipe, to which the rubber tube from the reservoir of the irrigator is connected at F, terminates in a small double channel (B), to the backflow of which a piece of tubing is attached (C) by a simple metal push joint. This tubing passes back to a receptacle through a ring (D), which conducts it under the thumb-push in such a manner that it can be readily compressed between the anterior edge of the push and the

[5] *On Means for the Prolongation of Life.* By Sir H. Weber, M.D., F.R.C.P. Fourth enlarged edition. Founded on a lecture delivered before the Royal College of Physicians on December 3rd, 1903. London: John Bale, Sons, and Danielsson, Ltd. 1914. (Demy 8vo, pp. 241. 4s. 6d. net.)

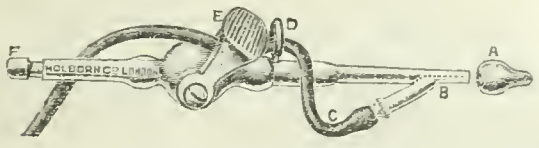
[8] *Astrology in Medicine.* By Charles Arthur Mercier, M.D. London: Macmillan and Co. 1914. (Cr. 8vo; pp. 100; 4 figures. 2s. net.)

upper surface of the pipe. A detachable metal urethra nozzle (A) caps the double-channelled end of the pipe. The patient, having emptied his bladder, reclines on a couch, comfortably propped by a back rest, his clothing is slipped down to the knees, and a small towel is placed in position. A urethral anaesthetic injection is given if the irrigation is likely to be at all painful or the patient nervous or resistant. The irrigator stand should be at the foot of the couch, and while the anaesthetic is being held in the urethra by the patient the reservoir is filled with the lotion selected, which should be quite warm. Air is expelled from the tubing and the reservoir raised to the required height. A receptacle is then placed on the couch between the patient's legs, the most convenient being a glass female urinal with a handle. The patient now allows the anaesthetic fluid to escape into a beaker, or on to the towel, and the surgeon takes the penis (with prepuce drawn back) firmly between the index finger and thumb of the left hand just behind the corona glandis, and lifts the irrigating pipe in the right hand, dropping at the same time the end of the outflow tubing into the receptacle. The urethral nozzle is now applied to fit the meatus, and kept accurately in position by pushing forward the glans with the left finger and thumb. The irrigating fluid is slowly turned on by a movement of the right thumb. If the anterior urethra alone is to be irrigated, this is all that is done (the position of the thumb push during anterior irrigation is shown in the illustration), since the lotion now runs into the urethra as far as the compressor urethrae and back through the outflow to the receptacle. The fluid can be felt rippling along the urethra by the fingers of the left hand. There can be no danger of creating



too great a pressure within the urethra (an important point in acute cases), because the outflow channel is constructed to be larger than the inflow. When, after thoroughly cleansing the anterior, it is desired to irrigate the posterior urethra, the thumb push is advanced still further, so as to nip the outflow tubing and to block it. The lotion is thus made to enter the bladder, until the patient feels that he has taken in as much as he can comfortably hold, when the stream is turned off completely. The pressure of fluid in the urethra is simultaneously relieved by the back flow (the tubing being unblocked when the thumb push is reversed), so that there is no spurting of lotion when the nozzle is removed from the meatus. The patient is now told to pass the contents of his bladder into a glass vessel. During the whole process of irrigation by this method there should not be any spilling or spurting of lotion at all. Should the pressure in the urethra become inconveniently great or painful, it can be instantly relieved by a movement of the thumb push to release the outflow tubing and convert the proceeding into an anterior irrigation. With experience the lotion can be easily made to enter the bladder, and I have been able to irrigate, without losing a drop, patients who have been most difficult to deal with by any other method. The apparatus can be easily kept clean and ready for use. The only part that touches the patient—the nozzle—can be boiled or washed and kept in spirit. It is useful to keep a set of these nozzles varying in size and shape. The outflow tubing can be detached and boiled or kept in lotion. The double channelled end can be unscrewed from the rest of the pipe and be boiled or immersed in spirit. The whole apparatus works smoothly. An anterior irrigation can be converted into a posterior without stopping the process to change a nozzle or turn a tap, a manœuvre that disturbs the patient and encourages spasm. Since working with this apparatus I have ceased to bemoan the absence of a third hand.

The Commission authorized by the New York State Legislature to make a scientific investigation into the causes of bovine tuberculosis and its economic and health effects on the State has been appointed by the Governor. Among the members of the Commission are Dr. Theobald Smith, Director of the Division of Animal Pathology in the Rockefeller Institute, New York; Dr. Hermann M. Biggs, Commissioner of Health, New York; Dr. Linsly P. Williams, Deputy Commissioner of Health, New York; and Dr. Henry L. K. Shaw, Professor of Children's Diseases in Albany Medical College.

THE ORIGIN AND DEVELOPMENT OF THE RED CROSS.

Care of the Wounded in Antiquity.

Historians give us accounts of battles, varying almost in every detail, but agreeing generally in this: that they say nothing of what became of the wounded. This is probably because there is little or nothing to tell. Some provision there was even in the earliest times, as may be gathered from Homer. In the Trojan war there was a special class of men skilled in removing arrows and in dressing wounds, and who knew means of stopping bleeding and relieving pain. Some knowledge of the surgery of the battlefield appears to have been possessed by nearly all the leaders, above all by Machaon and Podalirius, who may be assumed to have derived it from their father Aesculapius. Homer describes the cunning leech as being "worth many other men." The blind old bard himself described the wounds inflicted by his heroes with evident relish. De Quincey says he had a knowledge of wounds that would have made him fit for the post of house-surgeon at a London hospital, and a learned German, Fröhlich, has persuaded himself that Homer was actually an army surgeon. That the Spartans had a medical military service is shown by the fact that among the laws ascribed to Lycurgus is one ordering surgeons to retire to the rear of the right wing during a battle. Xenophon says that the surgeons with the Spartan army shared the same tent with priests, the minstrels, and any volunteers who might accompany the expedition. According to the same authority the Ten Thousand had at least eight surgeons with them. But it does not appear that there were ambulances; the wounded were carried on the backs of their comrades. In the *Cyropaedia* Xenophon tells us that Cyrus, who is drawn as the ideal ruler, not only provided his army with the most skilful surgeons he could find, but ordered them to look after the wounded of the enemy as well as his own. E. T. Withington, in his *Medical History from the Earliest Times* (London, 1894), thinks this must not be accepted as representing anything that actually existed in the sixth century before the Christian era, but at any rate it would seem to be the first germ of the great philanthropic idea which in our own day has blossomed into the Red Cross movement. One of the oldest authentic records of Greek military medicine, according to Withington, belongs to the period of the Persian wars about B.C. 450. This is an inscription found at Darli in Cyprus, which states that when the men of Idalion went to repel an inroad of Persians and Kitians, Onasilos and his brothers went with them and tended the wounded free of charge. Their services were, however, generously rewarded afterwards. The story of the death of Epaminondas at Mantineia when the arrow was extracted from his chest shows that in 362 B.C. there were surgeons in the Theban army. Philip of Macedon and Alexander the Great both had doctors, and a detailed account is given by Quintus Curtius of the extraction of an arrow from Alexander's chest by the surgeon Critobulus. A Hippocratic writer advises the young surgeon to seek opportunities of following a military expedition, and refers to works specially devoted to army surgery. Diocles invented the graphiscus, a spoonlike instrument for extracting embedded weapons, afterwards much used by the Romans.

The Egyptians had paid medical officers to look after their troops in war. Ptolemy Philometer, who defeated Alexander Balas, the pretender to the throne of Syria (B.C. 146), was thrown from his horse and died while in the hands of the surgeons, who apparently tried to trephine: Ptolemaeus in caput graviter vulneratus, inter curationem, dum ossa medici terebrare contendunt, exspiravit.

The Romans had a regular medical service with their armies, as is shown by many inscriptions. In his essay entitled Was the Roman Army provided with Medical Officers?[1] Sir James Simpson collected a number of passages from ancient writers showing that the Roman army as far back at least as the third century A.D. had physicians and surgeons serving in it. Vegetius who wrote a treatise, *De Re Militari*, towards the end of the fourth century, devotes a chapter to the care of the health of an army and refers to the care of sick soldiers by

medical art (*artc medicorum*). Before him Galen had said that the doctors employed in the German wars and having the opportunity of dissecting the bodies of the barbarians did not learn more than cooks know from handling dead animals. Each cohort, consisting of 1,000 to 1.500 men, was provided with four surgeons (*medicus militum* and *medicus cohortis*). The Pretorians had in addition *clinici*, or pure physicians. There was also the *medicus legionis*, an important rank, as each legion consisted of ten cohorts of about 6,500 men. The surgeons ranked with the standard bearers and trumpeters, among the non-commissioned officers, and they wore the ordinary dress and arms of the legionaries. With the standing army came the stationary camps with *medici castrenses* and a *valetudinarium* or military hospital; the first definite mention of such a hospital is by Hyginus Gromaticus in his treatise *De Castrometatione*, written in the second century. When more than three legions were in the camp there were additional hospitals. This system was continued during the Byzantine Empire with the addition of *deputati*, who rode immediately behind the fighting line with drinks and dressings and picked up the wounded, and the *nosocomi*, or male nurses, attached to the military hospitals. The Roman navy was also provided with surgeons, and the epitaphs of several *medici* of triremes still survive. According to Henry Brackenbury,[2] sometime professor of military history at Woolwich, the Emperor Aurelian, who flourished in the third century, issued instructions to his soldiers to aid the sick and wounded of his own army and that of the enemy.

CARE OF THE WOUNDED IN THE MIDDLE AGES.

In the twelfth century Saladin had a regular medical staff with his army, which even comprised apothecaries. He also allowed the Knights Hospitallers to minister to the wounded Crusaders in the conquered city of Jerusalem without interference. In the earliest Middle Ages the wounded soldier was looked after first by women and afterwards by surgeons, who either formed part of the general levy or were attached to the person of the king or some great noble. Withington says the English were the first of Western nations to originate something like an army medical service, but this is not quite accurate, for Luchaire in Lavisse's great *Histoire de France*, speaking of the great marshalling of the military forces of France by Louis VI against the Emperor of Germany, says that provision was made for the care of the wounded. This is shown by a passage in a record dated 1124 to the following effect: *Provisum est etiam ut ubicumque exercitus, apto tamen loco, certamen iniret, et carri et carrete aquam et vinum fessis et sauciatis deferentes instar castellorum in corona locarentur, ut a labore bellico a vulneribus defitientes, inibi potando ac ligaturas restringendo fortiores, indurati ad palmam optinendam concertarent.* Which may be translated as follows:

> Measures were also taken that wherever the armies joined battle (provided that the place was convenient for the purpose) carts and wagons carrying water and wine for the tired and wounded soldiers should be stationed in the fighting line after the fashion of small forts, so that those who left the fray on account of their wounds might renew their strength there by drinking and by loosening their armour, and so refreshed should continue to fight for victory.

It may be supposed that these "forts" served the purpose of field hospitals, although there is no distinct mention of surgeons or of medical treatment.

The first trace of a military medical service in the English army is found at the beginning of the fourteenth century, when Edward I took the field against Scotland. In his campaign he was attended by seven medical men. They included a king's physician and two juniors (*valetti*), a king's surgeon and two assistants (*socii*), and a simple surgeon. The king's physician and surgeon each received a knight's pay, 2s. a day; the others, who ranked as esquires got half that sum. The chief surgeon got compensation for three horses killed in Scotland on the king's service. He would therefore seem to have been kept busy. The Welshmen who fought at Crécy were accompanied by a surgeon of their own race; from this it may, perhaps, be inferred that there were other surgeons with the army. Mr. D'Arcy Power thinks it possible that John of Arderne, who was acquainted with the Black Prince, was present at that battle. Nicholas Colnet, physician, and Thomas Morstede, surgeon, went with Henry V to Agincourt. Both were attended by three mounted archers and Morstede had besides twelve assistants.

In 1563 William Clowes was a surgeon in the army commanded by Ambrose, Earl of Warwick, and he afterwards served in the English fleet against the Armada in 1588.[3] John Woodall, who was born in 1569, served abroad, and appears to have been the first to recommend lime juice in the treatment of scurvy. He was the author of *The Surgion's Mate*, published in 1617, and of a companion treatise, the *Viaticum*, which appeared in 1628. These two books were long the textbooks of naval surgeons. Richard Wiseman served as a surgeon on the King's side in the Civil War. He was for many months attached to the troops under the command of the Prince of Wales, afterwards Charles II; later he was sergeant surgeon to the King.

FIRST AMBULANCES.

The first mention of ambulances seems to be in Hirstius's *De Bello Africano*, where he says that after the battle fought near Ruspina, Labienus ordered his wounded to be carried in wagons (*plostris*) to Adrumentum. But the credit for the establishment of field hospitals and ambulances on any considerable scale seems to be due to Isabella the Catholic of Spain. During the war of Granada (1483-87) the queen caused a number of large tents, known as "the Queen's Hospitals," to be always reserved for the sick and wounded, and furnished them with the requisite attendants and medicines at her own charge. Speaking of the siege of Alora in 1484, the Spanish historian, Hernando Del Pulgar, writes:

> For the care of the sick and wounded the queen sent always to the camp six large tents and their furniture, together with physicians, surgeons, medicines and attendants, and commanded that they should charge nothing, for she would pay for all. These tents were called the Queen's Hospital.

On the surrender of Malaga, 1487, the Spanish army, on its entry, was followed by the Queen's Hospital in 400 wagons ("ambulancias"). At the siege of Baza, two years later, an eye-witness, Peter Martyr, wrote to the Archbishop of Milan as follows:

> Four huge hospital tents, the careful provision of queenly piety, are a sight worth seeing. They are intended not only for the wounded, but for those labouring under any disease. The physicians, apothecaries, surgeons, and other attendants are as numerous, the order, diligence and supply of all things needful as complete as in your suburban Infirmary of the Holy Spirit, or the great Milan Hospital itself. Every sickness and casualty is met and provided for by the royal bounty, except where Nature's appointed day is at hand.[4]

The queen herself frequently visited the wounded, and when her courtiers hinted that this was contrary to Castilian etiquette, she is said to have replied:

> Let me go to them, for they have no mothers here, and it will soothe them in their pain and weakness to find that they are not uncared for.

Pedro Bosca, in an oration delivered at Rome on November 1st, 1487, before the senate of Cardinals in celebration of the victory gained at Malabar, says:

> The Queen's Hospital comprised nearly 400 waggons with awnings, and the wounded were nursed not by the highly improper persons who usually follow armies, but by most respectable matrons selected for the work.[5]

MILITARY HOSPITALS IN THE SEVENTEENTH CENTURY.

The French army, which during the period of Richelieu's power rose from 12,000 men in 1621 to 150,000 in 1638, was without military hospitals. The first was established in 1639. Before that each company had a surgeon attached to it, and medical help was sometimes given by the priests who ministered to the spiritual needs of the soldiers. Disabled soldiers were quartered in monasteries, but the habits of military life did not tend to make them edifying inmates, and the monks were always glad to get rid of them as soon as they could. In the reign of Louis XIV Louvois tried to establish a regular military medical service, but without success. Disease raged in the army, and the condition of the sick and wounded was to the last

[5] Quoted by Withington, op. cit.

degree wretched. In 1667 an inspector reported that he found sixteen men in four beds in huts so full of straw that it was dangerous to make a fire, and with muddy floors constantly damp. Apparently the attempt to establish hospitals in 1639 had not been followed up, for Louvois made another effort, which was also a failure. A report made in 1689 on the hospitals of Mont Royal and Sarrelouis stated that the soldiers were lying on straw closely packed together; at Strassburg they lay three in a bed. The surgeons are described as ignorant and negligent, doing nothing but cut off legs and arms without endeavouring to save them. Generally all the wounded died of haemorrhage or sepsis.[6] It would have been better for them if they had been dispatched in the summary fashion described by Ambroise Paré in his account of the campaign in Turin in 1537, in which he accompanied Monsieur de Montejan, Colonel-General of the Infantry, whose surgeon he was at the time. He says:

> Being come into the city I entered into a stable thinking to lodge my own and my man's horse and found four dead soldiers and three propped against the wall, their features all changed and they neither saw, heard nor spake, and their clothes were still smouldering where the gunpowder had burnt them. As I was looking at them with pity there came an old soldier who asked me if there were any way to cure them. I said No. And then he went up to them and cut their throats gently (*tout doucement*) and without ill will towards them. Seeing this great cruelty I told him he was a villain; he answered he prayed God when he should be in such a plight he might find someone to do the same for him that he should not linger in misery.

If disabled soldiers were thus treated by their own side, it may be conjectured that as a rule the wounded and sick of the enemy were left to their fate. The dawn of a better state of things came in the eighteenth century.

Beginning of Neutralization of Hospitals.

In the Austrian War of Succession a treaty was concluded to regard the hospitals as sacred from attack. In 1743 the Duc de Noailles and Lord Stair agreed that the hospitals, the wounded, and the military surgeons should be treated as neutrals. In the seven years' war Louis XV and Frederick II agreed to consider all the medical staff as neutrals, and as such exempt from capture. In 1759 a similar arrangement was made between the Marquis de Barail, commanding in Flanders, and the English general, Henry Seymour Conway. The idea of neutralization of the wounded and those who tended them was making progress, when the French Revolution rudely checked its growth. The Convention decreed the immediate execution of prisoners, whether wounded or not. In 1800 Moreau and the Austrian General Kray, however, agreed to take equal care of all wounded in their hands, whether friends or foes. These were but isolated displays of humanity. The work of Florence Nightingale in the Crimea was a powerful stimulus to the organization of help for the sick and wounded.

The Founder of the Red Cross.

But unity of international action was still lacking. It was not till some years after the middle of the nineteenth century that the Red Cross organization had its birth. The founder was Henri Dunant, a remarkable man whose name has been almost forgotten. In the last edition of the *Encyclopaedia Britannica* he is dismissed in one line, in which he is wrongly described as a physician, and in the only mention of him in a leading London newspaper that we have seen since the outbreak of the present war his name was twice misspelt "Durrant." It may not be amiss, therefore, to give some account of a man who was one of the greatest benefactors of his fellow creatures in modern times. Henri Dunant was born at Geneva on May 8th, 1828, of a family belonging to the magistracy of the Swiss Republic. He was the son of a member of the representative council, and received a very careful education, which included a training in philanthropy, from his mother, *née* de Colladon. Her ancestors had been members of the nobility of the Berry before the Reformation, on the outbreak of which they left Bourges. One of Dunant's brothers was a distinguished doctor, long professor of hygiene in the University of Geneva, and organizer and general secretary of the International Congress of Hygiene held at Geneva in 1882. Dunant was greatly influenced by Florence Nightingale, Elizabeth Fry, and Harriet Beecher Stowe. With his mind full of the work of Florence Nightingale he visited the battlefield of Solferino, where he witnessed the sufferings of the wounded lying whole days on the ground. With the help of some women he organized a service of help in the little town of Castiglione, himself giving aid to the soldiers and dressing the wounds without regard to nationality. He was known as "Le Monsieur en Blanc" (the "Man in White") on account of his summer attire. These scenes of horror gave rise in his mind to the idea of volunteers trained in the work of stretcher drill and having a knowledge of first aid organized on a permanent basis, well disciplined and being, like the hospitals and their material, completely neutral. He thought that this result might be easily attained if nations by a special convention were to adopt a common symbol which should designate the character and function of such workers. In 1859 each nation indeed had for its field hospitals a special flag, but the colours were almost always unknown to the enemy, so that the ambulances were constantly fired on, the wounded taken prisoners and the surgeons arrested or killed at the very moment when they were looking after the wounded. This was the origin of a distinctive flag for ambulances and hospitals—the white flag with the red cross. The form of the flag was intended to be a compliment to Dunant's native country: it is the converse of the Swiss flag, which is a white cross on a red ground.

Four days after Solferino Dunant went to Borghetto, and spoke to MacMahon of the lamentable state of the wounded, begging permission to use the Austrian surgeons who had been taken prisoners by the French. The marshal advised him to go to Cavriana to see the Emperor, who received him favourably, and on July 1st the following order was published:

> The physicians and surgeons of the Austrian army who have been made prisoners while dressing the wounded shall be restored to liberty without condition on their request. Those who have ministered to the wounded at Solferino gathered in the ambulances of Castiglione will be allowed to go back first to Austria.

From that time Napoleon III interested himself in Dunant's scheme, and declared his adhesion to the principle of the neutralization of the wounded, of the ambulances, and their personnel. The Emperor himself suggested that inhabitants of the country who should give aid to the wounded should be treated as neutrals. On his return to Geneva, Dunant wrote his *Souvenir de Solférino*, which brought him the enthusiastic approval of many distinguished men, and was at once translated into nearly every European language. He did not, however, escape detraction or jealousy, but he was not discouraged and persevered with the work. One of his keenest critics was Marshal Randon, who in the true spirit of the old soldiers who resented the interference of Florence Nightingale, exclaimed, "Why should these civilians mix themselves up with what does not concern them?" On the other hand he had the approval of MacMahon, Canrobert, and other soldiers. His book also interested the King of Prussia, whose attention was called to it by Queen Augusta; Princess Louis of Hesse (Princess Alice); the Crown Prince, afterwards the Emperor Frederick; Von Roon, then Prussian Minister for War; Oscar II, King of Sweden, and many other influential persons. Dunant spared no pains to secure support for his scheme. He went about from one country to another trying to enlist the active sympathies of those in power, and gained for himself the name of the new Peter the Hermit. A conference took place at Geneva on October 26th, 27th, 28th, and 29th, 1863, at which the following States were represented: Austria, Baden, Bavaria, Spain, France, Great Britain, Hanover, Hesse Darmstadt, Italy, Holland, Prussia, Russia, Saxony, Sweden and Norway, Switzerland, Wurtemburg. Besides these, Denmark, Mecklenburg-Schwerin, and Portugal sent official intimations that they would accept the conclusions of the conference.

Before continuing the record of the development of the Red Cross, it will be well to tell briefly the story of the rest of the life of its founder. His disregard of his own interests led to the loss of his fortune in 1867. For twenty-five years he lived in poverty and obscurity. The Nobel Peace Prize was most deservedly awarded to him in 1901, and this, we may hope, enabled him to pass the remainder of his days in comfort. He died towards the end of 1910 at Heiden, Appenzell, on the shores of Lake Constance, where he had lived for many years.

British Medical Journal.

SATURDAY, OCTOBER 3RD, 1914.

BACILLI AND BULLETS.

"In the wars of the world they—bullets and bacilli—have been as Saul and David—the one slaying thousands, and the other tens of thousands." One could wish that these words of Sir William Osler to the officers and men in camp at Churn could be placarded in every camp. His appeal was to the men themselves—not to their self-interest, but to their patriotism. The efficiency of the army in the field "will be increased," he said, "one-third if we can prevent enteric. It can be prevented, it must be prevented; but meanwhile the decision is in your hands, and I know it will be in favour of your King and country." This last sentence followed directly on an appeal to his hearers to take advantage of the immunity to typhoid fever conferred by inoculation with antityphoid vaccine. Antityphoid vaccination is not compulsory in the British army; but though not compulsory, the British regular is so convinced of its value, that the special Army Council Committee on the subject found its statistical labours brought to an end by the circumstance that in all the test units they were studying a very large majority, and in some every man, had submitted to inoculation. We published a few weeks ago a letter signed by a number of the leading pathologists and men of science in this country, strongly urging that the example of the United States and France should be followed in this country, and antityphoid inoculation in the army made compulsory. Sir Almroth Wright, the originator of this method of immunization, published this week in the *Times* an article on the case for compulsion, in which, after stating the beneficial results of antityphoid immunization, he said: "It is not from the soldier that opposition to compulsion is to be feared. He has by entering the army shown that he desires to be put under orders. And all he asks is that he shall be put to use in the most effective way without being called upon to decide things that are outside his competence. If opposition comes—and we are told 'it is impossible but that offences will come'—it will come from that kind of person who, by his personal aversion to the principle of compulsion in anything, has brought down upon us, as our Nemesis, this European war." If inoculation were compulsory the work of the medical service of the army in all its branches would be very greatly simplified, and the amount of labour now expended in preaching the doctrine of prophylactic immunization would be saved and directed into other channels where it could be very usefully employed. Meanwhile it is satisfactory to know that the special department of the War Office charged with this matter has already issued on demand over 500,000 doses of vaccine, and that the daily requisitions average over 15,000 doses. Some regiments and units, we understand, have already 70 per cent. of their strength inoculated. Unfortunately Sir Almroth Wright states, and our own information confirms his statement, that many drafts and regiments have been leaving for the front with only a very small proportion of inoculated in their ranks. This has, we believe, in most instances been due to the fact that military considerations would not permit of the men being spared for inoculation while they were under orders to be ready to move at a few hours' notice.

We have received many communications from distinguished members of the civil public health service expressing their approval of the views expressed in the editorial articles recently published in this JOURNAL. They all feel the urgent need for an effective system of co-operation between the civil public health service and the medical staff of the Territorial Forces; and one correspondent urges that medical inspectors directly representing the Local Government Board should co-operate with both. The organization of a medical and sanitary service for the new recruits is a question that seems as yet hardly to have been faced. If, very shortly, we are to have a million recruits in training, it will be necessary to have between 4,000 and 5,000 medical officers. There are plenty of medical volunteers, and from our correspondence we know that more will at once be obtained if the War Office asks for them, but all will need to be trained in the special work required of military medical officers, not merely in the details of keeping returns which are necessarily complicated, but also in the very special kind of sanitary administration essential when large bodies of men are brought together in camps of exercise and training. The medical recruits stand in a totally different position from those enlisted in other departments of the army, because their services will be even more necessary and important during the period of training than afterwards, whereas other recruits cannot be expected to be of military value for months. "I can never," said Sir William Osler, "see a group of recruits marching to the dépôt without mentally asking what percentage of these fine fellows will die legitimate and honourable deaths from wounds, what percentage will perish miserably from neglect of ordinary sanitary precautions? It is bitter enough to lose thousands of the best of our young men in a hideous war, but it adds terribly to the tragedy to think that more than one-half of the losses may be due to preventable disease." As Mr. Lynn Thomas, speaking from his experience in South Africa, says in a letter published elsewhere, "Healthy camps depend upon early—it cannot be too early—and prompt sanitary operations." What we have constantly to keep in mind is that disease will not wait to take its toll until the men are in the field; if the sanitation of camps of training and exercise is not at once taken in hand the toll will begin to be exacted after a few months.

THE NEW RECRUITS AND THEIR TRAINING.

THE farm hand, miner, and fisherman have bodies inured to toil, hardened to stand the weather and exposure to cold, but they have not perhaps the quickness of nervous response in picking up the art of war possessed by the city recruit, who has been educated on the playing fields or in the street, and bred to the acuteness of business life. The latter may make the better soldier in the shorter period, if he can gain nerve power to endure the strain of war, for his body can be tuned up far more easily than can the slower nervous system of the other be made quick. In the training of the citizen's body the superfluous fat and tissue fluid go, and the muscles and sinews

become developed. His body becomes hardened, the heart and respiratory muscles develop to meet the demand made on them during severe exercise, when the pulmonary ventilation, the oxygen use, and the output of the heart in a given time increase ten and even fifteen times. The athlete's heart develops to meet the strain made upon it.

The trainer at first must go slowly with the city recruit. He must not push him to the point of exhaustion, for this results in a deficiency of oxygen in the tissues, consequent production of excess of acid, and actual destruction of muscle tissue and exhaustion of nervous energy. He must push to that degree of oxygen want and acid production which stimulates the blood formation, and the development of the respiratory and skeletal muscles. The enormous benefits which result from hard exercise are due to the vast increase in metabolism, with its concomitant increased circulatory, respiratory and cutaneous activity, the natural massaging of the belly organs, and complete utilization of foodstuffs, which limit bacterial decomposition in the bowel and prevent that chronic poisoning by bacterial toxins so common in the overfed, overwarmed, sedentary city worker. Nothing could be better for the nation than the daily drill in physical exercises which the war has led many to take up. May the habit once started continue, and be organized as a national discipline in peace!

Let it be noted that there is no purpose in developing muscles in the recruit which will not be used in the art of war. There is nothing to be gained by mere size and beefiness in the infantry. Frederick the Great's 7 ft. Irishman (secured by the expenditure of a small fortune) is not worth buying, even at the same figure as the medium size wiry man. What are wanted are brains to take cover and fight with skill and patience, and the power of endurance against cold, strength to stand periods of irregular feeding and broken sleep, and, above all, the power to march. The tall man needs more calories in his daily diet: the transport train must be bigger for an army of tall men. A man of 5 ft. 3 in. can shelter in a trench better, shoot as well while offering a smaller mark, and keep himself warm in a smaller space than the big man.

The record breakers in long distance walking races are generally lean light weights. Economy in muscular work is gained by perfect nervous co-ordination of muscular movement, practice making perfect: this means that the work comes to be done on less food. A sore heel, and consequent limp, at once show themselves in uneconomical work and the expenditure of many more calories in the performance of a day's march. The soldier thus handicapped is the first to fall out: the supplies of his bodily engine exhausted, he becomes a run down piece of mechanism. The trained man, hardened, carrying only the minimum but adequate quantity of fat (the natural garment of the body), sweats much less, and requires less water to drink—a most important matter in considering the prevention of disease under war conditions. The new recruit must be allowed more drink *per diem* in the first days of his pilgrimage. In hot weather such as our troops faced at Mons, before they had become war hardened, the water lost from their bodies was great, and the danger of heat-stroke was imminent unless this were made good. Tunics and shirts were opened, sleeves and trousers rolled up, to allow the escape of body heat. The men carried some 55 lb. (haversacks, war ration, rifle, three bandoliers of ammunition, trenching tool), and finally, in the exigencies of the march, discarded overcoats and other of their impedimenta, at the moment less important.

The work of the Army Medical Advisory Board has been of very great value in arranging on the best physiological principles the clothing and distribution of the weight carried, and in raising the war ration by a thousand calories. The soldier was partly starved on the old ration and lost weight continuously during severe marches. With the new value of 5,000 calories he keeps his weight after the initial and proper loss of some body fat and water. Of enormous importance, too, is the sterilization of water by chlorine by the simple method of adding bleaching powder to the water-cart a few hours before the water is used.[1] The day of the filter candle would seem to be over.

Weathering the recruit blunts his cutaneous sensibility, hardens his skin, and tones up the involuntary muscle. Exposure to cold and wet will do him little harm if he be well fed and not over-exhausted. Officers must realize that it is essential to keep up the recruit's immunity by the maintenance of his vigorous health and by keeping down massive infection. The innate power of the human race to resist cold and wet is enormous, and on good feeding and adequate rest depend over 90 per cent. of an army's fitness when on active service. For winter campaigning pure flannel garments are incomparably better than cotton. So much so-called flannel is adulterated nowadays with cotton that it is necessary to insist on pure flannel.

THE AFTERMATH OF SCLERECTOMY.

During the past five years there has been a veritable furore for the operation of sclerectomy or sclerotomy for the relief of glaucoma. Herbert introduced sclerotomy and Lagrange sclerectomy. Lagrange's method was modified by Freeland Fergus, who used a trephine, and again by Elliot, who improved the combined sclerostocyclodialysis advocated by the Glasgow surgeon. Elliot, by his enthusiasm and his vast command of material, has done more than any other ophthalmologist to popularize the operation, which is now often called "the Elliot operation." Holth of Christiania used a punch instead of a trephine, obtaining a similar result in a different way. The fact that a second edition of Elliot's book on sclero-corneal trephining has appeared within a year after the first is proof of the great interest taken in the newer operations for glaucoma. At the present time some form of sclerostomy is being performed by the majority of ophthalmic surgeons all over the world, and Elliot himself has published statistics of over 1,000 cases of trephining.

Yet no definite pronouncement upon the question can yet be made. Certain basal facts may be said to have crystallized out. It is pretty generally admitted that sclerectomy is better that sclerotomy. The majority of surgeons are trephining, or punching, or performing the Lagrange operations, though Herbert's operations are performed by some. It would appear that, provided a piece of sclera be removed, whether by trephine, punch, or scissors, the ultimate result is the same. But—and this is the most important fact of all—though the newer operations were introduced because they were safer and more satisfactory than iridectomy, yet to-day most surgeons add a supplementary iridectomy. In other words, the new operation is more serious than iridectomy, because it

[1] See Professor Sims Woodhead's paper in the JOURNAL of September 19th, p. 493.

is iridectomy and something more. If, therefore, sclerostomy is to supersede simple iridectomy in all cases, as Elliot would wish, it must be proved beyond doubt that the final results obtained by the new operation are decidedly better than the old.

At the Oxford Ophthalmological Congress[1] last July, a paper was read by J. Jameson Evans and T. Harrison Butler upon the results of their glaucoma operations during the past seven years. They stated that they were astonished to find when they came to make up their statistics that iridectomy headed the list as the most successful operation. Each of these surgeons came to this conclusion independently. In this paper only 160 cases were summarized, and a larger number is necessary before passing final judgement. In the discussion which followed the paper, several speakers narrated cases of "late infection." The operation had been a success for months or even years, then destructive iridocyclitis set in, or panophthalmitis developed. One speaker described a case of sympathetic ophthalmitis which had followed one of his trephining operations. Several cases of late infection have been published in Germany and elsewhere, and at the Aberdeen meeting of the British Medical Association Mr. Hill Griffith of Manchester recounted a melancholy example, and mentioned that thirty instances of this complication were on record. Several others were added to the list by the speakers who discussed the paper.[2] It is therefore obvious that every patient who has a filtering scar runs a risk of losing his eye from septic infection, and a slight one of losing the second as well from sympathetic ophthalmitis. There are other complications met with, one of which is delayed reformation of the anterior chamber, which may remain empty for a fortnight. In other cases permanent shallowness of the chamber has been noted. Dislocation of the lens may follow trephining, and post-operative iritis is said by Elliot to be common.

We have said enough to indicate that the claims made for sclerostomy cannot be admitted without question. The newer operations are valuable in many cases of glaucoma, but it would appear that they will not entirely displace simple iridectomy. It will be the work of the next decade to decide which cases are most suitable for fistulization and which should be reserved for iridectomy. We advise our readers who contemplate performing sclerectomy to study Colonel Elliot's book,[3] but to remember that it is the work of an enthusiast.

DRUGS WITH GERMAN NAMES.

WE have received letters from several correspondents which show that the question of the prescription of drugs manufactured in Germany is exercising their minds, and we propose to deal with the matter more fully in a subsequent issue. Meanwhile we may observe that it has to be regarded from several points of view. In the first place, when the drug is a body of definite chemical composition which can without any great difficulty be produced in a pure state, there may be no reason why the use of the German trade name should be continued in prescriptions. Acetyl salicylic acid is an example in point. It appears under that name in the French, German, Swiss, Spanish, and Italian pharmacopoeias. Advance copies of the new *British Pharmacopoeia* were made accessible for the inspection of the public on October 1st at the offices of the General Medical Council in London, Edinburgh, and Dublin, and we find that, as was to be anticipated, "acidum acetylsalicylicum (acetyl salicylic acid)" appears there, and the characters of the substance and the tests it must fulfil are duly set out. The new *British Pharmacopoeia* will come into force at the end of this year. Meanwhile all that the prescriber has to consider in the interests of his patients is that the drug should be chemically pure, and if he thinks it necessary to use a particular brand he will find in our advertisement columns evidence that British chemists supply brands which they guarantee to fulfil this condition. With regard to hexamethylenetetramine, special brands of which are known by the trade mark names of urotropine, cystogen, metramine, and vesalvine, and by other names which do not seem to be registered, it is in the United States, German, and Japanese pharmacopoeias under the name of hexamethylenamina, and it appears in the new issue of the *British Pharmacopoeia* under the name of "hexamina (hexamine)" with instructions as to the characters and tests which the product must fulfil. As reported last week, the trade mark "urotropine" was the subject of an application to the court appointed by the Board of Trade. A decision was postponed for three months, the applicants undertaking to draw their supply of the drug from the agents of the owners of the German trade mark so long as the stock in this country lasted. The Comptroller-General of Patents laid it down that the court would not recommend the Board of Trade to transfer to other businesses device trade marks found to be associated with foreign firms unless it were proved to be in the public interest. The object of the Board of Trade was, he said, to enable business in this country to go on, which would not always be possible without the suspension of patents or trade marks. With regard to disinfectants, we believe that as a rule British made preparations equally effective as those of German manufacture can be found. In fact the moral appears to be that the matter lies very largely in the hands of the profession itself, if individual members will take the trouble to analyse their reasons for certain preferences which have led them to prescribe drugs under trade mark names. With regard to certain other drugs, of which salvarsan may be taken as an example, the position is somewhat different, inasmuch as their manufacture involves difficult chemical processes which hitherto, we believe, have only been carried out by the patentees. The decision of the Board with respect to this particular drug has not been made public; its action in respect to it will be watched with much interest.

BERMONDSEY BOARD OF GUARDIANS AND MEDICAL ATTENDANCE ON PAUPERS.

THE Bermondsey Guardians are advertising for a whole-time district medical officer whose duties will be to attend the sick poor either at their homes or in the parish institutions under the direction of the medical superintendent of the infirmary. It is well that intending applicants for this post should realize that this is the first-fruits of a scheme for turning the district Poor Law medical service of Bermondsey into a whole-time service, of which the Camberwell Division has expressed the opinion that it is against the interests of the pauper patients and detrimental to those of medical practitioners. The main duties of the officer appointed will apparently be those of the ordinary Poor Law district medical officer. These officers, as is well known, have throughout the country the advantage of a superannuation scheme and of security of tenure. But, so far as we can ascertain, the Bermondsey officer will technically be an assistant to the medical superintendent, and will thus have no security of tenure. The value of the superannuation scheme will, therefore, be very much less to him than it is to the ordinary district medical officer. Applicants for the post—especially married men, to whom the preference is to be given—

[1] *Ophthalmoscope*, August, 1914.
[2] BRITISH MEDICAL JOURNAL, August 29th, p. 389.
[3] *Sclero-corneal Trephining*. Second edition. By R. H. Elliot, Lieutenant-Colonel, I.M.S. 1914.

should make careful inquiries on the points above-mentioned, and if the answers are not satisfactory, should seriously consider whether it is worth their while to take a post which is subject to these disabilities, especially in view of the fact that the scheme has only been sanctioned by the Local Government Board for five years.

AN IMPORTANT PUBLIC HEALTH APPOINTMENT.

We congratulate the West Hartlepool Town Council upon the decision at which it has arrived to pay a salary of £500 per annum to the whole-time medical officer of health it intends to appoint. His duties will include not only the public health work of the county borough, but also the school work and the work under the Tuberculosis Order. No one who appreciates the onerous and responsible nature of the duties thus to be assigned to the medical officer would for a moment regard the intended salary as excessive, but the Town Council has at least, on full consideration of the circumstances, fallen into line with the recommendation of the Local Government Board that the salary for whole-time medical officers of health should be not less than £500. A statement of the main facts in connexion with this appointment was published in the Journal of August 8th last (page 311), the Hartlepools Division and the Association having rightly taken exception to the salary of £400 then proposed by the Town Council to be paid for the combined duties, the minimum remuneration recognized by the Association for the appointment of tuberculosis medical officer being £500. As we have frequently pointed out, the need for adequate remuneration for medical officers of health is based primarily upon the importance of securing efficient service, and it is obvious that an inadequate salary cannot possibly attract practitioners of experience and standing in the profession. We are confident that much advantage to the public health of West Hartlepool will result from the present decision of its Town Council. The amended advertisement of the post will be found on page 33 of this issue.

THE BRITISH PHARMACOPOEIA, 1914.

Copies of the new issue of the *British Pharmacopoeia*, 1914, were placed for the inspection of the public at the offices of the Council in London, Edinburgh, and Dublin on October 1st, but the statutory notices of publication will not be inserted in the official gazettes until December 31st, 1914, so that until that date the new issue will not become official. It has been edited by Professor Tirard, M.D., F.R.C.P., of King's College, University of London, and Professor H. G. Greenish, F.I.C., of the Pharmaceutical Society, to whom in the preface acknowledgement is made for their skilful and assiduous services. In the preparation of the new issue constant use has been made of important practical researches carried on by British pharmacists at the request, in many instances, of the Pharmacopoeia Committee of the General Medical Council, the Pharmacopoeia Conference, or the Committee of Reference in Pharmacy. The last named committee has presented to the Council a series of important reports and recommendations, which have been published from time to time, and have evoked expert criticisms; these have been freely used in the preparation of the present issue. In the new edition the metric system of weights and measures has been employed for all pharmaceutical and analytical computations. It has also been employed for the specification of doses in the expectation that in the near future the system will be generally adopted by British prescribers; as a transitional provision, however, doses have also been expressed in terms of the imperial measure. The preface recommends that the symbols for drachm and ounce which are commonly used for both solids and fluids indifferently should be abandoned, since they are, it is said, apt to be misread. It is not, of course, possible in this issue to attempt any general examination of the changes introduced, but we hope to deal with the matter fully at as early a date as possible.

AN ANTIVIVISECTIONIST FINED.

According to the *Daily News and Leader* of September 30th Miss Beatrice Ethel Kidd, the secretary of the British Union for the Total Abolition of Vivisection, was on September 29th fined £5 and £10 10s. costs by the Bow Street magistrate "for publishing and dispersing a book entitled *Facts about Vivisection, 1913*, purporting to be a report of the inspector under the Vivisection Act for 1912, and to have been issued by the Home Office—on which the name and address of the printers were not printed." It was stated that the book contained statements which were in flat contradiction to the terms of the official report. Miss Kidd said that a Mrs. Phillips, one of the union's subscribers, had the book printed at her own expense in Manchester, and forwarded about 200 copies for distribution. The magistrate consented to state a case on the legal point raised as to whether the printers were the only persons liable under the Act.

REVISION OF MEDICAL BENEFIT REGULATIONS.

We have received as we go to press a copy of a memorandum to Insurance Committees on the revision of terms and conditions for medical service for 1915 (Memo. 201, I.C.), and a copy of the draft regulations proposed to be made by the National Health Insurance Joint Committee. The two alterations which, as indicated in the memorandum, it is proposed to make have to do with the introduction of uniform medical certificates, and with giving the Commissioners power to make further alterations in the regulations before the expiration of 1915. The Commissioners consider it desirable to take this power in view of the fact that the war has stood in the way of a full consideration of further changes which might prove to be desirable. In any case they notify that it is highly improbable that any changes which it may be proposed to make will take effect sooner than June 30th, 1915. We intend to discuss the bearings of the memorandum and new regulations in our next issue.

The opening meeting of the Medical Society of London for the session 1914–15 will be held on Monday evening, October 12th, when Sir John Bland-Sutton will deliver his introductory address. At the next following meeting of the society, on October 26th, a discussion on the operative treatment of tumours of the caecum and colon will be held, and on November 9th Mr. E. E. Austen, of the Natural History Department of the British Museum, will speak on the house-fly especially in relation to human health. The Lettsomian lectures will be delivered before the society in February and March by Mr. Arthur E. Barker, and the annual oration will be given on May 17th, 1915, by Sir William Osler.

The museum demonstrations at the Royal College of Surgeons of England, intended for advanced students and medical practitioners, will be resumed on Friday, October 16th, when, at 5 p.m., Professor Keith will show specimens illustrating gunshot injuries of the head—ancient and modern; on the following Fridays, at the same hour, Professor Keith will demonstrate specimens illustrating gunshot injuries of the limbs and of the thorax and abdomen. Mr. Shattock will show specimens illustrating carcinoma, tuberculosis, and repair on Mondays, October 19th, 26th, and November 2nd, at 5 p.m. On Wednesdays, October 21st and 28th, Mr. Colyer will demonstrate specimens of injuries to the jaws and teeth of animals and of dento-alveolar abscess and dental cyst.

THE WAR.

PREVENTION OF DISEASE IN WAR.

HEALTHY CAMPS.

We have received the following letter from Mr. J. Lynn Thomas, C.B., who was Senior Surgeon to the Welsh Hospital in South Africa during the Boer war:

The Need for Early and Continuous Vigilance.

Sir,—The medical profession has only just emerged from dreary darkness into brilliant light in the domain of surgical treatment of acute intestinal accidents, such as perforations. Light came when the grim reality that early and prompt operations formed the foundations of orthodoxy in treatment. We are convinced that the same axiom must be made the bedrock upon which healthy camps are to be maintained—namely, early and prompt sanitary operations with ever-watchful vigilant treatment during the quiescent periods between battles.

May I therefore be allowed to offer my sympathetic congratulations to the British Medical Journal upon its action in so pointedly drawing attention to the dangers our military forces at home must run if there be any failure in sanitation? I am personally keenly interested in the matter of promptness of action in placing camps under good sanitary conditions, for I had the experience of being at Bloemfontein in May, 1900, when enteric fever was rampant, and later on had to mourn the loss of friends and members of our staff, one of whom fell a victim to typhoid complications before she could receive the signal honour of R.R.C. (Royal Red Cross) in recognition of her brilliant services.

I saw the effects of good and of downright bad sanitary organization in camps in South Africa, and at the same time learnt from our officer commanding (now Sir Alfred Keogh) lessons which to me were invaluable, and have never been forgotten. I hope the Journal will peg away at the subject until the country can feel confident that the responsible authorities fully realize that free expenditure of money on proper sanitation at the very beginning is a vital principle governing the prevention of camp diseases. I have seen recently conditions of camp sanitation which have made me shudder at the prospect they hold out of outbreaks of disease, and on the other hand I have been more than pleased by the spirit of progress which permeates sanitary officers in the Royal Army Medical Corps camps, where every detail of sanitation was as perfect as existing sanitary knowledge could make it.

I may compare this spirit of progress in the Army Medical Department with another equally striking, which once came under my notice in civil work. Some years ago, when Dr. Charles Mayo, at Rochester, Minn., was getting ready to do an amputation at the hip-joint, I asked him, when he told me that he was going to use Wyeth's method for controlling haemorrhage, if he had ever tried a method we had found very useful; after explaining it to him, I was called away to see Dr. William Mayo. Later on in the day I learnt that Dr. Charles Mayo had done the operation by the—to him—new method, and afterwards, in commenting upon its simplicity, he expressed surprise that it had not been invented before. The other day, with a friend, I visited a Royal Army Medical Corps camp at ——, and under the guidance of Major ——, in command, we were shown some simple and extremely ingenious devices by which the camp was kept as clean as a new pin. While visiting the latrines (late in the afternoon), where the predominating smell was cresol, Major —— pointed out that the real trouble in dealing with excreta in the pails was the quantity of paper used; my friend told the major that in his cottage in the country he had been in the habit for some years of putting a lighted match to burn the paper, and one was there and then thrown in; the result was greeted with the exclamation, "Excellent! Why did you not tell us that before? I will get matches put here with instructions what they are for!"

There is no fear of sluggishness and inactivity when one meets such examples in the Army Medical Department.

One of the most dangerous defects in military sanitary administration in this country to-day is lack of appreciation of the principle that the enforcement of early, prompt and adequate sanitary operations is the essential for the preservation of health and for the prevention of avoidable diseases in camps. Since I started practice it has, in another department, taken a very long time before we were awakened to the same fact that early and prompt operations are the foundations of salvation in cases of intestinal perforations; even now one sometimes comes across ignorance on this subject, and those of us who find the old-fashioned methods of treatment adopted consider it culpable negligence. We must bear in mind that the lack of appreciation of this great principle involves as a rule in surgery only the risk to a few individuals, but in sanitation of camps it involves risk of life to thousands.

I would venture to record a couple of illustrations which I have found to be fairly common when dealing with the embryo soldier; they touch the root of some of the evils arising from ignorance. Half a dozen men were watched as they went to a latrine; each one urinated against the screen! When asked why they did not use the trench, they replied they thought that that was for something else: civilian habit of urinating against something. Another lot were asked why they did not cover their faeces in the trenches, and replied that they thought that to be the business of somebody else allocated for the purpose. Notices and shovels in latrines indicating what to do would undoubtedly be of some value with regard to the disposal of urine and faeces.

In conclusion I would once more repeat my insistent appeal to commanding officers, who are mostly laymen or fighting soldiers, always to realize and remember that healthy camps depend upon early—it cannot be too early—and prompt sanitary operations with constant and ever-watchful vigilance during the periods which exist between fighting.—Yours, etc.,

J. Lynn Thomas, Major (Ret.),
R.A.M.C. (T.).

September 28th, 1914.

FIXED CAMPS AND SANITATION.

Under this heading a letter from Dr. Christopher Childs was published in the *Times* last week in which he discusses, with reference to the Territorial Forces, the measures needed for the prevention of the infection liable to arise from imperfect camp sanitation, from contaminated soil or food, or tents and tent fittings, or through direct convection from man to man and from tent to tent. He points out that typhoid invasion of camps sets in slowly and that it is almost certain that the Territorial Forces have in the past escaped these epidemics owing to the fact that they have not been aggregated together in camps for a longer time than a few weeks. He illustrates the risk attending more prolonged residence in camps by referring to the report of the special commission appointed to inquire into the outbreaks in the camps of the United States during the Cuban war. An article giving the general conclusions of this commission was published in the Journal of September 19th, page 510, but Dr. Childs is able to speak with special authority on it because, as Professor Victor Vaughan, the surviving member of the commission, wrote in his "Letter of Transmittal" to the Surgeon-General of the United States Army, Dr. Childs, during the summer of 1904, went "over the greater part of the manuscript and made many wise suggestions." "If," Professor Victor Vaughan added, "governments ever learn that military campaigns should be conducted in accord with hygienic rules and that the commanding officer who needlessly and ignorantly sacrifices his men to disease is as unworthy of his position as one who makes a like sacrifice in the face of the enemy, it will be through the labours of such men as Dr. Childs."

Dr. Childs in his letter points out that the facts recorded in the report should forewarn us to take more than the usual precautions for the prevention of possible typhoid outbreaks in our Territorial camps, if they are to be occupied for long, and indicate that all possible paths of infection should be safeguarded. "If it be true," he

continues, "that infection from man to man is one of the chief causes of the epidemics in camp life, it is obvious that the most important measure for prevention is the detection of 'typhoid carriers'—that is, incubating or abortive cases—their separation from crowded tents, and isolation, and the disinfection of soil, tent, tent-fittings, etc., which may have been polluted by their excreta (faecal or urinary). In active service—away from the base—such detection may often be difficult and belated, but for encampments in our own country, with bacteriological laboratories and experts at hand, the diagnosis ought to be easy and prompt."

In this last sentence Dr. Childs deals with a matter which, as was stated last week, is already engaging the anxious consideration of some of the senior officers of the Territorial Forces. As was then mentioned, in at least one division the services of junior medical officers with special knowledge of bacteriological diagnosis have been made available by the principal medical officer in the diagnosis of doubtful cases occurring in any unit in the command. We have no doubt that medical officers of health for counties and boroughs would willingly place any laboratory facilities that might be required for carrying out such bacteriological investigations at the disposal of the military authorities, and from the circular of the medical officer to the Local Government Board it would appear that that Board would approve the use of local civil infectious hospitals for the isolation of cases of typhoid fever and other infectious diseases.

INSECTS AND WAR—LICE.

Dr. Shipley wrote in our issue of September 19th (p. 493): "I have been told that the German soldiers, before going to war, shave their heads. If this is so, they would afford no nidus for *P. capitis*, but, if it be the case, the fact has escaped the lens of the photographers and the pens of the artists."

Dr. Shipley has forwarded us a photograph taken from the *Daily Graphic* of September 25th, which, by the

permission of Newspaper Illustrations, Limited, we are able to reproduce. The photograph shows that the information given to the Master of Christ's was correct and that his statement with regard to the photographers, though at the date he wrote probably correct, was premature.

ANTITYPHOID INOCULATION.

The Report of the War Office Antityphoid Committee.

It may be useful at the present moment to recall the results of the elaborate inquiry carried out by the special Antityphoid Committee appointed by the Army Council in 1904 "to investigate practical prophylactic and therapeutic value of current methods of immunization against enteric fever." The inquiry carried out by the committee, which was presided over by Dr. C. J. Martin, was very thorough, and owing partly to this and partly to other causes, its report was not concluded until the end of 1912.

The inquiry included both laboratory experiments and statistical inquiry into the results of typhoid immunization in the army. For the latter purpose special medical officers were attached to regiments with instructions to follow out the history of the command in relation to typhoid fever over a period of several years. By this means the histories, as regards typhoid fever, of 19,314 soldiers, whose average period of service abroad was twenty months, were carefully followed, and every precaution possible was taken to verify the diagnosis bacteriologically. Of this number 10,378 were inoculated and 8,936 not inoculated. The case incidence of typhoid fever among the inoculated was 5.39 per mille, and among the non-inoculated 30.4 per mille.

There was no reason to suppose that this difference was to be attributed to a want of homogeneity between the two groups. The age distribution among inoculated and non-inoculated was approximately the same. They were intermingled, and lived under identical conditions. The experience of the inoculating officers lent no support to the view that soldiers who, from their character and habits, might presumably be more likely to incur the risk of infection, presented themselves for inoculation in smaller numbers than their more careful comrades. In the opinion of the committee the substantial difference in the incidence could only be attributed to inoculation.

The statistical study was brought to an end in 1909 for a very interesting reason. Military authorities had then become more sympathetic towards inoculation and the soldiers themselves more and more convinced of its efficacy in limiting the risks of infection. Consequently increasing numbers presented themselves for inoculation, with the result that in many units a very large majority of men were inoculated, and but few were left as uninoculated controls; indeed, in the case of some of the test units the figures showed 100 per cent. inoculated; such units, of course, became useless for any comparative statistical test of the protective value of inoculation. It should be stated that this investigation was not open to the objection made to the inquiry of the United States commission, for very special care was taken in the diagnosis of enteric fever by the medical officers of each unit. Examples of paratyphoid were discriminated, and the committee was able to show that no case of enteric fever occurring in the various groups could have been overlooked, since every developed case of continued fever was specially investigated by all the modern methods available. The "probable error" of the figures was worked out by Colonel R. G. S. Simpson, C.M.G., R.A.M.C., who concluded from his examination of the figures and the smallness of the probable errors that the difference in the incidence of enteric fever in the few groups was, in statistical language, "significant."

The committee summed this part of its report in the following sentence: "Expressing the ratio of one group-incidence to another gives the result of one case in an inoculated man to 5.6 cases among non-inoculated men, or, to put this mass of figures into still plainer language, they show that typhoid fever was between five and six times as common in the non-inoculated as in the inoculated."

The chief recommendation of the committee was that "every measure which may be considered practicable should be employed to extend the practice of antityphoid inoculation in the army. In the opinion of the committee its universal application is desirable."

With regard to the details of inoculation the committee came to the conclusion that the minimum degree of local inconvenience was caused when the dose was given either in the upper arm at the level of the insertion of the deltoid or in the infraclavicular region, but we believe that evidence since accumulated shows that the latter region is to be preferred. Considerable personal variation was observed in respect to the general or systemic reaction; in about 25 per cent. of the men there was none, or at least no complaint was made, and the temperature was found to remain either consistently normal or to rise less than 1° for a few hours on the

evening of the inoculation. Improvements in the methods of preparing the vaccine have resulted in a diminution of both general and local reactions, although there is a great difference in the degree to which different individuals react to the same dose in spite of indentity of age, condition, and procedure. The committee found some reasen to believe that an unusually severe reaction indicates an unusual susceptibility to typhoid fever. Precautions in addition to careful attention to sterilization, to which the committee considered special attention should be given in order to avoid the more severe type of reaction, were:

1. That the inoculation should be made in the afternoen and not in the morning, as then the time at which the symptoms, both local and general, may be expected to reach their maximum, namely, four to six hours after the inoculation, will be about the customary time for the men to go to bed, "which is certainly the best place for them if they are feverish or suffering pain at the site of inoculation."

2. A man should be warned to avoid undue muscular fatigue on the day he is inoculated; he should not, for instance, play football.

3. Exposure to the sun, especially in the tropics, should be avoided.

4. It was observed that the drinking of alcohol within twenty-four hours following inoculation was followed sometimes instantaneously by marked exacerbation of the local reaction. Further, it was found as a general rule that teetotalers had extremely mild reactions, while the regular beer drinkers, even such as were quite moderate in this respect, had reactions of a distinctly more severe type.

When these precautions were observed, it was found that in nine cases out of ten the symptoms, both local and general, were trivial, and in twenty-four to forty-eight hours the inoculated man was quite himself again, except perhaps for a slight tenderness at the site of inoculation which might last for a day or two longer. Arrangements, the committee added, should always be made for the men to be excused by their commanding officer from drill and heavy fatigues for one or two days after inoculation, but it was very exceptional for a man to be incapable of resuming his full work after forty-eight hours.

Organization of Antityphoid Inoculation.

Major W. A. Gibb, R.A.M.C.(T.), writes: The question of the inoculation of the troops is at present engaging the attention of a good many regimental medical officers. The procedure, though simple enough, becomes exceedingly tedious, especially when performed a great many times at one period by one man. This applies to units which are isolated when the regimental medical officer has to perform all the inoculations himself. The following is the procedure I have found easy and satisfactory: The medical officer can use any syringe. The best is the ordinary glass syringe with ordinary needles at about 3s. a dozen. The sterilizer is set going, and the syringe (it is, of course, kept going all the time) and needles are boiled. Orderlies can be used as follows: The first paints the arm at selected spot. (I find 1½ in. above the bend of the elbow to the outer side is a very good spot.) The man passes on to the surgeon, who makes the required injection, is then sent to another orderly, who either repaints the arm with iodine or puts a small antiseptic dressing with a small piece of strapping to secure it; after that the man passes to a table, when another orderly takes down regiment, regimental number, rank, and name, date of inoculation, and whether first or second dose.

By this means a considerable number of men can be done single-handed in a comparatively short time.

The points to remember are:

1. A fresh needle must be used for each injection.
2. A good light is essential.
3. Not to inoculate men in front of each other.
4. They must be told to avoid alcohol.

When going into the country to do small numbers of men, and where the billets are not convenient, it is a good plan to have boiling water put into the large water bottles. These being covered with felt, the water retains the heat for some time, and, on being poured into the sterilizer, it is a very easy matter to get this going quickly.

Dr. William Boyd (Professor of Pathology, Winnipeg University), Lieutenant 3rd North Midland Field Ambulance, R.A.M.C.(T.), writes: In the course of the last few weeks several papers have appeared in the Journal dealing with the question of typhoid inoculation, with special reference to the organization requisite for carrying out a large number of injections. From these one gathers that the average number of men one medical officer can deal with in the course of an hour varies from 25 to 60 or 70. On this basis it is evident that if a large body of troops, such as a Division, have to be inoculated, the consumption of time must be very great.

As in certain circumstances it may be necessary to inoculate large numbers of men in as short a time as possible, the method which has been adopted for inoculating the North Midland Division of the Territorial Force may be of interest.

The inoculations, which were carried out under the direction of Colonel Clark, Assistant Director of Medical Services, were performed in a marquee, the internal arrangements of which were as follows:

Two orderlies were posted at the entrance, with a bowl of tincture of iodine on a small table between them. They applied a dab of iodine to the arms of the men as they passed. A narrow table ran between the poles, on which were placed the sterilizer, vaccine, spare needles, etc. At the exit were two tables at which sat four clerks, who took the names of men as they passed out. The inoculators were four in number, two standing at each side of the central table. Each inoculator had an orderly who held a tube of vaccine at a convenient angle. Finally, an orderly was posted at each side of the tent, in order to insure that each inoculator had a constant supply of patients. Immediately outside the tent was a non-commissioned officer, who saw that each man removed his coat, rolled up the sleeve of the arm to be inoculated, and carried the coat on the other arm.

The men entered the tent in fours, two passing down each side. It was found that each inoculator could easily dispose of 250 men in an hour, so that the rate of inoculation was 1,000 men an hour. Further, one officer, who was sent back to Staffordshire for the purpose, in one day inoculated 840 men in three widely separated towns.

These figures are considerably in excess of those in recently-published papers, and the reason is probably twofold. In the first place, the subdivision of labour insures that a steady and rapid stream of men passes through the tent; very much depends on the orderlies, whose duty it is to direct the traffic. In the second place, the question of sterilization is one of great practical importance. The ideal theoretical method is to sterilize both syringe and needle between each inoculation. Even if a series of syringes and needles be available, however, the consumption of time will be very greatly increased. The same is true for the method of drawing hot oil through the needle. In addition, the oil is liable to become over-heated and to sputter over the table and the operater's hands. The simplest method is to pass the needle through a flame and then through cold sterile water. It is questionable, however, if any additional sterilization is really necessary. The syringe and needle are thoroughly boiled, and the needle only passes through iodinized skin. We have performed over 16,000 inoculations, with various sequelae, which will be discussed in a later paper, but there has not been a single case of septic arm. There are times when academic must give way to practical considerations, and this is one of them.

Lecture by Professor McWeeney.

Last week the fourth of a series of lectures under the auspices of the Dublin branch of the St. John Ambulance Association was delivered in the theatre of the Royal Dublin Society, and there was as usual a large audience. Professor E. J. McWeeney, who was the lecturer, chose for his subject prevention of diseases in war time. He said that the chief diseases that had to be guarded against in war time were wound infections, such as suppuration, blood poisoning, erysipelas, gangrene, and tetanus, and such diseases as typhoid, dysentery, diarrhœa, and cholera, which owed their spread to the unhealthy conditions under which men on active service lived. With regard to the latter group the lecturer pointed out that during the South African war there were over 58,000 cases of typhoid fever,

of whom 1,900 were invalided, and 8,000 died—more than were killed by the enemy's bullets. He emphasized the importance of keeping "germ carriers" out of the army. The common fly was a dangerous enemy as a breeder of typhoid. He strongly recommended every soldier and every nurse before going to the front to undergo anti-typhoid vaccination. For that purpose he offered the Government the resources of his own laboratory.

UNIVERSITIES AND THE WAR.

ADDRESS BY THE VICE-CHANCELLOR OF THE UNIVERSITY OF LONDON.

THE OFFICERS' TRAINING CORPS.

THE address at the opening of the session at King's College, London, was given by the Vice-Chancellor, Sir Wilmot Herringham, M.D., on September 30th. Principal Burrows presided over a large assembly.

Sir Wilmot Herringham spoke on the universities' duty to the country during the war. Their first duty, he said, was to carry on the education of the country. Of all the products that made up a nation's wealth none were so valuable, so expensive to produce, or so difficult to replace as educated men. If possible, the supply should not even be lessened because of the war. As employers, the universities should facilitate enlistment and treat employees who enlisted as well as possible, having regard to the fact that no institution lost more heavily by the war than a university. The loss to King's College in respect of fees from students would not be less than £20,000. He had ventured to pledge the university that no student who had volunteered—the number was well over a thousand—should be prejudiced in his university education by so doing, but of course, by law, the university could not excuse students from courses of instruction and examination. Strong as he felt the call of the country to be, he advised students within measurable distance of their final examinations—say six months—to finish their course before offering their services in the army. Meanwhile, they could be working in the Officers' Training Corps, and in view of the threatened shortage of officers he urged every student who possibly could to enroll in the corps. The country had extreme need of the brain and hand of every one of her sons at the present time. Defeat meant not only loss of Empire, crippling of trade and industrial misery, but the break-up of all the best and highest in civilization and progress. The Allies were fighting for the rights of weak peoples, for national faith, and the humane conduct of war, and the enemy maintained the opposite of all these. The German race was a great one, whose industry, accuracy and love of learning were a lesson to the world, but it had been going through the greatest of all temptations—the accession of riches and power—and its philosophers had destroyed every ideal except that of power. Above all nations, the English-speaking race on both sides of the Atlantic had fought and died for humanity, for justice, and for freedom—ideals which embodied all progress, all history, and all life—and could they do less than follow in the path their fathers trod, and give all they had, even their lives? (Applause.)

The Principal, in thanking Sir Wilmot Herringham, also emphasized the need for officers, and recommended students to enroll in the Officers' Training Corps. The proceedings concluded with the singing of the National Anthem.

THE UNIVERSITY SPIRIT.

PROTEST BY A NEUTRAL.

PROFESSOR L. M. BOSSI, Director of the Gynaecological Institute of the University of Genoa, has sent the following letter to the *Corpus Academicum* of the University of Leipzig and has furnished a copy of it to Emeritus Professor Sir Alexander R. Simpson, formerly Professor of Midwifery in the University of Edinburgh, who has been good enough to forward it to us for publication.

Professor Bossi, in his covering letter to Sir Alexander Simpson, says:

"Our science, which has for its object the physical and psychical maintenance and amelioration of the human race, cannot remain indifferent to the terrible tragedy that is now being enacted.

"I believe it to be our duty to protest against the erection of brutal force into a system of domination predestined to the physical and moral ruin of the peoples.

"The letter which I have sent to the professors of Leipzig represents, I am convinced, the sentiments of the majority of my colleagues in Italy."

Esteemed Colleagues of the University of Leipzig,

I received a copy of the special number of the *Leipziger Neuesten Nachrichten*, accompanied by a letter which invites me to communicate to the university students and to the press of my country the contents of that journal with respect to the responsibility for this ruthless war.

Then I read to-day the official notice that the Ministers of Public Instruction of the various German States have "by common agreement" forbidden the German universities to admit from this time forward as students Russians, Serbs, and Japanese.

Thus, while on the one hand German university authorities rely on the principle of the internationalism of science for the defence of their own political position, they commit an act of university reprisals in striking opposition to that principle.

The contrast of these two actions at the expense of the prestige of science and of the dignity of its cultivators is too evident to require any further comment; but it obliges me to break the silence which I had imposed on myself and to open my mind to you with loyalty and frankness, as I hold that to be now a duty imposed on me by my position as a university professor.

Science has no confines; its country is the world.

If this principle had been present to your mind, my esteemed colleagues of the University of Leipzig, I am sure that you would have avoided any attempt to implicate your colleagues of the Italian universities in a conflict of brute force, from which science and its cultivators ought to remain entirely aloof, in order to preserve, in the midst of the present unexpected return to barbarism, at least one patrimony of mankind pure and unspotted—that of the intellect.

But, since you have attempted to invade this field also, it is my bounden duty to reply to you that while we were such admirers of your advances in the immense fields of the positive sciences and of your scientific method as to recognize almost at a glance a true and peculiar hegemony of your nation, we cannot admire, much less approve, the horrible fact that has to-day come unexpectedly to light—emerging in all its terrific concrete reality—of the premeditated concentration of great part of the scientific and intellectual energies of your nation to bring about the triumph in the world of the dominion of brute force.

In our academies we shall teach our studious youth the great benefits that all mankind have derived from the experimental method of science which, initiated in Italy, received its largest development and reached its highest prestige in Germany. They will learn that the Latin peoples have owed much to the applications of disciplined German method in all spheres of life and in all branches of human knowledge. They will learn that the Latin genius has been largely assisted in its positive manifestations by the practical methodicalness of Germany; that Germany has contributed perhaps more than other nations to the application and the diffusion of Italian scientific initiative (a fact which I also am personally bound to affirm), and that for this we ought to retain gratitude.

But faithful always to the great principle that the prosperity and happiness of the peoples can be founded only upon human brotherhood, we shall not be able to approve:

1. The incitements to the use and abuse of violence and of brute force, which your Chancellor gave in full Reichstag with a cynicism which revolted the consciences—in your opinion perhaps too sentimental—of us Latins.

2. That for years peace is preached, while human slaughter is being prepared instead, and while even the hospitality of many European centres is being sterilized by the preparation there of arms and of nuclei of men ready for treachery.

3. That—an example almost unique in the modern history of the peoples—international treaties are trampled on, and such neutral states as Luxemburg and Belgium are invaded: unarmed peoples, destined by the law of nations exclusively to peace and to labour, being attacked unexpectedly and with unheard-of and (as the facts will demonstrate inexorably) premeditated violence.

4. That villages and also cities, of such neutral States, are burned and destroyed, without any respect either to the rights of property or to patrimony sacred to art and to civilization.

5. That open and tranquil cities are bombarded at night, without any respect to the inviolability of the asylums of the infirm.

6. That unarmed citizens are slain, solely because bound by affection to their native land.

It is a civilization wholly different from this that we feel it to be our duty to teach in our universities and to our studious youth, who from the very fact of our absolute neutrality, imposed by our people, and approved by their present Government, will learn that Italy desires the restoration of a civilization of scientific and social progress founded not on the dominion of violence, but of human solidarity in the brotherhood of the nations.

(Signed) Professor L. M. Bossi,
of the Royal University of Genoa.

Genoa, September 10th, 1914.

MOTOR AMBULANCES IN WAR SERVICE.

COLONEL P. BROOME GILES (County Director, City of London Branch of the British Red Cross Society) writes: I have read with great interest Mr. Massac Buist's remarks and agree with the trend of his deductions, and sincerely trust that the present idea of covering a chassis with a "Red Cross" edifice and calling the production a "motor ambulance" will cease.

I have recently tried practically a number of these productions, and consider the bodies made by Messrs. Salmon and Sons, of London Road, Newport Pagnell, by far the most satisfactory, as they possess the essential requirements of ambulances. This firm turn out two separate bodies: (*a*) For long chassis, (*b*) for short chassis. (*a*) Accommodates either 4 lying down, or 2 lying down and 6 sitting, or 12 sitting; (*b*) accommodates either 4 lying down, or 2 lying down and 4 sitting, or 8 sitting. The methods of altering the interior to meet the varied accommodations are most simple.

An important feature of either (*a*) or (*b*) is a door in the front between the driver and the attendant and a gangway between the tiers of stretchers, which enables the attendant to render assistance, when required, during transit, and when loading and unloading. This obviates the awkward method in other ambulances of the stretcher bearers having to climb into the ambulance to "load home" or release the stretchers, and, further, permits assistance being rendered to the sick without having to stop the ambulance and enter from the rear. Another advantage is that the ventilation is ample, and there is plenty of room between the upper tier of stretchers and the roof, which is not found generally. The price of (*a*) and (*b*), complete with four army stretchers, is respectively from £40 and £30.

Stretchers should all be of the regulation army pattern and so interchangeable. It is a terrible thing to find, in transporting wounded men, that the ambulance will not take the regulation army stretcher, and to have to submit a wounded man to the pain of changing him on to another stretcher simply because some one in his ignorance had built his "edifice" too narrow for the army regulation stretcher.

Those interested in motor ambulances can see (*a*) and (*b*) in practical use in Regents Park on Saturday, October 3rd, at 4.45 p.m., when I have a drill for recently joined City of London Red Cross men, or the ambulance can be viewed at Messrs. Salmon's, St. Martin's Lane, Long Acre.

RECEPTION OF THE WOUNDED.

THE following official statement was issued by the Press Bureau on September 26th:

OFFICIAL STATEMENT.

It may be of interest to the public to know how the sick and wounded of the Expeditionary Force are being received and distributed after their arrival in this country.

All the hospital ships proceed to Southampton, where there is a special staff for the reception and distribution of the sick and wounded officers and men who are being sent home on them. The arrangements are under the control of a surgeon-general, who holds the appointment of a deputy director of medical services. He has at his command twelve ambulance trains specially constructed for the conveyance of 4 officers and 96 men lying down, or for a considerably greater number of patients sitting up. Twice weekly telegrams are received by him from all the larger military and Territorial Force general hospitals stating the number of beds vacant in each. With this information before him he arranges convoys of sick and wounded on arrival, and dispatches them to their destination in one or more of the ambulance trains.

Already the sick and wounded from overseas have been comfortably placed under treatment in most of the large military or Territorial Force hospitals centres. At the railway stations of these localities arrangements are made by the military authorities for conveying sick and wounded in motor or other ambulance vehicles from the railway stations to the hospitals. Voluntary Aid Detachments have already done useful work in connexion with this stage of the movements of the sick and wounded, and it is expected that the scope for utilizing voluntary aid in this direction will be extended as its value becomes better known.

As the military hospitals get filled up arrangements have been made for transferring sick and wounded from them to various hospitals arranged by voluntary effort. Many schemes have been submitted to the War Office, through the British Red Cross Association, in accordance with Field Service Regulations. At present the opportunity of using private hospitals to any great extent has not arisen, as there are still several thousand beds vacant in the military and Territorial Force hospitals. There is no doubt, however, that in time private hospitals will be of much use as an overflow, and also when it is necessary to set free a sufficient number of beds for future requirements in the larger military hospitals.

Convalescent Homes.

When sick and wounded are sufficiently convalescent to be granted sick furlough, advantage is being taken of the many offers of accommodation for them in convalescent homes in different parts of the country; and, in order to prevent overlapping and to facilitate the means of placing men on sick furlough, so far as possible in their own counties, a Central Registry of Convalescent Homes has been formed by a joint committee of the British Red Cross Society and the Soldiers' and Sailors' Help Society. This Central Registry acts as a clearing house. Only convalescents who would be given sick furlough to their own homes, if they so desired, are being sent to convalescent homes. Convalescents who require continued hospital treatment will be sent either to the special home in connexion with the hospital from which they are transferred (under the supervision of the medical officer of the hospital) or to one or other of the private hospitals already referred to. In order to enable a convalescent to be placed on sick furlough in a convalescent home, all that he has to do is to inform the medical officer who is in charge of him where and what county or neighbourhood he would like to proceed to. These particulars are entered on a form and sent to the Central Registry. The address of the nearest railway station to the convalescent home in the neighbourhood is entered on the form, and it is immediately returned to the medical officer of the hospital. Whenever the convalescent is ready to leave on sick furlough the medical officer sends word to the convalescent home, stating the hour of the man's arrival at the railway station, where arrangements are made to meet and take him over. This arrangement has been working very well, and already over 100 convalescents have been received in various convalescent homes.

It may also be of interest to know that in all the hospitals arrangements are made for replenishing any deficiencies in the men's kits, and for giving them any additional clothing which it may be desirable for them to take with them when they go on sick furlough. The hospitals are, for this purpose, receiving many generous gifts of pyjama suits and other articles of clothing. At the end of their sick furlough the men are required to rejoin the dépôts of their regiments, in order to be refitted, until arrangements are made for their rejoining their units, either in this country or abroad. They are provided with railway warrants to enable them to go to convalescent homes and to rejoin at their dépôts. Arrangements have also been made that they shall receive their pay both while they are in hospital and while they are convalescent.

CONVALESCENT HOME IN PETROGRAD.

In Petrograd a British convalescent nursing home for wounded Russian soldiers was opened on September 24th. According to the correspondent of the *Daily Telegraph*

the cost has been entirely provided by donations and monthly subscriptions from the British community. The home contains fifty beds, and is under the superintendence of an English matron and a committee of British residents.

British Hospital for Antwerp.

The Women's National Service League has sent a fully equipped hospital to Antwerp to co-operate with the Belgian Red Cross. The medical officers are: Drs. Florence Stoney, Hansen, Rose Turner, Emily Morris, Joan Watts, and Mabel Ramsay. The unit includes twelve fully trained nurses, cooks, orderlies, and electricians in charge of the *x*-ray apparatus. The hospital has had the active co-operation of the St. John Ambulance Association, and is equipped for 130 beds.

BRITISH RED CROSS SOCIETY.

CONDITIONS IN PARIS.

Visit of Sir Frederick Treves.

Sir Frederick Treves, who has just returned from Paris, gave a representative of the Journal an account of his visit to the hospitals there which are receiving British wounded. The military general hospital, taking from 500 to 600 cases, is at the Trianon Palace Hotel, Versailles. The building is excellently suited for the purpose, is very well equipped, and is admirably administered under the charge of Colonel Smith, R.A.M.C. The large rooms on the ground floor—dining-room, drawing-room and reading-room—make magnificent wards and are filled with private soldiers. Amongst these are seventeen wounded German soldiers, who are very well pleased with their present lot. All the patients expressed themselves as very comfortable. As is already known, there is unfortunately a great deal of tetanus and "gas gangrene."* In the grounds of the hospital are two marquees for medical cases, but the patients are few, because the health of the troops at the front is excellent.

The second hospital is the American, situate at the Lycée Pasteur, at Neuilly. This is a new building which has not yet been used as a lycée; the structure, indeed, is not yet completed. It makes a most admirable hospital; the gymnasium takes 68 beds, the class-rooms take from 6 to 8 beds each; the operating theatre is a large chemical laboratory, and is as well suited for that purpose as if it had been designed for it. The surgical store-room is the chemical lecture theatre, fortunately not yet provided with seats. The number of beds is or will be about 300. On the day of Sir Frederick's visit there were 270 patients, of whom 162 were British. The Americans have reason to be proud of this hospital, which Sir Frederick has no hesitation in saying is the best of its type in Paris. The staff consists of 15 doctors, 75 fully trained nurses, and a personnel making a total of 180.

The third hospital is at the Astoria Hotel, which has been taken over by the British Red Cross Society. It will accommodate 300 cases, and is being gradually equipped. There are 65 patients at present, all except 3 being British. The other hospitals are at Claridge's Hotel, the Majestic Hotel, two large private houses, the Lycée Bouffon, and other smaller institutions.

Sir Frederick Treves said the great difficulty in the medical aspect of the war is the question of transport. The French are straining every nerve to deal with this problem, but considering the restricted number of railway lines, and the vast amount of ammunition, food and supplies that have to be sent to the front every day, the allotment of trains for the carrying of the wounded is necessarily limited, and unavoidable delays must arise in the passage of these trains from the front to Paris. More ambulance trains are being provided, but they will not be immune from the risk of being delayed at sidings. The great need in this campaign is for motor ambulances; the American hospital has 20, and in this fleet of cars rests largely the secret of its success. The British Red Cross Society is putting 200 motor ambulances into France at the earliest possible moment. The number may seem large, but 500 would not be too many. By means of these cars the wounded may be brought direct from the field ambulances to the base; the roads in France are good, and the obstacles in the way of motor ambulances few. The motor ambulance can come down from the front in a little over two hours, whereas a train may take ten or even twenty hours to accomplish the same journey. People in England could do no greater service to our wounded troops than by providing motor ambulances. It must be remembered that the whole question of transport of the wounded in war has been entirely modified by the introduction of motor cars, and when the history of this war comes to be written, Sir Frederick Treves is sure that the best work of the British Red Cross Society will be found to have consisted in the provision of an ample supply of motor ambulances.

Stores for Sick and Wounded.

Up to the present the society has provided garments, medical stores, and comforts for the wounded, to sixty-one recognized military hospitals in Great Britain, and the hospital ships for the Indian army have also been provided with a quantity of garments. The hospital ships running between France and England have received all the stores they have applied for, and they will receive regular weekly consignments. The number of garments now in the stores or on the way to France represents hospital kit for about 8,000 men, but Sir Alfred Keogh is still calling for unlimited supplies, and, having regard to this and the fact that many cases of sickness may soon be expected, the stores are to be increased at once to provide for at least 16,000 to 20,000 men.

Hospital Accommodation.

The total number of beds in the auxiliary home hospitals accepted by the War Office is 4,978. The constructional work at the Netley Red Cross Hospital is rapidly progressing.

A Hospital Unit for Paris.

During this week a large unit, consisting of 10 surgeons, 10 dressers, 30 nurses, and 40 orderlies, is being sent to Paris.

Scottish Red Cross Hospital.

A British Red Cross Hospital has been organized in Scotland, and the intention is to establish 100 beds at Rouen. The staff is drawn from Glasgow, Edinburgh, and Aberdeen, and the senior officer is, we understand, Mr. J. W. Struthers, Surgeon to the Royal Infirmary, Edinburgh; Dr. Burton of Glasgow is another member of the staff. An advance party left Glasgow on Wednesday to establish at once fifty beds. It included nurses and dressers; among the latter are Lieutenant Haig Ferguson, B.A., a final year man in medicine in Edinburgh, and the son of Dr. Haig Ferguson (assistant gynaecologist to the Royal Infirmary, Edinburgh), and Mr. Rhodes, who will be specially employed in *x*-ray work.

Dublin Branch.

Last week the Earl of Meath presided over a large and representative meeting in the lecture theatre of the Royal Dublin Society for the purpose of inaugurating a branch of the British Red Cross Society for the county of Dublin. A guard of honour from various troops of the Dublin Boy Scouts was drawn up on either side of the entrance to Leinster House, and lines of scouts were also stationed at the sides of the grand staircase and in the corridors. The Chairman said the British Red Cross Society was founded in 1905 by Queen Alexandra, and was now working in co-operation with the St. John Ambulance Association. This Red Cross Society was established for the purpose of furnishing aid to the sick and wounded in time of war, and it was the only organization of its kind that was recognized by the Geneva Convention. The British Red Cross Society desired that its organization should work through counties and cities, acting directly in connexion with head quarters in London. Mr. E. A. Ridsdale, Deputy Chairman of the Central Executive Committee of the British Red Cross Society, who was cordially welcomed, said that the work of the Red Cross Society might be divided into three heads,

* This is probably the acute spreading traumatic gangrene due to *B. aërogenes capsulatus* acting either alone or in association with *B. oedematis maligni*.

two of them military and one civil. The civil side was to educate the people to render first aid to the injured, and to render assistance to suffering humanity in many other ways. When war broke out it became the duty of the society to organize the supply of hospital garments and supplies of those little necessaries and luxuries which made all the difference to a sick man between comfort and discomfort. Another side of the work was to send out doctors and orderlies to the scene of the war. A very important part of the work was the formation of Voluntary Aid Detachments. Over 50,000 persons had been enrolled in these detachments in England and Scotland. Early in the present war the society sent out to Belgium 10 surgeons, 20 nurses, and 10 dressers; unfortunately, the very day they got to Brussels it was seized by the Germans, and they were shut up there. Their services had been used by the Germans in attending to the wounded, and some of the staff had been able to take the names and addresses of British soldiers and send information to their relatives at home. He wished it to be widely known that the Red Cross did not know nationality or party. Its members acted purely from the humanitarian point of view, attending to the wounded of the enemy as well as they would to the wounded of their own side. The society was at present setting up a hospital with 300 beds at Rouen, and also an auxiliary hospital with 500 beds at Netley. It had undertaken also a most useful task in endeavouring to ascertain the fate of the many thousands of missing soldiers. Dr. Lumsden, on behalf of the St. John Ambulance Association, said that it would gladly co-operate with the Red Cross Society in the work. It had eight ambulance divisions, numbering 384 trained ambulance men, eleven nursing divisions 187 strong, making a total of 571 now ready for service. Within one week after the outbreak of war 130 members were sent out and were now serving abroad. The association proposed to place its whole organization at the service of the Red Cross Committee, to be used in whatever way was thought right. The meeting concluded with the appointment of both Executive and General Committees.

ST. JOHN AMBULANCE BRIGADE.

SURGEONS FOR RED CROSS WORK.

THE Association of St. John of Jerusalem is continuing to send out surgeons to tend the sick and wounded at or near the seat of war. Applications from those who are willing to serve may be forwarded to Mr. H. T. Watson or to Mr. Edmund Owen, Chief Surgeon to the Brigade, at St. John's Gate, Clerkenwell, London, E.C.

THE LISTER INSTITUTE.

At the outbreak of hostilities the following letter was addressed by the Lister Institute to the Director-General, Army Medical Department:

Sir,—I am instructed by the governing body of this institute to inform you that, with an earnest desire at the present time to assist the Army Medical Department, they offer to you at the cost price of labour and material the whole of their stock in hand of typhoid vaccine, antitetanus and antidysentery serums, and to add that they will continue on the same terms to manufacture to the utmost of their capacity whatever further quantities of the same medicines your Department requires.

I am also desired to inform you that the governing body will be pleased to facilitate the performance of any further service on the part of members of its staff which they are willing to offer and capable of carrying out. On behalf of my colleagues I beg to inform you that we are anxious to help in whatever manner we can. We do not wish to embarrass your department with proposals at the present moment, but should it so happen that you have needs which we can satisfy, collectively or individually, we shall regard it an honour to be called upon.

There is also a number of medically qualified gentlemen who are or have been research workers at the Institute, who have expressed a desire to place their services at your disposal together with our own.

A list of these gentlemen, as well as of our staff, giving particulars as to age, capabilities, etc., is being prepared and will be forwarded in the next few days. I have the honour to be, Sir, your obedient servant,

CHARLES J. MARTIN, Director.

August 12th.

The Director-General informed the Director that the patriotic offer of himself and his colleagues and others working at the Lister Institute was greatly appreciated, and that he would gladly take advantage of it should a suitable occasion to do so arise.

Since then we understand that the Institute has furnished the Army Medical Department with large supplies of antitetanic serum for prophylactic purposes and upwards of 200,000 doses of antityphoid vaccine.

Six voluntary workers have received commissions in the R.A.M.C. and one in the infantry.

We now understand that the War Office has decided to despatch a motor field laboratory for use at the seat of war, and that Dr. Sydney Rowland, assistant in the Director's laboratory, has been appointed the bacteriologist in charge. Dr. Rowland has received a temporary commission in the R.A.M.C., and leaves immediately.

FURTHER CASUALTIES IN THE MEDICAL SERVICES.

ROYAL NAVY.

Killed.

Hopps, Surgeon H. J., R.N., H.M.S. *Aboukir.*
Turnbull, Surgeon A. E., R.N.V.R., H.M.S. *Cressy.*

ARMY.

Killed.

Dalton, Lieutenant-Colonel C., R.A.M.C. (previously reported wounded).
Hopkins, Lieutenant H. L., R.A.M.C.
Huggan, Lieutenant J. L., R.A.M.C.
O'Connell, Lieutenant J. F., R.A.M.C.
Ranken, Captain H. S., R.A.M.C.

Wounded.

Edmunds, Captain C. T., R.A.M.C. (previously reported missing, now reported wounded).
Fisher, Lieutenant E., R.A.M.C.

Prisoners of War.

Brown, Lieutenant A. J., R.A.M.C. (previously reported missing).
Brunskill, Major J. H., R.A.M.C. (previously reported missing).
Hills, Lieutenant H. W., R.A.M.C. (previously reported missing).
Williams, Captain, R.A.M.C. (reported by private sources as wounded and a prisoner at Brunswick).

Missing.

Field, Captain S., R.A.M.C.
Holden, Captain C. W., R.A.M.C. (previously reported wounded).
Leahy, Captain M. P., R.A.M.C.
Stevenson, Captain G. H., R.A.M.C.

Reported Missing, now Rejoined.

Bell, Lieutenant J. H., R.A.M.C.
Hildreth, Captain H. C., R.A.M.C.
Tulloch, Lieutenant F. L., R.A.M.C.
Walker, Lieutenant E. R., R.A.M.C. (wounded).

The three British cruisers which were sunk by torpedos by a German submarine on September 20th carried between them seven medical officers: The *Aboukir*, Fleet Surgeon O. Rees and Surgeon H. J. Hopps; the *Cressy*, Staff Surgeon E. C. Sawdy, Surgeon A. E. Turnbull, R.N.V.R., and temporary Surgeon G. N. Martin; the *Hogue*, Staff Surgeon Percival T. Nicholls and Surgeon L. C. D. Irvine, R.N.V.R. Of these seven officers, two—Surgeons H. J. Hopps and A. E. Turnbull—were lost.

Surgeon Hugh James Hopps took the M.B., Ch.B. at Edinburgh in 1911, and entered the navy on October 3rd, 1913, joining his ship in August, 1914.

Of Surgeon Alfred E. Turnbull, our Edinburgh correspondent gives some particulars elsewhere.

The casualty lists of September 24th and 25th announced the deaths of no fewer than four medical officers killed in the battle of the Aisne—Captain T. Scatchard and Lieutenants J. L. Huggan and A. K. Armstrong, killed in action; while Lieutenant-Colonel C. Dalton, who was reported as wounded in the casualty list of September 20th, died of his wounds. A full note of the services of Lieutenant-Colonel C. Dalton was given last week (p. 556).

Captain Thomas Scatchard was the youngest son of Dr. Scatchard, of Boston Spa, Yorkshire. He was educated at Leeds, and took the L.S.A. in 1902. After serving as house-physician of the Leeds Infirmary and House-Surgeon of the Beckett Hospital, Barnsley, he entered the army as lieutenant on July 31st, 1905, becoming captain on January 31st, 1909. He was recently stationed at Aldershot.

Lieutenant James Laidlaw Huggan took the M.B. and Ch.B. at Edinburgh in 1911, and got his commission as lieutenant on July 26th, 1912. He was recently stationed in London.

Lieutenant Arthur Keith Armstrong took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1907, and received a temporary commission as lieutenant so recently as August, 1914. He was honorary medical officer of Monmouth Hospital.

To the death of Lieutenant J. L. Huggan our Edinburgh correspondent refers elsewhere.

Two more officers of the R.A.M.C. were reported as killed in the casualty lists published on September 27th—Lieutenants H. L. Hopkins and J. F. O'Connell.

Lieutenant John Forbes O'Connell was educated at St. Mary's Hospital, where he filled the post of house-physician. He graduated M.B., B.S.Lond., in 1912, and entered the army on July 24th, 1913. He was recently stationed at Aldershot.

A notice of the brilliant career of Lieutenant Hopkins is published elsewhere.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

WALES.

A Welsh Army Corps.

The response of Wales to the call to arms was immediate. The mobilization proclamation at once brought out a strong force of Territorials, which within a few weeks provided a full division complete in all departments, including the proper proportion of ambulances, and furnished also detachments for many scattered posts, camps, and forts. At an early stage a movement was set on foot to fit out a Welsh Hospital for sick and wounded. Then for the time there was perhaps a feeling that all that was necessary had been done, but Lord Kitchener's appeal, reinforced by stirring speeches by Mr. Lloyd George to his countrymen in London and Cardiff, brought thousands of recruits to the new army, so that on Tuesday last Glamorganshire alone had given 24,000, and Monmouthshire, which for the purpose of raising the Welsh Army Corps, as for so many others, is to be reckoned part of Wales, 12,000.

This new movement, in which Mr. Lloyd George has the support of Welsh peers and bishops and men of all parties, will need thorough and practical organization, and many questions are arising as to the best way of adapting existing plans to the new conditions.

Among other questions that will arise is the establishment of a medical service for the new army corps, and one of the first matters that has come up in this connexion is the destination of the Welsh Hospital. It is under the command of Mr. William Sheen, Surgeon to the Cardiff Infirmary, who has, it is understood, nearly completed his staff. The intention has been that the hospital should be established at Netley, and it is understood that steps have already been taken to carry this plan out. It is now asked, however, whether, in view of the new circumstances, it would not be better to retain the hospital in Wales to serve as a base hospital for the new division or divisions of the Welsh Army Corps. The declared policy of the War Office has been, as far as possible, to send the sick and wounded to hospitals in the districts in which their families and friends reside, and it is urged that to put the hospital at Netley would not be in consonance with this policy.

Lieutenant-Colonel H. Jones Roberts, T.D., commanding the 6th Carnarvonshire and Anglesey Battalion, and now in charge of the reserve battalion which is being formed, has been appointed to command details of the Welsh Division. This command has previously been held by a major-general, and the honour thus conferred on Colonel Jones Roberts is a very high one. Colonel Jones Roberts has always been an active worker on behalf of the British Medical Association, and at the present time is Honorary Secretary of the North Wales Branch. Members will unite in congratulating Colonel Jones Roberts upon this recognition of his ability and military experience.

Scotland.

Fatalities among Recent Edinburgh Graduates.

The accidental death from drowning of Mr. L. C. Peel Ritchie, Ch.M., M.D., F.R.C.S.E., in Granton Harbour, has cast a gloom over these circles in Edinburgh in which the unfortunate surgeon was well known and amongst the members of the profession by whom his father, the distinguished physician Dr. Peel Ritchie, was greatly respected. A short obituary notice appears in this number (vide p. 607). The war also has been exacting a heavy toll from the list of recent graduates of the University of Edinburgh. Surgeon Hugh James Hopps, who graduated M.B., Ch.B., in 1911, and who was a Fifeshire man, has, it is feared, gone down in the *Aboukir*. James Laidlaw Huggan, who graduated in the same year (1911), and who was a lieutenant in the R.A.M.C., has been killed at the front. Dr. Huggan was a Scottish International Rugby football player, having received his cap last March. Among the list of the missing in connexion with the sinking of H.M.S. *Cressy* is the name of Alfred Edward Turnbull, son of Mr. Phipps Turnbull of Edinburgh. He graduated M.B., Ch.B. at Edinburgh University in 1907, and was surgeon in the Royal Naval Volunteer Reserve. Mr. Turnbull served as residential gynaecologist, as clinical assistant in the university surgical wards, and as resident house-surgeon in the Royal Infirmary of Edinburgh. He was also a Fellow of the Edinburgh Obstetrical Society, and made three contributions to the literature of obstetrics which were published in this Journal in 1909, 1911, and 1912, as well as one to the society's annual volume of *Transactions* for 1911. Mr. Turnbull was in practice at Faringdon, Berks, when the war broke out.

Canada.

[FROM OUR SPECIAL CORRESPONDENTS.]

The Canadian Army Medical Corps.

To-day Canada is justly proud of her Army Medical Corps. The work of preparation has been continued steadily during a period of peace, and now that the time has come for action, a large body of efficient men is ready, eager to relieve some of the horrors of the battlefield. It is difficult to obtain details concerning the part which is being taken by the medical profession in connexion with the present war, but there are over 700 officers ready for service, and doctors from every part of the country are now at Valcartier preparing to leave with the Canadian contingent. It is the intention that a base hospital shall accompany the troops, probably in charge of Dr. F. G. Finley, of Montreal, with Dr. R. P. Campbell as chief surgeon. Dr. C. B. Keenan, of Montreal, who served in the South African war as surgeon to Strathcona's Horse, accompanied the Princess Patricia's Light Infantry in the capacity of regimental surgeon. Dr. Murray MacLaren, of St. John, New Brunswick, will accompany the Canadian troops.

Antityphoid Inoculation.

A paper was read by Dr. S. J. S. Pierce, Pathologist to the Winnipeg General Hospital, at the recent meeting of the Manitoba Medical Association, in which some interesting facts were given concerning the results of inoculation against typhoid in the General Hospital at Winnipeg. The treatment was commenced in 1909, but at that date it was restricted to members of the laboratory staff. In 1911 routine inoculation of the nursing staff was begun. The results of the work of Richardson and Spooner in the Massachusetts General Hospital, and of Major Russell in the United States Army were then known, and the value of the procedure had been established. Statistics showed that before the treatment was commenced an average of seven cases of typhoid occurred each year amongst the members of the staff of the Winnipeg General Hospital, usually amongst the nurses in their first and second years of training, or amongst the medical orderlies. The vaccine employed is prepared in the hospital laboratory, and is from a stock strain, which has been used there for the past eight years. Subcultures are made on agar slants, and a growth of from twelve to twenty-four hours is emulsified in normal saline solution. Commercial formalin is added to the extent of one-thousandth part of the emulsion used, and at the end of twenty-four hours the mixture, having been tested and found to be sterile, is hermetically sealed and allowed to ripen for three weeks or longer. The stock vaccine is diluted with normal saline so that 1 c.cm. contains two thousand million bacteria. Three subcutaneous injections are administered, consisting of 0.25, 0.5, and

1 c.cm., at intervals of ten days. No ill effects have been observed from the employment of such large doses. The individuals vaccinated for the most part have been young women serving as nurses in the hospital. The results have been most encouraging. Since June, 1911, the number of persons inoculated has been 445, and in no instance has fever been contracted. One doubtful case did occur, but the diagnosis was not complete.

An epidemic of typhoid fever broke out last December in several towns on the banks of the Richelieu River in the province of Quebec. In most cases the fever was not of a severe type, and the infection is attributed to the river water which was used for drinking. It is reported that more than 2,000 cases occurred in the district, and in the town of St. John's alone 500 cases. Water purification plants have been installed at various places, and to prevent further spread of infection Dr. E. P. Benoit of Montreal was instructed to go to St. John's and to vaccinate against typhoid. Eighty persons were vaccinated—each person was carefully examined beforehand, and only those who were considered to be healthy were treated. The vaccine used was prepared in the laboratories of the Bureau of Hygiene, Paris, and was obtained from Professor Chantemesse. Four injections of this vaccine are necessary, given at intervals of eight days. The results have been entirely satisfactory. In no case were any ill effects noticeable and, in several instances, the person vaccinated escaped, while all the other members of the family fell ill with fever. Two persons, who had evidently already contracted the disease, had a slight attack of fever in spite of having been inoculated once; although one injection was not sufficient to prevent the illness, it did not aggravate the disease in any way.

India.

[FROM OUR SPECIAL CORRESPONDENT.]

Civil Medical Administration in Bengal.

A press *communiqué*, dated Simla, August 27th, published in the *Pioneer Mail* of September 4th, 1914, states that the Secretary of State for India has at last sanctioned the new arrangements for civil medical administration in Bengal, necessitated by the changes in civil government announced at the Delhi Durbar in December, 1911. These changes are sanctioned with effect from April 1st, 1912, the date when the new provinces were constituted, and are four in number. First, the Inspector-General of Civil Hospitals in Bengal, who hitherto ranked as Colonel, becomes a Surgeon-General, like the administrative officers of Madras and Bombay. Secondly, the appointment of an officer of the Indian Medical Service as Personal Assistant to the Surgeon-General, Bengal. Thirdly, the appointment of an Inspector-General of Civil Hospitals with the rank of Colonel, for the new province of Bihar and Orissa. Fourthly, the appointment of an Inspector-General of Hospitals to the small province of Assam, this officer also undertaking the duties of Inspector-General of Prisons and of Sanitary Commissioner.

The net effect of these changes is that the number of Surgeon-Generals in the Bengal Medical Service is increased from two to three, the Bengal Inspector-General, who formerly ranked as Colonel, becoming Surgeon-General. The Inspector-Generalship of Bihar and Orissa is a new appointment. The Inspector-General in Assam takes the place of the Inspector-General in the abolished province of Eastern Bengal and Assam. As a matter of fact, the Government of India had appointed an Inspector-General in Bihar and Orissa from April 1st, 1912, but he could not be formally promoted to the rank of Colonel until sanction was received from England.

Ambulance Field Day.

The first Ambulance Field Day in India was recently organized at Simla under the Assistant Commissioner of the St. John Ambulance Brigade. The general idea of the scheme was that a Northern Brigade with its head quarters at Simla was operating against a Southern Brigade with its head quarters at Subathu. The two forces had met at Jntogh, and the Northern Brigade had driven the Southern Brigade back on Subathu. Both forces sustained heavy losses, and the St. John Ambulance Brigade was called out to take over the sick and wounded and relieve the regular medical services, who were required to accompany the Northern Brigade marching on Subathu. The Simla Corps of the St. John Ambulance Brigade paraded under the command of Ambulance Officer P. H. Marshall, and the Nursing Sisters of the Simla Nursing Division under the command of Lady Superintendent the Hon. Mrs. Spence. The number of casualties in the engagement between the Northern and Southern Brigades was given as eighty-four. Of these there were twenty able to walk, fifty fit for transport sitting up, ten fit for transport lying down, and two unfit for removal. In addition to the twelve wounded, the Southern Brigade left behind two medical cases—namely, (*a*) a case of rheumatic fever, and (*b*) a case of small-pox. The twenty fit to walk and the fifty fit for transport sitting up were sent to Simla in rickshaws, 100 of which had been commandeered for the purpose. No form of transport for lying down cases was available. The St. John Ambulance therefore had 14 severe cases to deal with, and the personnel, in less than an hour improvised from scanty material and three empty rooms, a general ward, an operation theatre, and an isolation ward. The sick and wounded were dressed and actually put to bed, and those requiring it were ready for operation in forty-five minutes.

The inspecting officer was Colonel Hehir, Deputy Director of Medical Services, Army Head Quarters, who inspected the whole of the preliminaries and the wards, and discussed each patient in detail. At the close of the proceedings Colonel Hehir congratulated all concerned on the success of the first Indian ambulance field day, and expressed his high opinion of the remarkable degree of efficiency attained, and the great usefulness of the brigade to the Government of India in the case of war or national emergency.

Diabetes in Madras.

The Madras Government has for some time been impressed by the serious prevalence of diabetes among the educated classes of the presidency and the need for a close scientific investigation into the causation and prevention, and possibly the cure, of the disease. While the possibility of initiating the inquiry was under consideration, the Government received from an Indian gentleman, who prefers to remain anonymous, a generous offer of a sum, not exceeding Rs. 50,000, to be expended in aid of such an investigation. Government therefore placed themselves in communication with the advisory board of the Beit Memorial Fellowships for Medical Research with a view to secure a competent investigator, and they have been promised the services of Dr. S. W. Patterson, a holder of a Beit Memorial Fellowship. Dr. Patterson will accordingly carry out in this presidency an investigation into the causation of diabetes to extend over a period of three years, and during that period he will draw £800 per annum.

The Health of Bombay.

The improvement in the health of the city of Bombay, one of the compensating features of the hot weather season, has been steadily maintained throughout the past year, during which period plague mortality has dwindled down just on 400 deaths a week to 58. There has been a substantial drop also in the total mortality, which declined from 651 to 606, the present death-rate being 32.17, as against 35.46 in the corresponding period of last year. The present state of the public health may therefore be considered satisfactory, and to compare favourably with the mean death-rate for the past five years. There is one slightly disquieting feature, which illustrates the danger to which the city is exposed from infection brought from the mofussil. The returns record six fatal cases of cholera, no fewer than five of which were imported from Poona, Satara, and Nasik districts. The danger of an outbreak of this malady at this time of the year is not so great as during the first few weeks after the advent of the rains, but the presence of the disease at any time is always a disturbing factor.

DR. JOHN FLETCHER LITTLE, formerly a member of the London County Council, left estate of the gross value of £19,904, of which £17,697 is net personalty.

Correspondence.

THE NEW "BRITISH PHARMACOPOEIA."

SIR,—The new issue of the *British Pharmacopoeia* (1914) will, as has been already announced in your columns, be published on December 31st, 1914. Inquiries have reached me from more than one source with regard to the extent to which the Medical Council will permit the use of the contents of the *British Pharmacopoeia* in medical, pharmaceutical, and kindred works which are about to appear, or may hereafter be published. I am accordingly instructed, on behalf of the Council, to say that the Council wholly reserve their copyright in the new work; and that substantial extracts from it must on no account be published without the Council's express sanction. At the same time, no objection will be taken to such reasonable reference to the facts and figures therein set forth as may be properly made for purposes of criticism, review, and summary, or of study and research, but no information of any kind derived from the new issue may be published in book form before December 31st, 1914.

Advance copies of the *British Pharmacopoeia*, 1914, are now accessible at this office, and at 54, George Square, Edinburgh, and 35, Dawson Street, Dublin, for the inspection of the public, from 10 a.m. to 4 p.m. daily (Saturdays 1 p.m.), in order to give to manufacturers, pharmacists, and others interested an opportunity of ascertaining the changes that are about to be made in official requirements, and of making the necessary arrangements to meet them. Every person who takes advantage of this opportunity will be expected to observe the conditions above indicated, and will be required to sign an undertaking to that effect.

I shall be obliged if you will insert this letter in your next issue.—I am, etc.,

A. J. COCKINGTON,
Acting Registrar.

General Council of Medical Education and Registration of the United Kingdom, 299, Oxford Street, London, W., September 30th.

P.S.—The Medical Council Act, 1862, provides that:

The exclusive right of publishing, printing, and selling the said *Pharmacopoeia* shall vest in the said General Council.

The Copyright Act, 1911, may also be quoted in this connexion:

2 (1) Copyright in a work shall be deemed to be infringed by any person who, without the consent of the owner of the copyright, does anything the sole right to do which is by this Act conferred on the owner of the copyright; provided that the following acts shall not constitute an infringement of copyright:

(i) Any fair dealing with any work for the purposes of private study, research, criticism, review, or newspaper summary.

THE ACTION OF CHLOROFORM.

SIR,—In the obituary notice of Dr. Gaskell, in the BRITISH MEDICAL JOURNAL of September 26th, it is stated that "Gaskell, at the request of the Hyderabad Commission, undertook the investigation of the action of chloroform." This statement is somewhat misleading. Gaskell undertook to complete the work of the Hyderabad Commission on Chloroform at my request. The Commission had proved that the uncomplicated action of chloroform is to cause lowering of the blood pressure, with first unconsciousness, then anaesthesia, then stoppage of the respiration, and finally stoppage of the heart; and that any variation in this sequence of events is due entirely to the method of administration. The object of the Commission was therefore attained, since we had ascertained that the fall of blood pressure under chloroform is in itself harmless, and therefore could not be produced by weakening of the heart. To look after the breathing properly is, as Syme had always contended, all that is necessary clinically to ensure safety in anaesthesia. It was left to Gaskell to determine a purely physiological point—What is the exact cause of the fall of the blood pressure when chloroform is effectively given? In order to settle this question cross-circulation experiments were made by him and Dr. Shore with the intention of limiting the action of the anaesthetic to the heart alone. Before these experiments were made Gaskell wrote and informed me he had discovered that—

ligature of the two vertebrals and the two carotids does not entirely cut off all circulation from the brain region. After the ligature of these four vessels we have found, somewhat to our surprise, that a collateral circulation is set up, apparently through the vessels of the spinal cord, which is sufficient to keep alive the functions of the medulla oblongata. If chloroform be given to such an animal its respiration ceases remarkably quickly, before indeed the blood pressure has fallen to any great extent. Here when there can be only a small amount of blood containing chloroform reaching the respiratory centre, that centre is in such a condition as to be paralysed very quickly when the chloroform reaches it.

It is obvious from this statement that the cross-circulation experiments were foredoomed to failure, and that the essential condition—namely, to limit the action of the drug to the heart—could not be accomplished. They were finally demolished by Gaskell himself in the test cross-circulation experiment which he performed for my benefit on July 7th, 1894. In this experiment chloroform was administered to the "fed"—the animal whose heart was supposed to be isolated from its brain. The blood pressure fell in the usual way, and the normal sequence of events occurred. Dr. Gaskell was careful to explain to me that this was exactly what had happened in all his cross-circulation experiments, and he hoped I was now convinced that chloroform produces the fall of blood pressure by acting on the heart. I was convinced the anaesthetic had had access to the animal's brain, and begged him to make a *post-mortem* examination. Accordingly the aorta was injected, and he wrote next day to say that it was found that the ligature of the left subclavian artery was not properly secured, "so that the injection was able to pass both into the vertebral—that is, into the brain—and into the arm on that side. I have very little doubt that some blood must have passed along that vertebral," and chloroform also.

In the face of these facts it is manifestly unfair of the writer of the obituary notice to say, of Gaskell's cross-circulation experiments: "In this way, by limiting the action of the drug to the heart, it was conclusively proved that chloroform produces a fall of blood pressure by acting on the heart." On Gaskell's own showing, the action of chloroform was never limited to the heart in any of his cross-circulation experiments; consequently they proved nothing.

The matter has been finally disposed of by Mr. Lockhart Mummery's experiments with chloroform. In them the animals were beheaded under an anaesthetic and pithed. The heart was kept beating by artificial respiration and was practically the only organ left for the chloroform to act upon, so that it may be truly said that in Mr. Mummery's marvellous experiments the action of chloroform was limited to the heart alone. It was found impossible to stop the heart with chloroform given in the ordinary dose. When the air was completely saturated with heated chloroform the heart stopped, but it could always be revived, showing that it was not poisoned with chloroform, but was stopped either mechanically or by deprivation of oxygen. Mr. Lockhart Mummery's experiments completed the work of the Hyderabad Commission; they completed the proof that the fall of the blood pressure under chloroform is vasomotor and therefore in the first instance protective, and is not due to the action of the drug on the heart.—I am, etc.,

Hove, Sept. 28th. E. LAWRIE.

Universities and Colleges.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

AN extraordinary Comitia was held on September 24th, the President, Sir Thomas Barlow, Bart., K.C.V.O., being in the chair.

The War.

A report, dated August 14th, was received from the Committee of Management. The report referred to the decision to hold an additional Final Examination commencing on September 8th, and to the special conditions which applied to the candidates entering for the examination. The Committee of Management also recommended the Royal Colleges to adopt the following temporary regulations, namely:

1. That time spent as assistant on active service in one of His Majesty's ships or in a naval or military hospital, or any hospital utilized by the naval and military authorities not exceeding six months be allowed to count for the equivalent period of medical and surgical hospital practice and for three months each

of the required period of medical clinical clerkship and surgical dressership, provided that a satisfactory certificate is produced from the Principal Medical Officer under whom the assistant serves.

2. That medical clinical clerkships and surgical dressership served before second examination in anatomy and physiology has been passed, be recognized.

The report was adopted.

Licences Granted.

Licences to practise physic were granted to 122 candidates who had passed the required examinations.

Harveian Commemoration.

The College resolved not to hold the usual dinner this year on the evening of the Harveian Commemoration (Monday, October 19th), but that the Oration should be delivered as announced.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN ordinary meeting of the Council was held on September 24th.

British Expeditionary Force.

The Secretary reported that Sir Anthony A. Bowlby and Mr. G. H. Makins had left England to join the staff of the Principal Medical Officer of the British Expeditionary Force in France as consulting surgeons.

The late Sir Henry Howse.

The following resolution was adopted by the Council:

That the Council hereby express their deep regret at the death of Sir Henry Greenway Howse, and their sincere sympathy with Lady Howse and the members of the family in the loss which they have sustained. The Council remember with gratitude the many services rendered by Sir Henry Howse to the College as its President, the active part he took in the business of the Council, and his long service as an examiner. They also record their appreciation of the prominent part taken by him in the advance of modern surgery, and his simple-minded devotion to the interests of the profession in which he held so distinguished a position.

Issue of Diplomas.

Diplomas of Membership were granted to 122 candidates found qualified at the recent examinations.

The War.

On the recommendation of the Committee of Management the Council adopted the resolutions with regard to the curriculum printed above in the proceedings of the Royal College of Physicians.

University of Liverpool.

Sir Frederic Eve was appointed to represent the College on the Council of the University of Liverpool.

CONJOINT BOARD IN ENGLAND.

THE Royal College of Physicians and the Royal College of Surgeons, at their meetings on September 24th, conferred diplomas of L.R.C.P. and M.R.C.S. upon the following candidates:

H. L. Addison, C. L. Balkwill, L. W. Barlow, S. Batchelor, T. B. Batchelor, J. D. Batt, L. W. Batten, K. B. Bellwood, G. A. Berkeley-Cole, K. Biggs, W. M. Binning, Z. M. Bishara, W. H. Blakemore, Marjorie A. Blandy, W. H. Boyd, J. J. Brown, O. D. Brownfield, F. B. Bull, B. Burnside, L. J. Cameron, G. D'R. Carr, E. Catford, P. R. Chevreau, G. F. Clifton, J. S. Cocks, W. T. Collier, W. J. Cook, L. P. Costobadie, R. I. Dacre, J. H. Dancy, T. W. David, P. V. Davies, M. de Costa, E. R. Dermer, M. Dia, S. O. Dolan, A. J. D'Souza, H. Dunkerley, J. A. Durante, M. K. El Kholy, R. F. Fagan, F. E. Feilden, H. D. Field, R. O. Fisher, J. E. Foley, E. D. Fountain, H. R. Friedlander, C. de W. Gibb, G. F. P. Gibbons, E. H. H. Granger, G. L. Grant, A. R. Green, S. L. Green, E. R. G. Greville, E. F. Guy, Norah Hamill, E. E. Herga, A. E. Huxtable, L. M. Ingle, R. W. P. Jackson, C. E. Jenkins, Rosalie Jobson, S. W. M. Jones, S. H. Keys, G. P. Kidd, N. S. Koch, G. C. Kusumbeker, F. C. Lapage, R. A. Leembruggen, A. B. Le Mesurier, K. W. Lewis, J. A. Liley, A. H. Little, I. H. Lloyd-Williams, E. R. Lovell, H. D. McCall, F. O. MacGibbon, R. MacGill, Helen M. M. Mackay, A. S. L. Malcolm, Edith M. Martland, C. J. D. May, H. L. Messenger, V. R. Mirajkar, L. W. Mortimer, A. R. Muir, W. D. Newcomb, G. M. Oakden, G. W. Parry, H. R. Parslee, Margaret R. Paterson, J. E. Pearce, C. H. G. Penny, M. G. Pettigrew, L. R. Pickett, Emma C. Pillman, J. Pinder, J. A. Pridham, G. D. Read, F. T. Recs, H. C. C. Rennie, A. St. Johnston, E. A. L. Sansom, W. G. Shakespeare, J. P. Shaw, R. H. Simpson, B. H. Singh, H. Smith, C. S. Staddon, E. C. W. Starling, T. Sykes, L. H. Terry, G. R. S. Thomas, P. Thornton, N. Tribe, G. S. Trower, B. M. Tuke, J. L. Waller, E. Watson-Williams, G. C. Wells-Cole, L. H. W. Williams, M. U. Wilson.

ST. BARTHOLOMEW'S MEDICAL SCHOOL.

THE entrance scholarships in arts, value £100, has been divided equally between Mr. J. T. Long, the Coopers' Company's School, and Mr. D. Spurway, Bridgnorth Grammar School; and the Jeaffreson exhibition, value £50, has been awarded to Mr. A. B. Bernard, Dulwich College.

AN APPEAL TO EXAMINING BODIES.

The Higher Diplomas.

VOLUNTEER writes: In reply to "Another Volunteer," I should like to say that the reason for my first letter was the present shortage of medical officers, especially for the new Territorial units now being formed, coupled with the knowledge of at least one case in which an otherwise eligible man was holding back in order to go up for a higher examination. While admitting that the "reasons may be many and various" for staying at home, and acknowledging the magnificent response made by the younger members of the medical profession at the beginning of the war, the fact remains that most of the men now coming forward appear to be married men, many of whom are giving up their practices to do so. As most of the men who go up for such examinations as the F.R.C.S., M.R.C.P., and M.D. are young, unmarried, and at present not engaged in practice, I appealed to the examining bodies not to encourage them to stay at home. I do not include examinations for the M.B., which practically count as qualifying examination. Men are wanted, and wanted at once, as medical officers.

Public Health AND POOR LAW MEDICAL SERVICES.

POOR LAW MEDICAL OFFICERS' ASSOCIATION OF ENGLAND AND WALES.

A COUNCIL meeting was held on September 10th, at 34, Copthall Avenue, Surgeon-General Evatt being in the chair. The Honorary Secretary reported that the attempt of the Isle of Wight guardians to vary the Poor Law Orders by authorizing individual guardians to issue medical orders in cases of urgency had not succeeded, and the matter seemed to be in abeyance. The Council's report on the Poor Law Institutions Order, 1913, had been widely circulated, and had met with general approval.

Whole-time Appointments.—A letter was read from Dr. Clatworthy, Honorary Secretary of the Camberwell Division of the British Medical Association, stating that that Division strongly disapproved of the changes made by the Bermondsey guardians in the administration of outdoor medical relief. It thought that the guardians' latest schemes "are against the interest of the pauper patients of Bermondsey, and throughout Great Britain, and detrimental to the interests of medical practitioners." The Honorary Secretary reported that the Bethnal Green guardians had approached the Local Government Board for permission to follow the example of the Bermondsey guardians, and appoint whole-time infirmary medical officers in the place of the present district medical officers. The Council expressed its strong disapproval of the scheme, and decided that the association should oppose the action of the Bethnal Green guardians.

Burnley.—From Burnley it was reported that the local profession had decided to come to a temporary agreement with the guardians, and to support their arrangements for medical outdoor relief in the union during the war.

Temporary Appointment Negatived.—A letter was read from Dr. Todd of Wonston thanking the association for assistance given him in his dispute with the Winchester guardians, who had attempted to make his appointment a temporary one, when it should have been permanent, as he resided within his district. From a report in a local newspaper it appeared that at a recent meeting of the board the following letter was read from the Local Government Board:

I am directed to acknowledge the receipt of your letter of the 18th ultimo, relative to the proposal of the guardians to re-appoint Dr. Todd for a further period of three years. The Board have given consideration to this proposal, and are of opinion that the guardians should now proceed to make a permanent appointment, as contemplated by the regulations.

Insurance Act.—Dr. Major Greenwood was unanimously nominated again to represent the interests of Poor Law medical officers on the Insurance Act Committee of the British Medical Association.

The War.—A discussion followed on the effect of the war on the work of Poor Law medical officers. It was recognized that their work had already been increased, and that it would continue to increase. It was unanimously agreed that it was the duty of all Poor Law medical officers to do their utmost to assist members of the service who had volunteered, or been called upon for the military or naval service of the country. They might act as deputies in their absence, so that their offices might be reserved for them on their return. Some boards of guardians had taken charge of German prisoners. Exception was taken to attendance being given to these as part of the medical officer's duty. As the Treasury was going to pay the net expenses of these prisoners, an extra payment to the medical officer, if called upon, should be

reckoned among these expenses. The Council expressed the unanimous opinion that it would be very unjust to include such work in the ordinary duties of Poor Law medical officers.

REPORT OF MEDICAL OFFICER OF HEALTH.

Bootle.—Based on an estimated population at the middle of 1913 of 72,186 the birth-rate of the county borough of Bootle was 30.0 per 1,000 and the death-rate standardized for age and sex distribution was 18.4 per thousand. The infant mortality rate was 145 per 1,000 births, this rate varying from 106 in one ward to 205 in another. There is employed in Bootle a lady sanitary inspector, who appears to be doing very excellent work, but the medical officer of health, Dr. W. Allen Daley, considers that it would be a great advantage if there could be established in the borough a dépôt for the distribution of humanized or specially prepared dried milk and if a "school for mothers" or an "infant welfare centre" could be instituted. An epidemic of measles began in the autumn of 1912 in which year there were 62 deaths from the disease which continued in epidemic form until the summer of 1913; in the latter year there were 33 deaths. The disease spread from one school to another, but the incidence was never very great in more than one or two schools at the same time. Exclusion of individual children was carried out, and in most schools this was found sufficient to cope with the epidemic. It is interesting to record that among the 343 cases occurring among school children all recovered but one. Dr. Daley considers that to control measles effectually it is necessary to have an early knowledge of the existence of the cases; provision for isolation of all cases; means for nursing cases complicated by pneumonia; and to educate the public as to the seriousness of the disease and the danger of purposely exposing infants to infection in order to "get the measles over."

Medico-Legal.

LECTURER CHARGED WITH MANSLAUGHTER.

THE *Times* reports that at Brentford, on September 28th, Orlando Edgar Miller, a teacher and lecturer at Bechstein Hall on "higher thought" and Christian Science, was committed for trial on a charge of the manslaughter of Miss Kate Addison Scott at the Miller Institute, Isleworth, in June last. The prosecution stated that Miss Scott was admitted to the Miller Institute on June 2nd, and died five days later. The prisoner, who was not a medical man, submitted her to treatment by drugs. Medical evidence was given that death was caused by paralysis of the stomach set up by the administration of hyoscine, and that Miss Scott's life could have been saved had a medical man been called in in time.

A report of the inquest on Miss Scott was published in the JOURNAL of July 18th, page 156.

Obituary.

LIONEL CHARLES PEEL RITCHIE, Ch.M., M.D., F.R.C.S.E.,

ASSISTANT SURGEON, ROYAL INFIRMARY, EDINBURGH.

MR. L. C. PEEL RITCHIE, whose accidental death from drowning in Granton Harbour on September 24th came as a great grief to his many friends, was the younger son of the late Dr. Peel Ritchie, the well-known physician in Edinburgh. The accident occurred in the afternoon when Mr. Peel Ritchie was on his steam launch. It is conjectured that he may have slipped and fallen overboard, possibly striking his head as he fell. He took the degrees of M.B., Ch.B. at Edinburgh University in 1900, proceeded Ch.M. in 1905 and M.D. in 1907, and he was made a Fellow of the Royal College of Surgeons in 1904. For some years he acted as surgeon to the Western Dispensary, Edinburgh, and not long ago he was appointed assistant surgeon to the Royal Infirmary. Mr. Peel Ritchie was unmarried.

MR. DAVID WALLACE, C.M.G., writes: Mr Peel Ritchie's record as a student, and in the various junior hospital appointments which he held, pointed to the probability of a distinguished career. After study in Germany and in Vienna he returned to Edinburgh, and at once began the work best suited to equip himself as a surgeon. He was imbued with the idea that it was through the medium of clinical pathology that modern surgery would develop, and to this branch he chiefly devoted himself. He was extremely neat with his hands, and interested in the preparation and mounting of naked-eye specimens, and at many meetings of the Edinburgh Medico-Chirurgical Society and the Edinburgh Branch of the British Medical Association his work was greatly admired. An original method of mounting specimens gained considerable repute, and was adopted by others. He worked for a time at opsonins, and in connexion with this he studied the vaccine treatment of disease, and especially differentiated bovine from human tubercle. He was one of the first to emphasize the importance of bovine or human tuberculin being used in cases in which one or other of these was the source of infection. Perhaps for his pioneer work in this particular branch he got less credit than he deserved. Mr. Peel Ritchie was a loyal colleague, and unsparing of himself in working for the seniors with whom he was associated. The profession is the poorer by his loss, and those who were his intimates mourn the early passing of a sincere friend who, while retiring and shy by disposition, was unsparing in his endeavours to do his duty, and was at all times to be relied on to support a friend in need.

HERBERT LESLIE HOPKINS, M.D.Lond.,

LIEUTENANT, R.A.M.C.; KILLED IN ACTION.

LIEUTENANT HERBERT LESLIE HOPKINS, M.D.Lond., R.A.M.C., reported as killed on September 19th whilst serving with the Expeditionary Force in France, was assistant county medical officer of health for West Suffolk. Lieutenant Hopkins received permission from the county council on August 10th to volunteer for active service, and joined the forces at Devonport on August 15th, receiving the appointment of bacteriologist and pathologist to the Military Hospital there. On August 26th he sailed for France.

Dr. Hopkins was born on August 23rd, 1887. He was a student at Guy's Hospital, where he joined in 1905, having obtained an entrance scholarship in arts. During his student career he was a student demonstrator in physics, anatomy, microscopic pathology, and bacteriology, and pathological assistant to the surgical registrar. He took the degrees of M.B., B.S. of the University of London in November, 1911, and the diplomas of M.R.C.S. and L.R.C.P.Lond. in the same year. After devoting some time to special study in various departments at his medical school, he was appointed house-physician to the Derbyshire Royal Infirmary in February, 1912. A year later he was appointed house-physician to the City of London Hospital for Diseases of the Chest, which appointment he held until he commenced his work in West Suffolk in September, 1913. In July, 1914, he passed the examination for the degree of M.D. in State medicine in the University of London, being the only candidate in this very difficult examination. This achievement was specially praiseworthy, considering the amount of hard work which he was undertaking at the time in the county.

DR. BYGOTT, County Medical Officer of Health for West Suffolk writes: By the death of Lieutenant Hopkins, the medical profession, especially the sanitary branch of it, has lost one of its ablest junior officers. Dr. Hopkins was a man of high attainments, a sound physician, capable surgeon, and good bacteriologist; there was, in fact, no branch of medical work in which he did not excel. During the year he worked with me I formed the highest opinion of his capabilities, and had his life been spared I feel sure there is no height in his profession to which he might not have attained. Dr. Hopkins was an all-round athlete. He was also an able musician, and his kindly disposition and pleasant manners made him a general favourite both in official and social life. Able, energetic, conscientious, and very thorough in his work, his death is a calamity to his colleagues and to the council he so loyally served. At the first call he offered for service at the front and freely gave himself for his country. The sacrifice of this young life, bright in fulfilment, and still more brilliant in promise, will be deplored by all, and the deepest sympathy felt for his family in this great sorrow

DR. CHARLES STEELE, who died at his residence in Clifton on September 20th, aged 76, was a native of Macclesfield, and was the son of the Rev. John Steele. He received his medical education at the Bristol Medical School and the Bristol Royal Infirmary. He took the diploma of M.R.C.S.Eng. in 1860, and that of L.R.C.P.Lond.

in 1861. He became F.R.C.S.Eng. in 1869, and graduated M.D.Durh. in 1880. He was for many years a member of the surgical staff of the Bristol Royal Infirmary, and at the time of his retirement was senior surgeon as well as consulting surgeon to the Bristol Hospital for Sick Children. He was at one time lecturer on physiology in the Bristol Medical School. Dr. Steele retired from practice six years ago. The funeral, which took place on September 24th, was attended by a large number of friends, including many members of his own profession.

SURGEON-GENERAL SIR ANNESLEY CHARLES CASTRIOT DE RENZY, K.C.B., Bengal Medical Service (retired), died at Ealing on September 24th. He was born on April 7th, 1828, the son of Dr. Thomas de Renzy, of Carnew, county Wicklow. He was educated at Trinity College, Dublin, where he graduated B.A. He took the M.R.C.S. in 1851, and entered the I.M.S. as assistant surgeon on July 29th in that year. He became surgeon on March 12th, 1864, and in 1868 was appointed sanitary commissioner of the Punjab, being the first to fill that post. On July 29th, 1871, he became surgeon-major; on November 12th, 1877, was promoted to deputy surgeon-general, and retired on December 9th, 1882. He served in Burma in 1852–54 with the Bengal Artillery, was present at the actions of Martaban, Prome, and Rangoon, and received the medal with clasp. At the outbreak of the Indian Mutiny of 1857–58 he was at Nasirabad in Rajputana, whence he escaped alone to Beawar, and served afterwards in the siege of Lucknow (medal with clasp). He served also on the north-east frontier of India, in the Naga campaign of 1879–80, when he was mentioned in dispatches, received the medal, and was given the C.B. (1881). On January 14th, 1882, a good service pension was conferred upon him; and on June 27th, 1902, nearly twenty years after his retirement, he was made a K.C.B. He was the author of various reports on sanitary subjects. After his retirement he filled for many years the office of chairman of the Jokai Tea Company, which presented him with his portrait in oils. His funeral, which at his own request was strictly private, took place at Golder's Green on September 26th.

CAPTAIN HENRY SHERWOOD RANKEN, who on September 25th died at Braisne in France of wounds received on September 21st, was the son of the Reverend Henry Ranken, minister of the parish of Irvine, Ayrshire, and was born in 1883. He was educated at the University of Glasgow, and graduated M.B., Ch.B. in 1905; he was afterwards house-physician and house-surgeon to the Western Infirmary, Glasgow, and assistant medical officer to the Brook Fever Hospital, London. He entered the Royal Army Medical Corps in 1909, was employed with the Egyptian Army, and was a member of the Sudan Sleeping Sickness Commission. In conjunction with Mr. H. G. Plimmer and Captain W. B. Fry he contributed reports on the experimental treatment of trypanosomiasis to the *Proceedings* of the Royal Society (1910-11). Captain Ranken became a member of the Royal College of Physicians of London in 1910, and his death deprives the corps of a very promising officer.

Medical News.

THE session of the Hunterian Society will be opened on October 14th, when Sir Dyce Duckworth will give the first Hunterian Society's lecture on "the patient and the disease," at 9 p.m.

MAJOR W. H. G. H. BEST, R.A.M.C. (Special Reserve), Principal Medical Officer, Southern Provinces, Nigeria, has been appointed an official member of the Legislative Council of the Colony of Nigeria.

THE first graduation ceremony of the University of Western Australia, the youngest university in the world, took place at Perth on July 29th. The university was born into the world of learning in 1913.

THE Research Defence Society has issued a popular leaflet, explaining the great value of antityphoid vaccination. It has also arranged for the treatment to be given, to anybody desiring it, at the society's office (21, Ladbroke Square, London, W. Telephone, 975 Park). Supplies of the leaflet can be had on application to the honorary secretary.

Letters, Notes, and Answers.

☞ *Queries, answers, and communications relating to subjects to which special departments of the* BRITISH MEDICAL JOURNAL *are devoted will be found under their respective headings.*

LETTERS, NOTES, ETC.

LOUVAIN AND CAMBRIDGE.

DR. CLIPPINGDALE (London, W.) writes: I have been much interested in the recent articles on the University of Louvain. It seems fitting that the University of Cambridge should offer hospitality to the professors of the University of Louvain, seeing that it was at Louvain that Caius published at least three of his works. Another Catholic physician who fled to Louvain during the Reformation in England was Dr. John Clement, one of the medical men sent by Henry VIII to attend Cardinal Wolsey, when the Cardinal lay sick (and in disgrace) at Esher (see Cavendish's *Life of Wolsey*).

THE OSRAM LAMP.

SOME prejudice appears to have been excited against the Osram lamp on the supposed ground that it is a German product. It is true that the metal filament electric lamp, of which the Osram is one of the most conspicuous representatives, is an Austro-German invention; but if we are to dismiss the concrete result of every idea that has emanated from a Teutonic brain, we shall quickly find ourselves in an absurd position. As it happens, however, the Osram lamp is now practically from first to last produced by British hands and under British direction, and for their enterprise in acquiring the patents for the United Kingdom, and establishing what was, it is said, the first metal filament industry in this country, the makers of the lamp deserve the thanks of reflecting patriots rather than otherwise. In order to prove that the Osram lamp is a home product, the General Electric Company (Limited) threw open to representatives of the Press last week their large Osram factory at Brook Green, Hammersmith, where nearly sixteen hundred hands are employed, and lamps are turned out to the number of seven millions annually. Every delicate and intricate detail was demonstrated, and it was stated that 96 per cent. of the processes incidental to Osram lamp production, including the manufacture of the glass, are carried out in this country, and that provision for the remaining 4 per cent., hitherto carried out in Holland, is being established here. It was interesting to see the lamp actually growing under the hand, from the production of the tungsten metal in the laboratory to the last test of the finished product. The shaping of the glass, the fixing of the supports and the exhaust stems; the adjustment of the hooked carriers, made, we believe, of molybdenum, which hold in place the all but invisible filament, and the winding and sealing of the filament itself—an alloy of osmium and tungsten—called for the nicest manipulation; but of all the processes none was more fascinating to watch than the making of the tungsten wire. The particles of tungsten metal were first compressed by mechanical means into a bar, which was softened by a battery of blowpipes until the metal was capable of being drawn through a hole, one-thousandth of an inch in diameter, drilled in a diamond. In lamp production the machinery seems even more wonderful than the product.

DILATING THE PUPIL.

DR. LILIAS M. BLACKETT (C.M.S. Zenana Hospital, Multan Cantonments, Punjab) writes: In the BRITISH MEDICAL JOURNAL for April 4th, 1914, p. 800, I noticed the record by Dr. Prasad of Delhi, of a case of atropine poisoning in ophthalmic practice, which is remarked upon as unusual. Possibly the following case is of interest as adding another to the number: A healthy English boy, aged 4 years, was to be treated for internal strabismus. I instilled two drops of a 1 per cent. solution of homatropine and cocaine alkaloids in ol. ricini, into one eye only, and left the child till the pupil should be ready for examination. Almost immediately the mother sent a nurse hurrying to fetch me, and I found the child flushed and distressed, "feeling bad." The pulse had quickened and the temperature had risen slightly—to 99.4°. The flush was very marked on the face and forehead, and sweating was present; it was less marked on the abdomen. The symptoms lasted for about ten minutes and then subsided.

TETANUS:

ITS PREVENTION AND TREATMENT BY MEANS OF ANTITETANIC SERUM.

BY

ALFRED MacCONKEY, M.B., B.C.Cantab., D.P.H.,

BACTERIOLOGIST IN CHARGE OF SERUM LABORATORIES, LISTER INSTITUTE OF PREVENTIVE MEDICINE.

Tetanus cannot be said to be of frequent occurrence under ordinary conditions of life in time of peace, but the outbreak of war is often followed by a comparatively large increase in the number of cases of this disease.

These notes, the fruit of work in a serum laboratory and of a slight cultivation of the literature, were gathered together some months ago without any idea of their appearing in their present form, and I now publish them with the object of calling the attention of those who have not specially studied the question to the value of tetanus antitoxin, which is inestimable when the serum is used properly as a prophylactic. It is to be hoped that at the present time systematic use will be made of this remedy, so that one, at any rate, of the hazards run by those who are offering their all on the battlefield in defence of their country may be reduced to a minimum.

Historical.

Tetanus, or lockjaw, is a malady common to man and many animals. It was recognized in ancient times, and it has long been known that it was likely to follow the soiling of wounds with earth, dust, and similar material. About the middle of the nineteenth century the impression gained ground that it was due to the production of a poison in the wound, and in 1884 Carle and Rattone reported that they had conveyed the disease by means of pus from a case of tetanus.

In 1885 Nicolaier produced tetanus in mice, guinea-pigs, and rabbits by inoculating them with garden soil, and the pus from the wounds carried on the infection from animal to animal. In the local lesion Nicolaier found a bacillus with a spore at the end, but he did not succeed in obtaining a pure culture.

In 1886 Rosenbach found a similar bacillus in a case of human tetanus, but he also was unsuccessful in his attempts to isolate it. Knut Faber (1889) separated the toxin from mixed cultures by means of filtration through porcelain. Kitasato in 1889 was the first who succeeded in securing a pure culture of this bacillus and in proving that it alone was the causal agent of the disease.

Distribution of the Bacillus.

The *Bacillus tetani* is widely distributed in nature, being found in the soil of most cultivated areas, in the streets of cities, and in fact in any place where there is faecal contamination. v. Lingelsheim recalls the examination by Bossano of samples of dust from thirty-eight towns, only twelve of which were found free from tetanus bacilli. Nicolaier found it in twelve out of eighteen samples of earth in the neighbourhood of Göttingen.

Choukévitch (1911) demonstrated its presence in the intestinal contents of two horses out of eighteen, but Lukas (1914) was more successful, as he isolated it from the faeces of sixteen out of seventeen horses. Joseph (1910) examined the excreta of cattle, and came to the conclusion that the *Bacillus tetani* must be considered a normal inhabitant of the intestine of these animals. Römer (1909) also found it frequently in the faeces of adult cattle, but it was not usually present in animals under 2 years of age. Further, tetanus antitoxin was found in the blood of the older animals in more than 50 per cent. of the cases examined. Dolly (1910) found tetanus bacilli frequently in the wads of blank cartridges, and Graser (1910) reports a like result. Rabinowitsch (1907) found the spores of this bacillus in the water in which strawberries sold in Berlin had been washed. It is said to have been found in the mud of the Dead Sea.

This wide distribution of the organism emphasizes the necessity for extreme care in cleansing all wounds, but especially those which have come in contact with street dust, road sweepings, the soil of cultivated fields, garden earth, manure, etc.

Bahnson (cited by Anders and Morgan) stated that during the American Civil War he was put with other prisoners into a shelter that had been used for horses, and that all the wounded placed there who did not die as a direct result of their wounds developed tetanus, and all of them died.

Cultivation of the Bacillus.

Under the usual conditions of artificial cultivation in pure culture, the tetanus bacillus will not grow in the presence of oxygen, and therefore it is termed an "anaërobic" organism. But if some nutrient medium be inoculated with the *Bacillus tetani*, and also with some oxygen-loving organism such as the *Bacillus subtilis* (hay bacillus), the absence of oxygen is not so necessary, as the *B. subtilis* will use up the oxygen and produce conditions in which the *B. tetani* can grow. Further, Tarozzi and others have shown that if pieces of animal tissue be placed in a liquid culture medium the bacillus will grow alone in the presence of oxygen, the dead tissue acting as a reducing agent.

In nature we get a combination of these two methods of producing conditions suitable for growth; in the earth we have organic materials to act as reducing agents and the aërobic organisms to use up oxygen; in contused and dirtied wounds we have the dead tissues and the pyogenic cocci to act in a similar manner.

Production of Tetanus Toxin.

Tetanus toxin is prepared by growing the tetanus bacillus in nutrient bouillon, of neutral or slightly alkaline reaction, which may or may not contain some reducing agent such as glucose, sodium sulphindigotate, etc. Special flasks filled with such a broth are inoculated with the tetanus bacillus, hydrogen gas is passed through the liquid and the flasks are placed at 37 C. for eight to ten days, when the bouillon is filtered through porcelain to remove the bacilli and spores. The filtrate forms the tetanus toxin. The toxicity of such a filtrate varies very much. A mouse of 15 grams weight might be killed in three to four days by $\frac{1}{50000}$ c.cm., or it might be necessary to inject $\frac{1}{100}$ c.cm. or even more. The susceptibility of different species of animals to this toxin varies very markedly; thus it is stated that if a certain quantity of toxin will just kill 1 gram of mouse the same quantity will kill—

6 grams of guinea-pig	1/600 gram of cat
12 ,, of horse	1/1000 ,, of goose
1/2 gram of goat	1/4000 ,, of pigeon
1/150 ,, of rabbit	1/30000 ,, of hen

from which it is evident that the horse is one of the most susceptible of animals.

Production of Tetanus Antitoxin.

In 1890 Behring and Kitasato showed that animals could be immunized against the tetanus bacillus and its toxin, and that then their blood had acquired a new property, so that when it was injected in suitable quantity into other animals these were protected against doses of tetanus which otherwise would be invariably fatal. This new property, they thought, was due to the development in the blood of immunized animals of a substance which, as it neutralized the toxin, they called "antitoxin." When the fluid part of the blood has been separated from the solids it is found that the antitoxin is contained in the plasma or serum. Horses are the animals most frequently used in the production of tetanus antitoxin for therapeutic purposes. As they are so highly susceptible to the toxin the utmost care is required during the process of immunization to avoid the occurrence of accidents. Therefore, at the beginning of the immunization the toxin is not given in the pure state, but only after having been modified by chemicals or by being mixed with antitoxin. Sometimes the toxin and the antitoxin are not mixed, but are given simultaneously in separate parts of the body or the antitoxin is given a few hours before the toxin. Whichever method is used at the commencement, the object is always the same, namely, to produce a basal immunity so that after a time the animal will bear without ill effect the inoculation of pure toxin. Therefore, as the injections are repeated the amount of modifying agent is gradually decreased until only toxin is given. When the establishment of a basal immunity has been demonstrated the

loses are increased more rapidly, and finally 200 c.cm., 400 c.cm., or 1,000 c.cm. of pure toxin are injected at one time. The inoculations are usually given subcutaneously or intramuscularly (though some use the intravenous route) at intervals of five to ten days. After the final dose a rest of one to three weeks is given before the animal is bled, when on an average 8 litres of blood are withdrawn. If considered desirable another bleeding may be taken at the end of a week, and followed by a third, fourth, or fifth at intervals of seven or eight days. The animal then has a rest of three weeks or more before being reimmunized. During a bleeding, as well as during all subsequent processes, every precaution is taken to prevent contamination. When the plasma or serum has been obtained separate from the corpuscles and clot, a small amount of preservative is added, and it is put away in a cool dark place for a time.

As soon as possible after a bleeding the serum is tested to ascertain whether it contains enough antitoxin to render it fit for therapeutic use. This standardization is carried out according to the American method introduced by Rosenau and Anderson (1908), a description of which has been published in *Bulletin* No. 43 of the United States Public Health and Marine Hospital Service and in the *Journal of Hygiene*, January, 1914.*

When required for use the serum is filtered through porcelain and distributed into small bottles. Before being sent out for therapeutic use antitetanic serum is tested—

1. *For absence of toxicity* by animal experiment, 10 c.cm. of serum being injected subcutaneously into each of two guinea-pigs of 250 grams weight. The animals must remain well.
2. *For sterility* by cultural experiment aërobically and anaërobically. The media inoculated with the serum must not show any growth.
3. *For non-excess of preservative*, 0.5 c.cm. of serum being injected subcutaneously into a mouse of 15 grams weight. The animal must not show more than temporary symptoms of intoxication.

From the time the serum is first obtained its antitoxin content begins to diminish. This diminution takes place most rapidly at first; later the serum appears to reach a condition of comparatively stable equilibrium, when the deterioration proceeds much more slowly. To compensate for this unavoidable loss there is usually put into each bottle an amount of antitoxin in excess of the quantity stated to be present, sufficient to make it probable that the bottle will, at the end of two years, contain the amount of antitoxin stated on the label, provided it is stored in a dark cool place—preferably in an ice-chest.

Prophylactic Use of Tetanus Antitoxin.

Tetanus antitoxin may be used (1) prophylactically, (2) curatively.

As a prophylactic tetanus antitoxin yields excellent results.

Animal experiment has proved:

That if a fatal dose of tetanus toxin be mixed together with a suitable amount of tetanus antitoxin, the mixture can be injected into animals without giving rise to any ill effect whatever.

That the effect of a fatal dose of toxin can be completely inhibited by the injection of antitoxin twenty-four hours previously.

That a fatal result can be prevented by injecting a suitable dose of serum within a short time of the injection of the toxin.

From these results it would naturally be expected that tetanus antitoxin would furnish good results when used as a prophylactic. Such has been the case.

Vaillard (1912, p. 224) refers to the practice of eight veterinary surgeons from 1898 to 1906. In that period they inoculated 13,124 animals after operations or accidental wounds, and not a single case of tetanus occurred among them. During the same time two veterinary surgeons alone saw 139 cases of tetanus among animals which did not receive the treatment. If the figures of Nocard and Labat are added, we get 16,917 animals which had a prophylactic injection, and among them one single horse had tetanus—in this case the antitoxin was given five days after the wound, and the attack was very benign.

Hugnier (1909) used to give two injections of 10 c.cm. each of antitetanic serum, but for some years has been content to give one, and, although he operated in conditions under which infection was most possible, he has not had one case of tetanus among horses thus treated prophylactically.

Dieudonné (1909) records 1,009 operations for castration or hernia, with no case of tetanus, although only a single injection of serum was given. During the same period he observed 87 cases of tetanus among horses operated on or wounded which had not had a prophylactic injection.

Parker Hitchens (1910) has proved experimentally that a dose of 300 U.S.A. units of tetanus antitoxin will protect a horse against an infection fatal to the control animals.

Mohler and Eichhorn (1911) found experimentally that as regards an infection fatal to the control—

300 U.S.A. units given 48 hours after infection = no symptoms of tetanus.
500 U.S.A. units given 72 hours after infection = no symptoms of tetanus.
700 U.S.A. units given 96 hours after infection = no symptoms of tetanus.

Whereas—

250 U.S.A. units given 48 hours after infection = local tetanus. Recovery.
400 U.S.A. units given 96 hours after infection = local tetanus. Recovery.

They conclude "that 500 U.S.A. units is a sufficient dose of antitoxin for use as a prophylactic, even in cases where the infection has occurred four days prior to the injection of antitoxin."

The experience of veterinary surgeons is therefore all in favour of the value of the prophylactic use of antitetanic serum. The results of its use for a similar purpose in the human subject are scarcely less decisive.

Vaillard (1912) cites the experience of Biron and Pied. These surgeons did not use serum from 1895 to 1902, and had during those years 11 cases of tetanus, which were all fatal. In 1903 they began to use serum systematically in every case in which there was a chance of infection with tetanus. From 1903 to 1910 there was not a single case of tetanus in their practice, but during this period they received into their wards 4 cases of tetanus from outside; 3 cases of tetanus were taken into other wards of the same hospital, and there were 2 deaths from tetanus in the town. Vaillard refers also to cases of tetanus following wounds received during the celebrations on July 4th (Independence Day) in America. In 1903 there were 415 cases of tetanus. Then the prophylactic treatment was strongly urged and began to be made use of.

In 1904 there were	... ...	105 cases.
In 1905 ,, ,,	... ...	104 ,,
In 1906 ,, ,,	... ...	89 ,,
In 1907 ,, ,,	... ...	73 ,,

These figures suggest that, as the years passed and the beneficial results were recognized, more and more attention was devoted to prophylactic serum treatment.

Confirmatory evidence has also been brought forward by Brandenstein (1908); Bockenheimer (1909); Solieri (1910), thirty-five cases with one death; Graser (1910), no case of tetanus in eight years among patients treated prophylactically; Simon (1913, p. 236), citing Lieil's analysis of 350 cases of July 4th wounds and tetanus, shows a mortality of 98 per cent.; only seven recovered and of these five had prophylactic treatment. In 1907 the editor of the *Journal of the American Medical Association* summed up the case as follows:

> A fairly careful scrutiny of the American literature for the past five years has not brought to light a single report of the development of tetanus in a person who received a timely prophylactic dose of tetanus antitoxin.

We thus see that the inestimable value of tetanus antitoxin when properly used as a prophylactic is beyond question.

In connexion with the words "properly used" in the previous sentence it is important to remember that antitetanic serum is an antitoxic and not a bactericidal serum. It has no power to inhibit the growth of the bacillus. All antitoxin can do is to neutralize the toxin produced. A certain amount (x) of serum can neutralize a certain amount (y) of toxin and no more. Any further

* The Lister Institute serum is thus standardized.

toxin produced can exercise its deleterious effect uninfluenced by the serum. Thus if an animal has been infected by tetanus and has received a prophylactic dose of serum it is protected against the toxin produced until the neutralizing power of the serum has been exhausted. When that stage is reached, then, as Vaillard puts it, if more toxin is elaborated one of three things must happen, either:

1. More antitoxin must be given; or
2. The animal must produce its own antitoxin; or
3. The animal must become intoxicated.

Further (cf. Tarozzi *supra*), the tetanus bacillus can multiply and produce toxin in blood clots, or in necrotic tissue, especially in the depths of a wound; and as there is some evidence suggesting that a sharp fall may occur in the antitoxin content of the blood about one week after an injection of antitoxin, it is advisable to repeat the injections weekly as long as there is any necrotic tissue in a wound. Again, there may be necrotic tissue in a wound several days old, or a large amount of dirt may be ground into the tissue—for example, run-over cases—and it may be decided to operate and thoroughly clean up such a wound. In this case it is advisable to give a prophylactic dose of antitoxin intramuscularly some hours before the operation, as acute tetanus has occurred within twenty-four hours of such operation, and has in all probability been due to the rapid absorption, by the fresh tissues laid bare by the operation, of a large dose of tetanus toxin which had been elaborated in the necrotic tissue, or was present in the dirt with which the wound was soiled.

Dose.

The amount of serum which should be given at each injection depends entirely upon the number of units in each cubic centimetre of the serum. We have seen above that for the horse, which is the animal most susceptible to tetanus poison, the Americans have experimentally demonstrated the dose to be 300 to 500 U.S.A. units; but in the case of man we have no such evidence. v. Behring recommends 10 to 20 units. These units are German units, and one of them is equal to about 40 U.S.A. units. The dose would then be 400 to 800 U.S.A. units.

Vaillard mentions 10 c.cm. as the dose for superficial easily-cleaned wounds, not grossly soiled; 10 c.cm. of the tetanus antitoxin sold by the Pasteur Institute usually contains from 500 to 1,000 U.S.A. units.

Tizzoni considers that 200,000 of his own units is an ordinary prophylactic dose. I have only examined one sample of Tizzoni's serum.[1] The bottle contained 5 c.cm. = 200,000 units Tizzoni = 125 units U.S.A.

Park and Williams (p. 243) say: "It is the custom at many dispensaries in New York City and elsewhere to immunize all Fourth of July wounds by injecting 1,000 units. None of these have ever developed tetanus."

From this last statement we would conclude that 1,000 U.S.A. units is an ample prophylactic dose, as it has always prevented tetanus, and that it is quite possible a smaller dose would answer the purpose. This apparently has been found to be the case by von Behring, Vaillard, and Tizzoni.

Where there is plenty of serum at the disposal of the surgeon there is no need to take thought about the size of the dose, and the ample dose of 1,000 to 1,500 units may be given with the knowledge that it is better to give too much than too little. But when, as may easily happen during war, there is only a limited amount of serum available, then the question of the smallest protective dose becomes important. This may be put down as about 500 U.S.A. units for a simple uncomplicated case, and as the amount of soiling of the wound and contusion of the tissues increases so should the amount of antitoxin be increased.

The interval of time between the infliction of the injury and the injection of serum also has to be taken into consideration when fixing the dose. Dönitz (1897) showed experimentally in rabbits that if an hour were allowed to elapse between the injection of the toxin and that of the serum it required forty times the neutralizing dose (*in vitro*) of serum to save the life of the animal. Studying the same question recently on guinea-pigs I found that while $\frac{1}{10}$ U.S.A. unit of antitoxin neutralized 100 minimal lethal doses (M.L.D.) of tetanus toxin *in vitro* it required 1 unit of antitoxin to neutralize 1 M.L.D. when given subcutaneously and simultaneously but in different parts of the body, but 3 units did not save life when given four hours after the toxin. When the serum was given twenty-four hours after 1 M.L.D. of toxin it required 2,000 units of antitoxin to save life, though even this amount did not prevent the onset of the disease. In these animals 1 M.L.D. almost always caused the appearance of slight signs of tetanus at the end of twenty-four hours after the injection of toxin.

It is obvious, then, that the earlier the prophylactic dose is given the more certain will be its effect in preventing tetanus, the smaller within limits will be the dose, and the smaller the cost of treatment. This last item may seem insignificant, and it is so when it is only a question of the prophylactic use of antitoxin; but it will be found to loom large in the picture when it is necessary to consider the value of tetanus antitoxin from a curative point of view.

Curative Use.

"Premonitory" Symptoms.—In all diseases the earlier the treatment is commenced the greater the chances of a favourable result. If we could recognize tetanus in a stage as early as we can diphtheria, it would no doubt be possible to obtain just as good results from serum treatment. But tetanus, unlike diphtheria, has no characteristic lesion which appears early in the attack and gives an indication of the nature of the disease. As it has been aptly put by Dr. C. J. Martin, the diagnostic membrane in diphtheria corresponds to the dirt or other foreign body carrying the infection of tetanus, and so, just as we give diphtheria antitoxin when we see such a membrane, so ought we to give tetanus antitoxin when we see any such infecting material in a wound. When the symptoms of tetanus are distinct it means usually that the disease has made very considerable headway, and has reached that stage which in diphtheria would be looked upon by some as beyond the reach of the beneficial influence of antitoxin.

This explains to some extent the uncertain results which follow the use of antitoxin as a curative agent, and it also raises the question whether there are any "premonitory" symptoms the presence of which might rouse a suspicion that a case was one of commencing tetanus. A study of some of the literature of tetanus has shown that commencing tetanus has been mistaken for "colds," muscular rheumatism, stiff neck, sore throat, influenza, mumps, etc., and it has even been suggested that many cases which have been diagnosed and treated successfully as cases of the above diseases have in reality been slight attacks of tetanus. With the object of directing attention to what may prove to be "premonitory symptoms," K. Fyler (1910) relates 13 cases of tetanus with 2 deaths, which came under his personal observation, he himself being one of them. He describes these "premonitory" symptoms as being very varied and changeable.

A day or so after the infection there may be general restlessness, changing suddenly to a desire to rest.

Sleeplessness with distressing dreams, and it may be nightly delirium.

Difficulty in micturition due to spasm of the sphincter vesicae, which may last from a few minutes to half an hour.

Temporary giddiness, violent headache, excessive yawning.

The facial appearance changes and the patient looks anxious, though there is no risus sardonicus yet.

There may be trembling of the tongue which is put out to one side.

There is often a profuse sweating, and darting pains in various parts may occur.

The patient may have a feeling of chilliness, and there may be some swelling, without redness locally, of the injured member and throbbing of its arteries notwithstanding that the limb is raised.

Slight jerking may follow pressure on the flexor tendons, and these muscles may be noticed to be in a condition of increased irritability.[‡]

[1] Cf. *Journ of Hygiene*, January, 1914.

[‡] This condition of increased irritability of the flexor muscles has been noticed to occur in horses quite early in an attack of tetanus.

If symptoms such as these are present with a history of possible infection with the tetanus bacillus Evler considers that the administration of serum is justified. The later symptoms include:

Increased flow of saliva.
Reflex cramps of œsophagus.
Ocular symptoms: for example, nystagmus, strabismus.
Ear trouble, and spasmodic cough.
Tremors and clonic spasms which are not painful and which may not attract attention.
Pain persisting after muscular contraction induced by effort.
Swollen and reddened lymphatics, enlarged glands and tenderness in the infected region.

Evler infected himself during an operation and early symptoms developed within twenty-four hours. He presented nearly all of the symptoms mentioned. Serotherapy was commenced on the fifth day. Nutrient enemata became necessary on the seventeenth and eighteenth days, but on the nineteenth the teeth could be opened a little and recovery then progressed satisfactorily.

Evler's paper directed my attention to these "premonitory" symptoms, and since reading it I have carefully read through a considerable number of cases of tetanus described in the literature, and I have found that practically all the symptoms mentioned by Evler have been noticed as being present early in the disease. All have not been observed in the same patient, but usually the one or two present have been sufficiently prominent to force themselves upon the notice of the physician, and, if he had read Evler's paper, to remind him that such a disease as tetanus might be before him.

If tetanus be studied from the standpoint of these "premonitory" symptoms, there is reason to hope that as our knowledge of them increases so will our power of combating the disease be increased by our intervention earlier in an attack.

Curative Value.

The results following the use of antitoxin as a curative agent have been up to the present for the most part unsatisfactory. The reasons given to account for this are that the disease is usually diagnosed only when it has made considerable progress, and that the toxin is absorbed and travels along paths where it is beyond the influence of antitoxin.

In most cases the tetanus bacilli remain and multiply at the site of infection, and the toxin there produced is absorbed and carried to the central nervous system. As regards the path by which it travels, numerous observers have corroborated the findings of Meyer and Ransom that tetanus toxin is chiefly absorbed from the infected wound along the motor nerves of that region, and passes by direct extension into and through the spinal cord, but it may also pass into the circulation. It is also thought that in the nerves the toxin passes along the axis cylinder. Some observers, however, do not agree entirely with these conclusions.

Cernovodeanu and Henri (1907) have stated that if the vessels and muscles of a limb be tied while the nerves remain intact, a large amount of tetanus toxin may be injected without the production of tetanus, and they therefore conclude that, while some toxin is absorbed by the nerves, the larger part passes along the lymphatics and blood vessels.

Field (cited by Park and Williams) is of opinion that the toxin does not pass along the axis cylinder but along the lymphatics of the nerves.

Permin (1912-1913), from a critical analysis of the literature and from the results of a large number of experiments performed by himself, concludes that part of the toxin is taken up by the peripheral muscle nerves of the site of infection and passes along the axis cylinder to the spinal cord, and part passes into the lymph and blood and gaining the general circulation may pass directly to the ganglion cells of the cord or indirectly by means of the peripheral nerves.

There is, then, no unanimity of opinion as to the special road taken by the toxin, but what we know is that somehow the toxin passes along the nerves comparatively rapidly, but the amount found in the cerebro-spinal fluid is not great—on several occasions 1 to 2 c.cm. of this fluid have contained a fatal dose for a mouse but not more toxin than this.

The holding of the opinion that the toxin is absorbed by the nerve endings and passes along the axis cylinder—that is, in a situation which is beyond the reach of antitoxin in the blood—renders the curative treatment of declared tetanus practically hopeless, in the opinion of many clinicians. Antitoxin does not appear to penetrate readily into the substance of the peripheral nerves or of the central nervous system, and therefore all it can do is to neutralize only the toxin which has not been absorbed, or which is in the blood stream. (After huge doses of antitoxin, given intravenously, only traces of it can be found in the cerebro-spinal fluid.) So a cure can result from the employment of antitoxin only so long as a fatal dose of toxin has not been absorbed. Many cases are on record, and many experiments which seem to confirm this view.* The experiments of McClintock and Hutchings (1913) will serve to illustrate this point. They took sheep with long tails and inserted into the tip of the tail a splinter of wood which had been infected with tetanus spores free from toxin. The first symptoms of tetanus occurred six to eight days later, when the tail was at once amputated, 20 cm. being removed, and 4,500 U.S.A. units of tetanus antitoxin were given intravenously and repeated daily. Every animal but one died and the symptoms did not seem to be influenced by the serum. The amount of toxin in the blood, as proved by animal experiment, was at its maximum between the fifth and seventh day—2 c.cm. of blood containing a fatal dose for a guinea-pig of 350 grams weight. No toxin was found in 2 c.cm. of the blood twenty-four hours after the injection of serum.

From these results it has been concluded that as amputation of the tail had no effect upon the progress of the disease, and as there was toxin in 2 c.cm. of the blood before but not twenty-four hours after the commencement of serum treatment, therefore by the time that the first signs of tetanus appeared a fatal dose of toxin either had been absorbed and fixed, or if not completely fixed was in a situation where the antitoxin could not reach it to prevent complete fixation. This being the case, all that can be expected from serum treatment is the prevention of further absorption of toxin by blocking all the paths leading from the infected area—the nerve routes by injection into the nerves of the region affected and the vascular route by large injections into a vein—and all this merely in the hope that a fatal dose of toxin has not already been absorbed.

It is not certain, however, that these views are correct. They may be based on a false premiss, namely, that antitoxin must penetrate into the cell before it can neutralize the toxin attached to the cell.

But the recent work of Kraus and Amiradzibi (1910) suggests that, contrary to the usual acceptation, a toxin must pass out of a poisoned cell before it can be neutralized by its antitoxin, as the latter cannot penetrate into the cell; and further, that the rate of diffusion of the toxin out of the cell is accelerated by the presence of antitoxin in the surrounding fluid.

Moreover, von Graff and Menschikoff (1912) have shown experimentally that it is possible to extract tetanus toxin from liver cells by means of antitoxin. They allowed the cells to remain in contact with a solution of toxin during one hour at 37° C. Then they removed the cells and washed them free from surrounding toxin. Some of these washed cells were injected into mice and caused tetanus. The remainder were soaked in a solution of tetanus antitoxin for one hour at 37° C., and then removed from the serum, washed free from surrounding antitoxin and injected into mice, which remained quite well. Control experiments showed that while toxin could pass into the cell and be so firmly fixed that several washings would not remove it, serum, on the other hand, could not pass into the cell in any demonstrable quantity. It is justifiable, therefore, to presume that the toxin was extracted from the cells by the surrounding antitoxin, and that it is advisable to have as high a concentration of antitoxin as possible in the fluids surrounding poisoned cells.

This view of the action of the antitoxin gives more encouragement to the physician to persevere vigorously with serum treatment. It emphasizes the advisability of employing very large doses of serum so as to saturate

* Note.—For a most excellent review of the literature of this subject, cf. Permin, 1913.

the system with antitoxin, and thus not only neutralize any toxin which may be passing from the focus of infection into the blood, but also to extract toxin from cells into which it has already passed.

Such treatment, suggested by the results of experimental research, is practically identical with that employed by many physicians to-day as the outcome of years of bedside observation.

Ernest E. Irons (1912) analysed the 252 cases collected by Anders and Morgan* and classified them. The incubation periods of the fatal and non-fatal cases showed practically the same relation. His figures are:

			Mortality.
Total number of cases	252	...	71%
Cases treated without serum ...	142	...	77%
Cases treated with serum... ...	112	...	63%
Cases treated with small amounts of serum	71	112	70.1%
Cases treated with large amounts (100 c.cm. or more) of serum ...	41		51.0%

If we compare the mortality of all the cases treated with serum with that of the cases treated without we must allow that the use of serum brings little if any advantage. But if we compare the mortality in cases treated *with large amounts of serum* with the mortality of the cases treated *without serum*, then the beneficial results following such use of serum become manifest.

W. H. Park (1910) says that when a large intravenous dose is given within a few hours of the onset of the symptoms the effect is marked. More than 50 per cent. of the patients so treated recovered, "some of whom I feel perfectly sure would have died without the serum." At the first sign of actual tetanus 10,000 to 20,000 U.S.A. units should be given intravenously, and followed every twelve hours by further injections. The later injections may be given subcutaneously if the intravenous route becomes difficult. Torres (1912), after an experience of 110 cases of acute tetanus in eight years with a mortality of 32.7 per cent., gives an intravenous injection of 120 c.cm. of serum as the rule. He repeats it twice, or even oftener, in the first twenty-four hours if necessary, and then gives 100 c.cm. daily if the symptoms are still present.

Penna (1913) also gives injections of 100 c.cm. intravenously once or twice in the twenty-four hours, and keeps it up for several days *even though the patient may be improving*.

Van der Bogert (1913) cites:

1. Strock (1907) who treated his cases of tetanus during six years with small doses of serum and had a mortality of 100 per cent. Then he treated 5 cases with very large doses and the mortality was 20 per cent.

2. The 3 cases of Young (1912) which appeared hopeless, but recovered—a boy had 150,000 U.S.A. units, a man had 220,000 U.S.A. units, and a girl of 14 years had 587,000 U.S.A. units.

Many other similar records could be quoted, if space permitted, to show that among those who not infrequently meet with cases of tetanus the tendency of late years has been to use much larger doses of antitoxin than formerly, and that the use of these large doses seems to be followed by more uniformly beneficial results than were observed in former years when only small doses were employed.

Modes of Administration.

Besides the size of the dose the mode of administration of the serum has an influence upon the result. Serum may be given—

1. Intracerebrally.
2. Subarachnoidally.
3. Intraneurally.
4. Intravenously.
5. Intramuscularly.
6. Subcutaneously.

1. Intracerebral injections have given very good results in animals and in several cases in man also, but the risk of permanent injury to the nervous system has prevented this method coming into general use. Ballance (1914), however, suggests that the introduction of serum into the lateral ventricle might be used in tetanus, as he thinks that with reasonable care the operation as a whole is free from danger.

3. Intraneural injections were strongly recommended by Rogers (1905), but they are not free from risk, and are seldom used.

4, 5, and 6. As regards the intravenous, intramuscular, and subcutaneous route the final result is the same in all three. The only difference is in the time taken for the antitoxin to be absorbed and distributed throughout the body. In the case of the intravenous method it is a question of a few minutes; of the intramuscular, of a few hours; while after subcutaneous injections it is one to two days before the maximum concentration of antitoxin in the blood is reached. There remains the subarachnoidal route to consider.

Descos and Barthélemy (1902) experimentally showed that intraspinal injections gave the best result.

Von Graff (1912) carried out a number of experiments in the Serotherapeutic Institute in Vienna, and came to the conclusion that this route was the most effective, and that next to it came the intravenous.

Permin (loc. cit.) considers that intraspinal are just as good as intraneural, and are better than intravenous, inoculations.

W. H. Park (1914, personal communication) has treated 6 successive cases of tetanus by intraspinal injections, and all have recovered.

Hofman (1907) states that of 13 cases which had serum beneath the skin, 53.8 per cent. died, whereas of 16 cases which had serum subdurally only 12.5 per cent. died, and these 16 cases included a number of extremely severe cases with brief incubation periods. He recommends that the intraspinal injections should be given every two to three days and the subcutaneous daily. Graser (1910) also advises serum by intralumbar injection every two to three days and daily beneath the skin. Gobiet (1904), Neugebauer (1905), Jeric (1908), and Buffagni (1910) and others speak of the good effect of intraspinal injections of antitoxin, and Buffagni says:

> 1. After the first injection one observes an increase in the symptoms, reaching a maximum in forty-five hours, and then passing off and giving place to improvement.
> 2. The organization of the patient reacts to each injection of tetanus antitoxin by a rise in temperature of 1.5° to 2° C., which passes off in ten to twelve hours.
> 3. After each injection more or less distinct improvement of all conditions occurs, and especially of the tetanic attacks.†

The method of procedure in the serum treatment of a case of tetanus would then be somewhat as follows:

1. The injection beneath the arachnoid, or in very severe cases even (Ballance, 1914) into the lateral ventricle, of as large a dose of antitoxin as may be conveniently given—for example, 3,000 to 8,000 U.S.A. units.
2. The injection into a vein of a large dose—9,000 to 16,000 U.S.A. units—with the object of flooding the system with antitoxin as soon as possible.
3. The injection of antitoxin intramuscularly, and
4. The repeated injection of antitoxin subcutaneously—both with a view of keeping up the concentration in the blood.

Clinical experience both in man and horse has shown that it is absolutely necessary to continue the injections, even though improvement has apparently set in, as otherwise the symptoms are very liable to return—in some cases with greater intensity than at first.

"Idiopathic" Tetanus.

The absence of any history of injury sometimes makes the diagnosis of tetanus at first very difficult. In the past such cases were classed as rheumatic or idiopathic tetanus, but we know now that for tetanus to declare itself the tetanus bacillus must somehow have gained entry into the body.

It has been shown experimentally that tetanus spores free from toxin or foreign material may be injected into animals without causing tetanus, and that they can become disseminated in the body and remain latent for a time. Then if suitable conditions arise, such as the formation of a necrotic area in the tissues, such latent spores may germinate and give rise to tetanus.

Canfora (1907) infected animals subcutaneously with tetanus bacilli and found that they spread all over the body. He also injected toxin-free tetanus spores and found them in the blood, twelve hours later. They may remain in the blood for ten to fifteen days, during

* *Journ. Amer. Med. Association*, July 29th, 1905, p. 314.

† These observations of Buffagni are very like those made by some physicians with regard to intraspinal injections of antimeningococcic serum.

which time very slight injuries are sufficient to set up tetanus. Later, the spores became localized in the liver, spleen, lungs, kidneys, lymph glands, and marrow, where they may remain latent for some months.

Semple (1911) came to the conclusion that an injection of a solution of quinine might cause enough destruction of tissue to produce conditions favourable for the germination of spores.

It behoves us, therefore, to bear tetanus in mind, even though there be no history of injury, whenever we meet with symptoms similar to the premonitory symptoms mentioned by Evler and found to be present in so many cases of this disease.

Preservatives in Serum.

Most serums have a small amount of preservative (phenol, trikresol, chloroform) added to them, and when doses such as 120 c.cm. are given at one time the presence of preservatives requires consideration and raises the question as to how much preservative can be given without ill effect.

Baccelli (1911), who strongly recommends that tetanus should be treated with subcutaneous injections of carbolic acid, states that not less than 1 gram should be given daily; J. H. Haberlin (1913) in a case of hydrophobia gave 22½ grains of phenol subcutaneously in twelve hours without any evidence, either locally or generally, of any deleterious effects; Natoli (1899) injected 5.25 grams of phenol subcutaneously in eighteen days; and Ascoli (1898) gave 75 c.cm. of a 3 per cent. solution without any subsequent toxic symptoms.

The probability of ill effects being due to the preservatives in serum when administered intrathecally has been fully discussed and negatived by Flexner in the case of automeningococcic serum. It may, then, be safely assumed that the amount of phenol put into serum is not likely to have any serious consequences.

Conclusions.

Tetanus may be cured by the administration of antitoxin, provided that the serum treatment is begun early in the attack and is pursued vigorously and continuously. Unfortunately in the present state of our knowledge a diagnosis is as a rule made only when the disease is in a stage so advanced as to make the results of treatment uncertain, even though very large doses of antitoxin are used. These large doses are costly, and place the serum treatment of tetanus practically out of the reach of those with shallow purses—unless, of course, the serum be provided by the State. But in the prophylactic use of serum there is within the reach of every one a means of checking the disease. It has been proved beyond the shadow of a doubt that, wherever the prophylactic use of antitoxin has been carried out systematically, tetanus may be said to have disappeared. Tetanus should therefore be looked upon as a preventable disease, and, when one realizes this, there flashes across the mind the memorable question, "If preventable, why not prevented?"

INSECTS AND WAR:

IV.—*THE FLOUR MOTH IN SOLDIERS' BISCUITS.*

By A. E. SHIPLEY, Sc.D., F.R.S.,
MASTER OF CHRIST'S COLLEGE, CAMBRIDGE.

Where moth . . . doth corrupt.—MATT. vi, 19.

It is not only insects which destroy the continuity of the soldiers' integument which play a part in war. It has been well said that an army marches on its stomach, and the admirable commissariat arrangements which have been so distinct a feature of the British Expeditionary Force during the present war are the result of much patient care and attention during times of peace. Every one knows that recruits are frequently rejected for some defect in their teeth. A soldier, indeed, requires strong teeth, for his farinaceous food in the field is largely supplied to him in the form of biscuits—not that "moist and jovial sort of viand," as Charles Dickens described the Captain biscuit, but hard tack which challenges the stoutest molars.

During the summer of 1913 the authorities of the British Museum at South Kensington arranged a very interesting but somewhat gruesome exhibit in the Central Hall. The exhibit consisted mainly of army biscuits covered by horrible webs or unwholesome looking skeins of silky

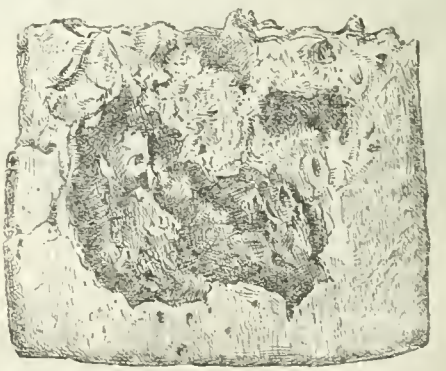

Fig. 1.—*Ephestia kühniella*. Moth-infested biscuit.

threads, eaten through and through by the larva of a small moth. Together with these were certain long metallic coils and other apparatus used in investigating certain phases of the life-history of the moth and the manufacture of the biscuit. The exhibit illustrates an article[1] which had recently appeared on the baking of army biscuits, by

Mr. Durrant and Lieutenant-Colonel Beveridge, on the "biscuit moth" (*Ephestia kühniella*), a member of the family Pyralidae, and records their efforts to arrive at a means of checking a very serious pest to service stores.

The biscuit moth, *E. kühniella*, was described two years before its larva had been noted damaging flour at Halle. There has always been a certain amount of international courtesy in attributing the *provenance* of insect pests to other countries, and when *E. kühniella* began, about ten years later, to attract attention in England it was believed to have been introduced from the United States via the Mediterranean ports in American meal. The American origin was, however, denied by Professor Riley, who, in a letter to Miss Ormerod, states, "I think I can safely say that this species does not occur in the United States." At the moment of writing these words Professor Riley was in the act of packing up to leave Washington for Paris. Possibly he was excited, certainly he was inaccurate, for the species was then known to occur in Alabama, North Carolina, and other States. In fact to-day it is recorded throughout Central America and the Southern States and in many more temperate regions of the New World.

The moth itself is rather insignificant, small, of a slaty-grey colour. The eggs, rather irregular ovoids, are laid on the biscuits, into which the issuing larvae bore. These latter are soft, and like most creatures which live in the dark, whitish but with a tinge of pink; the head, however, is brown and hardened. The larva is constantly spinning silken webs or tissues, which in the most untidy way envelop the biscuit, and finally entombs itself in a whitish silken coccon, and herein it ultimately turns into a chrysalis or pupa.

Fig. 2.—*Ephestia kühniella*. × 2.

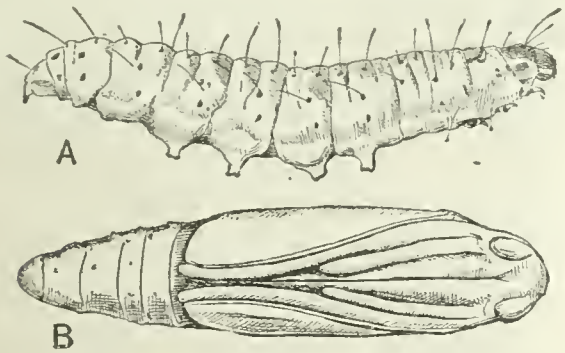

Fig. 3.—*Ephestia kühniella*. A, Larva; B, pupa. Greatly magnified.

Another Pyralid moth—*Corcyra cephalonica*—makes similar unpleasant webs all over biscuits, rice, or almost any farinaceous food, but, since its larvae are unable to live unless there be a certain degree of moisture in the biscuit, it is less injurious to baked food than the *Ephestia*, for whose larvae nothing can be too dry. *Corcyra* seems originally to be a pest of rice, and to have been introduced into Europe with Rangoon rice, but it readily alters its diet in new surroundings, and will live on almost any starchy stuff.

The problem that Lieutenant-Colonel W. W. O. Beveridge and Mr. J. H. Durrant, of the British Museum, set out to solve was at what stage in the manufacture of the army biscuits were they infested, and whether any steps could be taken to avoid or minimize such infestation.

First, as to infestation. Biscuit must become infested either (1) at home before packing, (2) during transit, or (3) in the country where stored. The biscuits are packed in tins, hermetically sealed, and enclosed in wooden cases to prevent injury; it was therefore obvious that if insects could be found within intact tins it would be demonstrated at once that infestment must have taken place in the factories, and not subsequently. With a view to determine the origin of infestation sample tins were withdrawn from stocks at various stations abroad, and inspected at Woolwich by experts, and tins which, after careful examination, had been pronounced intact, were found to contain

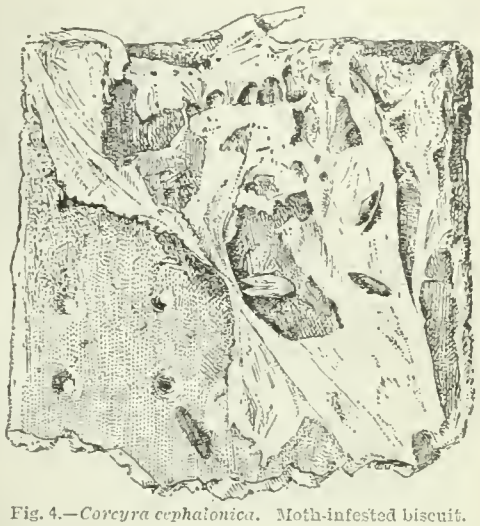

Fig. 4.—*Corcyra cephalonica*. Moth-infested biscuit.

Ephestia kühniella and *Corcyra cephalonica* in various stages of development, thus proving conclusively that infestation had taken place in the factories before the tins were soldered, and indicating that preventive or remedial measures must be undertaken within the factories themselves.

It is obvious either that the heat acquired by biscuit in the process of baking is insufficient to destroy ova present in the moist dough, or that moths and beetles deposit their ova in or on the biscuits after baking, and during the process of cooling and of packing in the tins. Cooling before packing is necessary, to allow the moisture in the centre of the biscuit to become evenly distributed throughout, and it is during the time occupied in cooling and packing that the biscuit is exposed to the greatest risk of infestation; any risk occasioned by subsequent injury to the case must be quite exceptional, and is probably negligible.

By a series of most ingenious experiments, the two investigators were able to determine the temperature in the centre of the biscuits during the various stages of its baking and cooling. Army biscuits are made from dough which contains about 25 per cent. of water. When stamped out they are placed in rows on the moving floor of an oven and are submitted to a high temperature for twenty minutes whilst they travel over a space of 40 ft. The dough at first contains 25 per cent. of water, but during baking this is reduced to about 10 per cent., and the moisture now collects in the centre of the mass of the biscuit in consequence of the external hardening or "caramelization" as it is called. The holes which are pricked in so many biscuits of course assist this process.

Too little attention has been paid to the internal temperature of edibles which are being cooked. Very few people, for instance, have any conception of what is going on in the centre of a joint of meat whilst it is being roasted or boiled. After two hours' boiling the temperature in the centre of a large ham has only risen to 35° C.; after six hours' boiling to 65° C., and it is only after ten hours' continuous boiling that 85° C. is reached. I have, I am sorry to say, no conception as to how long a ham ought to be boiled, but it is obvious that to be really effective against such parasites as *Trichinella*, the cooking of pork and ham should be more prolonged and thorough than seems to be customary. But this is another story.

However, to return to our biscuits. The Colonel and Mr. Durrant devised an ingenious instrument which determined the temperature of the centre of the army biscuits. When the tip of their recording apparatus lay within the moist area of the baking biscuit, the temperature registered was only a little over 100° C., but when the tip of the instrument rested on the hard "caramelized" portion much higher temperatures were observed, even as high as 125° C. Colonel Beveridge and Mr. Durrant were thus able to

establish the fact that the temperatures of the biscuit were such during baking as to rule out the idea that the ova, which do not survive a temperature of 69° C. for twelve minutes, were deposited in the biscuit before cooking.

After the baking is completed the biscuits are always cooled, and it is at this period that they are most exposed to risk of infestation by *Ephestia kühniella*. This is an insect of great nuisance in flour mills. So persistent and numerous are they at times that they clog the rollers with their cocoons, and sometimes completely stop them. The webbing of the elevators in the mills gets covered with them and their silky skeins, and also stops working. They mat together the flour and meal with their silken excreta, and so uniform is the temperature of the mill, and so favourable to the life of the insect, that they complete their life cycle in this country in two months, and in the warmer parts of America even more rapidly. In well heated mills the proceeding is continuous, so that six generations at least may be produced each year.

The only method of getting rid of this pest is a complete and thorough fumigation of the premises with carbon bisulphide. But, as this substance is not only poisonous but inflammable, it is well to get a chemist to undertake the proceeding, and also to notify the insurance company. Fumigation by sulphur ruins the flour. Another remedial measure is that of turning the steam from the engines on to all the infected machinery and walls.

That this destruction of the biscuit is a matter of considerable importance is shown by the fact that biscuit rations exported to the colonies in hermetically-sealed tins have become quite unfit for consumption, and this has been noted in places as far distant from each other as Gibraltar and Malta, the Sudan, Mauritius, Ceylon, and South Africa. But it is also an old trouble, as shown by the following quotation from the diary of Sergeant Daniel Nicol, of the 92nd Gordon Highlanders, which he kept during the expedition to Egypt in 1801:

> Some vessels were dispatched to Macri Bay for bullocks and others to Smyrna and Aleppo for bread which was furnished us by the Turks, a kind of hard dry husk. We were glad to get this, as we were then put on full rations, and our biscuits were bad and full of worms; many of our men could only eat them in the dark.[2]

With regard to the actual baking of the biscuit, Colonel Beveridge and Mr. Durrant suggest that the temperature conditions during the process of cooling should be made as unfavourable as possible for the moths by introducing screened cool air which can be forced in at one end and sucked out at the other. Could such a scheme be adopted it would be difficult, if not impossible, for the moths to lay their eggs, and the biscuit would thus be more rapidly cooled. In any case it should not be difficult to ensure that the cooling takes place in some chamber which is practically free from these destructive moths.

THE Ohio State Board of Administration has, we learn from *Science*, established a psychological bureau for the study and care of juvenile delinquents. The chief of the bureau, Dr. Thomas H. Haines, Professor of Psychology in the Ohio State University, has a staff of eight assistants, including three psychologists, a diagnostician, and a bacteriologist.

THE Belgian News Fund has arranged to publish weekly a small newspaper, entitled *L'Echo de Belgique* (*De Stem uit België*), the object of which is to supply information primarily to the Belgian refugees of current events, both here and in their own country. Owing to the war, many thousands of Belgians have lost all trace of their families and friends, and a special feature will be the free insertion of notices asking for information of their whereabouts and welfare. The paper is printed in French and Flemish and published at 43, Palace Street, S.W., and 69, Lombard Street, and it is hoped that Belgians resident in this country and other sympathizers will assist the publication by subscribing 5s., which will entitle them to free copies weekly until the end of the year. Copies of the paper will be distributed gratis to the refugees at the various places where they are being accommodated. *L'Echo de Belgique* is published with the authorization of the Belgian Minister, Comte de Lalaing, and it is issued for a philanthropic purpose and not as a commercial enterprise.

EIGHTY-SECOND ANNUAL MEETING
OF THE

British Medical Association.

Held in Aberdeen on July 29th, 30th, and 31st.

PROCEEDINGS OF SECTIONS.

SECTION OF DERMATOLOGY AND SYPHILOLOGY.

ALFRED EDDOWES, M.D., President.

DISCUSSION ON THE TREATMENT OF SYPHILIS.*

OPENING PAPERS.

I.—J. E. R. McDONAGH, F.R.C.S.

(Abstract.)

UNTIL we know the cause of a disease its treatment must be empirical. Knowing the cause of a disease, we cannot gauge the effects of the treatment until a sufficient number of years has elapsed to enable us to do so from clinical experience, since no tests can be sufficiently relied upon to take the place of clinical experience.

Most of you are no doubt aware that, in my opinion, the *Spirochaeta pallida* is not the actual cause of syphilis. It is merely the adult male of a complicated life-cycle. There is also a female, and spores result from the fertilization of the female cell by the *Spirochaeta pallida*. The adult sexual bodies are the main cause of the symptoms, while the spore is the cause of the disease.

Before describing to you the way in which I now treat syphilis, and giving you the reasons why such and such a course is adopted, it would be as well to make a few generalizations the knowledge of which is important, and which must be understood before treatment is prescribed.

It must be remembered that the tendency of all protozoal diseases, the symptoms of which are dependent upon the completion of a life-cycle by the organism causing infection, is towards spontaneous cure, as, the longer the parasite is in the host, the less able is it to complete its cycle and the less influence treatment has upon it.

Although treatment may do much to prevent the organism from completing its life-cycle, the host does more, and one may say, in effect, that treatment is only able to prevent the parasite from completing its cycles provided it is prescribed sufficiently early in the onset of the infection.

Salvarsan will kill the spores in the earliest stages of the disease, while it is without effect in the late stages. In the late stages the symptoms vanish, not from destruction of the spores, but from the destruction of the ripe gametes to which the spores give rise. Therefore it behoves us, more than ever before, to diagnose a recent infection as soon as possible, and without delay to give treatment which will be sufficient to cure the case.

Excision of the primary sore, when possible, is, in my opinion, essential, and a clinical observation in support of this view is the fact that many primary sores which become phagedaenic are not followed by further evidences of syphilis, or, in those which are followed by symptoms, their onset is frequently delayed for months.

Owing to the fact that salvarsan is the most potent antisyphilitic drug we at present possess, the remarks I have to make about the treatment of syphilis can be curtailed if they are made to centre around this drug. In discussing the action of salvarsan, reference will be made to the preparation which is now supplied, since it is considerably feebler in its action than the drug which was first used.

The majority of the cases of primary syphilis to which one injection was given over four years ago are now both clinically and serologically sound.

The majority of the cases of primary syphilis to which two injections of salvarsan were given when the drug

* This discussion took place in the combined Sections of Dermatology and Syphilology and of Naval and Military Medicine and Surgery.

came upon the market—that is three and a half years ago—have developed symptoms since. Of those which were already in the stage of general infection, nearly all showed recurrence within a year, and many within three months.

It is only since the rule has been followed of giving as many injections as are necessary to procure a negative Wassermann reaction in the blood taken between the seventeenth and forty-eighth hour after the last injection, and to prescribe a year's treatment with mercury, that the fewest recurrences have been observed. Probably, in a few more years, many of those cases which have not so far recurred will develop symptoms, but, until our knowledge increases, this procedure appears to me to be the best.

In the primary stage, provided sufficient injections of salvarsan are given to procure a negative Wassermann reaction in the blood withdrawn within the limits above specified, and that the treatment is further augmented by twenty-four intramuscular injections of mercury, given in three courses of eight weekly, within the twelve months, in the light of our present knowledge a cure is possible. In the secondary stage a cure may possibly be obtained, and it is wiser to continue the mercury for another year.

Success for the same treatment in the latent stage of the disease and in the stage of early recurrence is improbable, while in the stage of late recurrences, gummata, nervous syphilis, etc., a cure is impossible—that is, broadly speaking, since spontaneous cure may occur in any stage.

In the primary stage three to five injections, and in the secondary stage six to nine injections are required. It is best to give the five and nine injections respectively, as the Wassermann reaction is apt to be contradictory. In late cases, even fifteen or more injections of salvarsan may fail to procure a negative Wassermann reaction, and supposing a negative Wassermann reaction be obtained, it is not long before it becomes positive again.

In late cases, it appears wiser to give two or three injections of salvarsan to heal the symptoms, and to augment it with a course or two of mercury and iodides, meanwhile informing the patient that he should place himself under treatment again the moment the symptoms reappear. Such a patient may go for years without a recurrence, and, should symptoms reappear, they will probably do so in the site of the previous recurrence.

It is universally agreed that the best way to give salvarsan is intravenously, and it is my opinion that the requisite number of injections should follow upon one another at intervals of not longer than seven days. I usually prefer to give the injections every four days.

A most important point to remember in salvarsan treatment is that if too few injections are given to a patient with infectious symptoms, should the symptoms recur, they will simulate those for which the drug was prescribed. Several cases have been seen of patients who had condylomata, for instance, which disappeared under two injections of salvarsan, returning within three months with condylomata again, in spite of the fact that mercury was given as well. After insufficient salvarsan treatment, symptoms recur before the mercury, which has been prescribed afterwards, usually in the form of pills, has had time to exert its action. Insufficient salvarsan treatment in the early stages of syphilis will do more harm than good, as it gives the patient a false sense of security, and renders him for a longer period a danger to the community. I have seen six cases within the last year of patients who had had two injections of salvarsan infecting others, when they themselves thought, and had been told, that they were cured. Another reason why I prefer to give several injections together is because the organisms reach the nervous system very early in the disease, because the onset of nervous symptoms is largely dependent upon the treatment that has gone before, and because the only way in which nervous lesions can be prevented from occurring is by sterilizing the whole body, which can best be achieved by several injections given quickly after one another.

Although it is generally held that nervous diseases are on the decrease, I am quite of the opposite opinion, and I feel very strongly that, owing to the spasmodic and insufficient manner in which salvarsan is prescribed, tabes and general paralysis of the insane will in a few years' time increase, even more rapidly than is the case to-day, and that they will appear more quickly after the infection than hitherto. A still further reason why I prefer to give a series of several injections of salvarsan is because by so doing I have seen healthy children born to syphilitic mothers.

To women who are syphilitic I give, as soon after they have conceived as possible, six intravenous injections of neo-salvarsan, and I continue the treatment with mercury till as near the time the child is to be born as possible.

I can sum up my method of treating syphilis in a few words.

In the primary stage, I give five injections of neo-salvarsan and mercury for a year. I prefer neo-salvarsan to salvarsan, because, although injection for injection the former may not be quite so strong, it is less toxic, the injections can be given with safety every four days, and it can be administered to out-patients. For over two and a half years, giving more than 4,000 injections, I have treated practically every case as an out-patient, and many of them have travelled home by train immediately afterwards, without having suffered a single bad effect. For the first dose I give Dose III, for the second Dose III, for third Dose III, for the fourth Dose IV, and for the fifth Dose V, if it is to be the last injection.

In secondary syphilis I give nine injections and mercury for two years. Under these circumstances I give Dose IV for the fifth injection, Dose V for the sixth, and either Dose V or Dose VI for the seventh, eighth, and ninth. Cases of recurrent syphilis I treat individually. Broadly speaking, if the patient is going to marry, or if the recurrence has set in within two years of the infection, or if the previous treatment has been obviously inadequate, I treat the case as one of secondary syphilis.

If I am consulted by a patient who has been well treated, and if after a thorough examination nothing abnormal is discovered, I do not advise treatment because his Wassermann reaction is positive, since a positive reaction under such conditions often means that the protective mechanism is at its best, and therefore scarcely likely to be improved by treatment.

In the tertiary stage I give sufficient treatment to cure the symptoms.

Congenital syphilis is, on the whole, best treated with mercury only. Salvarsan, even when combined with mercury, is practically useless in cases of syphilis congenita tarda. The treatment of syphilitic diseases of the central nervous system must be again individual. Early cases of pure arterial disease, such as hemiplegia and transverse myelitis, should receive the same treatment as a case of secondary syphilis.

Cases of meningeal syphilis are best treated with two intrathecal injections of salvarsanized serum, and then they should receive the same treatment as a case of secondary syphilis. As any treatment may make a case of tabes worse, the position should be pointed out to the patient and treatment advised according to the symptoms. If the symptoms are such as to make the patient's life a misery, whether the case is one of active tabes or post-tabetic, eight to eleven intrathecal injections of salvarsanized serum should be prescribed.

The risk of making the patient worse is minimized if several injections are given.

Intrathecal injections must be used with caution in cases of general paralysis of the insane, and without much hope of success.

For the very early stages of syphilis, combined arsenical and mercurial treatment will cure many cases, but not all. For the few left uncured, and for all the cases of late syphilis, a cure has yet to be discovered.

II.—Brevet Colonel T. W. Gibbard, R.A.M.C., and Major L. W. Harrison, R.A.M.C.,

Rochester Row Military Hospital.

The second opening paper was read on behalf of himself and Major L. W. Harrison by Brevet Colonel T. W. Gibbard. It consisted of a detailed account of their long experience in the treatment of syphilis by modern methods at the Military Hospital, Rochester Row, and was supplemented by a series of elaborate tables showing the character of all the cases treated, the details of the treatment, and the results. The authors pointed out that when mercury and potassium iodide were the only

remedies used the wards of Rochester Row and other military hospitals were full of syphilis, and that many deemed to have been effectively treated subsequently relapsed. Taking the statistics of Rochester Row, for instance, there were in pre-salvarsan days 315 clinical relapses out of 371 cases, while the salvarsan statistics presented by the authors showed that out of 285 cases which had been treated by salvarsan and mercury only 9 had relapsed. They saw no reason to regard the use of salvarsan as dangerous, for among cases that had been treated in the British army by salvarsan only one fatality had occurred, the total number of injections used being nearly 4,000. Furthermore, the authors had met with no eye trouble nor lesion of the cranial nerves which had not proved amenable to further salvarsan treatment. It was still an open question what was the best method of using the drug and in what amounts it should be given. Whatever the system employed the immediate results were good, but to be certain as to the permanent value of the system the cases must be kept under observation for a very long time. Their own experience led them to agree with other workers that to combine salvarsan and mercury treatment was the wisest course. Salvarsan might be used alone, but if so it would have to be given for a very long period, first intravenously and then intramuscularly. This would prove a very costly undertaking, and consequently, on grounds of economy if for no other reason, it was preferable to combine mercury and salvarsan treatment. They believed that they had obtained their best methods by a three-period course: (1) One injection of salvarsan followed by five of mercury; (2) one injection of salvarsan followed by five of mercury; (3) one injection of salvarsan. But their general practice had been to give two salvarsan injections and nine mercurial injections, the former at either end of a nine weeks' period, the latter weekly during it.

DISCUSSION.

Dr. J. GOODWIN TOMKINSON (Glasgow) said he was distinctly in favour of combined treatment by salvarsan and intramuscular mercurial injections, but there was yet much observation and experiment necessary to form anything like definite opinion as to the desirable amount and duration of treatment. Meantime he was convinced that a prolonged course of mercurial injections—after salvarsan with mercurial injections in the intervals had ceased—was desirable in the interests of the patient irrespective of the Wassermann reaction. While salvarsan was indubitably a highly valuable addition to the means of combating syphilis, it had also served to establish the value of mercury as an antisyphilitic.

Dr. CRAWFORD TREASURE (Cardiff) said the remarks of Mr. McDonagh would indicate a pessimistic view of the treatment of syphilis; it would seem doubtful whether any case of syphilis could be definitely pronounced to be cured. The Wassermann reaction seemed to be regarded as inconclusive; even the examination of the cerebrospinal fluid was not conclusive; cases of nervous diseases arose even after negative reactions had been demonstrated. The field to be covered was so large that it was impossible to deal with every point, but some questions arose out of the discussion. Among them were: The comparative value of salvarsan *versus* neo-salvarsan; the value of soluble as against insoluble mercurial preparations; the comparative value of injections *versus* inunction. He emphasized the importance of immediate examination of doubtful sores, and mentioned a series of cases in which it had been possible to demonstrate the spirochaete even before induration of the primary sore had occurred, and referred to the immediate result of treatment by salvarsan.

Dr. NIXON (Bristol) said there was great danger in disregarding the personal idiosyncrasy to salvarsan. The average workhouse patient, for instance, was much more susceptible to its toxic effects than a healthy working man. The dosage and the interval between doses of salvarsan must be judged separately for every individual case. Like other speakers, he considered combined treatment with salvarsan and mercury superior to that by salvarsan alone. He had been interested to find how rapidly the news spread in the lock wards of the workhouse infirmary in which he worked. Syphilities, not only of the prostitute class, showed little reluctance to seek admission to these wards. There was, however, a danger that it was the rapidity of the cure that chiefly appealed to them, and they might be indisposed to continue under observation or under further mercurial treatment. In private practice the subsequent use of mercury was, he found, not as a rule left in his hands. The patients came to him for their intravenous injections of salvarsan, but the mercurial treatment was carried out under their own doctors.

Dr. HENRY MACCORMAC (London) thought every one who saw syphilis realized that the difficulty in altering the Wassermann reaction in old-standing cases was considerable. But this was a feature not only of syphilis but also of any chronic bacterial infection, such as *B. coli* infection or chronic staphylococcal lesions—for example, sycosis. The anti substances seemed to lose their effect, or the micro-organisms became accustomed to them. In his own practice he now gave three injections of salvarsan, and followed it up by two years of mercurial treatment. This was at least being on the safe side; with over 1,000 injections he had had no death or cranial nerve symptoms. He believed strongly in the Wassermann reaction both for diagnosis and as a guide to treatment. His experience of this test now extended over five years, but lately he had found that the formula of Desmoulière was more delicate than any other antigen; if anything, it was perhaps too delicate. Salvarsan was, perhaps, most useful in rendering an infective patient incapable of giving disease to others. This was of importance in large towns, where so many took meals in public restaurants.

Dr. J. C. MCWALTER (Dublin), after allusion to the enthusiasm with which early statements regarding salvarsan had been received, and indicating that the attitude taken up towards it had been unscientific, and expressing an opinion that the drug had caused many deaths, said that in carrying out the treatment of a case of syphilis it was best to remember that it was not proved that syphilis was solely due to the *Spirochaeta pallida*; that treatment should be carried on with several spirillicides, in small doses, for a long time, and that the only antisyphilitics were mercury, arsenic, and antimony.

Dr. NIXON (Bristol) said that Mr. McDonagh's investigations of the Wassermann reaction were particularly welcome at the present time. In subjecting to careful chemical and physical analysis the substances hidden under the names of antigen, complement, antibody, and so forth, a prospect of enlightenment was opened up. These mere words should be recognized as doing nothing but carrying our ignorance a stage further under a cloak of apparently increased knowledge. At first hearing, and without opportunity for consideration, one point seemed to stand out in Mr. McDonagh's paper which recalled the work of Nierenstein on atoxyl and trypanosomiasis—that is, the extreme importance of the NH_2 group in these problems of immunity, protection, and treatment. For while Mr. McDonagh regarded the presence of the amino-acid molecule as all-important in the production of protective bodies, so Nierenstein came to the conclusion that the NH_2 group served as an anchoring group between the serum and the arsenic of the atoxyl.

DISCUSSION ON THE NEED OF GREATER METHOD IN THE TREATMENT OF LUPUS.

OPENING PAPER.

By NORMAN WALKER, M.D., F.R.C.P.Edin.,
Physician for Diseases of the Skin, Royal Infirmary, Edinburgh.

IN one of the earlier programmes of this meeting the title of this paper appeared as "The need for *some* method in our dealings," etc. I wrote my friend the Editor, and pointed out the printer's error, saying that I was not prepared to admit we had *none*. But I must confess that this look back on my past has been a most useful occupation and a most humbling experience. It is just over

twenty-two years since I was appointed assistant physician for diseases of the skin to the Royal Infirmary. During fourteen and a half of these years I was assistant to my friend Dr. Allan Jamieson, and therefore not directly responsible for all the cases. But I saw all or nearly all of them, and our relations have always been so intimate, that any suggestions of mine for more method would almost certainly have been accepted; and so, with Dr. Allan Jamieson's consent, I shoulder the responsibility for the lot, and deal with all his cases as well as my own. From 1906 to 1912 I was in sole charge; since 1912 Dr. F. Gardiner has been my colleague, and he has given me leave to use the cases which have come under his care during that period for statistical purposes.

In the whole period, then, of twenty-two years six months—for, for a special purpose, I have brought the figures down nearly to the present date—1,054 cases of lupus have presented themselves for treatment. The figures have been very carefully sifted by my secretary, Miss Rae, and there are no duplicates included in that appalling list—1,054 cases—and I wish I could think that 100 of them had been cured. Now and again I come accidentally across a cure; the majority of cases disappear from our ken. Some persevere and attend regularly; far more come up at intervals of months or years, attend for a few weeks, or only once or twice, and then vanish for another period, to reappear with the disease more extensive than before; many we never see again.

It is a very unfortunate thing that lupus gives rise to so little discomfort, and so patients go on neglecting it for years. One day a woman came to my department, and, in answer to an inquiry as to the duration of the disease, said she thought it had lasted from thirty-five to forty years. She had lived all her life in Edinburgh, she had had several children, one side of her face and neck was extensively affected, but she did not think it of sufficient importance to mention to the doctor who attended her in her confinements, and he made no reference to it.

Here is the cast from a girl who lived in Edinburgh's seaside ward—Portobello. She had had the disease sixteen years, she had never consulted a doctor, and she only came to the infirmary because she was going to be married, and hoped she might be cured before that event took place. I took her into my ward, treated her for ten weeks. She attended the out-patient department once subsequently in 1908, and she has not been since. Here is a list of the duration of the disease in elderly patients since 1907.

Table showing the Duration of the Disease in all the Cases over 50 which have attended the Skin Department since 1907.

	Age.	Duration.		Age.	Duration.
1907.			1910.		
Mrs. Ellen M. ...	52	8 or 9 years	Mrs. Donella G.	50	1 year

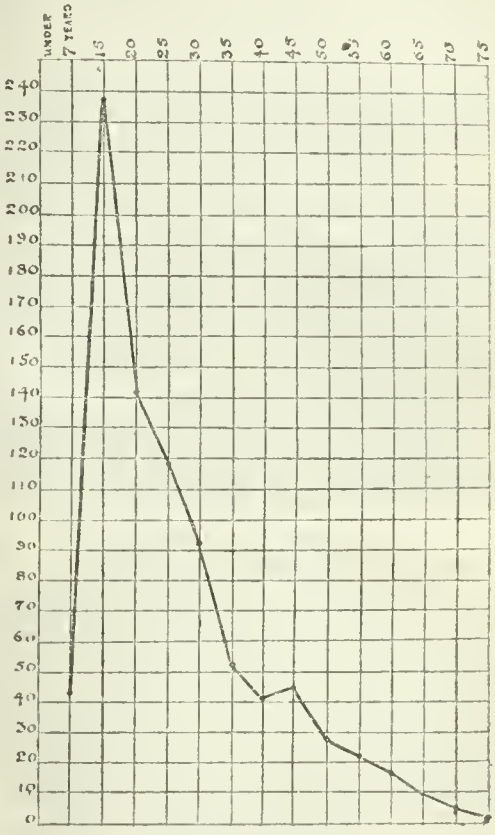
I have gone through my private case records and my three dermatologist colleagues in Edinburgh have kindly done the same. Of course, only Dr. Jamieson and my own cover the whole period. These figures are undoubtedly open to the fallacy that the same cases have been under the notice of more than one of us, which the hospital figures are not, and they are open to the further fallacy that private cases come from greater distances than hospital ones do, but, taking the figures as they stand, they arrest attention. Mere numbers convey very



Age incidence in lupus.

little of the relative incidence of the disease in the poor and the well-to-do—there are fewer of the latter. But when one takes large groups of figures and compares the incidence of tubercle the contrast is striking. Roughly, I may say that, while the hospital cases number 30,000, the private ones approach 20,000 and the figures show a percentage of 3.3 of tuberculosis in hospital and of 1.4 in private.

[As an interesting contrast I submit these percentages of lupus erythematosus: Hospital cases, 0.92 per cent.; private, 1.8.]

And the results are still more striking. Most of the private cases remain under supervision till they recover, which most of them do. This is not the result of any difference in treatment. I honestly believe that, while they attend, hospital cases are treated at least as efficiently as private cases. In most hospitals there are means of treatment not always available in private. And yet the private cases usually recover. In my judgement this is due to two things: the better hygienic conditions under which such patients live, and—and this is, I believe, the more important factor—the better understanding of the better classes as to what lupus is and their greater concern regarding blemishes on their children's faces. True, they usually have fewer of them.

It is not that tuberculosis does not attack the well-to-do. Operations for tuberculous glands are more numerous relatively in the hospital class, but it must be remembered that many a child in the better classes escapes operation as the result of a prolonged sojourn in the country or at the seaside.

A great many cases of lupus are secondary to tuberculous glands, and not only to those which spontaneously rupture and discharge. Quite a number of cases develop in the scars of what seemed at the time of discharge from hospital to have been perfectly successful operations. In patients under proper supervision in intelligent families these cases do not occur. The little red spot in the scar

is immediately recognized as something requiring attention and is seen to at once and destroyed. But among the poor it is neglected; it causes no pain, it does not look very different from the scar on which it is seated, and its progress is so slow, and to-day is such an inconvenient day to go to hospital. And so it goes on, and the patient gets used to it, and the rest of the family get used to it, and it spreads and spreads unless, happy accident, impetigo develops on the top of it and advice is sought.

Take the other common source of lupus—tuberculosis of the nasal mucous membrane. A nasal discharge is a cold in the nose to the working classes; very little heed is paid to it. The discharge waxes and wanes, and, as we all well know, it is often not until there is very marked infection, and even destruction, of the skin and cartilages that advice is sought.

The knowledge of the importance of adenoids and tonsils is now so widespread among the better classes that there are very few indeed who cannot show one or more receipts for laryngologist's fees. I say one or more because again the question of after-supervision comes in, and the mother, knowing what is involved, will not be satisfied till all trace of trouble is removed.

I have referred to the rarity of lupus in scars in the better classes, and how very rarely do we see lupus of the point of the nose in such children now. Only one of my private cases which could by any stretch of terms be called "recent" had the disease in this situation.

Methods of Treatment Employed.

It is clear that the number of cases which have been under my care have at least provided me with ample material for the testing of the various methods of treatment, and of several of these I desire to say a few words.

I have recently found myself resorting to scraping more frequently than I did ten or fifteen years ago. I think scraping would be more popular if it were universally recognized that though you *cannot cure lupus by scraping* you can take it a long way towards cure. If scraping is followed up by other treatment it is of great value in suitable cases, especially in those where there is a combination of lupus and scrofuloderma.

Some years ago I published a short note on uranium in lupus. The results—I used the oxide—did not bear out their earlier promise, and for many years the treatment was in abeyance. Recently I have used the powdered nitrate after scraping or other destructive means. It has an excellent caustic effect, and the results are good—sometimes very good. It dries the discharge and no doubt exercises some radio-active effect. I have found it useful as a packing in tuberculous sinuses.

There are cases of superficial uncomplicated cases of lupus in which Unna's salicylic creosote plaster is very hard to beat. I venture to suggest that all who use it do not get the full good of it because they stop its use too early. I go on with it as long as I can persuade the patient to continue or until the surface which it has ulcerated heals under its continued use.

Then I am a great believer in Brooke's ointment, or rather in Jamieson's modification of it. I thought at one time that the benefit might be due simply to the massage of the part, but experiments in this direction convinced me that it was not; pure carbolic acid, Hutchinson's favourite acid nitrate of mercury, or trichloracetic acid, patiently and perseveringly used, will work wonders; arsenious acid I have not used much of late, it is so very painful. My experience is that none of the analgesics recommended for use with it are very efficacious, and in consequence I fear that it does not always get fair play.

For many years I used *x* rays extensively and with great benefit; there can be no two opinions about the benefit produced in many cases; I will go further and say in the majority of cases in which they are used. But—and it is a terrible but—the occurrence of case after case of carcinoma compels one to consider the question of *x* rays very carefully. I admit that, in common I suppose with everyone else, I formerly used the *x* rays with a freedom I should never dream of using now; I admit that carcinoma occurs in cases of lupus which never saw an *x*-ray tube; I admit that is arguable, and I have myself argued that the explanation of the development of cancer is that the rays cause the crowding into one year of events which would otherwise have taken many years. I admit everything, but I cannot get away from the conviction that the *x*-ray treatment is lamentably often followed by carcinoma. Of the cases under consideration, 22 have to my knowledge developed carcinoma, and at least 6 have died of it. Five of the cases never had any *x*-ray treatment; most of the others had prolonged—sometimes very prolonged—courses of rays.

I am not prepared to say that we should abandon the treatment, but the occurrence of the complication should be a very powerful stimulant to us in our search for other methods not attended with this risk. Its occurrence is further support for the argument, which I hope to develop later, of the necessity of close and constant supervision of the cases. The earliest developments are very easily and satisfactorily treated if treated promptly, but lupus carcinoma soon gets beyond reach. I may just say, in passing, that, after several failures with the more conventional surgical procedures, I have abandoned them in favour of erasure and caustics.

My experience with the Finsen treatment is limited to the use of the old London Hospital and the Finsen-Reyn lamp. I am not sure that the former really deserved its early relegation to the scrap heap. I have cases which were greatly benefited by its use, and it had the great advantage over the Finsen-Reyn that it did not require so much and such expert attention. I found the necessity of an expert nurse a great drawback to the use of the Finsen-Reyn lamp, and in my department it is almost entirely supplanted by the Kromayer mercury vapour lamp. I should just like shortly to relate my experience of this. I have had it in use for about three years, and at first it was used almost exclusively in cases of alopecia areata and lupus erythematosus. It was tried in one or two cases of lupus, but with such disappointing results that I abandoned its use in that disease until last autumn, when my attention was again directed to its value by my friend Dr. Stainer, who was using it extensively at St. Thomas's. I began again with, I suppose, more faith, and I find myself using it much more and with distinctly encouraging results.

Tuberculin Locally.—I do not think that we sufficiently recognize the benefits of this. As an aid to diagnosis in a doubtful case its value is very great, but it is with its therapeutic effect that I am dealing now. A 5 per cent. ointment of old tuberculin produces in forty-eight hours a very marked local reaction, followed by sloughing and ulceration of the nodules. We are in the habit of taking advantage of this ulceration to make various applications to the raw surface, to one of which, uranium nitrate, I have already referred. But perhaps the most striking effect of this treatment is the relaxation of contraction which it induces. I may illustrate this by the case of a young man whose left elbow was fixed at a right angle, and who after two courses of this treatment did a round of golf in 77.

Tuberculin Injections.—It was my fortune to be closely associated with the early use of old tuberculin when, in the winter 1890-91, I was "voluntär assistent" to Professor Pick in Prag. The experience is one I shall never forget. What we regard to-day as enormous doses were administered, and administered often. As you all know, the treatment was soon almost but not entirely abandoned, and it is interesting to recall here in Scotland that McCall Anderson from the very outset used doses far less than were customary, and that he never abandoned its use. The doses he administered were $\frac{1}{200}$ of those then commonly used. Some years ago I began to use T.R. in doses of $\frac{1}{2000}$ to $\frac{1}{1000}$ mg. at intervals of three or four weeks. Though the improvement was neither striking nor rapid it was there, and we still continue the method. Later we resumed the use of old tuberculin in small doses (0.0005 up to 0.015) at intervals of a month. The usual local reaction along with a rise of temperature to 100° or 101° was usually produced, and some of the cases did well. But with the improvement there was not infrequently simultaneous extension at the edges, and though many of the patients were greatly delighted with the improvement one felt that all was not satisfactory. About a year ago we began to use the intensive method. Beginning with a dose of $\frac{1}{10000}$ mg. of T.R. the dose was doubled every third day until a dose of about $\frac{1}{100}$ mg. was reached. Then 0.0005 P.T.O. was substituted, and the dose steadily increased.

If there was any rise of temperature the dose was either not increased or was diminished for a dose or two. I shall show you later a patient who has been treated by this method, along with a cast of her condition when the treatment commenced, and I think you will agree that the improvement (in four months) is very satisfactory.

The time at my disposal will not permit of my referring to many other methods of treatment which we have tried.

There are many—too many—remedies for lupus; there is one necessary ingredient in every method, and that is perseverance. This is the great lesson which Finsen taught; no method will succeed without it; I almost believe that almost any method will succeed if it is really persevered with.

And now, for the purposes of my suggestions, I here interpolate some references to my experience with ringworm and favus.

In the twenty-two years I am dealing with, we have had 3,426 cases of ringworm and 482 of favus.

Tinea. Year.	No. of Cases.	*Favus.* Year.	No. of Cases.

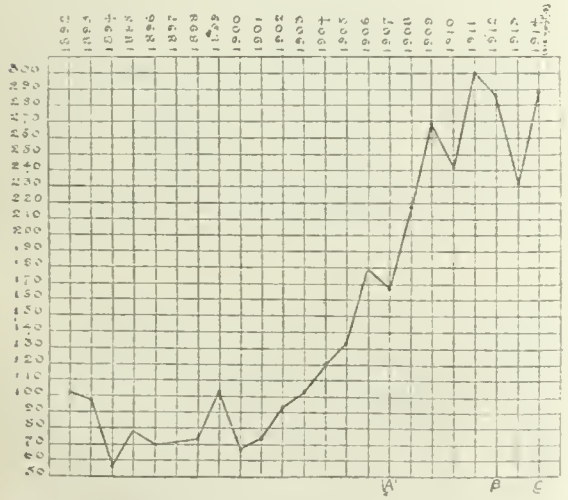
We knew we made rather a speciality of favus in Edinburgh, but we did not realize we were quite so bad as the figures show, and the worst is that the numbers were not diminishing. It was 1902 before the figures touched 20; we had 40 new cases in 1912.

There are many points of interest in the ringworm figures. They remained round about 100 annually till 1902, since which date they have steadily increased: they reached 200 in 1908, 300 in 1911, and we have had 382 cases in the first six months of 1914. Medical inspection of schools began in 1907, and we increased by 100 in



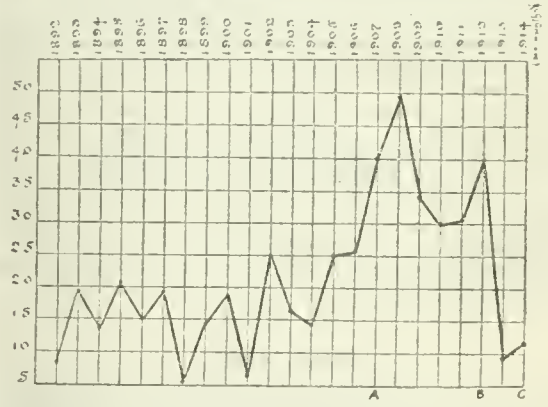
Tinea. A, Medical inspection begun; B, skin school opened; C, *x*-ray forms distributed.

two years. In January 1912, a favus and ringworm school was opened. For months before an animated correspondence had filled the columns of our evening papers. Lurid pictures were drawn of the danger to the community of this aggregation of cases, and it was said that medical students—the school was placed for convenience near the infirmary—would be driven from Edinburgh by fear of infection. A great deal of attention was directed to ringworm, and we have never got below 300 cases since. The enormous rise this year is due to the placing of *x* ray treatment on an organized basis.

I asked my secretary to make a close study of all the attendances of the ringworm cases for one year. In 1903 (the year quite accidentally chosen) there were 140 cases of tinea capitis. Of these, 38 attended once, 14 twice, 12 three times, 56 irregularly, and 20 regularly. Of those last, 10 were cured and the others were carried on to the next year, or did not return, presumably because they were cured.

Though our position with regard to children from outside Edinburgh remains as it was, matters are now very different for the Edinburgh children. By arrangement with the school board some method has been introduced. Nurses in the board's employment supervise all our cases and see to their treatment. They see that the cases come on the days fixed for their *x*-ray treatment, they see to their regular attendance afterwards, and they do nearly all the necessary book-keeping. Truants are hunted up, and though the plan has enormously increased the work of the skin and electrical departments the satisfaction of having got a real grip of the situation is very great.

In the chart of the incidence of favus we see a hopeful promise. Owing to the greater gravity of the disease we



Favus. A, Medical inspection begun; B, skin school opened; C, *x*-ray forms distributed.

devoted ourselves at first mainly to it. One sees in the chart the reflection of all those events to which I have referred, but in addition the abrupt fall—the result of the methodical treatment which is my theme.

And now we come back to lupus.

We stand to-day on the threshold of a new era. On the first of this month lupus became a notifiable disease in Scotland; in the date of issuing the order England was six months ahead of us. I give notice to our friends south of the Tweed that we shall endeavour to catch them up and to enter on a friendly rivalry as to who shall make most use of this new weapon that has been put into our hands. There will, I hope, be a sort of dossier of every case of lupus; we shall, I trust, be able to persuade—if necessary, to compel—regular attendance. I am not afraid to confess that I am socialistic enough to contemplate the foundation of farm colonies where the adults can work, and of replicas of Berck-sur-Mer, where the children will be collected and treated *de die in diem* until they are on the road to become useful citizens. I would follow them up in their after career and inspect them annually, or more frequently if necessary; I would apply the same principles to tuberculous gland cases, especially those on which any operation had been done; and I anticipate that in forty or fifty years lupus will be as rare as leprosy. We can learn a useful lesson from Hansen's successful management of that disease in Norway. If cases were being properly treated at home they were allowed to remain there, and we should copy that example. But we must treat them more perseveringly than we do. Not one of us is in a position to cast stones at our brethren in this matter. I have felt ashamed many times as I perused my records for the purposes of this paper that I had not been

more insistent in—it is a Scotticism—wearying on my patients the importance of perseverance. We think we shall frighten them away if we tell them of the months, perhaps years, of treatment before them; they go away with the impression that a few weeks of diligent treatment will suffice, and when these weeks run into months they weary, and all the treatment is wasted. They do not go at once to another doctor—it would be all right if they did; a year or two elapses before they do; the disease has considerably spread, and his task is greater than ours was.

I expect the effect of notification will be a repetition of our experience with ringworm and favus. We shall have an increase at once. Later, when we are able to organize treatment on efficient lines, there will be a further increase, and then I hope and expect a steady diminution.

I have a word or two to say in conclusion on the subject of notification. They are words of warning.

I have here the circular issued by one medical officer of health which contains these words: "Notification of cases should be strictly limited to those which are beyond all doubt of a tuberculous nature, and which imply some possible danger to persons with whom the patient may be brought in contact." I do not think any of us would go the length of saying that every case of lupus is a public danger. I will even say that in many cases the danger is so slight as to be negligible, but I do not think it is fair to put on the practitioner the responsibility of saying: This case of lupus is dangerous and that one is not; this one I will notify and that I will not. We want to get a hold of these cases to cure them, and the earlier we get them the better the chance of cure. I hope that this is the only circular of the kind which has been issued.

[In connexion with his paper the author showed four patients; two of them—very extensive cases—had been cured after years of persevering treatment; both had developed carcinoma, which had been successfully treated; one of them had been treated on one side of her face by *x* rays and on the other entirely by the old London Hospital lamp, and the result of this was a very smooth, presentable scar. The other two cases were under treatment with tuberculin, and both showed very marked improvement.]

DISCUSSION.

Dr. J. GOODWIN TOMKINSON (Glasgow) said that to obtain anything like satisfactory results from the treatment of lupus vulgaris required not only perseverance on the part of the physician, but the recognition by the patient that he was suffering from an eminently rebellious affection, and consequently must assiduously co-operate by regular attendance for treatment. While deferring to Dr. Norman Walker's long experience, the speaker personally was strongly opposed to scraping in lupus vulgaris, particularly near orifices where lamentable cicatricial contractions might follow the use of the sharp spoon. He could, however, unreservedly support Dr. Walker in his high opinion of the value of Unna's No. 81 salicylic acid and creosote plaster. This he habitually used in conjunction with mild cauterization by carbolic acid, etc., and carefully regulated small doses of *x* rays. In some 270 cases so treated in the Western Infirmary, Glasgow, he had no case of epitheliomatous degeneration to record. If inquiry were made into cases of epitheliomata following *x* rays, it would be found that heroic or at least heavy or too prolonged treatment had been given. Visible reaction, even of the mildest degree, should never be attempted, otherwise telangiectases and pigmentation might follow, with the risk of subsequent keratotic growth, often the precursor of epitheliomatous degeneration. The tendency of *x* rays to diminish keloidal tissue was a further argument in favour of their careful employment in tuberculous skin affections. As a house physician he had had experience of old tuberculin, but did not now employ it, as relapses frequently occurred. A much-neglected treatment was systematic direct exposure to unmodified sun rays, carried out where sunshine was a dependable quantity. He had experience of its value in cases treated by himself at Helouan, in Egypt—a locality peculiarly suitable, not only on account of the prevailing uninterrupted sunshine, but also because of its dry, invigorating desert air. Now that the State was assuming so much responsibility in matters medical, surely sanatorium treatment in Egypt of lupus vulgaris—with a complete therapeutic armamentarium for this affection—might be undertaken by it. As regards *x*-ray treatment of scalp ringworm, this country had been somewhat slow in adopting the method with which Sabouraud's name was so intimately associated. For several years the speaker practised it in hospital and privately, and as dermatologist to the Glasgow School Board, where the *x* rays had been installed. He employed it for over twelve months. School treatment had greatly reduced the number of hospital cases of ringworm. There was no doubt that the medical inspection and treatment of school children was a step in the right direction, not only in combating actual cases of disease, but also in preventive medicine.

Mr. HALDIN DAVIS (London) said the difficulty in treating lupus was almost in exact proportion to the area affected, and it was impossible to lay too much stress on the value of early diagnosis. As a rule, examination of the lesion when pressed upon by a watch-glass would disclose the tell-tale apple-jelly nodule. For small patches on the limbs excision was the method of choice; even on the face, for a small patch in which only two or three nodules were present, it was preferable to every other form of treatment except Finsen light. By excision he meant real excision including a definite margin of healthy tissue, certainly not scraping or erasion. The resulting linear scar became in course of time almost invisible where children were concerned. As regards the treatment of ringworm, he had lately had considerable experience as medical officer in charge of a ringworm clinic under the Education Committee of the Willesden Urban District Council. North-West London was one of the largest, if not the largest, urban district in the British Isles. The area contained about 24,000 children of school age. At the present moment about 180 of these were excluded on account of ringworm. The clinic was open once a week for three hours, but they were unable to keep pace with the new patients continually discovered by the school authorities. They administered *x*-ray treatment in a way not very different from the standard methods generally adopted. For cases in which the whole head had to be exposed, the Kienbock-Adamson five point system was always used. One of the most important sources of disaster in *x*-raying for ringworm was the possibility of exposing the same area twice. For this reason they always made a point of giving the five exposures in the same order—that is, the forehead, vertex, left side, right side, and occiput. They also used a rubber stamp which printed a simple outline of the head. On this it was easy to mark in roughly the position of the principal patches of disease. This was the only way of which he was aware that it was possible to make useful notes of a case of ringworm, and without notes it was quite impossible to remember details of these cases. For the measurement of the pastille dose he had been using for the last six months Corbett's radiometer—a useful instrument which was badly named, for it was really a tintometer. It was a great improvement on the old method of comparing the pastille with the so-called standard tint B supplied in the book of pastilles. This was usually a monument of inaccuracy. On the other hand, even Corbett's instrument gave different readings in bright daylight from what it did on a dull day. On a dull day the pastille appeared darker than on a bright day, and therefore the time taken to match the pastille to the standard glass was shorter than on a bright day. Consequently one was liable to give too little a dose. With practice, however, it was easy to allow for this, and in any case it was better to give too little than too much. In order to stop any reverse current he employed one of Leslie Miller's revolving mica discs, and it was to the excellent work done by this instrument that he attributed the good fortune he had had with his *x*-ray tube. Since the Willesden Clinic was first opened, on August 30th, 1913, he had only used one tube. With it he had given over 400 separate pastille doses, and it was still going as well as ever. At first he ran it with only half a milliampère of current, and it took about twelve minutes to turn a pastille; he was now running it with about 0.8. to 1 milliampère, and it took about eight minutes to turn a pastille. Thus, in three hours he could treat three whole heads, and while the apparatus was running he could

examine about forty children's scalps in the course of the morning. In regard to the very short ringworm stumps which were loosened by the exposure to x rays but refused to fall out, and might possibly reinfect the new hair, the best way was to arm the forefinger with a piece of zinc-oxide plaster and with it to rub the patch where the stumps were seen. The stumps, if loose, stuck to the plaster, and the patch was left bare and clean.

Dr. Winkelried Williams (Brighton) said that the form of local treatment which appealed most strongly to him was the application of potassium permanganate, which in his hands had given good results when persistently utilized. A point which he considered was often lost sight of was the importance of withholding alcohol from patients suffering from lupus. He was sure that it had a deleterious effect. He had carried out some experiments on himself with reference to the effect of alcohol upon his opsonic index to tubercle, but was unable to draw any definite conclusions from them.

Dr. Bolam (Newcastle) agreed with Dr. Norman Walker that lupus was very unmethodically and casually treated, and that to this circumstance was due the unsatisfactory results obtained. On the other hand, he differed from Dr. Walker in thinking that lupus was a disease of the poor rather than of the rich to a greater extent than Dr. Walker's figures suggested. The salient features of the disease were its chronicity, its rebelliousness to treatment, and its tendency to relapse, hence the pressing necessity for continuous treatment. He hoped for considerable assistance from the new order for the notification of the disease. As regards the therapeutic methods which he advocated, he expressed himself strongly in favour of scraping. He was nervous of x rays, even in the small doses recommended by Dr. Tomkinson. He regarded sanatorium treatment as very important, and was especially in favour of open-air treatment combined with rest in bed. He practised this method as far as he could in his own wards.

Dr. Milne (London) said that as medical officer to a large number of children he had considerable experience of both diseases under discussion. He was strongly in favour of scraping for lupus and the local application of potassium permanganate. He found ringworm a very trying disease to treat, but he had seen some unfortunate results from x rays, of which he was consequently very shy. He was fond of a modified croton-oil treatment, by means of which he was often able to cure cases in five or six weeks.

Dr. Russell Green (Birmingham) said that in his experience the incidence of a bald patch in cases of ringworm treated by x rays was certainly less than 1 in 350 cases treated. As regards the life of a tube, he had found it possible to give as many as 600 Sabouraud doses with one tube, using a valve tube. In lupus he had been much impressed by the exhibition of vaccines. Streptococci or staphylococci were very frequently found, especially in the catarrhal cases, and were much benefited by the use of the appropriate vaccine. In addition he administered small doses of x rays and treated single nodules by electrolysis.

Dr. Norman Meachen (London) said he endorsed the opinion expressed by Dr. Bolam as to the value of in-patient hospital treatment in cases of lupus. Hospital authorities were still only too unwilling to provide beds for skin cases, and personally he thought that lupus should receive as much care and attention in the wards of a hospital as any other form of tuberculosis. He considered that scraping was a valuable measure, in early cases especially, but it was often advisable to apply some chemical germicide immediately after scraping, such as the acid nitrate of mercury solution, or the organic form of copper known as "lecutyl," a note on the treatment by which he had the honour to bring before the Section last year. Small areas of lupus also did very well by the judicious application of the solid carbon dioxide, either with or without scraping.

Dr. MacCormac (London) said that he too had been extremely struck with the bad results of the treatment of lupus. In dry forms of the disease he personally preferred surgical measures—preferably excision. Ravaut in Paris had obtained good results by the use of air superheated to 700° C. in extensive cases, but wounds were thereby produced which took a long time to heal. With tuberculin he had been very disappointed. He thought that patients got so attached to tuberculin, apart from its therapeutic value, that they actually developed a drug habit with it. As regards the treatment of ringworm, he was strongly in favour of x-ray treatment. He invariably x-rayed the whole head even when there was but a single patch of the disease—he had seen such unsatisfactory results from x-raying single patches only.

Dr. Norman Walker, in his reply, pointed out that his particular object in reading his paper had been to point out the necessity for more method in dealing with lupus. As regards the observations made by various speakers, he said that he did not look upon the doses of x rays given by Dr. Tomkinson as so very small. As regards scraping, to which several speakers had referred, he wished to point out that he did not depend upon scraping alone. He remembered one case in which a surgeon had scraped no less than seventy-seven times and the patient was still uncured. He was strongly in favour both of sanatorium treatment and heliotherapy, but he wished to emphasize the fact that the most important ingredient in all the treatments of lupus was perseverance. The speaker concluded by calling upon the profession to do its best to guide the State along the right lines in its new departure, the treatment of lupus.

ANTIMONY IN SYPHILIS.

By J. C. McWalter, M.D., LL.D., F.R.F.P.and S.,
Dublin.

The true antisyphilitic drugs, according to Neisser, are those which have the power of killing spirochaetes. These are mercury, arsenical compounds, including salvarsan, and antimony. Concerning antimony, Neisser does not think there is any evidence yet of its efficacy in human syphilis, but he states it has a destructive action on the spirillosis of animals.

Neisser's view of the ideal drug is one which would combine arsenic, as in salvarsan, with mercury, and he considers it would be made still more powerful by the addition of antimony.

The whole world is now drenched with salvarsan, given mostly in heroic doses, and a reaction has set in. (1) Instead of the "Therapia Magna Sterilisans" of Ehrlich, Neisser advocates a combination of drugs, in moderate doses, continued for over a year. He states that while a non-toxic dose of each drug may be given, the combined effect is powerful. (2) Some spirochaetes are affected more by mercury, some by arsenic, some are probably more affected by antimony. (3) Mercury and arsenic destroy spirochaetes in different ways. More modern views seem to suggest that the treatment of syphilis must consist not only in killing the treponemes, but in rendering the blood unfavourable to their reproductive functions, and resistant to the life-cycle of the infective organisms. The seed, the soil, the cycle, have all to be modified by therapeutic agents, and to suppose that any one drug could have such varied and opposing qualities is surely fantastic.

A substance called "antilutin" has recently been introduced by Tsuzuki. It is a compound of antimony oxide with potassium tartrate and ammonium, and it is administered hypodermically in solution, about 3 grains being given in divided doses in four days.

I have used antimony in the treatment of syphilis for fifteen years, and it appears to be a drug of very considerable value for both the nervous and epithelial tissues.

It is worth noting that although Neisser states that there is no evidence whether antimony cures syphilis in the human subject, Plummer's pill, which contains sulphide of antimony, has been in the pharmacopoeias for ninety years. It was claimed then that it had a specific action on skin diseases of a syphilitic type. My experience goes to show that, whilst the curative effects of antimony on syphilitic lesions are very much like those of arsenic,

it is distinctly milder in character, and seldom or never followed by optic neuritis or by the fatal effects attributed to arsenical compounds. It seems proper to analyse the therapeutics of each one of what Neisser classifies as antisyphilitics, in view of a very recent conclusion, after a careful analysis of all the fatalities by salvarsan, that "death by salvarsan is nothing less than death from acute paralysis of the circulation by arsenic. Theories which attribute catastrophes to impurities of the solution, alcoholism in the patient, injudicious selection of cases, or technical errors in administration, must be abandoned. Both salvarsan and arsenic are vascular poisons, acting directly on the blood vessel wall, the blood itself, and the vaso-constrictor centre, producing a circulatory stasis or local thrombosis and their associated symptoms." In Ireland, where famine or relapsing fever, one of the earliest diseases proved to be due to a spirillum, was unhappily frequent, antimony appears to have been given both in that disease and in typhus.

I have nothing miraculous to report about the effects of antimony in syphilis, except the fact that I have given it for many years, and absolutely without fatalities. I do not think it will cure syphilis if given alone, but it certainly assists the cure if mercury be also given. It appears to be particularly useful in the dermatological manifestations of the disease, and the cases which I treated with it were notably free from nervous complications. I think the red sulphide—or antimonium sulphuratum—is the most convenient salt to employ. The dose should not exceed from 1 to 2 grains, but must be continued daily for two or three months—with occasional intermissions of a few days. It is, I think, a peculiarly useful drug in the fatal bronchopneumonia which carries off so many infants the subjects of inherited syphilis. Antimony was a panacea for almost every disorder in the seventeenth and eighteenth centuries. It cannot be denied that it had frequent good effects in various types of mania, and it seems safe to assume that many of them were of a syphilitic genesis, and it is fair to suppose that any beneficial effects were due to the spirillicidal properties of the antimony.

THE RATIONALE OR MODUS OPERANDI OF THE WASSERMANN REACTION.

By J. E. R. McDONAGH, F.R.C.S.

(*Abstract.*)

THE antigen in the Wassermann reaction owes its activity to the amino groups which it contains. If a trace of formalin be added the antigenic properties are increased, and at the same time the amino-acid content is decreased. Formalin increases the antigenic action because the replacement of the amino groups by a methane group increases the size of the colloidal particle.

$H.COH + R.NH_2 = R.N.CH_2 + H_2O$. Since the formalized product will act as an antigen, it looks as if the size of the colloidal particle plays an important rôle in the reaction.

The reagin (antibody) is a lipoid-globulin. There is no constant ratio between the lipoid and protein molecules. The greater the quantity of lipoid molecules, the more positive is the reaction; but those colloidal particles in which the lipoid molecules are in excess are liable to have a free fatty acid group. A free fatty acid and a free amino-acid can readjust complement, and therefore a negative reaction may be obtained when it should have been a positive one. An excess of free fatty acid and amino-acid molecules have a marked anticomplementary action, and cause all serums to give a positive reaction.

Any factor causing hydrolysis will naturally set free fatty and amino acids. That is why normal serums become positive on keeping, and why raising the atmospheric pressure at which serums are kept makes them give a positive reaction.

Any factor which increases the size of the colloidal particle (reagin) will also result in normal serums giving a positive reaction. This is why serums become positive if kept in the cold, if heated above 57° C., if frozen, if the atmospheric pressure is diminished, and if they are treated with barium sulphate.

The fact that syphilitic serums under ordinary conditions give a positive reaction and normal serums a negative reaction is due to the difference in size and number of the lipoid-globulin colloidal particles. Complement is the normal lipoid-globulin of the serum in an ionic state, and it has its origin in the lymphocytes. Complement is the same substance as antibody. It is the ever-ready protective substance in the serum, and it becomes antibody when its colloidal particles increase in size and number to combat the infection. Inactivation of complement alters its ionic state and rids it of oxydases, which are probably primarily responsible for its action.

The Wassermann reaction is an adsorption phenomenon; the lipoid-protein molecules (complement and reagin) coalesce, and thereby become precipitated. Precipitation deionizes complement and destroys its oxydases. Therefore there is no electrically charged lipoid-protein molecule to bring about haemolysis.

The Wassermann reaction is not a specific reaction; it is purely a physical reaction. Under ordinary circumstances, syphilitic serums have the physical properties necessary to produce the reaction, but normal serums can easily be made to possess them. Therefore any modification of the reaction, the addition of cholesterol to the antigen, etc., can only have one result—that is, to increase the tendency of normal serums to give a positive reaction.

In true bacterial complement-fixation tests the test is specific, and the specificity lies in the physical and not in the chemical molecular configuration of the lipoid-protein colloidal particles. When homologous lipoid-protein molecules meet they coalesce; in other words, the phenomenon of adsorption comes into play. This adsorption process requires molecules which are electrically charged and which have oxydases attached to them, and as all antibodies arise from and constitute the complement, it will be readily understood that complement is necessary for all these reactions, since it is the only perfectly charged molecule in the serum, and it is the molecule to which the oxydase is attached.

When an antibody meets its homologous molecule in the antigen—and the body always meets its foe with the same weapons as those with which it is attacked—an adsorption of the two molecules will take place, provided that the antibody is fresh—that is, has the action of complement. Adsorption results in precipitation and consequent hydrolysis, and during the act of adsorption the complement properties of the antibody molecule are destroyed.

Haemolysis is explained in the same way. The stereochemical molecular configuration of the lipoid-globulin in the amboceptor is the same as that in the red blood corpuscles of the sheep. If complement is present, or if the amboceptor (antibody), which is the serum of rabbits immunized against the sheep's corpuscles, still possesses its complement action as well, adsorption between the red blood corpuscles and the amboceptor takes place. This adsorption alters the osmotic pressure, with the result that haemoglobin is freed from the corpuscles. As antibody and complement are contained in the same molecule, and as the action of the former is enhanced by the latter, it is justifiable to use serums in the active state—that is, not heated to 57° C. for half an hour. If serums are used active, the addition of guinea-pig's complement is nevertheless essential.

Once a serum has had its adsorptive capacity increased, as occurs to the lipoid-globulin molecules (reagin), in a syphilitic case, it is always liable to exhibit the same phenomenon, should circumstances arise which give it the opportunity. Most of these opportunities arise only after the blood has been withdrawn. Moreover, it will be seen that several factors may be responsible for a positive reaction—an increase in the size of the protein molecule, a preponderance of lipoid atoms in the lipoid globulin complex, a breaking down of the large lipoid-globulin molecule into several smaller ones, and an excess of fatty and amine acids.

These various factors may be at work without the observer's knowledge, and they cannot be prevented or differentiated; therefore it must be wrong to state that a positive Wassermann reaction is necessarily indicative of active syphilis.

Since a free amino group, or a free fatty acid group, can prevent what would have been a positively reacting serum from giving a positive reaction, it can be easily understood

that a negative reaction can neither exclude syphilis nor be taken as an indication of a cure.

It must be obviously incorrect to say that a positive Wassermann reaction means that there are spirochaetes in the body, because, if true, a ratio would exist between the positivity of the reaction and the number of spirochaetes present. This is by no means the case, since the most positive reactions are obtained from those cases which are suffering from diseases caused by syphilis, as the intermediary cutaneous and visceral lymphocytomata, in which no parasites are present, and then in tertiary cases in which only a few parasites are present.

The complement is the most important factor in the reaction; therefore any modification which relies upon the patient's own complement must be fallacious, as the action of the complement is altered by the behaviour of the radicles to which the complement is attached.

Some modifications rely upon the patient's own complement and sheep's blood amboceptor. Results obtained by such modifications must be untrustworthy, since the action of amboceptor upsets its complement action, and vice versa, for both exist in the same molecule. Hence the reason why so many positive reactions are obtained in patients who have never had syphilis. Furthermore, the complementary action of different serums varies enormously; therefore it is essential that a standardized strength of complement be employed, which means, in other words, that only the original Wassermann technique is reliable, and that, when the reaction is positive, it can never mean more than that presumably the patient has had syphilis at some time.

The paper, of which this is only an abstract, will appear *in extenso* in a future number of the *Quarterly Journal of Medicine*.

FOUR CASES OF LAHORE SORE.

By J. Goodwin Tomkinson, M.D.,

Skin Physician to Out-patients, and Dermatological Medical Electrician, Western Infirmary, Glasgow; Dermatologist to the Glasgow School Board; Consulting Dermatologist, County Council of Lanark, etc.

Four patients—a father and three of his children—recently arrived from Sialkot, in the Punjab where the family had been living, and who were suffering from Lahore sore, came under my care at the end of May of this year. When living at Sialkot they had been sent to a member of the staff of the Lahore Medical College, who made the diagnosis of Lahore sore, and advised treatment with solid CO_2 or with x rays. Prior to this tincture of iodine and an ointment had been used at Sialkot. The following brief history was obtained early in June:

Daughter, aged 10. About a year ago a red pimple appeared on the left cheek in the malar region, free from itching and all other subjective symptoms, and began to enlarge. It was treated with solid CO_2.

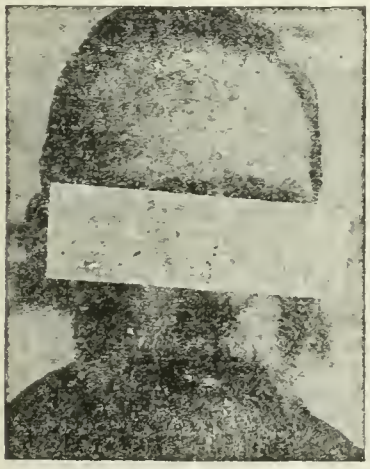


Fig. 1.—Father, aged 56. Lesion on forehead.

Inspection reveals a lesion about the size of a florin. The inner half presents a crescentic, yellowish-grey crust covering an infiltrated, pale-red projecting area. The outer half gives evidence of cicatrization—being pinkish-white and stippled—doubtless the result of solid CO_2 treatment. External to this is a vertical row of what appear to be four small deep-seated pustules.

Father, aged 56. A red pimple appeared about five months ago to the right of the middle line of the forehead near the margin of the hairy scalp. It was free from subjective symptoms. It increased in size, and presented an angry red inflammatory appearance. There was no ulceration. It was treated with tincture of iodine and an ointment, and subsequently with solid CO_2, at the Civil Hospital in Sialkot.

Examination reveals a vividly red infiltrated lesion about 3 or 4 in. by 2 in.—the long axis directed across the fore-

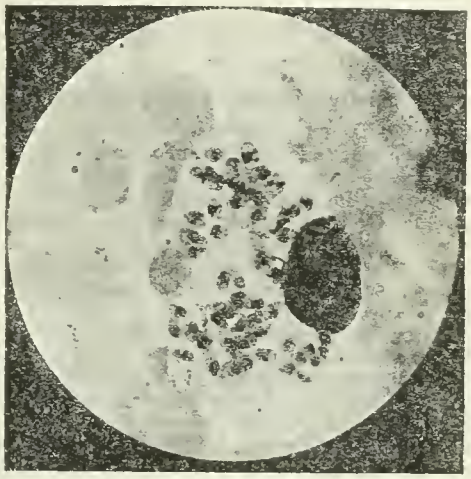

Fig. 2.—Father. Photomicrograph of blood film showing causative bodies, *Leishmania tropica*, in endothelial (?) cell.

head—gradually merging into the normal skin. It is not adherent to the bone. The centre is covered with a firmly adherent crust in which there is evidence of a powder deposited from a lotion used three weeks ago on board ship. Slight itching and very slight burning sensations are present.

Son, aged 3. About five months ago there appeared two tiny skin-coloured pimples, one to the left of the middle line of the forehead midway between the margin of the hair and eyebrow, but nearer the former; the other near the middle of the left cheek. They increased in size. There was some little fever during development. They were treated with solid CO_2.

Inspection reveals disappearance of the upper lesion, a pinkish cicatrix having resulted from the treatment. The lower lesion remains as a pea-sized pinkish nodule, giving distinct impression of infiltration on digital investigation. Its lower and inner margin is surrounded by a pinkish-white cicatrix, doubtless induced by the solid CO_2 treatment.

(*Subsequent Note.*—The patient has had three attacks of fever in his own home since arrival in Scotland, the temperature once reaching 106 F.)

Son, aged 11. A little more than three months ago two pimples developed—one above the outer half of the left eyebrow, the other about the middle of the left cheek. The onset was associated with a little itching. They were treated with solid CO_2.

On inspection a pinkish pea-sized infiltrated nodule is found in the middle of the left cheek, and a smaller livid infiltrated lesion is found above the outer half of the left eyebrow. In contact with the outer margin is a cicatrix, presumably resulting from the application of solid CO_2.

In the case of the children solid CO_2 treatment was resumed. The crust on the father's forehead was removed with an oil dressing—preparatory to treatment with x rays—and Dr. Thomas J. Mackay, Assistant in the Clinical Laboratory of the Western Infirmary, very kindly made sections of a small portion of the granulation tissue exposed on removal of the crust and took blood films from the lesion, in both of which the causative bodies, *Leishmania tropica*, were found.

Daniels in his work, *Tropical Medicine and Hygiene*, remarks, "The cells composing the granulation tissue are almost exclusively of the mononuclear type. They are large rounded cells with prominent nuclei, and are apparently of endothelial origin. The appearance is thus very different from that of simple ulceration of the skin in which polymorphonuclear cells predominate." In this

case the photomicrograph of a section of the granuloma shows a marked predominance of mononuclear cells.

A differential count of the leucocytes in blood taken from the finger—for which I am indebted to Dr. C. H. Browning, Director of the Clinical Laboratory, Western Infirmary—would suggest some disturbance of the ratio of polymorphonuclear and mononuclear elements—diminution of the former and increase of the latter:

Neutrophile polymorphs ...	...	55 per cent.
Lymphocytes ...	...	26 ,,
Large hyalines ...	...	12 ,,
Eosinophiles ...	...	6 ,,
Mast cells ...	...	1 ,,

Number of leucocytes 5,500 per c.mm.

No abnormality was observed in the red cells. (Film stained with Jenner's fluid, 200 leucocytes counted.)

In the photomicrograph of the blood film a large endothelial (?) cell is seen containing many of the parasitic bodies, round or oval, mainly the latter, containing two masses of chromatin, one considerably larger than the other, which is rod-shaped, with one end directed to the larger mass. In the main they occupy the shorter diameter of the bodies.

In a recent conversation I elicited from the father that the onset of disease appeared to be related in some way with the cold season—the daughter's lesion appeared at the end of the cold season, the elder son's lesions in the middle, and the father's and younger son's lesions at the beginning of the cold season. With the exception of July and August, when they visited Dalhousie, 7,000 to 8,000 ft. above sea level, the whole year was spent at Sialkot. The drinking water was obtained from deep wells. Near the house were two stagnant pools—one now dry, except for a very short time in the rainy season, my patient having partially filled it up to prevent, if possible, a breeding ground for mosquitos; the other pool, over which he had no control, was never quite dry and had a bad smell.

The patients when living in Sialkot slept in the open air in the hot season, *and the children state that they habitually sleep on the right side.*

In reviewing the above details one remarks the absence of subjective symptoms, save in the elder brother's case, and then only slight, during the development of the lesions. The most arresting feature, however, is the uniformity of the site of the lesions in the case of the three children. Each child has a lesion approximately on the middle of the left cheek, and the two sons, in addition, have each a lesion on the left forehead. The daughter has no forehead lesion; her greater quantity of hair may account for this.

The proximity of the stagnant water, the sleeping in the open air, the assumption by the three children of the right lateral decubitus, and all their lesions being situated on the left side of the face is strong presumptive evidence in favour of the opinion that the causative parasites, *Leishmania tropica*, are conveyed by insects, and, it might be added, obviously of nocturnal habits.

DISCUSSION.

Dr. CRANSTON LOW (Edinburgh) said he had seen one case with a chronic ulcerated lesion on the rim of the ear of a military man who had lived many years in India. It was more chronic than the lesions described by Dr. Tomkinson, and had caused considerable destruction of tissue. Microscopically no parasite was to be seen, but subsequently the parasite was demonstrated in scrapings from the surface.

INFANTILE ECZEMA.

By HALDIN DAVIS, F.R.C.S.

(Abstract.)

THE eczema of infants has afforded since many years material for dermatological speculation. To one who has been for some time in charge of the skin department of a children's hospital it appeals very forcibly. It is common, for cases of eczema form a large proportion of the more serious cases which pass through the department, its origin is often a mystery and its treatment is sometimes very difficult.

Before entering any further into its consideration it is advisable to attempt to obtain a clear understanding of the type of eczema with which we have to deal. I am here concerned exclusively with an eruption which is primarily vesicular in character, in which the main area attacked is usually on the face, but with which almost any other part of the cutaneous surface may be associated. Most often, however, the other parts principally affected are the limbs, and it is common in children who in early life have been the subjects of eczema to retain as "legacies" residual patches in the antecubital fossae or popliteal spaces. It is, of course, to be noted that eczema of the face in babies is unlike eczema of the face in adults which is erythematous in being markedly vesicular in character. I exclude from consideration in this paper the irritative rashes or erythemata found on the napkin areas and buttocks of infants, which are due to insufficient and incomplete removal of the excretions.

The first problem of this disease is the etiology. Many observers, especially those on the Continent, hold strongly the opinion that it is due to some error in metabolism and to overfeeding, others, on the contrary, think that external causes are most potent. The present writer is strongly inclined toward the latter theory. The Continental advocates of the theory of metabolic error are divided into two schools—the French on the one side and the German on the other. The French ascribe the disease to the "arthritic diathesis," the German to the "exudative diathesis." Although so dissimilar in name, in essence each of these two rival schools is ascribing to the diathesis that it favours not only eczema but practically all the troubles of infancy whose etiology has not been precisely established.

In neither case does any one really know what the diathesis is—whether it be some peculiarity of the blood or other body fluids, or a chemical or morphological anomaly; so, to offer it as an explanation of the existence of eczema or of any other morbid condition is, in fact, no explanation at all.

The other theory—that of external irritation—certainly does, however, afford an adequate explanation in some instances. We are all familiar with cases of eczema in children brought on by washing them with unsuitable soaps, which may or may not be suitable for washing clothes, but which certainly are unsuitable for washing babies' faces. We are also all familiar with the common cases of intertrigo and napkin rashes, which, although not cases of eczema, are in certain stages of the lesions scarcely distinguishable from it. On the other hand, it must be admitted that there are many cases which cannot be explained in this easy way, and which must be accounted for. In my opinion the best work which has been done on this subject is that of Dr. Hall of Sheffield, published in a series of papers in the *British Journal of Dermatology*, 1905. He is a strong supporter of the external irritation theory. His work has been unaccountably neglected by Continental writers, notably by Feer, who published in 1912 in the *Ergebnisse der innere Medizin* an almost exhaustive article on eczema of children, with an extensive bibliography of the subject.

Hall pointed out several very suggestive facts in his papers. In the first place, in the great majority of cases the eruption starts on the face and head. These are the only exposed parts in the warmly swaddled infant. (1) An infant is exposed to many new external surroundings which are capable of acting as irritants. (2) The most exposed part of its surface—that is, the face and head—is in almost all cases the starting point of the eruption. (3) The skin reflexes are far more widely distributed and easily called forth in the infant than the adult. (4) There is evidence that the majority of cases begin in the colder seasons of the year. As the children grow older their skins become obviously tougher, less sensitive, and therefore less vulnerable. Hence the tendency in most cases to recovery. It is only exceptionally that eczema persists beyond the third year.

This last point brings me to the consideration of the prognosis in infants. The mortality among eczematous infants in hospital practice is exceedingly difficult to ascertain; they cease to attend the skin department, and one presumes it is because they are cured; in a few cases it is because they are dead. It is well known that eczematous infants are liable to bronchitis and asthma; in fact, that they have delicate chests. This tendency is quite likely *prima facie*, for, as they have hypersensitive

skins, so it is not surprising that they have hypersensitive mucous membranes.

When an eczema baby is attacked by a serious chest complaint it is brought, not to the skin department, but to the general physician, and the result is that its demise remains unremarked by the dermatologist. There seems to be a considerable amount of evidence that the expectation of life in these infants is not so good as in normal children. A paper read before the Children's Section of the Royal Society of Medicine shows that of twenty-eight babies who were sufficiently seriously ill with eczema to be admitted as in-patients to a large hospital six died from various causes. In every case the eczema disappeared, or nearly disappeared, before death. The explanation I would offer of that fact is not that the disappearance of the eczema killed the baby but that the fall of blood pressure on the near approach of death removed the erythema and rendered the eczema nearly invisible.

I do not believe in the eczema being a safety valve for the discharge of toxins from the system. Nor do I believe that it is dangerous to soothe an eczematous eruption suddenly into quiescence. Cynical individuals hold the opinion that that is a legend invented by a clever but—may I say?—a somewhat unscrupulous practitioner to console an anxious parent for the obstinacy of her child's affection. Probably most dermatologists will agree that the difficulty of soothing infantile eczema is quite sufficient to prevent any risk of too speedy a cure.

As regards the treatment, believing as I do in the preponderating importance of external conditions I consider the adequate protection of the inflamed cutaneous surface of the greatest importance. It is obtained by the application of a bland emollient which has no chemical action upon the skin but which checks evaporation from the surface and which prevents irritation from the deposition of dust and from friction of clothing. The form of friction against which it is most necessary to guard is that of scratching. For this purpose it is usual, when dealing with infants, to apply splints to the arms about the elbows, thus preventing them from being bent and keeping the hands off the face. Formerly, when the children were confined to bed, I used to have the arms tied to the edge of the bed, but lately the sister of the medical ward at Paddington Green Children's Hospital, Miss Probyn, has devised a much better method. A large towel is taken; the child is wrapped up in this, it is pinned down the back, while the lower edge is drawn up and pinned round the child's forearms, which are flexed to a right angle at the elbow. Thus the infant is confined in a sort of straight jacket which has the advantage of keeping the child warm and does not interfere with proper nursing as it can be lifted up out of bed and carried about without undoing any bandages.

The drug which I regard as the therapeutic sheet anchor in this condition is zinc oxide, which may be made up either into a thin cream or a thick paste. Except in very mild cases it is spread on a mask of butter muslin for the face or on lint for other parts. Treated on these lines most cases clear up within a reasonable period. On the other hand, it must be admitted that there are some which refuse to do so. The only other drug which in my experience is of much avail is lenigallol, which may be added to the zinc paste in the proportion of 10 or 20 grains to the ounce. This sometimes seems to effect an enormous improvement. Occasional painting with a weak solution of silver nitrate also in some cases is very helpful. Still there remain some extremely obstinate cases which persist for many months. In their treatment I think I have made some advance, for during the last eighteen months I have been trying the effect of using small doses of x rays for these, and I may say at once I have been much gratified by the results. As I have only used x rays for the very worst cases, I have not collected a great number—only 8 in all—but every one of these has been very greatly improved by their use. Now, it will be readily understood that a baby who has not sufficient intelligence to keep its head still when requested to do so is not an easy object to which to apply x rays. Those who have tried to x-ray young children for tinea will appreciate the difficulty. I have overcome this difficulty by giving the patients a little anaesthetic—just enough to put them to sleep. As the application of x rays is quite painless, far less anaesthetic is necessary than for surgical anaesthesia, and I have never known any ill effects from its employment. The dose of x rays which I am in the habit of giving for these cases is one-third of a pastille at intervals of once a fortnight for not more than three doses in succession. After that an interval of at least a month must be allowed to elapse, and then, if necessary, another series of applications may be made. Of the 8 cases which I have treated in this way, 5 are practically well, except, perhaps, for a slight roughness of the skin, while 1 is still under treatment. I am sufficiently encouraged by my results to continue this method in cases obstinate beyond the ordinary.

One case which had been attending a skin hospital seven months before I saw it I had as an in-patient in Paddington Green for three months, and beyond getting the condition cleaner I effected but little improvement until I applied x rays in March last for the first time. There is now only a very small area in the middle of the forehead.

DISCUSSION.

Dr. Norman Walker (Edinburgh) agreed with much which Dr. Haldin Davis had said. He believed the most important element in treatment was continuity of application. He agreed that zinc oxide was very useful, and he believed this was because it was an inert application. He avoided bandaging on ointment which contained salicylic acid. He had a strong affection for the old-fashioned tar, especially in the form of lotion. It often relieved itching, and then the scratching ceased. Though he believed that external causes were of prime importance, he found the old-fashioned mercurial purge often of great value.

Dr. Nixon (Bristol) said that sudden deaths in cases of infantile eczema usually occurred after the eczema had been cured. Some of these deaths were due to status lymphaticus. The children were fat, but not necessarily healthy; they were often fat, white, and flabby. Other deaths were due to pulmonary diseases—bronchitis and bronchopneumonia. The eczema in such cases was truly urticarial in origin and the children frequently exhibited the alternations between eczema and asthma. The other class of eczema owed its origin to external irritants. One common cause liable to be overlooked in male children was a long dribbling prepuce. Circumcision would hasten the cure and avert relapses when this factor was present.

Dr. R. Cranston Low (Edinburgh) spoke with regard to the causation of so-called infantile eczema. He regarded these cases as being due to three factors: (1) Susceptibility of the patient, (2) an external irritant, such as soap, etc., (3) a superinfection with the organism causing seborrhoeic dermatitis on the irritated area. In order to get a case developing these three factors must all be present. He considered the severe cases of "eczema" which persisted after 3 years of age, and which were often associated with asthmatical symptoms, as really mild cases of prurigo, and the fact that these cases often showed lesions closely allied to urticaria supported that view.

KERATODERMIA BLENNORRHAGICA.

By A. Winkelried Williams, M.B., C.M.Edin., D.P.H.Lond.,
Brighton: Dermatologist, Royal Sussex County Hospital, and Royal Alexandra Hospital for Children.

(*Abridged.*)

This paper deals with the fourth case of blennorrhagic keratosis recorded in this country. J. H. Sequeira published the first case,[1] myself the second,[2] G. Little the third.[3] On the Continent some seventeen cases have been published (see references).

The clinical features of the eruption in this disease are very distinctive, and the following description of it applies to all the four cases mentioned above. The eruption consists of very hard, nearly transparent yellow cones and domes capping a thickened keratosic base. In the newer lesions there is a reddish areola, but this is often absent in the older. Some of the lesions are joined at their keratosic bases, and form ridges like mountain chains from which conical peaks project; others are

isolated, the latter being usual in the dome-shaped lesions. Sometimes a diffuse keratosis of the soles accompanies the typical lesions. The type eruption begins either as telangiectasic spots, red papules, or plaques; on these the keratosis with horny cones or domes rapidly develop. After several weeks the keratosic bases crack, and, together with the cones or domes, peel off, leaving a reddened area glazed by a thin epidermis. If the peeling is hurried by tearing off the mass with sterile forceps, the under surface of the removed mass is coated with a greyish-white slimy or putty-like material, in which careful histological and cultural examinations have failed to find any micro-organisms.

All the cases hitherto recorded excepting those of E. Robert[7] were suffering from gonorrhoeal arthritis, and Robert's cases had ophthalmia.

The histology of the lesions has been studied by A. Chauffard[6] and by Turnbull and Scqueira.[1] It consists of a great thickening of the horny layer, leucocyte infiltration, and acanthosis of the prickle layers of the epidermis, oedema, and infiltration with plasma cells and leucocytes of the upper layers of the corium. The pathological processes leading to the development of the keratosis have been experimentally studied by Chauffard and Fiessinger.[11 16] They raised a horny growth from the foot, and scarified the underlying skin, and some of the exuding fluid was smeared on places on arms and legs which had previously been gently scraped. Over these areas watch-glasses were fixed with strips of strapping; a very rapid development of a keratosis followed, which was indistinguishable both macroscopically and microscopically from the spontaneous blennorrhagic keratosis. Similar inoculation of the serum without the watch-glass failed to produce a keratosis, and a negative result also followed the application of the watch-glass without the serum.

This appears to indicate that the serum of these patients when accompanied by a macerating hyperidrosis has a peculiar capacity for producing a keratodermia.

The two cases that I myself have had an opportunity of observing—both being well developed—I owe to my colleague, Dr. Hobhouse, at the Royal Sussex County Hospital. The first occurred in the course of an acute gonorrhoeal rheumatism, the history and diagnosis of which were clear and definite. The skin lesions were absolutely typical, and details regarding it were published in the *British Journal of Dermatology* for December, 1910. In my second case—the one now to be recorded—the history was very unusual, for if the patient's story is to be believed—and I have reason for regarding him as truthful—a very long period had elapsed since the original infection with gonorrhoea.

The patient, a waiter, was admitted into the hospital for rheumatoid arthritis, under Dr. Hobhouse, on May 15th, 1913, and gave a history to the following effect. He contracted syphilis twenty years ago and was treated for six months, and he had apparently had no after-effects. Gonorrhoea he acquired twenty-three years ago; it was followed by chronic gleet, which finally disappeared ten years ago. He had been married for over ten years. His present illness commenced with pain in the right foot two years ago, and this pain had troubled him fairly constantly ever since. During the past three months he had suffered from severe pain in the right buttock and back of the leg to ankle. It was relieved by exercise, and returned after rest. Two months ago the knees became painful, and six weeks ago the right wrist, hand, shoulder, and back were similarly affected.

State on Admission.—Great swelling of right wrist and hand involving practically all the joints, and some swelling of left wrist. Right foot and ankle also much swollen. No swelling of knees. All joints stiff and painful on movement; no definite creaking nor grating. Pain along line of sciatic nerve. Pyorrhoea alveolaris. Psoriasis of superficial type. Wassermann reaction negative.

Treatment.—The patient was treated for his pyorrhoea, his psoriasis, and with rest, iodides, and antistreptococcal serum for his joints. He left hospital relieved on June 27th.

Progress.—After leaving hospital he gradually got worse, and was readmitted on August 27th. There was much deformity of both hands and wrists, which were much swollen and acutely painful; his feet also were affected acutely, but less so than the hands, and he suffered from acute pain in neck and back along the vertebral line. He had very inflamed psoriasis of the groins, nails, and scalp. A few horny growths were noted on the soles. He was given a streptococcal vaccine, and treated internally with quinine and iodides.

Second Admission.—I was away when he returned to hospital. I saw him on September 22nd, and noted in addition to psoriasis of nails of both hands, a number of typical gonorrhoeal cones as follows: *Right hand.*—Dorsal aspect: One on wrist beginning to peel, one on metacarpal region, three over first phalanx of ring finger, four over joint between first and second phalanx of middle finger, and one in interdigital region; two cones, one on each interdigital surface of index finger, and a red area where cones had peeled off; also the lunula of nail was deformed by a conical thickening from below. Three conical thickenings raised the thumbnail from its bed. Palmar aspect: Five cones, two on little and three on middle fingers. None on palm. *Left hand.*—Dorsal aspect: Two small cones on ulnar border and one on little finger. *Left foot.*—Psoriasis lesions of toes including the nails, also typical lesions of blennorrhagic keratosis; of the latter only one exists on the dorsal aspect, namely, one small yellow translucent cone over third metacarpo-phalangeal joint, but a large number exist on sole, both cones and domes, which are mostly on pressure regions. *Right foot.*—Psoriasis of nails. Dorsal aspect: Two yellow translucent domes on outer aspect and a red peeled area. The sole shows typical yellow cones and domes mostly on pressure regions of foot, but a dozen also exist on inner side of arch in front of heel. *Left leg.*—Forty or fifty small cones scattered especially about knee, also three on thigh about junction of middle and upper third. Posterior aspect: Three small cones and many small psoriatic lesions. *Right leg.*—Similar distribution of cones but less numerous, also psoriasis patch on knee. *Groin.*—Acutely red moist intertrigo with well defined border which is scaly and psoriasiform; no fungus found in scrapings.

Comparison of photographs of this case with photographs similarly taken of my previous case illustrates their very close resemblance.

Vaccine Treatment.—I prescribed small doses of a gonococcal vaccine. There was a little delay in obtaining this, so that he did not get the first dose before October 1st. During this week's interval no noticeable change occurred to the lesions. A few days after the vaccine cracking at the bases of all the blennorrhagic lesions was noted, and a week later all had gone, the psoriasis lesions alone remaining of his skin troubles. Another dose was given two weeks later, and afterwards at weekly intervals in increasing doses until December 15th; this time excepting local treatment of his psoriasis he had no other treatment.

Result.—The joints at first slowly and later rapidly improved, so that when he left the hospital on January 7th, 1914, he could use his hands and walk with freedom and ease. I saw him last June, when he ran after me in the street to thank me for his perfect cure; he was quite free from all pain and deformity; he had resumed his old occupation and was apparently in robust health.

Since the first cases of this disease were recorded in Britain I have suspected that it is far less rare than the recorded cases would indicate. The larger proportion of cases recorded on the Continent is probably due to the fact that gonorrhoea is considered part of the dermatologist's speciality. Here a lesion which in itself is of little importance, and gives rise to but little suffering to the patient, is not considered worthy of record by physicians not especially interested in dermatology. I inquired of my friend Mr. McDonagh whether he considered this to be the case, and he told me that mild cases are not infrequently seen in the London Lock hospitals. Of the four cases published in England, the two I saw nearly escaped record. The first case under Dr. Hobhouse came into hospital during his holiday, and only on his return was the unusual character of the lesions observed, and he asked me to see it; the second case was nearly overlooked for a similar reason. I told one of my dermatological friends at the Royal Society of Medicine I had a second case. He smilingly told me he feared we had very bad blennorrhagia in Brighton, but I do not think that we are an exceptionally bad lot in Brighton, but merely accident that led to their being noted.

The disease, however, is not without importance, as my second case shows. I have described at some length the joint symptoms and history in this case, and I think most will agree that until blennorrhagic keratosis indicated the probable cause there was no reason to specially diagnose the gonococcus as the probable cause of his rheumatoid arthritis. The keratoses in this case led to the man's cure; a bad prognosis was altered, and a perfect cure resulted. This case is a further support of the opinion that rheumatoid arthritis may have, even in unlikely cases, a gonococcal origin, and that a gonococcal vaccine may be considered as one of our valuable remedies in cases of this disease.

As for the treatment employed, Dr. Graham Little's case was cured in an exactly similar way to my second case—namely, by a gonococcal vaccine; this is a remarkably rapid and active specific and no other treatment is required.

MEDICAL, SURGICAL, OBSTETRICAL.

AN EXTRAORDINARY SHELL WOUND.

A Seaforth Highlander, aged 23, was brought to the temporary field hospital at Bucy le Long, suffering from a severe shell wound in the back, sustained two days before, while lying in the trenches. He had on his field dressing, which had been applied at the time he was wounded. On removing this dressing a compound comminuted fracture of the right scapula below the spine presented itself accompanied by extensive laceration of the soft tissues. The gaping opening in the skin was about 7 in. by 5 in. This appeared to be the only injury he had received, and was cleaned up, dressed, and bandaged, but on removing his kilt an extraordinary lump was seen lying immediately above the base of the sacrum and slightly to the right side, giving exactly the appearance that might be expected in a case of complete fracture dislocation of the spine. The skin above this was like parchment, and being quite insensitive a cross incision was made through the skin and subcutaneous tissue, beneath which the object was found. This turned out to be the complete time fuse of a large shell, familar to laymen as the brass nozzle of the shell. This object weighs 2½ lb., and while it may be interesting to conjecture as to the exact manner in which it travelled the whole length of his back, passing in its course beneath the tight belt of his kilt, the fact that he should have lived to tell of his marvellous escape makes the case, in our opinion, one worth recording. As he was transferred the same night to the base, his subsequent history has not been obtainable.

Sketch of time fuse by M. Nichol, French interpreter.

HERPES AND VARICELLA.

In view of recent correspondence and articles in the British Medical Journal, I think the following is of interest. On September 12th I was called to a boy with varicella. The rash was three days old. On August 24th his mother had an attack of herpes zoster; none of my colleagues have any cases of varicella, and I can learn of none in the district. In both cases the rash was typical and unmistakable. It will be noted that the incubation period of varicella is accurately fulfilled. I think there are so many recorded cases that coincidence does not explain them, and we do not know how many unrecorded cases there may be; for instance, my attention was only arrested on account of the publication on the subject in the Journal.

Beaumaris. J. Hepworth.

"RAT-BITE FEVER" CAUSED BY A FERRET.

F. L. L. was bitten by a ferret whilst ratting on April 2nd. As the wound, inflicted on the left thumb, was small, no particular attention was paid to it. On the third day the healed wound became inflamed and the glands in the axilla painful. The general symptoms were extreme weakness, shiverings, sweats, and fear of impending death. The patient looked very pale and exhausted and his temperature ran up to 104° F. He quite recovered in four days, but a week later had a recurrence of symptoms, and on this occasion in the neighbourhood of the healed wound there was an erythematous rash. The glands in the axilla were swollen and hard to the touch, but only moderately tender. After four days in bed he expressed his condition by saying he felt as well as ever he did in his life, and was considerably surprised to have a relapse ten days later, with a repetition of former symptoms together with pain in the throat and diarrhœa. On this occasion the erythematous patches were present on both arms and chest; the inguinal glands and a few of the cervical glands were affected.

Dr. Carey Coombs, of Bristol, saw the case and supported the diagnosis of "rat-bite fever." The blood count was as follows:

Red blood corpuscles (no abnormal forms)	4,856,000	
Leucocytes (normal in number)—		
Polymorphs	64	per cent.
Large mononuclears... ...	18	,,
Lymphocytes	16	,,
Mast cells	2	,,

No causal protozoan could be demonstrated.

The patient responded so well to inunctions of mercury that recourse to neo-salvarsan was deemed unnecessary. The attacks have become slighter and the intervals between them of longer duration.

On looking through the literature of rat-bite fever I find a case recorded of a ferret-bite leading to such consequences, and, curiously enough, it occurred in this neighbourhood at Malmesbury, and was eventually under Dr. Luff's care at St. Mary's Hospital.

GOVERNMENT HOSPITAL, MBARARA, UGANDA.

ABDOMINAL WOUND: PROLAPSE OF STOMACH: RECOVERY.

(By R. E. McConnell, M.D.McGill, Medical Officer.)

A male Ankole native, of poor physique, aged about 22, was carried to hospital on December 1st, 1912, suffering from a penetrating abdominal spear wound which had been self-inflicted five days previously at a village about seventy-five miles away. The incision was about 4 in. long, running diagonally downward from the left side of the epigastrium into the left hypochondrium. Through this the entire stomach presented. It was wrapped in a filthy cloth and bathed in green offensive pus.

The viscus was washed with carbolic lotion four times daily and a wet dressing was left on it during the intervals. For the rest the treatment was one of moderate stimulation with strychnine. The temperature on admission was 99° F., but at the end of thirty-six hours became subnormal. The patient took food well, and his bowels behaved in a normal manner.

On December 7th I had to leave my station before a relieving medical officer arrived in order to connect with a homeward-bound steamer at Mombasa. The stomach, though not yet altogether healthy in appearance, had become clear, and to replace it in the abdominal cavity seemed the lesser of two evils. It was found to adhere firmly in its whole circumference to the surfaces of the wound. This adhesion was broken down with the fingers, aided, when necessary, by scissors. As considerable difficulty was experienced in returning the organ, the abdominal wall near it was transfixed by three long strands of stout silk; by pulling on these the wall was elevated and the return satisfactorily made. The wound was then closed by through-and-through sutures.

The further record of this case, kept by the sub-assistant surgeon, Mr. Gokal Chand, states that on the evening of December 8th the temperature reached 99.6° F., but on the following day became normal and remained so. Recovery was uninterrupted, and the patient left the hospital well on January 2nd, 1913.

This case is reported, not as a triumph of surgery, but as an astounding example of the recuperative power of negroes.

Reviews.

VITAL STAINING.

The monograph by Dr. Kiyono[1] on vital carmine staining is a valuable contribution to normal and pathological histology, especially in respect to all differentiation in normal and inflamed tissues. Dr. Kiyono carried out his elaborate series of experiments and observations in the laboratory of Professor Aschoff at Freiburg.

It may be remembered that the late Professor Goldmann of Freiburg made most valuable and original contributions to our knowledge by the employment of a vital staining method. He, however, used pyrrol blue, isamin blue, and trypan blue. A full account of these researches was published in this JOURNAL about a year ago. Dr. Kiyono claims that the Ribbert carmine method which he has used possesses certain advantages over the methods employed by Goldmann. The Ribbert method consists in the successive intravenous injection of small quantities of lithium carmine solution and subsequent microscopic examination of sections of the tissues. Sections show that certain types of cells contain granules of varying size carmine stained whilst other types are entirely devoid of the carmine granules. The reticulo-endothelial cells of the bone marrow, of the spleen, of the lymph glands, of the liver, and of the cortex of the adrenals, contain the carmine granules; moreover, certain types of connective tissue cells, namely, polymorph cells designated klastomycetes, or cells which can store fat in their interior, and fibroblasts contain carmine granules; whereas the proper blood cell elements of the marrow and lymphatic glands are free. The reticulo-endothelial cells which Kiyono terms "histiocytes" contain abundance of carmine granules in their protoplasm so that they are readily recognized in normal and inflamed tissues. The liver is stained red by this vital staining method, and sections show that not only do the stellate interstitial cells contain the coloured granules, but the liver cells also; the epithelium of the bile ducts is unstained, but the fibroblasts and the klasmatocytes of Glisson's capsule contain coloured granules.

It is interesting to note that the central nervous system is unstained, whilst the membranes and the choroid plexus are stained red. The cells of the ependyma of the ventricles and the neuroglia cells are unstained. The cerebro-spinal fluid is unstained. These results are in conformity with those of Goldmann, except that the carmine stains the membranes. Kiyono does not find any staining of the capillary endothelium of the hypophysis, although the interstitial klastomycetes contain abundant carmine granules. These interstitial stained cells are found in both the glandular and neuro-hypophysis. Goldmann and others, after injection of trypan blue, however, found the capillary endothelium of the glandular portion stained, which was a different result from that of Kiyono. Neither lymphocytes nor plasma cells nor myeloid cells are stained, nor are smooth muscle fibres, heart muscle, and striped muscle fibres. Borrell has shown that carmine is deposited in the ovary only in cells of the "corpora involutionis." Kiyono agrees, and thinks these cells are histiocytes. In pregnancy the carmine never passes into the fetal animal, in spite of the fact that the placenta is intensely stained red. Kiyono's results, therefore, agree in the main with those of Goldmann, except in the fact that the amniotic fluid is unstained by the carmine method.

Some interesting observations have been made by Kiyono on inflammation of the cornea. He found that when this structure is experimentally inflamed, not only is there a migration of leucocytes from the circumference of the cornea, but also of klasmatocytes containing carmine granules.

He has also made observations by vital staining on fowls suffering with sarcoma and mice with cancer. His researches show that in sarcoma both the sarcoma cells and the interstitial cells contain the coloured granules, whilst in carcinoma only the interstitial cells are stained.

What are these intracellular coloured granules, and why are they present in some cells and not in others? We have a solution of carmine injected into the blood stream, and yet neither the living endothelium nor the blood cells contain the pigment, but only certain tissue cells. Is it because the cells contain a substance in granule form of varying size, which has an affinity, either physical or chemical, for the colouring matter; the chromo-receptor theory of Ehrlich, which Goldman favoured; or is it the carmine has an elective affinity for soluble lipoid substances existing in granule form in the cells? To Kiyono it does not appear probable that the carmine granules are of the nature of bioblasts or living elemental particles (Altmann's granules).

It is impossible in a review to do more than call attention to some of the many interesting facts contained in this valuable monograph, illustrated with five excellent coloured plates and provided with a very complete bibliography. The work is well worth a study by histologists.

NEUROLOGY.

THE second edition of Dr. GORDON'S textbook of *Diseases of the Nervous System*[2] has been brought up to date by the addition of various paragraphs on important subjects of recent origin, such as the Wassermann reaction and psycho-analysis, and aims at giving students and practitioners a plain and practical account of the subject. In addition, a considerable amount of space is given to treatment, where treatment is likely to be of service. The book is clearly written, full of detail, and well illustrated. It shows a tendency to pass lightly over the difficulties of the subject, for which, perhaps, the readers for whom it is intended will be grateful. The author is an American, and not seldom uses words with a breezy disregard for their finer shades of meaning. For example, on p. 382, he describes "An insolated neuritis . . . . of the musculo-spinal nerve," where the word "insolated"—no doubt a hybrid between "insulated" and "isolated"—has no reference to the sun. On p. 528 it is stated that in "trumpet players a spasm of orbicularis palpebrarum has been observed," much as if that muscle were identical with the orbicularis oris. Evidences suggesting a rather hasty compilation may be found throughout the book, and not a few misprints.

Professor MAX VERWORN'S treatise on *Irritability*[3] consists of a series of lectures delivered in 1911 at Yale University under the terms of the Silliman Memorial Fund. It contains not only the results of the author's laborious and systematic investigation of the general effects of stimulation but also a wealth of information with regard to those of other workers. The treatment of the subject at the hands of Professor Verworn is masterly, and will doubtless command the widest interest. Among the many problems treated there is not one upon which a flood of light is not shed by the insight and zeal of his research. He holds that the chemical process which in the functional disintegration of aërobic-bearing substance accompanies the transformation of potential into kinetic energy, consists in the breaking down of a loosely combined complex molecule into simpler elements through the sudden addition of oxygen. He demonstrates the applicability of the "all or none" law to the normal functioning of the medullated nerve and the muscular fibre, that is, that in every normal nerve impulse or contraction, from cross-section to cross-section, the entire number of irritable molecules are broken down as the wave of activity proceeds. He adduces evidence favouring his belief in the presence of a reserve supply of oxygen in the aërobic cell. He shows how the refractory period which follows excitation must be absolute for organisms or structures to which the "all or none" law applies, relative merely for those in which functional disintegration is incomplete. He defines fatigue as "the refractory period prolonged by deficiency of oxygen." He demonstrates the fatigability and the functional dependence upon oxygen of nerves. He regards inhibition as merely "an expression of a refractory period persisting as a result of dissimilatory

[2] *Diseases of the Nervous System; for the General Practitioner and Student.* By A. Gordon, A.M., M.D. Paris: Second edition, revised and enlarged. London: H. K. Lewis. 1914. (Roy. 8vo, pp. 632; 169 figures. 17s. net.)

[3] *Irritability.* A Physiological Analysis of the General Effect of the Stimuli in Living Substance. By M. Verworn, M.D., Ph.B. London: H. Frowde. 1913. (Med. 8vo, pp. 276; 65 figures. 15s. net.)

excitating stimuli," considering that it as well as tonus is based upon a state of equilibrium between excitation and recovery, disintegration and restitution, the two conditions differing merely in the level at which this equilibrium is maintained. The lectures were written in German, and the English version has been prepared by the author's wife, aided by Dr. Lodholz. The only fault we find with it is the profusion of split infinitives.

THE EXTERNAL SECRETIONS OF THE DIGESTIVE GLANDS.

An enormous amount of work upon the processes of digestion has been carried out in Russian physiological laboratories during the last quarter of a century. So far as British readers are concerned, there is reason to believe that most of it has been obscured in German periodicals or lost in Russian publications, to speak in a general way, although it was brought into prominence in 1898 when Pawlow published his book on the work of the digestive glands, which was soon translated into English. A well written and comprehensive account of all these and other kindred researches is to be found in a recent publication by Babkin,[4] for ten years an assistant in Pawlow's laboratory.

The book deals with the work and mechanism of these glands in man and carnivores, and does not attempt to go deeply into the chemistry or the activity of the ferments of digestion. It opens with 86 pages on the salivary glands, their action, secretion, innervation, and control. Then follow 150 pages on the secretion of the gastric juice, a subject in which physiology owes so much to Pawlow and his pupils. A special chapter is given to the pars pylorica of the stomach and Brunner's glands in the duodenum, for in the dog both these secrete a digestive fluid continuously, whether the animal is fed or fasting. A hundred pages are given to the pancreas and its secretion. The effects of the passage of bile into the duodenum are briefly noted, and in the remainder of the volume the intestinal secretions and certain peristaltic phenomena are considered. An index of authors' names and a fair subject index bring the volume to an end.

We have nothing but praise for Dr. Babkin's book. It is clearly and succinctly written, full of references to the literature, and apparently complete within the limits set by the author. It is dedicated to Pawlow, and may probably be taken as an authoritative exposition of the views held by that eminent physiologist. It appeals primarily to the physiologist but contains much that is of interest to medical men, and should be found in all medical libraries.

TEXTBOOKS OF CHEMISTRY.

In the preface to Dr. H. T. Clarke's *Organic Chemistry*,[5] the author expresses the opinion that there are two distinct and incompatible methods on which such a book may be written, the one keeping chiefly in view the practical aspect of the science, and the other its symmetry and homogeneity. He declares himself a convinced adherent of the latter method, and points out that no real knowledge of the subject can be acquired without laboratory work, details of which should not be given in a textbook to be memorized. Organic chemistry, with its innumerable compounds related to one another in an orderly system, is a subject in regard to which it is particularly important for the author of a textbook to proceed on a well-considered plan, and Dr. Clarke has certainly achieved the clearness of presentation at which he has aimed, while the fascinating character of the subject can hardly fail to appeal to the student who takes this book as guide. In scope it is intended to meet the requirements of the new syllabus of the lower examination of the Board of Education, and is also designed for those preparing for the medical examinations. It can be strongly recommended to students requiring a work covering this ground.

The *Elements of Chemistry*,[6] by Mr. H. Ll. Bassett, is put forward as containing in one volume all the chemistry—general, inorganic, organic, and practical—that is required for the various first medical examinations, and is intended principally for those who do not wish to devote more than one year to the chemistry and the other subjects required for such examinations. In what is thus frankly an examination textbook one does not of course expect to find the student led from experiment to theory, or from particular cases to generalizations. Its method is to enunciate the various "laws" as *ex cathedra* statements, and then marshal a few facts exemplifying them. It is obvious, too, that if the desired ground is to be covered in a moderate-sized book no words must be wasted. In the present case the author has succeeded in accomplishing his object; and while such a method of treating the subject is not suitable for those who wish to learn chemistry, those who wish to acquire only a sufficient acquaintance with it for the examinations referred to are not likely to find a better book for the purpose than this of Mr. Bassett's.

Mr. F. H. Jefferey's *Notes on Elementary Inorganic Chemistry*[7] adds yet another to the large number of books of all sorts on the subject of chemistry written primarily for the author's own pupils. It is intended to be used in connexion with a course of lectures and laboratory work; it is quite elementary in character and little ground is covered. It will no doubt be useful for the purpose for which it is intended, but possesses no special character to differentiate it from many others.

NOTES ON BOOKS.

Lambart's *Practical Handbook of the Tropical Diseases of Asia and Africa*[8] may prove useful to any one who wishes to run rapidly through the chief points of the diseases found in these continents. The contents are arranged alphabetically, and the work embodies the experience gained by the author during residence in various parts of the tropics. Its aim is to be concise and practical, and theory and disputed points are therefore omitted. Special attention is given to treatment, and the recommendations are sound. The matter throughout the book is good, and care has been taken in its compilation, though one or two small errors have crept in. Without wishing to cast any aspersions on the author's artistic skill, we may say that he might have been well advised to have used photographs instead of some of his own drawings.

OPENING OF THE WINTER SESSION AT THE MEDICAL SCHOOLS.

All medical schools in London commenced work for the winter session last week, but at most of them there was no opening ceremony whatever. At none of the schools was there the usual gathering of old students round the table, and only at the Middlesex and the London School of Medicine for Women were opening addresses delivered. At the former school there was a prize distribution, at which Sir John Bland-Sutton presided, and an address on the subject of alienism, and its attractions and shortcomings as a career, was delivered by Dr. Hubert Bond, one of His Majesty's Commissioners in Lunacy.

At the London School of Medicine for Women the address was delivered by Dr. Frances Ivens, Honorary Medical Officer for Diseases of Women at the Stanley Hospital, Liverpool. After some general remarks on the work of the school and its position among its compeers, and some aspects of the National Insurance Act, she said that there had recently been a swing of the pendulum towards whole-time inspection appointments for medical women. It was to be hoped that by the time those whom

[6] *The Elements of Chemistry.* By H. Ll. Bassett, B.A., B.Sc.; with an Introduction by Professor W. J. Pope, M.A., F.R.S. London: Crosby Lockwood and Son. 1914. (Cr. 8vo, pp. 380; 31 figures. 4s. 6d.)

[7] *Notes on Elementary Inorganic Chemistry.* By F. H. Jefferey, M.A. Cambridge: University Press. 1914. (Demy 8vo, pp. 55. 2s. 6d.)

[8] *A Practical Handbook of the Tropical Diseases of Asia and Africa.* By H. C. Lambart. London: C. Griffin and Co., Limited. 1914. (Post 8vo, pp. 339; 6 plates, 82 figures. 8s. 6d. net.)

the speaker was addressing were qualified it would have swung back. Not only was it in many cases a form of blind-alley employment, but it compared as unfavourably with mixed general practice as did machine work to hand work in its tendency to kill individuality and initiative.

If they were obliged, for financial reasons, to take it up, let it be for as short a time as possible, unless they found that they really were interested in what they were doing and were doing it well. Let them not think, however, that for general practice they would not need to put out their best energies. No idea could be more erroneous, for the bulk of medical work had to be done by the general practitioner, who must be prepared to face all emergencies. The world in general was in a position to criticize his smallest error with severity and based its judgement of the whole profession on the representatives with whom it was brought into contact. If they chose this exacting branch of practice they would need a sound medical education, good health, much wisdom and all the virtues. Failing these it were wiser to tread a less thorny path such as that of surgery. The surgeon from remote times had been permitted to be less perfect than the physician. But if they were as courageous as the speaker expected, the easier path would not appeal; consequently she would place before them some of the attributes which might be considered necessary for an ideal practitioner. First came the gift of imagination, the power of seeing with the eyes of the mind. This would glorify the common task and daily round, for they must not expect that all medical work would be interesting and thrilling.

Imagination would enable the fortunate possessor to place herself in the position of those with whom she was brought into contact, and so to realize the facts of life as they affected another. It would prevent her from wounding the feelings of her patients and from blurting out the truth with somewhat brutal candour, when a little reticence might be advisable. In her dealings with her fellow-practitioners it would give her the power to recognize how a given course of conduct would affect them, and would thus partly take the place of experience. She would be better able to acknowledge their rights and privileges, to realize she was not the only pebble on the beach, and must not play her own game regardless of the tactics of the team. Having the power to see, she was able to show forbearance and courtesy to the most unreasonable and exacting patients, and had nothing with which to reproach herself when she discovered there were many extenuating circumstances to account for their whims and fancies. However tried she would not terminate abruptly the long-winded story of the old lady who, meeting a medical woman for the first time, seized the opportunity to pour out her medical history in copious and uninteresting detail. Still more would imagination prevent her from resembling ever so slightly that repellent person—"one that would peep and botanize upon his mother's grave." She would not forget that the patient was a suffering human being, not a case, and as such was entitled to the most sympathetic handling and the tenderest consideration. However zealous and enthusiastic as a student, she would have always regarded the patient's comfort before her own need for knowledge, and though she might have missed examining an unusual case, her soul would not be stained by thoughtless cruelty. Taking as her patron saint St. Hildegard, the Abbess of Ruppertsberg in the twelfth century, the first physician who ever attempted to make nauseous drugs palatable, she would spare herself no effort to give physical and mental relief with as little pain as possible. A student of human nature, born with a sense of humour, she would never be bored, but find endless scope for interest in the constant variety her profession opened out before her. Judgement and sense of proportion would enable her to view with detachment, and as a whole, many things which might otherwise overwhelm her with their desperate sadness. Honesty and sincerity would lead her to expect to find truth in others, and she would rarely be disappointed. Accurate in thought and thorough in detail, the ideal practitioner would be no machine, and would not fail to respond with enthusiasm to any note of human interest. Although possibly but recently qualified, she would not regard herself as infallible, and, recognizing that she herself occasionally might make a mistake, would be charitable to others. She would listen, therefore, somewhat coldly to the tales of wrong-doing on the part of other practitioners, poured out by neurotic and dissatisfied patients, conscious, too, that she herself would probably be the next subject for complaint.

Narrowly observant, she would gain the confidence of others, not by brilliant guesses, but by avoiding rash conclusions based on insufficient data and impressing them rather by a well-balanced judgement. Although by no means unsocial and of an open disposition, she would respect with the strictest rectitude the confidences of her patients. Generous to a fault, she would realize that her profession was an art, not a trade, and having an artistic sense of perfection, she would give only one form of service, her best. Not always counting the cost to herself, she would be rewarded bountifully by the affection of her patients. Tolerant of others, she would express no harsh judgements. Remembering the words of Hippocrates, she would not shirk responsibility, "knowing that the physician himself acting should do the things that are useful." Having a strict sense of duty, her word would be her bond, and what she promised she would perform faithfully to the best of her ability. Not lacking in courage, she would be able to face difficult situations with calmness, and would not be dismayed by the first obstacle. Not forgetting that she was a woman as well as a doctor, she would use her intuition on many occasions with startling success.

SLEEPING SICKNESS.

THE following statement, which reaches us from Nyasaland, was drawn up by request at a recent meeting of the mission council by the medical men working in connexion with the Livingstonia Mission. It expresses in brief form opinions and recommendations which had been placed before the home authorities at earlier dates. The years inserted after each signature show the terms of service in the country.

Statement.

The members of the Livingstonia medical staff desire to express their approval of the Livingstonia Committee's action in keeping in touch with the Colonial Secretary regarding the question of sleeping sickness in Nyasaland and Rhodesia.

They reaffirm their belief that we are facing one of the gravest problems with which these territories have been confronted; and in this connexion they wish to emphasize the following points:

1. That the tsetse fly is rapidly encroaching upon districts where within the memory of living man it was never before encountered, causing great loss among cattle, and endangering human lives.

2. That the cases of sleeping sickness officially reported in Nyasaland during a period of about two years number nearly 200, while the actual number of cases is much larger. The number of officially reported cases in Rhodesia is not known to us, but we are aware of some districts being heavily infected.

3. That missionary operations are being seriously interfered with, the medical members of the Livingstonia Mission Council having had great difficulty about recommending suitable sites for mission stations in the Chinsali, Lundazi, and Fort Jameson divisions of Rhodesia, these districts forming geographically about one half of the Livingstonia sphere.

The Dutch Reformed Church Mission working in Nyasaland has been compelled at great trouble and expense to move its headquarters from Moera, where it had worked for twenty-five years, to Mkoma, owing to the advance of infective fly.

4. That it is well known to us as medical men and old residents in these territories that tsetse fly is not in itself a source of danger. It is a troublesome pest, but not more so than many other biting insects abounding in tropical Africa.

In the presence of infective game, however, it at once becomes a menace to the welfare of the whole community, game being the natural reservoir of several varieties of trypanosome pathogenic to domestic animals, and, we believe, of one or more varieties pathogenic to man.

5. That the measures suggested by the Liverpool Commission and by medical missionaries of experience in

tsetse-infested areas should at once be put into force. Briefly summarized, these are the suspension of our present game laws in the vicinity of human settlements and public highways. This need not interfere with the work of the recently-appointed Entomological Commission, as ample opportunity would still be afforded in many parts for the study of the bionomics of the tsetse fly.

6. That, considering the knowledge now available of the intimate connexion between game, tsetse, and the various forms of trypanosomiasis, the time has fully come for the Colonial Secretary to implement his promise to the missionary deputation.

We request the Livingstonia Committee once more to approach the Colonial Secretary with this end in view. Should his reply be unsatisfactory, we recommend the committee to use every power at its command, political or other, for the protection of our people and ourselves from the deadly scourge which is slowly but steadily spreading abroad in the land. The medical members of the Livingstonia staff who approve of the above statement are:

THE ORIGIN AND DEVELOPMENT OF THE RED CROSS.

(Continued from page 591.)

Help for the Wounded during the American War.

The movement which developed into the international organization, conveniently designated by the general term "Red Cross," was definitely started at the conference at Geneva in 1863, held in response to the efforts of Henri Dunant. It should not be forgotten, however, that an independent organization for the aid of the wounded came into existence in America during the Civil War. At the outbreak of the war in 1861 a women's central association of relief was formed at New York. They announced that they wished to organize the scattered efforts of the women of the country; for that purpose they said "they will collect and disseminate information on the actual and prospective wants of the army, establish recognized relations with the medical staff, and act as auxiliary to it, that they will maintain a central dépôt of stores, and open a bureau for the examination and registration of nurses." Dr. Valentine Mott was elected president. They met with the greatest difficulty in getting themselves recognized by the authorities, and even President Lincoln thought they would "be adding a fifth wheel to the coach." Notwithstanding every discouragement, they succeeded in securing the appointment of a "commission of inquiry and advice in respect of the sanitary interests of the United States Forces, to serve without remuneration, and to be officially recognized within the limits of their authority." The commission divided itself into two committees, one of inquiry and one of advice. A central office was established at Washington, and agents were sent to every part of the army. Only three weeks after the formation of the Commission its general manager, Mr. Olmsted, made a detailed report on the hygienic condition of the troops and the probable needs of the volunteers. A system of camp and hospital inspection was organized, and the necessity of better sanitary arrangements was urged on the Government, but the laxity of discipline rendered improvements all but impossible. Supplementary hospital accommodation was organized at every station in the army. An idea of the work of the association may be gathered from the account of the battlefield relief given after the battle of Antietam, fought on September 17th, 1862, which closed the campaign in Northern Virginia and Maryland:

> More than 10,000 Federal wounded, besides a large number of the enemy, were in need of succour. Every house, barn, church, or building of any kind for miles was filled with them. The supplies of the medical authorities were not a tenth of what was absolutely needed. But throughout the campaign a waggon train laden with supplies had been sent from the head quarters of the Commission to the army every day, and after the battle relays of these trains daily arrived. Thus the first wants of the wounded were at once attended to, and by the nineteenth the most pressing necessities of all were relieved, and it must be borne in mind that the aid given in the first two days is worth all in the next ten—chloroform, opiates, instruments, bedpans, and everything required for the treatment of the wounded was supplied. "Within a week after the battle of Antietam there were dispatched to the field by the sanitary commission and distributed by its agents the following articles: 28,763 pieces of dry goods, shirts, towels, bedticks, pillows, etc.; 30 barrels of old linen bandages and lint, 3,188 lb. farina, 2,620 lb. condensed milk, 5,000 lb. beef stock and canned meats, 3,000 bottles wines and cordials, and several tons of lemons and other fruit, crackers, tea, sugar, rubber cloth, tin cups, and hospital conveniences."[1]

The Commission continued to do excellent work throughout the war, not only by helping the surgeons and supplying medicines, food, and other necessaries, but by trying to comfort the patients and ministering to them in mind as well as in body. Some members were arrested and sent to prison, but nothing stopped them. The overworked medical officers, with no medical comforts and often without the most necessary appliances, had often occasion to say: "Thank God, here comes the sanitary commission; now we shall be able to do something." Twenty-two thousand wounded were succoured at Gettysburg alone. After the battle of the Wilderness the train of carriages containing wounded men stretched for ten miles in length. The Commission established three healing stations on the road, whence nourishing food was borne to the wounded men in the ambulances. A notion of the nature and variety of the help given may be got from the record of one day's work of a member of the corps when the first days of agony were over:

> Yesterday I went round with a basket on each arm and a haversack on my neck. A rough estimate of the day's work from the morning and evening stock on hand showed that I had given out writing paper and envelopes to about 700 men, pencils to 90, a large lot of newspapers . . . crutches to 136 wounded below the knee, who were thus enabled to get up and move about, arm slings to 115 wounded in the arm, a piece of chewing tobacco each to about 370, smoking tobacco and matches to about 450, and pipes to 73 who had lost theirs. . . . The sleep last night was sweetened by bearing out 38 nice warm new blankets to as many blanketless men whom I found as I came from a distant part of the camping ground at a late hour of the evening.[2]

The Commission continued its beneficent mission to the very end of the war. How its work was appreciated by the fighting men is well shown in Bret Harte's verses entitled, "How are you, Sanitary?"

> Down the picket-guarded lane
> Rolled the comfort-laden wain,
> Cheered by shouts that shook the plain,
> Soldier-like and merry:
> Phrases such as camps may teach,
> Sabre-cuts of Saxon speech,
> Such as "Bully!" "Them's the peach!"
> "Wade in, Sanitary!"
>
> Right and left the caissons drew,
> As the car went lumbering through,
> Quick succeeding in review
> Squadrons military:
> Sunburnt men with beards like frieze,
> Smooth-faced boys, and cries like these—
> "U.S. San. Com.," "That's the cheese!"
> "Pass in, Sanitary!"
>
> In such cheer it struggled on
> Till the battle-front was won:
> Then the car, its journey done,
> Lo! was stationary;
> And where bullets whistling fly,
> Came the sadder, fainter cry:
> "Help us, brothers, ere we die—
> Save us, Sanitary!"

The Geneva Conference.

It would be tedious, and at this time of day unprofitable, to follow the movement set on foot by Dunant through all the complicated details of the negotiations which led to the successful establishment of the Red

[1] Brackenbury, *Help for Sick and Wounded*, London, 1870, p. 436.
[2] Ibid., p. 438.

Cross. A summary narrative will enable the reader to appreciate the exact objects aimed at and the difficulties that had to be overcome before they were attained. In a circular addressed to the Powers asking for their co-operation in an international conference, Dunant recommended the creation in all the countries of the world of permanent national committees which should arrange that on the outbreak of a war they should have ready an adequate provision of aids for the sick and wounded, without risk of seeing them wasted or diverted to other purposes. He urged that there should be co-ordination of the various national committees, each working for the same philanthropic end, in accordance with the differences of national temper, custom, religion, and so forth; that each committee in time of war should act in the interests of its country; that the sick and wounded and the personnel and material of hospitals and ambulances should be treated as neutrals. The committees of non-belligerent States were to be asked to help impartially the committees of those at war. He also advocated periodical international conferences, either of the national committees or of the military health services, to study the improvements in hospital, transport, care of the wounded, and other questions relative to the care of the sick and wounded. Another point on which he laid stress was the creation of international expositions, and the regular and continuous instruction of voluntary helpers. Dunant further sent to the press of all countries an urgent appeal that every country should profit by the experience acquired by its neighbours, and contribute in turn to the obliteration of national prejudice. His ideas were hailed with sympathetic interest by charitable societies in France, Germany, and other countries. The Genevan Society of Public Utility appointed a committee consisting of the Commander-in-Chief of the Swiss army, General Dufour, Gustave Moynier and two Genevan doctors, Théodore Maunoir and Louis Appia, with Dunant himself, to study the question of the attachment to belligerent armies of a corps of volunteer male nurses.

A draft concordat consisting of ten clauses with an explanatory circular signed by five members of the committee was drawn up for submission to the Conference. Dunant attended the fifth International Congress of Statistics at Berlin in September, 1862. The fourth section of that congress was composed of army doctors, and on their programme of discussions was one on the comparative statistics of health and mortality in the civil and military population. At the general meeting the congress passed a resolution recognizing Dunant's work, and expressing the hope that the projected conference at Geneva would help to diminish the sacrifice of health and life entailed by battles. The Crown Prince, afterwards Emperor, had a long interview with Dunant, who was presented to General von Roon, Minister for War, who received him with these words: "Ah, ah, then you wish to make our surgeons neutrals?" As Dunant insisted upon the importance of neutralization of the wounded, von Roon replied: "We will come to that later." After some minutes of reflection he said: "In point of fact the neutrality of the doctors and the voluntary helpers implies that of the wounded." Von Roon enthusiastically adopted Dunant's ideas, and declared himself in favour of a uniform and international flag. Prince Karl of Prussia, brother of the King, and Grand Master of the Order of St. John of Jerusalem, promised the concurrence of his Order, and he sent Henry XIII of Reuss as his representative to the Conference.

The Conference was attended by thirty-six persons, including delegates from fourteen States, some of whom were army medical officers. General Dufour welcomed the delegates, and then vacated the chair in favour of M. Moynier. Dunant was Secretary. The Conference sat for four days, and passed a number of resolutions, of which the chief are the following:[8] In each of the countries which shall adhere to the Convention proposed by the Geneva Bureau a committee shall be formed with the object of co-operating in time of war, if there should be need for it, by all means in its power with the medical services of the armies. Each committee shall organize itself in the manner that appears to it most suitable and divide itself into sections according to need. Each committee shall make application to the Government of its country to get its services accepted. In time of peace the central committees and the sectional committees shall occupy themselves with arranging the means to make themselves truly useful in time of war, especially in preparing material helps of all kinds and seeking to form and instruct volunteer hospital workers. In case of war the committees of the belligerent countries shall furnish help to their respective armies in proportion to their resources. They shall organize the hospital volunteers, mobilize them and in accord with the military authority arrange places for the care of the wounded. They may ask for the support of the committees belonging to neutral nations. With the permission of the proper authority, the committees shall send to the battlefield volunteer helpers to work under the direction of the military commanders. They must all wear, to whatever country they belong, a white brassard or arm badge with the red cross. In addition to these the Conference passed *vœux* asking that ambulances, hospitals, official sanitary personnel, and the inhabitants of countries helping the wounded should be completely neutralized; that a distinctive uniform badge for the health services of all armies should be admitted diplomatically, and that an identical flag for ambulances and hospitals should be adopted by all countries. The Geneva Commission was appointed the International Committee, and as such entrusted with the carrying of its resolutions into effect.

The committee got to work at once and in July, 1864, fifteen States had agreed to the suggestions of the Conference for the formation of help committees. The French Emperor informed Dunant that he had instructed the Minister for War to authorize some general officers to become members of the committee then being organized in France. After the Conference Dunant, who had previously laid down the bases of the Central Prussian Committee, asked Prince Henry to be its president. The Committee was founded in February, 1864, and the Minister for War, von Roon, wrote that it might count on active co-operation and keen sympathy from the Prussian military authorities.

International Congress.

In April, 1864, the French Minister of Foreign Affairs informed Dunant that if, with the view of transforming the idea of neutrality into an international law, Switzerland invited the Powers to a congress, France was ready to support the proposal. It was accordingly arranged that a congress for the purpose should be held at Geneva, and, after some discussion, it was agreed that the Federal Council should send out invitations to twenty-five States. Sixteen sent official delegates—namely, Baden, Belgium, Denmark, Spain, the United States, France, Great Britain, Hesse, Italy, Holland, Portugal, Prussia, Saxony, Sweden and Norway, Switzerland, Würtemberg. Great Britain, the United States, Saxony, and Sweden had not given their delegates the necessary powers to sign the treaty, but had reserved to themselves the right of signing the protocol. Soon afterwards these countries adhered to the Convention. Russia, which had accepted the invitation, could not send a representative at the proper time. Brazil, Greece, Mexico, and Turkey expressed regret for being unable to send delegates in time, but the three last named States held out the hope of a later adhesion to the resolutions. The congress met in August, 1864, and sat from August 8th to 22nd, under the presidency of M. Moynier. It concluded its labours by drawing up a number of articles which were embodied in a formal Convention.

[8] *Les Origines de la Croix-Rouge.* Par Ch. F. Haje et J. M. Simon. Stuttgart. Imprimerie de A. Lindheimer, Amsterdam. Academische Boekhandel, Delsman, and Nolthenius. 1900. The account of the foundation of the Red Cross here given is largely based on this work.

THE BRITISH PHARMACOPOEIA, 1914.

In the period—nearly sixteen years—which has elapsed since the appearance of the present *British Pharmacopœia*, the number of new substances and combinations which have come into use has probably been far greater than in any previous equal period of time; it is of much interest and importance, therefore, to consider in some detail how far the new *Pharmacopœia*, which will become the official standard on January 1st, 1915, gives statutory recognition and definition to new medicines, and generally what are the changes in formulæ which are introduced by it. A certain proportion of such changes, of course, merely represent improvements in the pharmacy of various

preparations, and are of subordinate interest from the point of view of the prescriber. In the present and succeeding articles, changes of this kind will not be discussed in detail, but attention will be given to those alterations, additions and omissions which are of particular interest to the medical profession.

The publication in 1900 of the *Indian and Colonial Addendum to the British Pharmacopoeia 1898*, represented the first attempt, to some extent provisional, to give the *Pharmacopoeia* an imperial scope. In the new volume, those drugs and preparations of the *Addendum* which it has been decided to retain have been incorporated in the body of the book, and the work is thus, for the first time, a British Imperial Pharmacopoeia. The list of divisions of the British Empire referred to in the new *Pharmacopoeia* is somewhat greater than that given in the 1900 *Addendum*, as it includes Northern and Southern Rhodesia, Swaziland, Weihaiwei, and some colonial provinces and divisions not previously mentioned individually.

The alterations of a general nature which have been made are to some extent summarized and indicated in the course of the preface. A comparison of the preface of the new *Pharmacopoeia* with that of the 1898 issue shows that the greater part of it is identical, but the following matters are pointed out as having been dealt with differently.

Weights and Measures.

In all the formulae for the preparation of galenicals and compound medicines the metric system is now exclusively employed. Doses are stated both in the metric and imperial systems, the metric doses being given first; the equivalence of the doses in the two systems is necessarily only approximate. The term "cubic centimetre" is now entirely dropped, and is replaced by the more correct term "millilitre," defined in the appendix as the volume at 4° C. of 1 gram of water; this term, however, is shortened to "mil" in stating doses, the word "mil" having been given official recognition by the Board of Trade in 1908; the subdivisions decimil (one-tenth of a millilitre, approximately 1.69 minims), and centimil (one-hundredth of a millilitre, approximately 0.169 minim) are also regularly used in the same connexion. It was stated in 1898 that "it is still optional with the physician *in prescribing* to use the symbols ℈ (scruple) and ʒ (drachm), the former representing 20 and the latter 60 grains"; but in the present preface no reference is made to the scruple, and in regard to the symbols ʒ and ℥ it is remarked, "in prescriptions the symbol ʒj is often used to represent 60 grains, and also to represent 1 fluid drachm; and the symbol ℥j to represent sometimes 480 grains, sometimes 437.5 grains, and also to represent 1 fluid ounce. As these symbols are apt to be misread, it is recommended that prescribers should cease to employ them." With regard to this recommendation, it is no great inconvenience to discard the symbol ʒ, and to express the quantities of solids in a prescription in grains, and small quantities of liquids in minims; but for larger quantities of liquids, including the total volume to which a liquid medicine is to be made up, it is hardly likely that the symbol ℥ (indicating 480 minims) will be readily given up until such time as the use of the metric system in writing prescriptions may become general.

Dosage.

It is again pointed out that the doses mentioned in the *Pharmacopoeia* are not authoritative, but are merely intended for guidance, and represent the average range of quantities usually prescribed for adults, while the medical practitioner must act on his own responsibility in respect to the amount of any therapeutic agent he may prescribe or administer. It is added that "where an unusually large dose appears to be prescribed, it is the duty of the pharmacist or dispenser to satisfy himself that the prescriber's intention has been correctly interpreted." It would have been of considerable assistance in this direction if it had been definitely recommended that where a dose of any potent medicine greatly in excess of the official maximum dose is prescribed, a note of exclamation or the initials of the prescriber should be appended to show that it is intentional and not a slip of the pen.

Preparation of Chemicals.

The descriptions of processes of manufacture of medicinal chemicals mentioned in the monographs have not been amplified; such changes as have been made are in the direction of further reduction, while the general phrase used is, "it may be obtained by . . .." instead of "it is obtained by . . ." It is not possible to include in a pharmacopoeia descriptions of the actual processes employed in manufacture of chemicals on the large scale, nor would it serve any useful purpose; as, moreover, new processes are frequently introduced which supplant the older ones, it is more correct to say of any given substance that it *may be* than that it *is* prepared in a particular way. On the other hand, the standards of purity for such substances have in most cases been more exactly defined, particularly in regard to traces of such serious impurities as lead and arsenic.

Tests for Drugs and Chemicals.

Generally, throughout the work, the characters which a substance must possess and the tests which it must pass are defined with greater precision, and several analytical processes not previous included are described in an appendix. This matter will be referred to more fully in a subsequent article.

Standardization of Drugs and Galenicals.

The number of drugs and galenical preparations which are required to contain a definite proportion of the chief active constituent is further increased.

Atomic Weights.

The atomic weights now adopted in the *British Pharmacopoeia* are those agreed upon by the International Committee on Atomic Weights, based on the atomic weight of oxygen as 16. This is an improvement on the present *Pharmacopoeia*, in which atomic weights are referred to hydrogen as 1, giving a series of figures differing somewhat from those employed in standard works on chemistry.

International Conference on Potent Drugs.

Changes have been made in the preparation, composition, and strength of certain galenical compounds containing potent drugs, to bring them into accordance with the recommendations of the International Conference which met at Brussels in 1902. In a few cases these recommendations have not been followed, and the reasons for this are duly set forth.

General Nature of Alterations.

The new *Pharmacopoeia* is a volume of 602 pages, which is slightly more than the aggregate number of its predecessor and the *Indian and Colonial Addendum*. This increase, however, is only due to larger spaces having been left between the monographs, the actual amount of matter being less than in the *Pharmacopoeia* of 1898 and *Addendum*.

Examination of the lists of alterations shows that 168 articles have been omitted, while only 43 new ones have been introduced. These figures indicate clearly that the general policy has been one of exclusion and not inclusion. The drugs omitted, with all their galenical preparations, include many still in fairly common use, such as arnica, gamboge, hemlock (leaves and fruits), cimicifuga, saffron, cusparia, galbanum, hops, mezereon, pareira, sarsaparilla, etc.; of preparations, all the liquores concentrati (first introduced in 1898, and never adopted in practice to any considerable extent) are omitted, and also several plasters, extracts, juices, tinctures, and ointments. The drugs cantharides, coca, jaborandi, and physostigma are dropped, but their active principles—cantharidin, cocaine, pilocarpine, and eserine (the last two in the form of salts only)—are retained; blistering preparations are all made from cantharidin. Figs, prunes, and black pepper are no longer described in monographs, and in the formulae for the preparations into which they enter they are ordered as "of commerce." Chemical substances which are omitted include cerium oxalate, iron arsenate, and phosphate (the latter being replaced by a saccharated salt), lead carbonate, sulphocarbolates of sodium and zinc, and iodide of sulphur.

The drugs and preparations now included for the first time and the alterations in composition, strength, or name of those retained from the 1898 *Pharmacopoeia* require more detailed description, and will be dealt with in the sequel.

(To be continued.)

British Medical Journal.

SATURDAY, OCTOBER 10TH, 1914.

TETANUS AND ITS PREVENTION.

THE article on the prevention and treatment of tetanus by Dr. MacConkey, the bacteriologist in charge of the serum laboratories of the Lister Institute, which appears elsewhere, arrives most opportunely, for it is known that a good many cases of this disease have occurred in France among wounded men both of the British and French forces. Thanks to antisepsis tetanus is not now common in peace at home, and many members of the profession have seen little or nothing of it. In the Boer war few cases occurred, so that many of our military surgeons are in like case. In South Africa the men were for the most part fighting over upland grass lands, and the majority of the wounds were occasioned by rifle fire. The conditions of the present campaign are different. In France the soldier is fighting over cultivated land, and shell wounds bulk large among the casualties. Many wounds are necessarily contaminated by the kind of earth which is particularly liable to contain the bacillus of tetanus.

Dr. MacConkey's article is primarily concerned with the prophylactic and curative use of antitetanic serum, but it includes a careful summary of the various premonitory symptoms of tetanus, which should be of the greatest service, as the chances of successful treatment by antitoxin diminish enormously as the disease develops.

It is, however, very doubtful whether, under war conditions, much is to be hoped from treatment other than prophylactic. Experience has shown that if the *toxin* be given but a few hours' start one million times the dose of antitoxin which would save an animal if injected previously may be ineffectual. It is true that apparently hopeless cases have recovered after the administration of large and sometimes colossal doses of high potency serum—as much as one pint being employed in some cases. The amount of serum necessary to effect a cure may no doubt be diminished by administering some of it by lumbar puncture; but an attempt to treat adequately quite a limited number of cases of developed tetanus, even if some measure of success were attained, would soon exhaust all the tetanus antitoxin available.

It is sometimes asked why, when antitoxic treatment is so satisfactory in the case of diphtheria, it should be so ineffective against tetanus. But the contradiction between the two sets of facts is only apparent. By the time symptoms of tetanus have developed the poison has done its work, it is already combined with the nerve cells, and although it may perhaps be gradually dislodged by swamping the fluids bathing the cells with antitoxin, this is a very slow process and the result uncertain. Diphtheria is diagnosed from the local lesion and antitoxin can be administered in time to be already circulating in the body fluids to fix the toxin as it is elaborated by the bacilli. In this way it is prevented from reaching the nerve cells.

The true analogy to treating a case of developed tetanus by tetanus antitoxin is the treatment of a case of diphtheritic paralysis by diphtheria antitoxin. The latter is as unsatisfactory as the former.

On the other hand, it has been abundantly shown that if a small dose of tetanus antitoxin be injected within twenty-four or even forty-eight hours of the time an animal (for example, a horse) is inoculated with a culture of the tetanus *bacillus*, which, without treatment, would be surely fatal, the animal does not contract the disease. The same satisfactory results have followed in veterinary practice and in human surgery in countries, such as India, where wounds soiled by earth are particularly liable to become infected with the tetanus bacillus.

The proper use of tetanus antitoxin in war time is prophylactic rather than curative, and it is most important that those responsible for the care of our wounded should realize this fact. A prophylactic dose of tetanus antitoxin should be the routine treatment in all cases of shell, bayonet, and other wounds, when there is risk of soil contamination, as soon as possible after their infliction. It may not be possible to do this at the time the wounded are first attended to on the actual field of battle, but it should be done at the field ambulance or clearing hospital, and in any case at the earliest possible moment. Only a few cubic centimetres of serum of good potency are required. The injection in no way harms the patient or delays his recovery, and it is horrible to think of the chances of tetanus being added to the sufferings of our wounded for the lack of this precaution.

SLEEPING SICKNESS.

THE statement on sleeping sickness by the medical men working in connexion with the Livingstonia Mission, published in another part of this issue, brings up again the vexed question of the connexion which exists between game, tsetse flies, and trypanosomiasis.

The report of the Committee on Sleeping Sickness, which sat recently in London, was discussed in the JOURNAL of May 30th, 1914. It showed a considerable diversity of opinion with regard to the prophylactic measures which should be instituted. Many of the members of that Commission, however, had never been in Rhodesia and Nyasaland, and it was pointed out in the JOURNAL that it would have been better if the Commission had actually worked on the spot and had studied the conditions locally. The feeling seems to exist amongst the workers of the Livingstonia medical staff that some of them should have been called to give evidence, especially when the number of years many of them have served in these areas is remembered. Sir David Bruce and his fellow workers, as well as Drs. Kinghorn and Yorke, after laborious and painstaking studies, are convinced that the wild game is the real source of the human disease in Rhodesia and Nyasaland, and this opinion is strongly confirmed by the medical missionaries who have signed the statement now published. It is undoubtedly an important document, and cognizance must be taken of it.

The tsetse fly, not in itself a serious danger, is, in the presence of infected game, as the signatories state, a menace to the welfare of the whole community, for game is the natural reservoir of several varieties of trypanosomes pathogenic to domestic animals, and of one or more varieties pathogenic to man. The conclusion is obvious that these reservoirs must be removed, or at least driven back from the haunts of man, by no means an impossible task. No one, of course, suggests for a moment that the whole fauna of Africa is to be destroyed; what is advised is

the local destruction of wild animals around towns, villages, and other habitations of man. The authors of the statement believe that this may be accomplished by the suspension of the present game laws in the vicinity of human settlements and public highways. If this were done, then the game would quickly become scarce or disappear entirely, and the tsetse fly would not be able to acquire the virus; even though it still existed in such a zone, it would be rendered relatively harmless. That game disappears from around townships and cultivated land is well illustrated by the experience of the more southern parts of Africa. As civilization advances and the land is put under cultivation the game gradually disappears, its presence being incompatible with agricultural work and stock rearing. No country will develop properly that cannot rear domestic animals for its food supply, and on this ground alone infected game should be driven far from such situations. As regards danger to human beings, it has been stated that the Rhodesian and Nyasaland form of sleeping sickness is only feebly endemic and not epidemic, but it is difficult to verify this assertion completely, and undoubtedly there are more cases of persons suffering from the disease than have ever been reported. The statement now published shows that in Nyasaland during a period of about two years nearly 200 cases were actually reported, but it adds that missionary operations are being seriously interfered with on account of the spread of infective tsetse flies.

Taking all these things into consideration, therefore, there is no doubt that the time has now arrived for some definite plan of campaign to be adopted for the prophylaxis of sleeping sickness and the trypanosome diseases of cattle in these regions. Sir David Bruce's suggestions on the subject are good and sound and might well be followed by the Nyasaland Government and its staff in the affected zones. There is a chance at present of stopping the further spread of the disease, but if this chance is allowed to pass there is no saying what the cost will be at a later date. The suggestion that the Livingstonia Committee should approach the Colonial Secretary again on the subject seems a useful one, and it is sincerely to be hoped that the Government will not only act in the matter but act energetically. Little or nothing seems to have been done since the Sleeping Sickness Committee concluded its labours, and this is not as it should be. The time for half-hearted measures is past.

COUNTY ADMINISTRATION AND THE HOME FORCES.

In the scheme for the sanitary organization of the regular army issued in 1907 it was provided that on mobilization a sanitary inspection committee should be formed for service in the field, consisting of a combatant officer as president, a field officer Royal Engineers, and a field officer Royal Army Medical Corps, as members. The scheme proposed that the committee should act under the orders of the General Officer Commanding-in-Chief, and that its duties should be: "(*a*) To ascertain that sanitary appliances and materials of all kinds required for the army are forthcoming, and that an adequate reserve is maintained. (*b*) To assist general officers and the medical service in their efforts to maintain the health of the army by co-ordinating not only the work of the different military branches, but also the military and the civil sanitary organizations of the country or area occupied. (*c*) To initiate schemes of general sanitation, and to serve as a board of reference for the solution of sanitary questions. (*d*) To visit and inspect stations occupied by troops, to advise local authorities regarding necessary sanitary measures, and to further in every way the maintenance of satisfactory sanitary conditions. They will report to head quarters any measures they consider necessary, but which they cannot arrange for locally."

No public announcement has been made of the appointment of such a committee to carry out the duties indicated in respect of the forces now serving abroad. Possibly it may have been considered that during the early operations the movements of troops were so rapid that sanitary questions of this kind were of secondary importance, since experience has shown that camp epidemics as a rule only arise after troops have been for some three or four weeks in the same place. As the events of the last three or four weeks show, conditions demanding the appointment of such a committee may now shortly arise.

But if such co-ordination of sanitary work is necessary in the regular army, where all the regimental officers are trained in sanitation, still more is it necessary in dealing with the Territorial Forces in this country and the new recruits. We do not intend to suggest that an exactly similar system would be desirable or efficacious in this country; on the contrary, we believe that, unassisted, such a committee would accomplish very little work, although it might be useful as a general advisory and co-ordinating body.

When the Territorial Forces were organized medical officers of health were invited to enroll themselves in its medical corps; they were asked to take voluntarily upon themselves the duty of considering the problems to be solved during active operations within their own home area, and to be ready to place their knowledge and experience at the disposal of the officers commanding the Territorial Forces. Many of them responded to this call by becoming commissioned officers whose services would be available on mobilization as sanitary officers (or sanitary specialists). When put to the test by the recent mobilization the system has not worked satisfactorily, and the special local knowledge of medical officers of health has not been utilized to the best advantage, except in a few areas such as London, as was explained in an article published a fortnight ago. A Division may be, and in many instances has been, moved out of its district. Even if it has as sanitary officer a medical officer of health in the area from which the Division is drawn, his local knowledge becomes valueless to it, while his own area and the troops in it are deprived of that knowledge at a time when it is most urgently needed: moreover, a Division usually, probably in all cases, leaves behind detachments on special duty in various parts of its own area. It seems highly desirable that the system should be reconsidered. We believe that in the county medical officers of health the military authorities have at hand medical officers of large general and local experience whose advice would be of the highest value to the command in each district. We are inclined to believe that the originators of the scheme founded it too much on the divisional organization, and did not attach sufficient importance to the points mentioned in the penultimate paragraph. There are six commands in England and Wales, and in each command a large number of counties are included. The Northern Command, for instance, includes Northumberland, Durham, Yorkshire, Lincolnshire, Nottinghamshire, Derbyshire, Staffordshire, Leicestershire,

and Rutland; the Western Command, again, includes Wales and Monmouthshire, Cheshire, Shropshire, Herefordshire, Lancashire, Westmorland, and Cumberland. The head quarters where the Deputy Director of Medical Services is stationed are in the one case at York and in the other at Cheshire. It is clear that effective supervision of local sanitary conditions cannot be exercised by these officers save in the most general sense. Moreover, the Army List shows no sanitary officer on the staff of the Deputy Director of Medical Services at head quarters of commands, and we venture to think that the first step in organizing an effective service would be to appoint an expert sanitary officer in each command, with authority and instructions to consult the county medical officers of health with regard to all proposals for the establishment of camps, or for billeting on an extensive scale. The county medical officer of health would either be able to advise from his own knowledge or would quickly be able to obtain the necessary information. He would know the local difficulties, and would, moreover, be able to superintend any measures which the military authorities were advised to take in order to overcome them.

SURGERY IN THE WAR.

ACCORDING to a statement by Dr. Henry de Varigny in the *Journal des Débats* (quoted by the *Times*), among over 6,000 wounded men admitted to the Vichy Hospital only some 600 operations were required, and of these not ten were amputations. This is, we believe, in accord with the experience, so far, of the general hospitals in this country, but we fear that it cannot be taken as fully representing the facts. The worst cases have not been brought to this country from the British forces in France, and it is unlikely that cases from the French fighting line have been removed as far as Vichy, which boasts itself to be the central town of France. There is much evidence that the conditions by which the surgeon in this war is confronted are very different from those encountered in South Africa. The general experience seems to be that bullet wounds are comparatively rare. There are wounded men returned to this country from the seat of war who have never seen a German soldier, and it is to shell fire, often at long ranges, that most of the serious casualties are due. Some of the shell wounds are extensive and severe, and we fear it will be found that the number of amputations it has been necessary to perform has been greatly in excess of experience in recent campaigns. The rapid collection of wounded from a position which is being searched by the enemy's heavy artillery must often be a physical impossibility. In spite of all that can be done—and the casualties in the Royal Army Medical Corps have unfortunately been heavy—severely wounded men must sometimes lie out perhaps for many hours before aid reaches them. The congestion of the railways at the rear of the Allies has often caused great delay in getting them to hospital, and this has combined with the severe nature of the wounds and their frequent contamination by earth to make tetanus and traumatic gangrene more frequent than in the past. A medical correspondent at Aix-les-Bains informs us that since the beginning of September a large number of wounded have been admitted to the hospitals in that well-known watering place. Many of them had been two or three days in the train in horse trucks without change of first aid dressings, and the grave cases were in a pitiable state. Since then all the big hotels have been converted into hospitals. The first batch, which arrived at 1 a.m., were, thanks to a very good distribution service, in bed in the hospital by 2.30. The two British surgical volunteers worked on till 10.30 a.m. before the more serious cases had been attended to. Since then attendance at the hospital has averaged seven or eight hours a day, and a good many operations have been performed. There were very few cases of bullet wounds, most of the men suffering from shrapnel wounds, especially of the thighs, buttocks, and genitals. At the time of writing, about a fortnight ago, there had been five deaths, two of them from tetanus and two from secondary haemorrhage. Many of the fifty serious cases in the hospital were then still in a very precarious condition.

WAR PSYCHOLOGY "MADE IN GERMANY."

THE war seems to have turned the heads of German men of science, or perhaps it would be truer to say that it has revealed the innate incapacity of the Teutonic mind to see things from any but its own point of view. How otherwise are we to account for the ravings—we can call them nothing else—of Professor Hugo Munsterberg, who has analysed the value of human testimony and other problems of psychology with such subtlety, when he seeks to persuade Americans that his countrymen have been foully wronged by jealous rivals and have committed no crime but defend themselves against unprovoked attack? The same line has been taken by Professor Haeckel of Jena. The calm assurance with which these eminent men ignore facts destructive of their case is a striking illustration of the belief in the general stupidity of all other men which is characteristic of the "cultured" German. We need not insist on the extent to which this attitude of mind must tend to lessen the estimation in which much of the work done in the laboratories of the Fatherland must be held. The most amazing instance we have yet seen of the mingled impudence and simplicity of the German professor is the deliverance—which would be delightfully funny if the subject were not so horrible—of Professor Albert Moll, president of the Berlin Society of Psychology. He professes to give a psychological explanation of the atrocities committed by the German troops in Belgium. It is all, he would have us believe, a matter of hysteria and hallucination. Women are violated, unoffending men, women, and children are murdered, homes are wrecked, a peaceful country is laid waste. But it is not the Germans who are responsible for these things; it is, forsooth, because the Belgian people has been for years and decades left in blind ignorance by the Belgian Government and the Belgian press. Owing to this the Belgian nation has been reduced to a condition which can only be described as national hypnotism! Well, they have had a rude awakening, these unhappy Belgians. The Germans have taught them to know what education means. They are not likely to forget the lesson. And Dr. Moll dares to talk of the "lies" of the Belgian Commission! Are the smoking ruins of Louvain "lies"? Is the wrecked cathedral of Malines a "lie"? The Germans, wherever they could, have left a track of wanton destruction and bloodshed; yet we are complacently told by Professor Moll that it is all the fruit of the Belgians' ignorance, when it is not downright "hallucination"! Either the President of the Berlin Psychological Society has allowed his patriotism to hypnotize his common sense as well as his humanity, or he is seeking to deceive the world. We recommend Dr. Moll to apply his psychology to the moving spirits among his own countrymen who kindled the flame of this tremendous war among the nations. He will find among some of the highest of them excellent subjects for the study of hysteria, hallucination and megalomania. He might also with advantage study an interesting letter from Dr. Kaufmann of Aix-la-Chapelle, which, according to the *Evening Standard and St. James's Gazette* of October 6th, has recently appeared in the *Koelnische Zeitung*. It appears that soldiers passing through the railway station at Cologne declared that the hospitals at Aix were crowded with their comrades mutilated by the Belgians. These tales of cruelty, says Dr. Kaufmann, spread like

wildfire among the soldiers, and a single case of a man being mutilated by a shell is magnified into an outrage, and only one of a hundred similar instances. The soldiers by auto-suggestion come to believe their own wild fancies. We congratulate Dr. Kaufmann on his honesty in making this statement, which may serve to show Dr. Moll that hysteria and hallucination are by no means confined to "ignorant" Belgians.

WAR POETRY.

The war has already produced quite a large crop of poetry of very varying merit. Even the Laureate, Mr. Kipling, and Mr. William Watson seem to us to have shown only a moderate degree of inspiration; perhaps the reason is that the subject is too tremendous. The events are too near to be dealt with even by the most devoted lover of art for art's sake in a purely aesthetic spirit. The songs of Tyrtaeus fired the Spartans to deeds of valour during the Messenian war, but the ditties that stir the spirits of our soldiers and sailors are more of the music-hall than the military order. Neither Dibdin nor Campbell has ever, we believe, had much vogue among seamen. Probably the most popular song at the present time is "It's a long, long way to Tipperary," though in its origin it had, we believe, no association with the war. A fine marching song which one often hears from the recruits on their way to Hampstead Heath or other drilling ground is "John Brown's body lies mouldering in the dust," but that dates from the American Civil War. Of the songs inspired by the present war the best, we think, is Mr. Harold Begbie's "The homes they leave behind," set to music by Mr. Walter Rubens. It is published by Messrs. Enoch and Sons for the benefit of the National Relief Fund; 25 per cent. of the profits are to be given to the variety artistes fund. The tune has a fine lilt, and the words should appeal to all patriots. The refrain will give an idea of the spirit by which it is inspired:

Men are rolling up in thousands.
And they've flung their jobs behind,
They have kissed their girls and mothers
And they've told them not to mind.
You have called them to the Colours
Where the battle breaks and foams.
Well! they're rolling up in thousands,
It's for you to help their homes.

Dr. F. Barber Wells, of London, is the author of two little books of verse which have been sent to us by the publisher, Messrs. W. H. and L. Collingridge, 148 and 149, Aldersgate, E.C. The proceeds of these poems are also to be devoted to the National Relief Fund. They are entitled respectively "1914, a War Poem," and "The Roll of the Drum." The former denounces the Kaiser, and predicts that

The Teuton sword shall yet be sheathed in shame
And every blade engraven "Ichabod."

The second celebrates the heroism of our troops, of whom it is said:

They hail from the castle and slum;
They heed not the wounds that are galling;
They die to the roll of the drum.

The author has a decided gift of verse, and he is to be congratulated on the patriotic feeling which has led him to use that gift in the service of his country. *Drina Drippings* comes to us from a hospital ship. It is a monthly periodical and is intended for the entertainment of those serving on board the *Drina*. The contents are varied and amusing. The verse is of a comic character. The editors are worthy of high praise for their enterprise and success in producing their little magazine under the difficulties they must have had to encounter.

FIRST-AID USE OF ANAESTHETICS IN THE GERMAN ARMY.

Professor Schleich, whose name is associated with modern improvements in local anaesthesiā, has recently advocated the more extensive use of anaesthetics in the field. He even goes so far as to urge the administration of anaesthetics by every soldier, who should carry a small bottle on active service. Chloroform alone is too dangerous for the layman to give himself, while ether is apt to excite the patient, making him toss about and aggravate his wounds. Neither of these drugs should, therefore, be entrusted in the pure state to the soldier. Professor Schleich recommends the following mixture, the efficacy of which he has already tested in the present campaign. The mixture contains ethyl chloride, chloroform, and ether in the proportions of 20, 40, and 120. The man saturates a handful of cotton-wool with this mixture, and presses it to his nose and mouth while he breathes deeply. He quickly loses consciousness, and no longer being able to hold the cotton-wool to his face, the further administration of the anaesthetic is automatically prevented; so Professor Schleich believes, but if the man were lying on his back this might not happen. The loss of consciousness is followed by a prolonged sleep, and when death supervenes it is, according to Professor Schleich, invariably due to the wound and not to the anaesthetic.

The new calendar of the Royal Society of Medicine for the session 1914–15, which has recently been issued, shows that many of the sections have felt compelled to reduce the number of their meetings, in view of the fact that so many of their members are engaged, directly or indirectly, in connexion with the war. The president of the society is Dr. Frederick Taylor, who recently succeeded Sir Francis Champneys.

THE WAR.

ANTITYPHOID INOCULATION.

ANTISEPSIS: RESPONSIBILITY OF INOCULATORS.

Much has been written in the Journal recently on the subject of antityphoid inoculation, but we have reason to believe that some uncertainty may still exist in various directions regarding the exact procedure which it is desirable to adopt, and the precautions that require to be taken to guard against the possibility of septic infection in carrying out inoculations on an extended scale.

In antityphoid inoculation we possess a method of protection of the utmost value. It is a preventive measure which can confidently be relied on to remain effective at the seat of war. It is almost, if not quite, inevitable that sanitary measures of all kinds should fail from time to time in the emergencies of active service. It is, therefore, a matter of the highest importance that the inoculation method should be recognized by our troops, and by the country at large, as being not only reliable but also harmless.

Clearly, no hard and fast rules can be laid down in regard to actual detail, but it may not be amiss to indicate again in general outline the methods which are broadly applicable, and the precautions which should be regarded as essential.

The Vaccine.

The vaccine employed is a sterile suspension of killed typhoid bacilli, sent out in sealed phials, which should be kept in a cool, dark place until required. Before use each phial is well shaken to ensure a uniform distribution of its bacillary contents. It is then opened with all due aseptic precautions, the neck of the vessel being carefully "flamed" both before and after opening. Except in special cases and in the hands of experts, a phial once opened should never be resealed or preserved for further use, otherwise the vaccine may become contaminated. Whatever remains of the contents when the inoculations are completed for the time being must be discarded.

The Apparatus.

The apparatus required for properly carrying out inoculations consists of a small sterilizer and spirit lamp (or Bunsen flame), a bowl of antiseptic solution for the

hands, one or two 1 c.cm. all-glass syringes with a selection of fine needles, and a pair of forceps. The syringes and needles are well boiled at the outset, and during the inoculations are replaced in the sterilizer and reboiled from time to time, the work being carried on meanwhile with a fresh syringe taken from the sterilizer by means of the "flamed" forceps.

It is best to make use of platinum iridium needles. These can be sterilized by heating to redness in the flame after each inoculation. Steel needles quickly lose temper and sharpness in the flame, and if they are used "flaming" is inadmissible, and a fresh needle must be picked out of the sterilizer for each inoculation, so that half a dozen or more needles would be required by each operator. It is important to insist emphatically on the resterilization of the needle before each and every inoculation, not only to avoid sepsis, but also to prevent the possible transmission of other grave infections.

The vaccine is drawn up into the syringe from the phial, and when the dose is measured care is taken that no air is left in the nose of the syringe.

Site of Inoculation.

The site of inoculation is so chosen that the local reaction may cause a minimum of discomfort and incapacity to the subject. The left upper arm, at a point just below the deltoid muscle, has been the situation usually selected, but we understand that it is now considered better to make the injection below the clavicle. The injection is made into the deep subcutaneous tissue—not hypodermically and not into muscle or fascial planes, otherwise the local reaction is likely to be more severe and painful than it need be.

Method of Inoculation.

The arm being clean (in the ordinary sense of the word), the assistant-cleanses the site of inoculation either with ether and alcohol or an antiseptic. Probably the quickest and most satisfactory method of preparing the skin is to dab a small area liberally with tincture of iodine (*B.P.*). The operator then takes up a generous fold of tissue. If the injection is made into the upper arm the limb should hang limp and relaxed. The needle is introduced from above downwards and pushed well in before making the injection. The fluid should run easily, encountering no appreciable resistance. As the needle is withdrawn a small pledget of sterile cotton-wool is momentarily pressed over the point of puncture and the inoculation is completed. But, if the needle is not fine or not very sharp, the puncture may be sealed with a drop of collodion.

The Subject.

The subject should not be told that the inoculation is quite negligible and will cause no inconvenience. He should be told that there will probably be soreness for some days and that he may feel more or less indisposition, headache, or feverishness for a day or two. He will then be under no unnecessary apprehension when these symptoms appear, and if he escapes them he will not feel any the less satisfaction. He should be advised to avoid alcohol for the time being. Whether the injection be made in the arm or into the infraclavicular region, the local reaction will be much diminished if the arm be kept at rest so far as possible, and the general reaction is both diminished and curtailed if the subject is allowed a full day off duty after inoculation. The first symptoms are usually felt within from four to eight hours.

Systematic Organization of Inoculations.

Vaccine inoculations are extremely simple and easy to perform, and they are practically free from risk of any kind when carried out singly under the ordinary conditions of medical practice. But where large numbers of individuals are dealt with in rapid succession, probably in surroundings not particularly adapted for the purpose, and the sitting extends over a period of several hours, accidents and mistakes can easily occur if the operators allow haste, or familiarity, or fatigue to lessen carefulness and concentration of attention. The greater the number of inoculations to be made the greater is the need for scrupulous cleanliness as well as for a precise and methodical technique. And since the observance of a due ceremonial is probably the best check on any tendency to negligence or inattention in a routine procedure, the operator and his assistant or orderly may with advantage put on clean white coats and otherwise prepare and maintain themselves as for a minor operation of aseptic surgery.

Responsibility of Inoculators.

It is impossible to use too much care in carrying out the inoculations. The men who are now being urged to undergo the treatment are told, and are rightly told, that the vaccination is a simple and harmless procedure, ordinarily entailing at the most a day or two of moderate indisposition and a rather sore arm. It is therefore not right, and it ought not to be possible, that any man who has been given an assurance of that kind should, through inadvertence, negligence, or the operator's fatigue, be submitted to the risk of septic infection. Should such an infection occur there will of necessity be a strong presumption, and indeed a very high degree of probability, that the technique of the inoculation was at fault, and the responsibility of the operator will be very grave. In particular cases there might possibly exist some other explanation. But unless and until such an explanation appeared the operator would remain under suspicion. Moreover, if such accidents occurred not only would the risk of a serious injury be entailed on the individual sufferers, but by discrediting the procedure and bringing it into disrepute among the troops a gross disservice would be done to the State.

THE HOUSING OF THE RECRUITS.

THE expeditious housing of a new army in training has presented a serious problem to the military authorities. During recent years the method of placing soldiers in barrack huts has grown in favour, both in the British and German armies, and in the present emergency this form of structure appeared to furnish the most ready and simple means of housing troops on Salisbury Plain, and also the new recruits where it was not advisable to billet the latter upon the civilian population. Huts are being erected accordingly on an extensive scale in various parts of the country, to serve both as quarters for the men, from twenty to fifty of whom are accommodated in each hut, and as places of storage and general military use. The advantage of huts as compared with tents in the winter time is obvious, and if they are to serve only a temporary purpose the use of a wooden frame with some kind of asbestos roofing commends itself on the ground of economy. Timber hospitals also are being erected in the South of England.

The increasing scarcity of timber, however, has to be reckoned with. Practically the whole of the cheap timber imported into this country comes from the forests surrounding the Baltic, and a state of war has the effect of limiting severely, where it does not annul, this industry. In the event of protracted war, involving greatly increased enlistments, the expenditure on timber huts would become formidable. In the United States wooden buildings have hitherto been extremely common, but the price of lumber has advanced during the last few years almost to prohibitive figures, and a substitute has been found in concrete. In addition to the advantage that it is a more stable material, its final cost has proved to be not much greater, and in some localities even less, than that of wood. The result has been to make concrete structures popular in America, even for quite unambitious purposes, such as stables, dairies, greenhouses, barns, and farm buildings.

The possibility of erecting concrete huts for the men in training has been brought under the notice of the War Office, but it appears that at present in this country timber has the advantage over concrete for temporary structures on the score of cost, expedition, and mobility. The question remains as to whether the higher degree of sanitation and comfort which is secured by concrete is sufficient to reverse the balance. Although wooden huts, when well constructed, may pass a hygienic test, they are far from ideal. The protection afforded by timber against cold and damp is frequently very unsatisfactory. Timber harbours vermin; as the Master of Christ's College pointed out in his recent article on the subject of bugs,[1] the minute interstices of wood furnish readily an almost unassailable home for those insects which are among the plagues of camps. Yet again, the inflammability of timber is a consideration

[1] BRITISH MEDICAL JOURNAL, September 26th, 1914.

which has ruled out the timber dwelling-house from urban areas.

A concrete hut would certainly be a protection against these evils. Concrete is vermin proof and lends itself more readily than wood to disinfection and sterilization. The interior of a concrete hut could be quickly and thoroughly flushed from top to bottom with hot steam, or washed with an antiseptic. The rat also is known to have a great aversion to concrete structures. The fact that this material would stand the conflagration test is worthy of being borne in mind, in view of the possibility of bomb dropping. Properly made concrete, further, is a protection against the weather. The hollow concrete blocks of 8 in. thickness, which are usually recommended for one-story erections, have the advantage that the cavity between the two facings acts as a non-conductor, with the result that the temperature within the structure is equable; like the tube railways, it is cool in summer and warm in winter. This concrete-block construction is an alternative method to the better known reinforced concrete. In the latter there is no cavity, but the ordinary materials of concretion (sand, broken stone, and cement) are strengthened by the addition of a steel skeleton. The experts we have consulted agree that reinforced concrete would offer no advantage for this particular purpose over concrete blocks, that the process of manufacture would be too unwieldy, and that the longer time which the reinforced concrete takes to dry and harden (at least six weeks) is against its use in this instance. An even cheaper and more rapid concrete method consists in the use of what are known as concrete slabs, some 3 in. in thickness, which can be waterproofed by roughcasting on the outside surface, but it seems likely that some method of strengthening would have to be employed in order to support the roof.

The question of relative cost is difficult, and only the roughest estimate can be given. Much depends upon whether the materials for making concrete are available in the locality; in Lancashire, for example, rapid and cheap concreting of this description would be impossible, as the materials would have to be carried thither from Wales or Yorkshire. Given a favourable locality, it would seem, from some figures supplied to us, that the concrete shell of a hut, apart from finishing, might be put up at a cost of less than £5 per man, supposing each man to have a cubic space of 500 ft., which is the minimum of the military hygienist. One builder of wide experience assured us that the first cost of a concrete would be at least twice as much as that of a timber hut; but as the turning out of sized concrete blocks is merely mechanical repetition, the price would diminish in inverse ratio to the size of the order, and if timber goes on advancing in price—it has already appreciated by 25 per cent. since the war started—the difference between a concrete and a timber structure would probably be nearly negligible. First cost, however, is not the only consideration. Timber structures can be made in sections at the works, and sent down to the camp, where each marked piece can readily be put up by the soldiers themselves. Concrete buildings, on the other hand, would require a gang of labourers to be sent down for the laying. The timber hut also can be taken down and removed quickly to another site, whereas the concrete hut, which must have, by the way, a concrete foundation, does not lend itself to this treatment. When the purpose of these structures has been served, the timber can be sold, but the market value of the concrete blocks would be small, owing to the cost of transporting them. Timber huts may be put up very quickly, but the making and seasoning of the concrete blocks would involve a delay, varying with the degree of humidity in the atmosphere, but usually about four weeks, from the giving of the order to the commencement of laying. The laying, however, would be a very rapid process, and the huts would be habitable immediately after erection.

Although as many as possible of the new recruits will be lodged in private houses, a large proportion must necessarily have hutment. A great number of these recruits come from gentle homes and sedentary occupations, and the rough initiation into camp life must expose them to certain physical perils, which might, however, be diminished by a little extra attention to the question of healthy and comfortable housing.

THE BRITISH RED CROSS SOCIETY.

Adequacy of Arrangements for British Wounded.

Sir Frederick Treves informs us that so far as the British wounded in France are concerned it is probably now safe to say that the supply of surgeons, dressers, orderlies, and nurses meets every demand; indeed, more surgeons and nurses have been sent out than have been actually applied for. In addition to the large British Red Cross party of surgeons, dressers, orderlies, and nurses—numbering 100 in all—already dispatched to Paris, the Society on October 6th sent another 15 surgeons and 54 nurses. There are still about 200 surgeons and 1,000 fully trained hospital nurses on the waiting list—a fact that should be noted in view of statements appearing from time to time in the lay press that there is great need for surgeons and nurses.

Plight of the French Wounded.

Matters are not so satisfactory, unfortunately, with regard to the French wounded. The problem of dealing with them is, of course, a far larger one, and the finances of the French Red Cross Society unhappily seem to be restricted. Payment of expenses is promised, but beyond that the Society apparently is able to do little. There is no doubt that the French Society is greatly in need of help both as to personnel and supplies. A few surgeons and nurses have gone out as unpaid volunteers, and any British Red Cross surgeons and nurses who are not required for the British wounded will be placed at the disposal of the French, the British Society meeting all expenses and paying all salaries. Instructions to this effect have been given to the party just sent out. An enormous strain has been cast by the war upon the Army Medical Department of France and the French Red Cross Society, and it is not a matter for surprise that to some extent they have failed to meet it.

Tons of Stores.

The British Red Cross Hospital at Netley is nearly ready for occupation. The stores sent to the front amount to many tons a week; the *Sunbeam* alone on one voyage took nearly 1,000 cases, representing 50 tons of goods. The number of garments in the stores at the moment is about 75,000.

Supply of Motor Ambulances.

The Society is sending out a large number of motor ambulances, a special ship being chartered for the purpose. So generous has been the response of the public that it is hoped before long to have 200 motor ambulances in France at the disposal of the British army medical authorities and to add rapidly to this number.

THE NEED FOR MOTOR AMBULANCES.

We drew attention last week to the urgent need of motor ambulances for the conveyance of wounded soldiers in France from the field to the base hospitals, and it is gratifying to find that the need had only to be stated to meet with a ready response. The Scottish branch of the British Red Cross Society has promised that Scotland will provide ten motor ambulances, three commercial vans for transporting stores, and three motor cars for general use on the Continent. Early this week the number of ambulances promised, in addition to these, was 63—all offered free of cost to the Red Cross Society.

Sir Frederick Treves has addressed the following letter to the panel practitioners of London, to whom an appeal is being made by the Panel Committee to provide a motor ambulance for the British Red Cross Society:

October 4th, 1914.

Dear Sir,—A very striking feature in the present war has been the eagerness of the medical profession to be of help, and the splendid generosity with which that help has been tendered. A motor ambulance presented to the British Red Cross Society by the panel practitioners of London would, I think, be a crowning act in this display of whole-hearted patriotism. Such an ambulance at work on the road to the front would bear practical testimony to the sympathies of those medical men who are compelled to stay at home.

From the point of view of the wounded the motor ambulance is a very urgent need. The wounded, when picked up by the stretcher parties, are cared for in the field ambulances by the Royal Army Medical Corps, and there is abundant evidence to

show that the work of that corps has never been better done. At the advanced base also the wounded soldier has every possible comfort and attention. It is between the field ambulance and the advanced base that the grave difficulty lies.

As is well known, there is no special transport for the wounded. Some travel down in empty ammunition waggons, supply carts, and lorries, but the majority come by rail. The first demand upon the railway is for reinforcements, ammunition, food, and supplies. As a result, the ambulance train may be for hours standing in a siding. Sometimes, owing to constant delays, the journey has occupied three or four days. If the wounded be in a proper ambulance train this delay, although serious, is not disastrous, but when—as is often the case—they have to lie in cattle trucks and horse trucks on unclean straw, the result is terrible.

Most of the wounds are lacerated wounds due to shell fire, and the base hospitals abound with cases of "gas gangrene" (the acute traumatic gangrene of old days) and tetanus. These alarming troubles could only be effectually met by early treatment. Long delay on the road, under the worst possible surgical conditions, is deplorable and indeed calamitous. The motor ambulance makes use of the open road (and the roads in France are good), and brings the wounded down promptly to the advanced base—brings him, let us suppose, from Soissons to Paris.

Rapid transport is everything. With the lack of such transport, the wounded must suffer terribly, and the greatest kindness that the practitioners of London could do would be to help in providing the means for conveying the wounded man promptly from the front to a hospital bed.

Yours faithfully,

FREDERICK TREVES.

We are glad to learn that subscriptions to the fund are coming in so well that sufficient money is already in hand to provide one ambulance, and there is every prospect that the amount received in subscriptions will soon permit the provision of a second.

The suggestion is made in the following letter that the practitioners in each county should provide an ambulance by means of a guinea subscription:

Sir,—At the present time many medical practitioners must be wishing that they could be of direct assistance to our army in France, and yet they know that it is their duty to stay behind and look after the sick at home. There appears to me to be at least one way in which their interest might be made more direct, and I suggest that the medical profession as a whole should adopt it.

At the present time there is a lack of motor ambulances in France for conveying the wounded from the front to the nearest hospital. May I suggest that the medical profession supply this want?

A motor ambulance, I understand, costs about £400, and it would be a fine thing if the medical men and women in each county could supply one such ambulance. It might be understood that the subscription should be one guinea, and this could be collected by the Medical Officer of Health, who would know all the medical practitioners in his district, and forwarded by him to the County Medical Officer, who would, no doubt, be willing to undertake the general organization of the scheme.

If this idea appeals to any medical man or woman, he or she should communicate with the Medical Officer of Health, who would then urge the County Medical Officer to initiate the scheme.—I am, Sir, your obedient servant,

WALTER T. CORFIELD,
Medical Officer of Health.

Colchester, Oct. 5th.

AMBULANCE WORK AT THE FRONT.

By H. MASSAC BUIST.

DURING the past fortnight the need for still greater numbers of motor ambulances has become more and more widely recognized. The response to the appeal for these vehicles for the British Red Cross Society and for the St. John Ambulance Association is of a gratifying character. But there is still much to be done. The area of operations is very extensive, and the casualties experienced are on an unprecedentedly large scale; therefore, a dozen machines here or there is as nothing. Further, too large a proportion of the gifts received towards this end appear to take the form of ordinary pleasure cars, whereas it is undoubtedly better, wherever possible, to have vehicles specially constructed for the purpose, as distinct from the adapted class, which, as was shown in a previous article, can nevertheless be made to serve on occasion.

In order the better to grasp the situation, it may be as well to consider what takes place at the front, because that reveals so clearly that the need for motor ambulances is more urgent in this campaign than in any previous one. That might not appear on first considering the matter, because the answer would be that the campaign in the west is being waged in a region well furnished with railways. These, however, must first be used for assisting in the conveyance of troops and supplies to the fighting line, therefore the wounded have perforce often to be delayed in trains shunted on to sidings, and so forth, apart from which the injured have frequently to be transported many miles from the field ambulances to the advance base. They can only be picked up at night, because of the shells falling in the daytime. Any available conveyance has to be used to take them to the rail head, where the train may be shunted into a siding to allow of the transport of troops, ammunition, or supplies to the front. Wherever a sufficient number of motor ambulances are available, however, all such difficulties are obviated, the injured being taken straight from the field ambulance to the advance base hospital, hence the need for motor ambulances and more motor ambulances.

Some two hundred extra ones have been sent by the British Red Cross authorities, but hundreds more can be used with advantage at the front. Therefore every effort should be made to swell the funds that are being raised for the purchase of such machines and for adapting ordinary cars to motor ambulance requirements. All wealthy owners of large cars, and especially such folk as keep a stud of motor carriages, should be urged to offer one or more to the British Red Cross Society or the St. John Ambulance. They should give machines of as strong, as well sprung, and as long a wheel base as possible, since these are most easily converted to the needs of the hour. Experience has shown the immense superiority of the motor ambulance over the horse variety, wheel litters, or similar contrivances.

PETROL VEHICLES ALONE PRACTICAL.

At the front, of course, it is possible to employ only one class of vehicle—the petrol variety. The electric sort is impracticable, first, by reason of its comparatively short range of action without recharging; secondly, by reason of the great disadvantages under which it labours should it be operating in a region where there are any appreciable gradients; and, thirdly, because, whereas about seven years ago the electric vehicle was the most luxurious form of town carriage, to-day these run by no means as smoothly as the best petrol cars, the weight of the batteries and the comparative brevity of wheel base rendering them considerably subject to vibration. I speak of this from personal experience, having tried the electric vehicle in town when recovering from illness some two years ago, when I found the petrol variety infinitely better. Indeed, the situation has changed vastly since 1907, when the Corporation of the City of London began employing some electric motor ambulances. That was the slump year of the motor industry, and the petrol carriage as we know it to-day was really begun to be developed towards refinement in the following year.

Detachments of the City of London Branch of the British Red Cross Society have lately had motor ambulance drill in Regent's Park under the command of Colonel P. Broome Giles. He was particularly desirous of ascertaining which of the various types of motor ambulances assembled could be loaded most efficiently in the shortest time. It appeared from that particular test that the best was designed and built by the coach-making firm of Salmons and Sons, of St. Martin's Lane and Newport Pagnell. This has a door in the front, and an interior gangway between the tiers of the stretchers, whereby the wagon orderly is enabled alike to assist in loading and unloading, so obviating the entrance of the stretcher bearer for that purpose, and to give assistance to the wounded during the passage of the vehicle without having to stop it. This point was particularly appreciated by a number of medical officers present, and the time occupied in each instance in loading and unloading this particular ambulance was only one-third that taken by others present on the ground. This type of wagon accommodates four persons lying down, or two lying and half a dozen sitting, or, again, twelve in a sitting position.

The first batch of the British Red Cross Society's motor ambulances that assembled outside the Royal Automobile Club in Piccadilly before proceeding to France come out very badly from the engineering points of view brought out in notes published in these columns at the end of September. There was an extraordinary amount of overhang. Despite the fact that chassis of long wheel base were used, in some cases more than half of the portion

designed to accommodate the injured projected behind the back axle. This is very bad construction, and it is to be hoped that after the first rush is over better methods of adapting vehicles than have been employed in these particular cases will be exploited, for such systems mean that the injured are subjected to the maximum oscillations possible to be set up on the ambulance. Further, the mere provision of all manner of spring suspension for the interior fitments does not obviate the main drawback, though, of course, of two evils the lesser is that the patient should be plunged about on a sort of plangent stretcher in place of being subjected to jars.

Points when Adapting.

The early examples have necessarily had to be improvised with practically not a moment's delay, for in a war in which motor transport of all sorts was foreseen to be a vital factor, it is unfortunately the tragic truth that this country, which of all was in the position to have proportionately vastly more ample supplies than any other, nevertheless started the campaign with far too few motor vehicles, and especially with the most inadequate proportion of motor ambulances. Therefore at the moment we are in the position of having to improvise motor ambulances at short notices. It is only as the campaign proceeds to a later stage that we can hope to have leisure to send out to the front only such types of vehicles as are ideal for the purpose. At the moment we have still to continue making the promptest possible use of whatever material comes to hand. The rear springs of many pleasure cars taken have to be reinforced by a leaf or so each, not only to accommodate Continental road surfaces, but also to make them capable of carrying what is the equivalent of heavily loaded covered limousine body work. In the case of an ambulance the centre of gravity is somewhat higher than that of a pleasure car, owing to the disposition of the stretchers, and so forth; hence in the interests of the patients the difficulty of arranging suspension to avoid swaying. Drivers of motor ambulances, too, require to be specially instructed, particularly in the manner in which they take their corners, and so forth. Expedition is a good enough quality, but a few minutes extra taken in traversing each ten miles is time well spent if it is taken off the corner work. Further, there should be no slapping gears in and out in endeavours to rush up gradients. All the changes with the power transmission mechanism ought to be made as smoothly as possible.

The motor ambulance is needed not only between the field and the advance base, but also between various railway stations and important centres on the Continent where large hospitals are established. The wounded have to be taken from the stations to the hospitals. Motor wagons ordinarily employed for estate purposes are suitable for transporting certain types of casualties, as well as for the work of carrying hospital stores from point to point as need arises. There is some tendency to try the motor cycle and side-car, since these forms of attachments are often very plangently sprung. Against this, however, is the fact that the motor bicycle itself is generally an extremely noisy vehicle. There are many other disadvantages such as point to this being desirable only when no other instrument of transporting the wounded is available.

THE WOUNDED IN FRANCE.

[From a Special Correspondent in Paris.]

The late Lieutenant-Colonel Dalton.—Army Rank for Consultants.—Ambulance Trains.

The list of casualties among officers and men of the Royal Army Medical Corps is already very long, and seems certain greatly to lengthen. But whatever name may hereafter be included in the list, the loss of no officer will be more generally regretted than that of Lieutenant-Colonel Charles Dalton, whose career was briefly outlined in the issue of the British Medical Journal for September 26th. Not only was he a first-class officer of exceptionally wide experience in actual warfare, but he was an excellent comrade. The Army Medical Service has never lacked men of gallantry, but no man ever afforded better evidence of his possession of true courage than did Dalton. Several events in his life sufficed to prove it, namely, his conduct on the occasion of the sinking of the steamship *Cotopaxi* off the coast of South America some twenty-four years ago, for which he was awarded medals by both the British and French humane societies; and later in West Africa, when his efforts to save a wounded comrade were adjudged by those aware of all the circumstances to be worthy of the highest honour which it is possible for a soldier to gain. For his gallant conduct during the South African war he received the Arnott medal, a distinction open to graduates of Irish medical schools who perform any noble deed in the cause of humanity. The wound from which he died was not his first wound, for he was shot through the stomach during operations near Ladysmith, in South Africa, but made a complete recovery. There have been occasions when losses among the Army Medical Service have been asserted to have been due to officers and men thoughtlessly exposing themselves to quite unnecessary risks, but the fact that so experienced an officer as Dalton should have been twice wounded affords ample proof, if any be needed, that wounds and deaths among men who are nominally non-combatants are absolutely inevitable. At the time that he received his wound he had only just joined the head quarters of the 2nd Division 1st Army Corps as assistant director of the Medical Service, in succession to Colonel Harry Thompson, D.S.O., who fell into the hands of the Germans during the retirement from Mons. Dalton was well known in sporting circles in Ireland, where he won most of the events open to army officers at the military meetings—on one occasion riding his own horse. Only last year his horse Thoul Pin carried off the Irish grand military steeplechase at Punchestown. Those who knew him in his student days will remember him as a member of one of the best Irish International Rugby teams of those times. Dalton was never married.

I see in the *Morning Post* for October 2nd a record of the gazetting of Mr. Makins and Sir Anthony Bowlby to the Army Medical Staff. They came over about a fortnight ago and are attached to General French's staff as full colonels. Both of them gained experience of war surgery fourteen years ago in South Africa, and both joined the Territorial Force on its formation, and took commissions in its medical branch. These appointments are a compliment to the officers themselves, some think an even higher compliment to the profession as a whole than the appointments made by the Admiralty at the beginning of the war, of half a dozen more or less well-known men to serve as consultants at base hospitals in Great Britain at rates of pay equal to that of a Cabinet Minister. The new appointments, however, are far more than merely complimentary; they are a very practical step which affords fresh evidence of the sound sense with which the affairs of the medical department of the army are being conducted. Colonel Sir Anthony Bowlby and Colonel Makins are, practically speaking, free medical lances, able to visit any part of the line that they may deem desirable, and act as consultants in any case where a second opinion may seem desirable.

It seems to be generally admitted that the medical arrangements for the care of the British army have on the whole worked very well, and that, so far as avoidable suffering has not been avoided, it has been due to the immense difficulty of bringing down large numbers of wounded from the rail heads or clearing hospitals to the base. The journeys have often been very long and interrupted, little food has sometimes been obtainable, and the rolling stock employed has frequently been unsuited to the purpose to which it has been put. So long as a limited number of lines have to be employed for the dispatch of reinforcements, ammunition, and food there is bound to be considerable delay on the railway; but matters promise to be remedied to some extent by improvements in the type and reconstruction of French railway rolling stock and by the arrival of a complete ambulance train which is being fitted in England with wheels suited to Continental railways. It is expected to arrive quite shortly. In the meantime the British Red Cross Society has provided two trains, and is preparing a third, and has greatly increased its fleet of motor ambulances.

THE HOSPITALS AND THE WAR.

2ND LONDON TERRITORIAL HOSPITAL.

THIS hospital, which has been already described in the JOURNAL (SUPPLEMENT, September 5th, p. 163) has been admitting men from the Territorial Force for some time past; on September 29th it received 78 men from the front and on October 1st 141 more. Lieutenant-Colonel Eustace M. Callender, the commanding officer, this week gave a representative of the JOURNAL some interesting particulars of the cases. Most of them are wounds, many being very serious. There are a great many wounds of the upper extremity, compound fractures caused by gunshot; a few compound fractures of the femur, and two cases of wounds of the chest, one very serious, with pyopneumothorax. Most of the wounds were septic when the patients arrived at the hospital, but notwithstanding the majority have done extremely well under treatment.

One man has a rifle bullet lodged in the muscles of the upper part of the thigh. He was carrying a tin of tobacco in his trouser pocket and the bullet expended much of its velocity in passing through the tin. Consequently the wound is not serious, whereas, but for the obstruction, the shot would probably have been fatal. In another case two men were sharing between them the task of carrying a tin of "bully beef." One of them was arguing with his comrade that it was his turn to carry it and had received a refusal. Just then a bullet hit the tin and embedded itself in the beef which it never fully penetrated. If it had, the carrier's wound must have been fatal. Another man, when lying down firing, was shot in the neck. On his arrival at the hospital the bullet was found near the eighth rib, the wound in the neck having quite healed. The man stated that when hit he was convinced that his right arm was blown off. There was no paralysis of the arm, but the man suffers from intense and almost constant neuralgia.

Nearly all the wounds are due to shrapnel and very few to rifle bullets. The men express the greatest contempt for the German infantry soldier, and have no fear of him as a shot and still less of his bayonet.

There are a few bullet wounds passing through both buttocks, the men having been shot when lying prone. A few interesting medical cases have been received. One is that of a man who was on a canal bank when a large shell exploded close to him. He was uninjured, but the concussion disabled him and hurled him into the canal, where he remained, unable to help himself and up to his neck in water, for sixteen hours. As a result of the explosion he is quite deaf in one ear and partially so in the other, and is suffering from neurasthenia. Whether the deafness is due to nerve injury or to injury of the ear has not yet been ascertained. Another man was struck on the right side of the head by a piece of shell. It did not wound him, but ever since then he has had diplopia on the side on which he was struck. He is getting better; at first he had diplopia in using both eyes, but now only when using the right eye alone. There are some cases of heart disease, including two or three cases of mitral disease in which compensation has broken down. There are a good many cases of rheumatism and sciatica, attributed to the men having been constantly in wet trenches. There are several cases of gastric trouble of various sorts, due to imperfect teeth. There is only one case of enteric fever and one of dysentery; the latter was acquired in India years ago and has reappeared under service conditions.

There are about 400 men in the hospital, of whom 219 have been received from the front. The balance is made up of members of the Territorial Force embodied in various parts of this country. Service in the field brings out any defects in the men. The surgical staff has already operated on 25 or 30 cases of inguinal hernia, and there are still many in the hospital waiting for operation. A considerable number have been admitted for operations on varicose veins. In several cases serious heart disease—chiefly mitral—has rendered men unfit for further service. One man has complete congenital paralysis of the right deltoid, and can hardly raise his arm to an angle of 45 degrees from his body. Several cases have been received of extreme defective vision of the right eye. There are a considerable number of cases of acute tonsillitis, several cases of pleurisy, and several of pulmonary tuberculosis. So far only two cases of appendicitis have been admitted, and no cases of infectious disease amongst Territorials.

Men who have been at the front or who have been mobilized as Territorials tend to become verminous, and a regular routine is followed at the hospital to prevent the beds from becoming infected with lice. Each man's clothing is taken away on admission; his personal linen is steeped in a solution of cresol, disinfected in a high-pressure steam disinfector, and then sent to the laundry. The patient is given a bath and supplied with a complete outfit of hospital clothing. The outer clothing is disinfected by hot air, as steam is liable to shrink the material; the clothes then remain at the packstore until the soldier leaves the hospital. All cases of scabies and impetigo are isolated in separate wards. Men have reached the hospital in a deplorable condition—haggard, dirty, with matted hair, unshaven faces, and clothes stiff with mud or blood from wounds. In twenty-four hours, however, the change is so complete that the men are hardly recognizable as the same.

Enteric cases are kept entirely separate in every particular, alike as to nursing, bedpan, sink, etc. There has been no case of insanity, although this is rather common in a big war, and the hospital is equipped for such cases. Colonel Callender agreed with the suggestion that freedom from mental trouble might be due to the British soldier's philosophical attitude towards life. He said the men were extraordinarily cheerful; the more seriously injured a man was the less he grumbled. One lad, who was wounded at 11 o'clock in the day, spoke of his good luck in being picked up by the field ambulance as soon as 6 o'clock in the evening. Other men, with compound fracture of the femur, passed days in cattle trucks: they "did not mind when the train was running—it was when it stopped."

Colonel Callender said the adapted buildings of the hospital are serving their purpose admirably. Difficulties arise, but they are not serious; the sanitary and bathing accommodation is found adequate, and the school classrooms make satisfactory wards. A section of the hospital (200 beds) is established at St. Thomas's, and another (40 beds) at the Great Northern Hospital, Holloway. Of 124 cases admitted to St. Thomas's Hospital early in the war all except 7 have now been discharged; hardly any of them were seriously ill. The fact that these hospitals are so far from Chelsea, where the 2nd London Territorial Hospital is situated, makes the work of administration somewhat difficult; but matters have been considerably easier through the kindness of a lady, who has placed a motor car at the disposal of the medical staff.

3RD LONDON TERRITORIAL HOSPITAL.

Of the four Territorial General Hospitals in London, the most considerable structural works have had to be carried out at the 3rd London, for which the Royal Victoria Patriotic School has been vacated. Each general hospital is required to provide 520 beds, but the buildings of the Patriotic School afforded accommodation for about 200 only, and hut hospitals are being erected in the grounds. Until these are ready the number of cases that can be taken is limited; 120 men have been received from the front and some Territorials. These cases are being treated in the main buildings of the school, an early Victorian edifice built round a central quadrangle, and others have been received at the Middlesex Hospital, where a section of the Territorial General Hospital is established. Amongst the cases received from the front are two of tetanus; both are recovering, thanks to the early injection of antitetanic serum. Most of the cases call for no special comment; progress towards recovery is rapid, and there has not been a single death. A finely-equipped *x*-ray installation has been of great service, and bullets have been located that in earlier times must have been allowed to remain. In many cases, too, bullets have been found where their presence was not suspected. The patients received from the Territorial Force have been mainly cases of "young soldiers'" complaints; generally speaking, no serious defects have been revealed.

The commanding officer here is Colonel H. B. Bruce-Porter, the registrar is Major Miller, and the quartermaster Lieutenant Leopard. The consulting staff consists, on the medical side, of Lieutenant-Colonel Sir

James Kingston Fowler, Major Sir J. Rose Bradford, Major Lough, Captain Voelker, Captain Rissien Russell, and Captain F. J. Wetherell; on the surgical side, Major Sir Alfred Pearce Gould, Major Mayo Robson, Major A. E. Barker, Captain Sir John Bland-Sutton, Captain Murray, and Captain Kellock.

The grounds of the Patriotic School are ample in extent for the erection of supplemental buildings. The hut hospitals are ten in number, each containing 20 beds. They are placed on either side of a covered way, and are connected under cover with the main building. The material used in construction is corrugated iron lined with asbestos felt painted to render it impervious. Each hut has a verandah for convalescents, and the sanitary offices are connected with a main drain passing through the estate. At some distance from the principal building is an isolation camp, and in an outlying field are tents for the staff. Here huts are being built in readiness for the winter. A water tank at a considerable height above the temporary buildings provides a supply under head in case of fire. Some tumbledown sheds have been rebuilt to form a pathological laboratory, where Captain Dennis Embleton is doing valuable work. There is hot and cold storage for bacteria, a *post-mortem* room and mortuary, destructor and disinfector, the latter similar to those installed at municipal cleansing stations. The kitchens, which were already in order for feeding large numbers of people, have been supplied with hot-water mess-tins for the conveyance of food. Extensive as are the works, either completed or in progress, the grounds are large enough to provide ample space for convalescents. The 3rd London Territorial Hospital is a most interesting example of the work being done for the reception of wounded soldiers.

The London Hospital.

At the time of writing no fresh cases from the front have been received at the London Hospital beyond the 300 whose arrival some weeks ago was duly chronicled in the Journal (Supplement, September 5th, p. 162). The greater number of these men have gone to convalescent homes or have returned to the front, but the machinery for dealing with the wounded is still maintained in readiness even to the special lighting installation in the courtyards to facilitate admission if a batch of wounded arrives during the night. In the out-patient department soldiers discharged from the hospital, or soldiers on sick furlough, are being treated, the former in many cases for nerve injuries the after-effects of bullet wounds. Looking back over a period of strain, the medical staff is able to congratulate itself that a full service has been maintained for the treatment of the local sick; no suitable case presenting itself has been denied treatment. The daily surgical operating list is as heavy as before the war, and the only work suspended is purely clinical research. In the case of wounded soldiers injuries have been largely of the class with which the South African war familiarized surgeons. Each man has been submitted to *x*-ray examination as a matter of routine, and bullets have been found in men who did not know they had got them.

There is a good entry of students in the medical school this year, and the greater number of them have joined the Officers' Training Corps, so that when they get commissions they can be useful at once without preliminary dépôt training in drill. In the hospital promotions in the way of house appointments are now very rapid. Junior men are getting at once posts for which they might have reasonably expected to wait eighteen months. It is felt desirable that they should be trained by the hospital rather than by the Royal Army Medical Corps, though the arrangement gives added work and anxiety to the supervisory staff.

An Officers' Hospital in the City of London.

For the first time in any war—so it is claimed—a hall of one of the ancient City companies has been converted into a hospital for the wounded. At the instance of the City branch of the British Red Cross Society, and mainly through the generosity of City firms, approached through the wives of the aldermen of the several electoral wards, the Fishmongers' Hall at the north-west corner of London Bridge has been converted into a hospital for officers and completely equipped. Only the spacious apartments on the first floor are used for this purpose. The Great Hall, a lofty and handsomely decorated room, whose gilded walls and ceilings are as little like those of an ordinary hospital as it is possible to conceive, has been subdivided to form five cubicles, each containing two beds. The cubicles occupy that side of the hall on which the windows are placed, and are formed by wooden partitions 7 ft. 6 in. in height, covered with white enamel paint. About half the floor space is thus left free, except for a cubicle forming the matron's room. A smaller room overlooks the river, and affords a view of river and bridge traffic of unceasing interest and charm, all the more that the distance is sufficient greatly to reduce the noise of the vehicles crossing the bridge. This apartment has been divided into two cubicles, each containing two beds. Another room provides three cubicles of similar size and accommodation. At the back of the building—entirely removed from the sound of traffic—is a room which has been divided into three single-bedded cubicles, intended for the reception of very serious cases. All the rooms thus divided adjoin one another and are on the same level. Smaller apartments serve as the Roentgen ray room, anaesthetizing room, and operating theatre. The kitchen department is situate in the basement, two floors distant. This, if the hospital were a larger one, would probably prove an unsuitable arrangement, especially as a lift cannot be installed. The Fishmongers' Company, however, has lent the services of the men who carry the dishes at the periodical banquets, and arrangements which have been good enough for so epicurean a gathering as a City company at dinner will doubtless satisfy men fresh from the hardships of active service.

Not only in the surroundings, but in the furnishings, is the Fishmongers' Hall in its new guise very unlike a hospital. Each cubicle is distinctly homelike in appearance, with furnishings more like those of a private house than a public institution—down quilts on the beds, electric radiators for warming, an electric light and reading table to each bed, armchairs, and so on. Much thought and care have evidently been expended on every detail.

The medical administrator of the hospital is Dr. Howarth, the Medical Officer of Health of the City of London; the civil administrator is Dowager Lady Dimsdale. The resident medical officer is Dr. Mackenzie Wallace, of St. Bartholomew's; the consulting surgeon, Mr. D'Arcy Power; and the consulting physician, Dr. Samuel West. The matron is Miss Lightfoot, who nursed through the South African war; and the nursing staff consists of three sisters and eight nurses, all fully trained.

MEDICAL ATTENDANCE FOR DEPENDANTS OF MEN SERVING WITH THE COLOURS.

Belfast.

At a meeting of the Executive Committee of the Belfast Division of the British Medical Association the following resolution was passed unanimously:

> That we strongly approve of the extension to Ireland of the scheme of free medical attendance for dependants of men serving with the colours, and consider that the necessary steps should be taken to set up committees modified to suit the exceptional requirements of this country.

North Suffolk.

The following resolution was carried unanimously at a meeting of practitioners held at the Lowestoft Hospital on September 25th:

> We, the medical practitioners of the North Suffolk Division of the British Medical Association, agree that the dependants of those men who are serving in His Majesty's Forces should be attended gratuitously when their circumstances require it; we are prepared to give such attendance, but we consider that such charitable attendance should be a private matter between doctor and patient.

This resolution has been signed by the following:

> H. C. Barraclough (Chairman), H. M. Evans (ex-Vice-Chairman), W. Tyson (Honorary Secretary), J. M. Taylor, H. P. Helsham, O. W. Owles, E. W. Toulmin, D. Craig, L. B. Perry, W. Berry, J. F. Carver (for the Medical Institute), E. W. Wade, E. A. Collins, W. L. Bell, J. Aylen, M. Ffoulkes (L.T. for Dr. Boswell), J. C. Mead, C. Tiecburst (pp. H. M. Evans), R. T. Worthington, D. Hutchinson.

W. Sly, F. C. James, C. J. Acton, F. Maidment, P. J. de Nyssen, J. Allnutt, G. Schilling, W. E. Dixon, T. Lawson, R. W. Mullock, A. Marshall, G. Colbourne.

Dr. Warwick (Halesworth) and Dr. Fox (Beccles) have written expressing their agreement with the terms of the resolution, holding that each medical practitioner should decide for himself upon the merits of each case. In addition, the three medical men in Bungay, we are informed, express themselves as satisfied with local conditions. It appears, therefore, that the whole of the medical men in active practice in North Suffolk are in sympathy with the principle that the doctor should decide for himself upon the merits of each case coming under his care, and are willing to act on these lines.

Edinburgh and Leith.

On September 5th (Supplement, p. 161) a report was published of the meeting of medical practitioners of Edinburgh and Leith, at which it was decided that they should systematically co-operate with the Soldiers' and Sailors' Families Association, and with the local committee of the National Relief Fund with regard to the provision of medical attendance on persons rendered necessitous by the war. Dr. R. A. Lundie, convener of the Edinburgh and Leith Medical Emergency Committee then appointed, has addressed a circular letter to the medical profession in Edinburgh and Leith, stating that the bodies mentioned cordially welcomed the proposal, and had agreed to co-operate with the Committee in the manner therein suggested, and that the medical representatives nominated had been elected members of the various committees. The Edinburgh and Leith Medical Emergency Committee has issued the following memorandum:

Edinburgh and Leith Medical Emergency Committee.

Memorandum regarding proposed co-operation of the Medical Practitioners of Edinburgh and Leith with the Soldiers' and Sailors' Families Association and the Edinburgh and Leith Committees of the National Relief Fund with regard to the provision of Medical Attendance on persons rendered necessitous by the War.

For the purpose of this co-operation it is necessary that there should be medical representation (with nomination by the profession) on these committees to the extent of two members on each district committee of the Soldiers' and Sailors' Families Association, and on each local committee and ward subcommittee of the National Relief Fund.

This proposal does not invade the province of dispensaries, maternity hospitals, and other charitable medical institutions, or of the Poor Law. Persons who have been in the habit of receiving medical attendance from any of these should be directed to apply to them as before.

With regard to this limitation, it is suggested that these committees should confer, if need arise, with representatives of charitable institutions (hospitals, maternity, and dispensaries) with reference to the medical attendance on persons who would properly come within their sphere.

While it is recognized that in a large proportion of cases arrangements will be made privately between those affected and their medical attendants, there are likely to be others (their number depending on the acuteness and duration of the crisis) for whom special provision will be required. With regard to these, it is suggested that provision for their medical attendance might be facilitated by co-operation with the above committees thus:

(*a*) In the case of persons who have already applied to these committees for help:

1. By all information with regard to the persons whose applications have been granted or refused being made available to any medical practitioner applying for it. (The details of this can be subsequently arranged.)
2. By these committees furnishing to persons who, in their view, should receive free private medical attendance, vouchers to be presented to their previous medical attendants, or, if they had none, to some practitioner within a reasonable distance. In all cases in which it is possible the voucher should be presented in the first instance to the previous medical attendant.

(*b*) In the case of persons who have not yet applied to these committees for help:

1. By these committees inquiring, on the request of medical practitioners, into the cases of those who have applied to them (the practitioners) for free medical treatment, and about whose circumstances they may be in doubt.
2. By medical practitioners informing these committees of any necessitous cases which come under their notice.

An essential condition of this arrangement is that no voucher for medical attendance be given on a less stringent inquiry than is required for pecuniary relief, or its equivalent in other forms, and that vouchers be only given to persons who under ordinary conditions would have employed a private medical attendant.

A patient bringing a voucher to a doctor will be exactly in the same position, except as regards the payment of fees, as any other private patient. The doctor to whom he applies may undertake his case or decline to do so as he thinks fit. In the latter case the patient may apply to any other doctor.

The proposed arrangement is an entirely voluntary one on the part of the medical practitioners. It must in the meantime be regarded as provisional and experimental.

Dr. John Stevens, the Honorary Secretary of the Committee, sends us the following notes on some of the features of some the arrangements made:

1. It is automatically open to *all* members of the profession in the district, so far as they find themselves able to give service, and avoids any limitation of the service which might, and which in Edinburgh we know *would* to a considerable extent, result from the formation of a special list of those who consent to their names being put on it.

2. The co-operation with the committees secures important safeguards against practitioners being unduly taken advantage of.

3. The presence of medical representatives on the committees is an important service in itself, and is expected materially to promote the smooth and efficient working of the arrangements.

4. It does not commit any individual practitioner to give any service beyond what he considers it right to undertake, having entirely the nature of a free-will offering without anything of the nature of an obligation or guarantee; nor does it commit the profession to more than it is found possible to accomplish.

5. By the arrangement being made with the local committees of the National Relief Fund, as well as with those of the Soldiers' and Sailors' Families Association, it provides not only for the necessitous dependants of those serving with the colours, but also for the possible distress among the rest of the civil population due to, though arising indirectly from, the war.

NOTES.

OVERSEAS DOMINIONS.

Canada.

(From Our Canadian Correspondent.)

At the time of writing the first contingent of Canadian troops, consisting of over 30,000 men, is leaving Valcartier on its way to the front. With it goes a general hospital with equipment of 500 beds, under the direction of Dr. Murray MacLaren, of St. John, New Brunswick. The staff of twenty-one doctors and forty-two nurses is recruited chiefly from the Montreal General Hospital and from the eastern part of Canada; it includes Dr. F. G. Finley, of Montreal, as Physician-in-Chief, and Dr. Kenneth Cameron, also of Montreal, as Chief Surgeon. A stationary hospital also accompanies the troops. It is the intention that a second general hospital and a stationary hospital shall be sent with the next contingent that leaves the Dominion. No. 2 General Hospital will be recruited from Ontario and from Western Canada. Valcartier, which is seventeen miles from Quebec, was chosen some time ago as an artillery training ground. The health of the men has been excellent. A few cases of pneumonia have occurred and one or two cases of typhoid, but the latter were not contracted at the camp. It has been necessary to chlorinate the water as, on examination, it was found unfit for drinking purposes, and the success of the measures taken is shown by the fact that no cases of typhoid have originated at Valcartier. Inoculation against typhoid has been carried on systematically, and the results have been most satisfactory.

A splendid response has been made throughout Canada to the appeal for funds and the patriotic fund campaigns that have been conducted in the various cities have been successful beyond all expectation. The money will be expended in providing assistance for the families of the soldiers who have gone to the front. Over a million and a half dollars have been subscribed in Montreal alone, and other cities have been equally generous. The Canadian

naval militia is being organized, under the direction of the Hon. J. D. Hazen, Minister of Militia and Defence. One command will be sent to the Pacific, one to the Atlantic, and one to the Great Lakes.

FURTHER CASUALTIES IN THE MEDICAL SERVICES.

ARMY.

Killed.

In the casualty lists of October 3rd the names of Lieutenants W. O. W. Ball and J. Crocket, R.A.M.C., were entered as killed in action in the battle of the Aisne.

Lieutenant William Ormsby Wyndham Ball was educated in Dublin, where he took the M.B., B.Ch. and B.A.O. in 1912, and entered the army as Lieutenant on January 24th, 1913. He was recently stationed at Aldershot.

Lieutenant John Crocket was at Edinburgh University, where he graduated as M.B. and B.Ch. in 1908. Subsequently he served as house-surgeon in three Edinburgh hospitals consecutively—the Royal Infirmary, the Chalmers Hospital, and the Royal Hospital for Sick children. He got his commission as Lieutenant on January 24th, 1913, and was recently stationed in Edinburgh.

Missing.

Flood, Lieutenant R. A., R.A.M.C.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

EXPENDITURE OF DUBLIN HOSPITALS.

THE fifty-sixth annual report of the Board of Superintendence of the Dublin hospitals for the year 1913–14, just issued, deals with nine institutions. All the hospitals inspected fulfilled in an economical and thorough way the objects for which they were founded, and zeal and efficiency were displayed in their management. During the year the board went specially into the cost of maintenance of patients in hospitals and into the differences that exist. The inquiry satisfied the board that, while it was impossible to reach absolute uniformity, inasmuch as there was no recognized standard of living, there was practical uniformity. The differences above or below the average shown in the returns were mainly due to the class of patients treated. Those in which the number of children and fever cases treated was large showed a comparatively small expenditure under that head, and vice versa.

THE BELFAST WAR BABIES.

Queen Mary has graciously intimated her great interest in and her approval of the Belfast scheme for looking after the "war babies," the idea of which appears to her "to be an excellent one." The organization is working in connexion with the Soldiers' and Sailors' Families' Association, of which it is a branch of the Belfast division; it was among the first of such special schemes to be started in the United Kingdom. Already it is proving a very marked success, as is shown by the large and increasing number of wives resident in Belfast of soldiers fighting for their country, who are bringing their children—from earliest infancy up to 2 years of age—for advice and direction as to their general care and management to the Babies Club, Divis Street, Belfast. The greatest care is being taken by the ladies, who are voluntarily giving an immense deal of time to the work, so that by investigation and inquiry no unfair advantage shall be taken of the aid that is supplied. Indeed, the aim of the movement is, while providing assistance in absolutely necessitous cases, to encourage thrift and self-reliance on the part of the mothers, and to point out to them the best way by which they can help themselves.

PRESENTATION TO DR. WILLIAM MAGNER, CORK.

An interesting ceremony took place on September 30th at the Police Court, Cork, when Dr. William Magner, Assistant to the Professor of Pathology at University College, Cork, was presented by Mr. Starkie, the Resident Magistrate of Cork with the certificate of the Royal Humane Society for having on July 6th, 1914, gone to the rescue of a boy who was in imminent danger of drowning in the river Lee at Cork. Dr. Magner gallantly jumped into the water without waiting to divest himself of any of his clothing, and brought the boy safely to the bank of the river. Mr. Starkie, on behalf of the magistrates of Cork, handed the certificate to Dr. Magner, and congratulated him on his very plucky conduct in rescuing this poor boy. Dr. Magner said that while not wishing to assume an air of false modesty, he thought too much had been made of the affair, but he was very proud to receive the certificate which he would treasure. He thanked Mr. Starkie very sincerely for the kind reference he had made to his conduct.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

MANCHESTER AND DISTRICT.

THE RADIUM SUPPLY.

THE war has had an unforeseen effect in facilitating the work of the Manchester Radium Committee. At a meeting of the committee on October 2nd it was stated by Sir William Milligan that the committee would be able to commence work at the beginning of November, and would be much better equipped than was at first expected, as it had been able to obtain a supply of radium quite six months earlier than anticipated. About £5,000 worth had already arrived, and Sir William stated that on the outbreak of the war he had communicated with Pittsburg, in the United States, from which locality radium is largely obtained, and he had learnt that a considerable amount had been ordered for use in the German hospitals, but that Germany could not now take it, and he had accordingly wired that the Manchester committee would purchase the stock. This was agreed on, and by the end of next week it is expected that about £15,000 worth will have arrived. The total amount of the Radium Fund now stands at about £31,000, and sums are still coming in.

THE MANCHESTER DENTAL HOSPITAL.

The committee of the Manchester Dental Hospital is to be congratulated on the valuable assistance it has rendered to the recruiting for the army. If the ordinary dental standard for the army had been strictly enforced, the examining medical officers would have been compelled to reject a large number of candidates, and the Dental Hospital has undertaken to attend to the teeth of all men who are in other respects suited for enlistment. Over 3,000 extractions have been made and a large number of fillings have been done, and artificial teeth have been supplied in about 300 cases. In order to cope with the extra work, the ordinary staff has invoked the assistance of dental practitioners in Manchester. All extractions and fillings have been done free, but where artificial teeth have been supplied the patients have been asked to contribute as far as they could afford, but as many of the patients were out of work and unable to contribute anything, only a comparatively small amount has been received in this way. The total cost of materials used is something like £500, and to meet this the committee has been compelled to make a special appeal to the public for funds.

Correspondence.

ANTITYPHOID VACCINATION.

SIR,—Through the courtesy of your JOURNAL, may I ask my colleagues to send details of cases in which unusually severe or protracted symptoms have followed antityphoid vaccination? That they occasionally occur is well known, but I am being bombarded with antivaccination literature, some of which contains reports of very unpleasant results. Special cases within a reasonable distance of London I should be glad to see with my colleagues.—I am, etc.,

Oxford, Oct. 3rd. WILLIAM OSLER.

INSECTS AND WAR.

SIR,—In the interesting papers by Dr. Shipley I have not seen any mention of a simple preventive to, I think, nearly all insects—for example, fleas, lice, bugs, etc.; I mean ordinary flowers of sulphur.

Over thirty years ago, when house-surgeon at the Children's Infirmary, Liverpool, I used this with absolute success in all cases of plaster of paris jackets who

formerly had been much distressed by vermin getting under the jacket. The sulphur was rubbed well into the underclothes. I suggest all on active service should rub it into their clothes, and gently shake out the superfluous sulphur into their change clothes.—I am, etc.,

Leyton, N.E., Oct. 4th. HARDING H. TOMKINS.

PNEUMOCOCCI AND BILLETS.

SIR,—I always read Sir William Osler's addresses with pleasure and advantage, and his address to the soldiers in camp at Churn is no exception to the rest. Sir William names three diseases which may almost certainly appear, even in sanitary camps, as the winter progresses—namely, dysentery, pneumonia, and typhoid. For two of these—the first and the last in the series—he gives good preventive advice. For pneumonia he does nothing of the sort—that is, he seems to me to leave it to warm clothing, etc., which auxiliary aids to health are of little value to a half-starved private at the bottom of a muddy trench! "Fools rush in," to quote a familiar tag, and, classing myself in this category, may I be permitted to suggest a preventive course of treatment which the university professor has overlooked? I speak from many years' personal and professional experience. The pneumococcus with other microbes are commonly billeted in healthy oral and nasal cavities, where they apparently live a symbiotic life of peace and comfort and cause little inconvenience to their healthy host. When, however, his health fails, they immediately start the exploration of his unhealthy tissues, get, it may be, into his blood vessels, and sooner or later upset his "apple cart." Now, the problem before us is how to check this invasion—how, in military parlance, to turn their wrong wing! This is effectively done in nine cases out of ten (to be modest in my estimate) by cleaning the mouth and throat daily—that is, by brushing the teeth and gargling the posterior nares thoroughly with clean water. If, however, the soldier still feels discomfort in his throat (and nearly all chills, I believe, affect this region at their onset), then let him place a pinch of salicylate of quinine on the tongue and draw in his breath, when the powder will spread itself over the pharynx and remain there to the great discomfort of the microbes. Another way is to gargle with ammoniated tincture of quinine (ʒj to ʒj) and swallow the result. As regards tooth cleansing, why not pluck a "twig" from the tree of Indian knowledge and use one for that purpose?—I am, etc.,

October 3rd. W. A. H.

AN ANTIVIVISECTIONIST FIXED.

SIR,—May we point out that by giving prominence to the charge of the prosecution in the case of Rex *v.* Kidd on a point which was not accepted by the magistrate, you have conveyed a totally false impression, doing our client the grave injustice of suggesting that she published and dispersed a spurious copy of the official report of the inspector under the Vivisection Act? The magistrate, Mr. Hopkins, expressed himself satisfied that the book in question did not purport to be the inspector's report. Such an assumption was clearly untenable by the fact that on the second page of the small booklet referred to occur the words: "Two prominent features mark the inspector's returns under the Vivisection Act for 1912. The first is the extreme laleness of their issue," etc. Thus it criticized the very document it was alleged to purport to be. The booklet was one published and printed by another lady in Manchester, and our client infringed the law by gratuitously distributing a limited number, being unaware that the law requires the name and address of the printer to be appended to all published matter, and holds the disperser responsible.—We are, etc.,

UNDERWOOD, PIPER, AND HEYS-JONES.

London, W., Oct. 5th.

*** We can scarcely be held responsible for "conveying a totally false impression," as the account of the case which appeared in the BRITISH MEDICAL JOURNAL was taken from the *Daily News and Leader*, a newspaper which we have always regarded as favourable to the anti-vivisectionist cause. The letter in the *Daily News and Leader* of October 1st from Miss Beatrice Kidd's solicitors, explaining her position, only came under our notice after the JOURNAL of last week had gone to press.

Obituary.

SIR HENRY D. LITTLEJOHN, M.D., LL.D.EDIN., F.R.C.S.E.

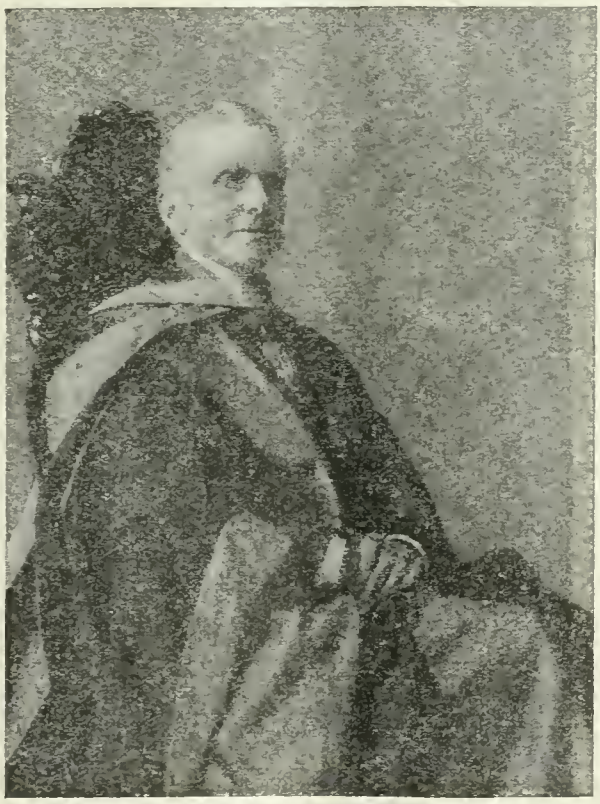
IT may be three years ago, it certainly is not much more, since Sir Henry Littlejohn's lithe, active, and wonderfully youthful figure was seen on the streets of Edinburgh. He would take his stand between two of the stopping places on the cable car system; the driver of the oncoming car would receive from a slight imperious gesture of Sir Henry's hand the intimation that he was not even from courtesy to slacken speed; and then, with an easy spring, well timed and adroitly accomplished, the professor was on board before the onlooker had time to speculate on what might befall. The incident was characteristic of Sir Henry Littlejohn's whole career: boundless energy, amazing vitality, a perfect grasp of the psychological moment, and rapidity of performance which no sooner met with than it overcame one after another of the sanitary difficulties of the health conditions of the city of Edinburgh. For over forty years he was an ideal medical officer of health, and for years to come his cleverly conceived and masterfully accomplished hygienic reforms will continue to shine forth from the pages of the annual reports of the health of the city, and to work their beneficent way in the slums and closes which cluster round the Cowgate and Canongate. There would have been worse slums and many more closes had it not been for the cleansing wrought during Sir Henry's long term of office as health officer. There is talk already about the raising, when these days of stress are over, of a permanent memorial to Sir Henry Littlejohn; but Edinburgh's low death-rate is his great monument.

Henry Duncan Littlejohn was born in Leith Street, Edinburgh, in 1828, and he died at Benreoch, Arrochar, on the last day of September, 1914, having attained the great age of 86. His education was accomplished at Perth Academy and at the Edinburgh Royal High School, whilst his medical training was gained in Edinburgh University and in the Royal College of Surgeons of that city. At the Sorbonne, too, in Paris he studied for a time. L.R.C.S. in 1847, he graduated M.D. in the same year, and became a Fellow of the Royal College of Surgeons of Edinburgh in 1854.

A year later, in 1855, he began to lecture in connexion with the School of Medicine of the College, and for forty-two years he edified and delighted successive generations of students with lectures and what may be called field demonstrations on medical jurisprudence and public health, which certainly have never been surpassed for their vividness, raciness, indestructible memorability, and compacted contents. With humour which was contagious, with wit which was sparkling and even disconcerting to the unwary, with gestures which were intensely dramatic, and with an immense collection of extraordinary anecdotes, each one illustrating a "point" in forensic medicine or hygiene, which it was well should be remembered, Littlejohn held his students spellbound whilst in his class and sent them out from it with certain invaluable pieces of knowledge impressed upon their mind with a security and permanence which resisted the tooth of time for a life's span. When at the present day three or four of Sir Henry's old students meet and when the talk turns upon his teaching, the conversation with absolute and rapid directness takes the form of successive interrogations, such as, Do you remember his story of that murder trial, of that railway journey from Granton, of the burial of the foot in Inchcolm, of the suffocation with the piece of tripe, of Madeleine Smith and Madame Tussaud's, of the ventilation of the Albert Hall, of the water supply of ancient Rome and of modern Athens, and of the drainage system or no system of such and such a place? The Saturday excursions, too; what exciting memories cluster round them. The visit to Craigentinny sewage farm with its odours and its obelisks (which "had nothing to do with the case"); the look in at the law courts—stuffy, empty, but filled in a moment at the touch of Sir Henry's wand of reminiscence with judge, jury, criminals, medical witnesses, and perspiring general public; the climb at break-neck haste up Liberton Hill to see the filter beds with Littlejohn far ahead explaining details all the way and appealing to his breathless students

in the rear for an assurance that they "followed him"; the examination of the slaughter-houses, the graphic description of the abattage of cattle and of the mysteries of how the blood was got rid of for the scouring of the amenity of the neighbouring dwelling houses; all these experiences come back as in a flash to the men who were privileged to take part in them. When in 1897 Sir Henry was placed into the chair of Medical Jurisprudence in the University of Edinburgh, that institution received from the extra-mural school of medicine a rich gift indeed; the professor was then 69 years of age, but he believed, and rightly, that he had some five or seven good years of teaching ability still left in him.

But Sir Henry Littlejohn's full life contained much more than his work as a teacher. He was made medical officer for the city of Edinburgh and surgeon of police in 1862, and the former post he held for forty-six years; during this time, practically half a century, all that was done for the improvement of the health of the city (and it was much) bore the impress of Sir Henry's personality; drainage, water supply, bake houses, byres, street widening, overcrowding, epidemics, notification of infectious disease, fever hospital—all these, and many more, received from him in turn his keen attention, and never without a following advantage, which was easily recognized in the improved vital statistics of Edinburgh. A favourite saying with him was that a medical officer of health should always be poking about looking for things that were wrong (hygienically) and then be busy putting them right; and he practised what he preached.



SIR HENRY D. LITTLEJOHN.
(Photograph by J. Moffat, Edinburgh.)

Then, again, there was his work as medical adviser to the Crown in Scotland in criminal cases, and his appearances in court as an expert witness. Some one has said that he loved the witness box; truly when he was in it, and especially during his cross-examination, there was no lack of interest, and the lawyer who faced him was lucky if he got off with only a few "palpable hits."

He had also a leading part to play in the foundation of the Royal Hospital for Sick Children; he gave years of service to the Board of the Royal Infirmary; he was an examiner in medical jurisprudence in connexion with the triple qualification of the Royal Colleges; and in later years he was to be seen many a time at the daily religious service held in the Moray Aisle in St. Giles's Cathedral, a few yards distant from the public health offices in the High Street.

Into this fully packed mosaic of a life Sir Henry Littlejohn also managed to introduce the doings of his duties as President of the Royal College of Surgeons (1875–6), of the Medico-Chirurgical Society (1883–5), and of the Institute of Public Health (1893). How he found interstices for these pieces of work no one could say, not even himself; but we may conjecture that it was because, as some one said of him, he had "no to-morrow in his vocabulary," because his maxim was "Don't put off to the next moment what can be done in the present one." Besides this, he had a healthy body, which seemed almost immune against all ordinary ailments—there is a legend that he once had typhus, simply because every one took it in these early days—and he seemed, as Sir William Turner expressed it, to have "found the elixir of unfading youth." These are possessions which enable a man, if of the right sort, to do much work. Bailie Pollard, who was intimately associated with him in the health of Edinburgh, said he had "not a lazy muscle in his body," and someone else capped this with "nor an idle fibre in his brain." With such an equipment one can go far and achieve much. It is no wonder that his Alma Mater made him LL.D. in 1893, and that two years later Her Majesty Queen Victoria conferred upon him the honour of knighthood. To the writer of this appreciation he gave many signs of kindliness, from the time when the former modestly endeavoured to accept his teacher's invitation to write an essay on abattoirs up to the last year during which Sir Henry occupied the Chair of Forensic Medicine in the University. It must have been a great satisfaction to Sir Henry Littlejohn, when, on his retirement from the Chair, the Crown elected to it his son, Professor Harvey Littlejohn; and the University has every reason to be satisfied likewise.

Sir Henry Littlejohn was one of Edinburgh's and of Scotland's great men, and his work as medical jurist and as hygienist will be enduring and fruitful everywhere.

In accordance with his own wishes—for he was strongly in favour of cremation—the remains of Sir Henry Littlejohn were cremated in Glasgow on October 3rd; the ashes were afterwards interred at the Dean Cemetery, Edinburgh.

Mr. D. Scott Moncrieff (Edinburgh) writes: Some of the many admirers of the beloved and lamented Sir Henry Duncan Littlejohn have asked me, as having once been a school fellow of his, if I can give them any idea as to his characteristics and appearance in his boyhood. Although a school fellow of Sir Henry, I was not one of his class fellows, my intercourse with him having been confined to the session of 1840–41, when he was an earnest student in the class-room of Dr. Carson, the respected rector of the Royal High School of Edinburgh, while I was an idler in the class next to the rector's, then under the charge of worthy Dr. Boyd. I had thus no opportunity of seeing how Sir Henry acquitted himself in the class-room. It was well known, however, amongst the school boys that he was a hard worker, and that for the gold medal given by the town of Edinburgh to the dux of the school there had been a keen contest between him and his class fellow William Maclagan, afterwards Archbishop of York. Although young Littlejohn must obviously in his boyhood have been very exceptionally gifted, I can vouch for it that he gave himself no airs, and that in the playground he was always most kind and considerate to boys like me who were younger and less gifted than he. I can still well recall his lithe and active figure, always well dressed and well groomed; his merry, laughter-loving eye; and his open, manly brow. Amongst the rough schoolboys he was essentially one of the gentlemen. In after-years I occasionally met him in connexion with business matters, and I can never forget the care and attention with which he listened to all that one had to say; the way in which he was always ready to make allowance for mistakes in others; and his readiness to admit any oversight which was chargeable against himself. As an illustration of his genuine kindheartedness I may mention that on one occasion I had to call upon a servant girl, the daughter of a policeman, who spoke to me in the most grateful way of the great kindness shown to her father by

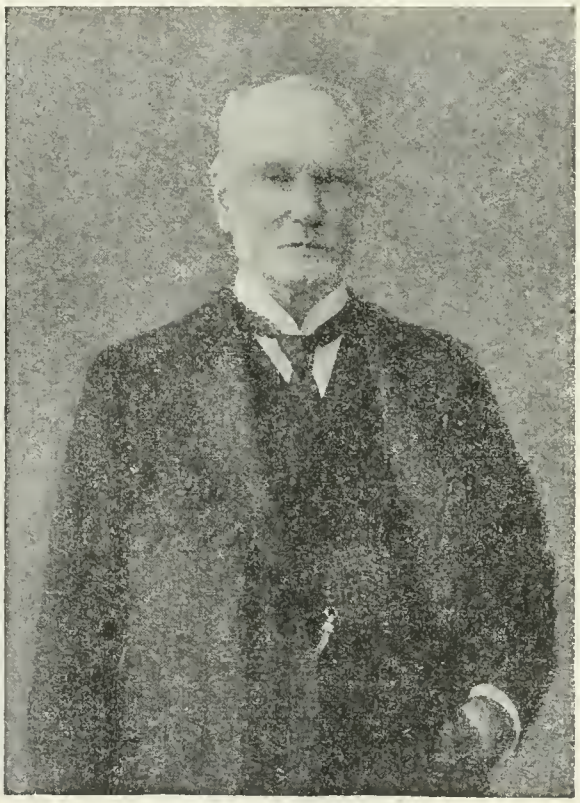
Sir Henry when surgeon of the police. She added that once, when she was handing dishes at a large dinner party where Sir Henry was one of the company, he had recognized her and told her to take care of her fingers, for the dishes were very hot. Sir Henry had a merry laugh over this incident when I repeated it to him.

Take him all round, Sir Henry Duncan Littlejohn was one of the best and noblest men I ever met with.

EDWARD HOOPER MAY, M.D.St. And., F.R.C.S.Eng.,

CONSULTING SURGEON, PRINCE OF WALES'S GENERAL HOSPITAL.

By the death of Dr. E. Hooper May, on September 23rd, the medical profession of the North of London has lost its oldest and most prominent member. A man of a singularly retiring disposition, he possessed the peculiar charm and old world courtesy that characterized what is called the "old school." During the many years that I have known him, he was never heard to say an unkind word of any one, and his help and encouragement to the younger men of the profession endeared him to all his colleagues. Essentially a surgeon at heart, he yet made an ideal general practitioner, and throughout his long life he was ever foremost in efforts to advance the welfare of his neighbourhood. Perhaps he will be best remembered for his work in connexion with the Prince of Wales's General Hospital, of which he was one of the founders in 1867, and on the surgical staff of which he served until advancing years caused his retirement from the acting staff to become consulting surgeon. Nothing, he has told me, gave him greater gratification than the rapid advance of this hospital, and there is no doubt that it is to his energy and devotion that its present position among the London hospitals is due.



EDWARD HOOPER MAY.

Edward Hooper May was born on November 2nd, 1831, in the house at Tottenham in which he died; he was educated at a private school and at St. Bartholomew's Hospital, where he was dresser to Edward Stanley and clinical clerk to Sir George Burrows. After qualifying in 1854 he went for an extra year's study to Edinburgh, to be under Syme. For Syme he had the greatest admiration, and only a few days before his death he told me that he still thought Syme was the greatest surgeon of modern times. He also worked with Lister in 1855, at that time resident surgeon at Edinburgh Infirmary. He used to tell a story of Lister which is interesting. When he was his dresser they used to work late at night at the infirmary, and when work was over Lister used to pull out his flute, and say, "Now I will give you a tune," and play to them. Apparently they used to keep it up rather late, because they had to climb over the gate when they left.

Dr. May obtained the F.R.C.S.Eng. by examination in 1856, and settled in practice in Tottenham, where his father, who came of old Quaker stock, had been in practice before him. In 1860 he took the degree of M.D. of St. Andrews. In 1864 he assisted in establishing a dispensary, now known as the Tottenham and Edmonton General Dispensary, and in 1867 he was one of the founders of a hospital in connexion with a community of Evangelical Protestant Deaconesses. This became the Tottenham Hospital and eventually the Prince of Wales's General Hospital. Excellently trained for the work, he introduced Listerian principles at Tottenham, and used to say that the carbolic spray was used earlier at Tottenham than at any other hospital in London, and given up earlier too. At this time he maintained a close friendship with, among others, Paget and Jonathan Hutchinson senior, and Hughlings Jackson was one of his most intimate friends. Dr. May did the first nephrolithotomy in England, though it was not done as a planned operation, the credit for which, I believe, belongs to Sir Henry Morris.

Dr. May did not make many contributions to medical literature, but his opinion was widely sought, and not only in surgical cases, so that he did much consulting work in the North of London. To the end he retained perfectly his eyesight and hearing, and his interest in affairs and his mental activity were unabated. He leaves a widow and family, but none of his sons is in the profession. One cannot say all one would of a man who won the love of so many; it is enough to say that he spent his long life for the welfare of others, and all his work was done with his whole might.

The funeral, which took place on September 28th, was attended by, among others, a number of medical friends and representatives of the Prince of Wales's Hospital.

H. W. C.

JOHN FLETCHER LITTLE, M.B.Cantab., M.R.C.P.Lond.,

VICE-PRESIDENT OF THE MEDICAL GRADUATES' COLLEGE AND POLYCLINIC, LONDON.

We have to record with much regret the death of Dr. John Fletcher Little, which took place on August 9th. He was born in co. Tipperary in 1843. His early education, including the first part of his medical training, was obtained in Dublin. In 1866 he took the diplomas of L.R.C.S. and L.R.C.P. Edin. Shortly afterwards he commenced practice at Woolton near Liverpool, an experience which he frequently afterwards used to quote as having been of much value to him. After some years he established himself at Ben-Rhydding. It was at this time that he became interested in physical methods of treatment, especially in massage, and was able to pay a visit to the United States of America to study the ideas which found development later in treatment of the Weir Mitchell type.

In 1879 he began to attend the medical courses at Cambridge and Charing Cross Hospital; he took the degree of M.B. in 1888, and the diploma of M.R.C.P.Lond. in 1889. He had already opened a school for the training of both men and women in massage, one of the earliest institutions for this purpose in London.

Dr. Little acquired a considerable practice, but his wide interests soon induced him to give a large amount of time to public duties. He served for a considerable period on the London County Council and on the Marylebone Borough Council. In both positions he gave evidence of a wide and sympathetic outlook on public affairs, and his advice was of much assistance on many occasions when matters involving the public health and medical interests were concerned. In politics he was an enthusiastic Liberal, and contested Oxford City in the year 1895.

During his career Dr. Little held various posts of importance in London; for some time his medical work centred in the London Temperance Hospital and at the Mount Vernon Hospital, in both of which institutions he held the appointment of physician. A post to which at one time he gave a large amount of care and assiduous

attention was that of medical officer of health for Harrow. He held this position up to the time of his death, never losing interest in Harrow and its neighbourhood, and had the strength to prepare the report of his work to the Harrow Council for the year 1913.

To medical men in London Dr. Little was well known on account of his early advocacy and unfailing interest in schemes for post-graduate instruction. He had personally appreciated the value of this in his own career, and felt sure of the desirability of making post-graduate study easily obtainable. He assisted in starting a post-graduate course at Charing Cross Hospital, which was for many years very successful, and was almost the only course of instruction at the time arranged for post-graduates in London. Later, in association with the late Sir Jonathan Hutchinson, he was greatly instrumental in starting the London post-graduate scheme which ultimately developed into the Medical Graduates' College and Polyclinic, an institution which has done so much good work for the medical profession.

He was a man gifted with a sanguine temperament, enthusiastic in all that he undertook; difficulties were never too great to be overcome, and his optimism was of unfailing value to his colleagues in the various undertakings with which he was associated during his career. His cheerfulness of disposition never stood him in better stead than during the long and trying illness which preceded his death. His resourcefulness and brightness of character will always remain a pleasant memory to those who had the privilege to know him well.

Lieutenant A. K. Armstrong,
(Photograph, by Stereoscopic Company, London.)

Dr. Little was a member of a family consisting of three sisters and five brothers. Two brothers—William and Joseph—entered the medical profession, and practised in Australia; Shepherd Little, a barrister, was at one time M.P. for Whitehaven, and during the latter years of his life stipendiary magistrate for Liverpool; the remaining brother was the late Reverend R. Wentworth Little.

SIR ALFRED EDWARD THOMSON, M.D., M.Ch., R.U.I., L.M.R.C.P.I., M.R.C.S.Eng.,

VISITING SURGEON, NEW SOMERSET HOSPITAL, CAPETOWN, S.A.; FELLOW ROYAL SOCIETY OF MEDICINE.

It was with deep regret that the announcement of the death of Sir A. E. Thomson, M.D., of Capetown, South Africa, was received in Ulster. He died in Belfast on September 27th. He had resided long in Capetown, but those who were his fellow students and who had met him from time to time on his visits to his native land felt that a personal friend, a conscientious and highly skilled surgeon, and a personality of exceptional worth had been lost. Sir Alfred had long been an invalid, and had suffered much from stomach and subsequently bowel trouble. He had been operated on in London four years ago, and had come back once more to Belfast to seek for aid, but numerous adhesions between coils of bowel, into which old abscesses had evidently emptied, and finally perforation brought about the untimely end. His old fellow students and personal friends gave him all that skill and affection could do for him. Sir Alfred Thomson's work and success in South Africa under such most painful and trying conditions proved his courage and determination.

He was the second son of the late Dr. Thomson, of Bangor, County Down, and entered the Queen's College, Belfast, and Royal University of Ireland. After taking his degree in 1886, he was for a time resident medical officer in the old Belfast Royal Hospital, and York Road Lying-in Hospital in London; even then the gastric ulcer troubled him, and he sought health in the south of France in charge of a patient. Going to South Africa he became resident medical officer of Kimberley Hospital. He was most successful in Capetown, where he finally settled, and soon entered the leading ranks of the profession. Within the last year he received the honour of knighthood, which gave great pleasure to his friends in Ulster, who recognized the suitability of the bestowal and the merit of the recipient.

Sir Alfred Thomson was unmarried, and leaves an aged aunt, with whom he resided at home before he went into the private hospital, and a brother, Dr. Robert Thomson, of Margate, with whom deep sympathy is felt.

LIEUTENANT A. K. ARMSTRONG, R.A.M.C., MONMOUTH.

Lieutenant Arthur Keith Armstrong died in France on September 15th from the effects of wounds received in action. The sad news was conveyed to Mrs. Armstrong in a War Office telegram as follows: "We beg to inform you that Lieutenant A. K. Armstrong died of wounds on September 15th. With Lord Kitchener's regrets." Lieutenant Armstrong, who was only 33 years of age, was the only son of Mr. and Mrs. Henry Armstrong, of 42, Dartmouth Park Road, London, and grandson of Dr. Armstrong, J.P., Gravesend. He was educated at Highgate School, where he was a member of the cadet corps. He afterwards entered St. Bartholomew's Hospital. In 1907 he was appointed house-surgeon at Huntingdon County Hospital, and afterwards became surgeon to the British IndiaMail steamer *Jelunga*. In 1909 he began practice in Monmouth in partnership with Dr. Lloyd-Smith, and became a member of the staff of the Monmouth Hospital. At the outbreak of the war he offered his services to the Government and was granted a commission in the R.A.M.C., being stationed first at Woolwich Hospital and then ordered abroad. During his residence in Monmouth Dr. Armstrong had made himself very popular with his colleagues and had earned the respect and regard of the public. In the town of his adoption he will be much missed and the deepest sympathy is felt for his widow and two children. He was a member of the British Medical Association, and published in this Journal in 1911 a paper on a case of eclampsia treated by saline infusion and another on hydrocephalus as a sequel to shock in 1912.

Universities and Colleges.

UNIVERSITY OF LONDON.

University College.

The following entrance scholarships and exhibitions have been awarded in the Faculty of Medical Sciences: Bucknill Scholarship (135 guineas), B. Rosenstein, of Westminster City School; First Medical Exhibition (55 guineas), H. N. F. Cook, of University College, London; Second Medical Exhibition (55 guineas), A. W. Holgate, of Alleyn's School, Dulwich; *proxime accessit*, M. Baranov, of King Edward VII School, Johannesburg, and University College, London; Epsom Free Medical Scholarship, N. E. Beasley.

London Hospital.

The entrance scholarships have been awarded as follows: Price Entrance Scholarship in Science (£100), Mr. I. H. Zortman; Price Entrance Scholarship in Anatomy and Physiology, for students of the Universities of Oxford and Cambridge (£52 10s.), Mr. H. D. McIlroy, Jesus College, Cambridge.

St. Mary's Hospital.

The competition for entrance scholarships at the medical school resulted in the following awards: The three open *Scholarships in Natural Science* (value £100, £50, and £26 5s. respectively) to Mr. J. O'F. Fletcher, St. Mary's College, Trinidad; Mr. W. F. Francis, Berkhamsted; and Mr. H. E. Suter, Epsom College. The two *University Scholarships* (each of the value of £52 10s.) to Mr. J. W. G. Phillips, St. Mary's Hospital Medical School, and Mr. T. S. Evans, University College, Cardiff. A *University Exhibition* was also awarded to Mr. R. A. Woodhouse, Downing College, Cambridge.

Guy's Hospital.

The following were the successful candidates for the entrance scholarships awarded at the Medical School in September. The two *Senior Science Scholarships* (for University students), value £75 and £35, Mr. J. M. H. Campbell, New College, Oxford, and Mr. F. A. Unwin, King's College, London. The two *Junior Science Scholarships*, value £120 and £50, Mr. A. E. Sawday and Mr. S. A. Sharpe, both of Guy's Hospital Preliminary Science Class. The two *Scholarships in Arts*, each of the value of £50, Mr. E. E. D. Gray, St. Paul's School, and Mr. M. W. O'Bryen, Oratory School, Edgbaston.

ST. GEORGE'S HOSPITAL.

The entrance scholarships in Anatomy and Physiology, of the value of 70 guineas and £50, have been awarded to Mr. R. Salisbury Woods, of Downing College, Cambridge, and Mr. A. Birrell, of the University of Wales, respectively.

VICTORIA UNIVERSITY OF MANCHESTER.

THE following candidates have been approved at the examinations indicated:

FIRST M.B.—*Part I (Inorganic Chemistry and Physics)*: Mary G. Cardwell, S. E. Critchley, F. L. Heap, F. S. Horrocks, A. W. Kirkham. *(Physics)*: F. H. Moor, V. T. Smith, Marie Wardman, James Yates. *Part II (Elementary Biology)*: Mary G. Cardwell, Elizabeth C. Davies, F. S. Horrocks, Kathleen O'Donnell, Marie Wardman, Ethel D. Willis.

Medical News.

THE 1st (Home Service) Home Counties Field Ambulance, with head quarters at the Old Palace, Maidstone, requires officers to complete its establishment. Inquiries should be addressed to the officer commanding.

AS announced in our advertisement columns, the autumn session of the Post-Graduate College, West London Hospital, Hammersmith, will open on Monday, October 12th. Full information can be obtained on application to the dean or vice-dean at the college.

THE winter term of clinical lectures and demonstrations at the National Hospital for the Paralysed and Epileptic, Queen Square, Bloomsbury, commenced on Tuesday, October 6th, and will be continued on Tuesdays and Fridays, at 3.30 p.m. up to and including December 11th.

A MEETING of the Society for the Study of Inebriety will be held in the rooms of the Medical Society of London, 11, Chandos Street, Cavendish Square, W., on Tuesday, October 13th, at 4 p.m., when Dr. Robert Armstrong-Jones will open a discussion on drug addiction in relation to mental disorder.

THE Local Government Board has issued a revised list of sanatoriums approved by the Board under the Insurance Act for the treatment of persons suffering from tuberculosis and resident in England excluding Monmouthshire. Under the provisions of Section 42 (1) of the Insurance Act, 1913, sanatoriums for the treatment of insured persons suffering from tuberculosis and resident in Wales and Monmouthshire are subject to the approval of the Welsh Commissioners.

THE prizes of the School of Dental Surgery of the Royal Dental Hospital, Leicester Square, will be distributed on November 17th by Mr. Arthur Hood, Chairman of the Managing Committee, in place of Sir Charles Wyndham, who, it is hoped, will distribute the prizes next year. The dinner of past and present students will not be held and the post-graduate lectures announced for October and November have been postponed, but will be given in the new year if circumstances permit.

INCOME tax used to be accounted a war tax, and though it has been largely used to meet other expenditure, it is reasonable to anticipate in the next and the following years a considerable increase in the amount of taxation levied on income. While no one wishes to shirk his responsibilities in this respect, it is only right that each should secure the advantages by way of exemption and abatement that the law permits. Returns are often difficult to make out, and we may therefore call attention to the advertisement of the Income Tax Protection and Relief Association, 7, Staple Inn, Holborn, W.C., published in this issue, offering assistance in the preparation of returns at an annual subscription of half a guinea.

A SPLENDID gift of £57,000 has been made by the women of Canada to show their sympathy with the sufferers through the war. Of this sum £37,000 has been set aside, by request, for a naval hospital at Portsmouth, the remainder being placed at the disposition of Lord Kitchener for use in connexion with our forces in the field. The Admiralty have gratefully accepted the gift on behalf of the navy, and have undertaken to identify the hospital with the women of Canada, whose happy inspiration and thoughtful sympathy have thus forged a new link between the navy, Portsmouth, and the Dominion. The hospital of the Canadian War Contingent Association, particulars of which were given in the JOURNAL of September 19th, is being established in a country house at Shorncliffe, lent by Sir Arthur and Lady Markham.

Letters, Notes, and Answers.

☞ *Queries, answers, and communications relating to subjects to which special departments of the* BRITISH MEDICAL JOURNAL *are devoted will be found under their respective headings.*

LETTERS, NOTES, ETC.

MR. A. W. BALL, Director of Oppenheimer, Son and Company, Limited, asks us to state that the product sold by that company under the name Metramine, and mentioned in the note on "Drugs with German Names," published in the JOURNAL of October 3rd, page 594, is a trade mark name for purified hexamethylenetetramine. The name is registered in London and other British-speaking countries, and also in Italy. The process used in its manufacture is not a protected or patented process of German origin, but a secret in the company's laboratories. Mr. Ball also asks us to state that the company was founded in Great Britain by William Oppenheimer, who was born in 1849 at Manchester, whose wife also is of British origin; his children were born in Great Britain and are the only Oppenheimers interested in the business, all the other shareholders are British-born subjects, the capital is British, and all the members of the staff are British-born subjects, and the products of the company are manufactured in London.

PROPOSED SPECIAL SERVICE (CHOLERA) CORPS.

DR. A. WHITE ROBERTSON, Honorary Secretary, writes: As there seems to be no call for the services of this corps in the immediate future I have, after correspondence with the War Office and British Red Cross Society, to inform the large number of medical men and nurses who have applied for special training that the project will now be dropped, leaving its members free to accept other appointments.

LECTURER CHARGED WITH MANSLAUGHTER.

MR. ORLANDO EDGAR MULLER, who has been committed for trial on a charge of manslaughter, was incorrectly described in the JOURNAL of last week, page 607, as a teacher of Christian Science. He described himself at the inquest as a lecturer on higher thought, and a practitioner of faith-healing, and said he was not a Christian Scientist.

ELEVATION OF DEPRESSED FETAL CRANIUM.

FUSTER of Algiers (*Bulletins de la Soc. d'Obstét. et de Gynéc. de Paris*, etc., June, 1914, p. 496) delivered a big multiparous woman, aged 47, by turning, after an unsuccessful attempt at delivery by forceps had been made by a resident assistant at a lying-in hospital. The patient had been delivered normally six times in succession, but version had been employed at the seventh labour, the forceps at the eighth, and embryotomy at the ninth. On this occasion, the tenth labour, the first stage was greatly prolonged, pituitrin was given, and the dilating bags applied, but oedema of the cervix developed. On that account the forceps was applied, but unsuccessfully. Fuster detected a deep depression in the fetal cranium, which was quite movable. He turned and delivered with ease. The child was a well-developed female, weighing 8½ lb., the occipito-frontal diameter was 4½ in., the occipito-mental 4¾ in., and the biparietal 3¾ in. It was asphyxiated when delivered, but revived a little after the usual treatment; the left parietal bone was so completely depressed as to be concave instead of convex. Fuster cut down through the scalp on the depressed bone, making an incision about a fifth of an inch long at the level of the uppermost part of the parietal eminence. The only instrument at his disposition, as it happened, was a Farabeuf's perforator employed for symphysiotomy, but with it he was able to open the parietal bone. Then he pushed the instrument under the inner surface of the bone and succeeded in elevating it almost completely. The scalp was closed by one suture and a drop of collodion applied to the wound. At the end of three weeks, when the mother was discharged, the child was in perfect health. Fuster notes that Hauch recently elevated a depressed frontal bone in a newborn child by means of a small corkscrew. If immediately undertaken, with aseptic precautions, elevation of the depressed frontal cranium, on its delivery, is a safe and simple operation.

ON CANCER OF THE DUODENUM AND SMALL INTESTINE.

Being the Presidential Address delivered to the Medical Society of London, October 12th, 1914,

by

SIR JOHN BLAND-SUTTON, F.R.C.S., LL.D.,

surgeon to the middlesex hospital.

The distribution of cancer in the section of the alimentary canal known as the gastro-intestinal tract is remarkable. Cancer is very common in the stomach, but in the intestine between the pylorus and the ileo-caecal valve it is uncommon. Primary cancer is rare in any part of the small intestine, but it occurs more frequently in the duodenum, short as it is, than in the jejunum or the ileum.

Cancer of the Duodenum.

A study of the effects produced by cancer of the duodenum shows that the time-honoured division of this section of the small intestine into first, second and third parts is of little use for the purposes of clinical medicine. It is more convenient, following Sherren, to call the portion above the bile papilla the supra-ampullary segment; the portion containing the bile papilla, the ampullary, and the remainder the infra-ampullary segment.

Supra-ampullary Cancer.

Duodenal ulcer is a common affection, and observations made on the living in the course of operations, and on the dead, have shown that the ulcer, for it is nearly always solitary, occurs most frequently in that section of the duodenum immediately adjacent to the pylorus. The chronic indurated duodenal ulcer is usually situated in the first 2 cm. of the duodenum, and four-fifths of the patients are men.

Fig. 1.—The pylorus and supra-ampullary section of the duodenum. A sarcoma occupies the scar of a chronic ulcer. Excised from a man aged 55.

Many surgeons who have had great experience in gastric surgery believe that a chronic ulcer of the stomach is a precancerous condition. There is much evidence to support the view that a chronic gastric ulcer—like a chronic ulcer of the leg, a lupus patch, or a chronic syphilitic ulcer of the tongue—occasionally becomes cancerous. Physicians and surgeons admit the difficulty of early diagnosis in cancer of the alimentary canal from the pylorus downwards; the disease furnishes no sign until it becomes septic or obstructs the gut. This explains our great ignorance of the early stages of cancer arising in the stomach, duodenum, and on through the intestine to the anus. It is insisted by some surgeons that if chronic gastric ulcers are liable to become cancerous the same changes should affect chronic duodenal ulcers. Observation teaches that cancer of the duodenum is a rare disease, and there is no evidence that it arises in a chronic duodenal ulcer. Malignant disease of the duodenum of any kind is uncommon, and very few specimens of cancer of the small intestine are preserved in the hospital museums in London. This is sufficient to indicate, not only that the disease is uncommon, but the important fact that cancer of the duodenum is rarely excised by surgeons. The only example of malignant disease in the supra-ampullary section of the duodenum I have seen associated with a chronic duodenal ulcer was a sarcoma. A man, aged 55, had well-marked symptoms of pyloric obstruction, and at the operation a polypoid mass could be felt in the duodenum, and was easily pressed into the pyloric ring. There was a well-marked scar on the serous surface of the duodenum opposite the pylorus. I resected the pylorus with the adjacent part of the stomach and the duodenum to within half an inch of the bile papilla. The duodenum was closed, and the stomach also. Union of the stomach with the intestine was re-established by a posterior gastro-jejunostomy. The parts exsected are drawn of natural size in Fig. 1. A fungating growth springs from the floor of a chronic ulcer. Microscopically, it is a spindle-celled sarcoma. The post-operative course of this case is of some interest. A few days after the operation the duodenal stump leaked and much bile-stained fluid escaped through the lower angle of the abdominal incision. Frequently the fluid was quite clear, alkaline, and excoriated the skin. This fluid was mainly pancreatic juice, and in a few days the patient was in the condition of Pavlow's famous dog. This animal had an artificial pancreatic fistula, and the escaping fluid eroded the skin. The dog was tied up in the laboratory and at night scraped the plaster from the wall and lay with its belly in the débris. This suggested a plan of treatment, and a bed of sand was prepared for the clever dog, and the pancreatic juice no longer eroded the skin. I did not give my patient a bed of sand, but the erosion of the skin was prevented by covering the skin surrounding the fistula with gauze, or lint, soaked in paroleine. A perusal of Pavlow's experimental observations helped me a great deal in the management of my patient. We know the average amount of fluid secreted daily by important organs, such as the liver, kidneys, and stomach, but no one has determined the average amount of fluid secreted by the pancreas, because the pancreatic secretion varies in quantity with the nature of the food. The greatest stimulant is fat. In my patient there were times when the fluid flowed in an almost continuous stream and quite clear. This happened when he swallowed milk. A fat-free dietary was then arranged, consisting of whey, beef-tea from which fat was carefully removed, water, and tea. The fistula soon closed. It was unfortunate that, after piloting the patient through many difficulties, he died a month after operation with apparently an abdominal dissemination of the disease. The man being a Jew, his relatives refused a *post-mortem* examination.

Cancer arising in the duodenal mucous membrane around the bile papilla is known as circum-ampullary cancer, in order to distinguish it from cancer arising in the ampulla, or in the common bile duct, but the three varieties lead to obstruction of the bile duct, jaundice, and distension of the gall bladder. There can be little doubt that cancer of this section of the duodenum would often escape detection if it were not for the obstruction it offers to the flow of bile from the common duct. It is very difficult to distinguish clinically between circum-ampullary cancer, ampullary cancer, and malignant disease of the head of the pancreas, for all give rise to obstructive jaundice, often associated with an over-distended gall bladder.

Cancer of the Ampulla.

From a practical standpoint the distinction between cancer arising in the mucous membrane of the duodenum near the ampulla and cancer arising in the ampulla may not be important, but primary cancer of the ampulla is interesting in itself and exhibits some remarkable peculiarities. Nowhere in the body does so small a growth lead to such grave interference with digestion. A cancerous growth, sometimes no larger than a small cherry, will block the outflow of bile and pancreatic juice, causing intense jaundice, and great emaciation by interfering with digestion in consequence of the obstruction to the outflow of pancreatic juice. The three clinical signs of cancer of the ampulla are painlessness, intense jaundice, and great emaciation. The pathological features of cancer in this situation are its slight tendency to infiltrate surrounding structures, the infrequency of dissemination, and the enormous dilatation of the main bile ducts and the gall bladder. A feature of cancer of the ampulla which distinguishes it from cancer of the gall bladder is the infrequency with which it is associated with gall stones. In spite of the local nature of the disease it quickly

destroys life. When cancer of the ampulla gives rise to jaundice, death usually follows within six months.

The daring resourcefulness of modern surgery is well exemplified in the attempts to deal with this singular form of cancer, and there can be little doubt that some means will be found for dealing with it successfully. Some valuable papers have been written on this subject by Hartmann, Körte, Schuler, Kausch, and Upcott. An American surgeon, Osterbridge, has recently collected 100 reported cases. An example from a case under my care at the Middlesex Hospital is represented in Fig. 2.

Very few specimens of ampullary cancer have been described in London, and there are few specimens in the metropolitan museums. Perhaps it is only necessary to draw attention to this deficiency in order to have it remedied.

Cancer of the Transverse or Infra-ampullary Duodenum.

This is the common place for duodenal cancer. The symptoms associated with it are like those set up by cancer of the pylorus, but the vomited matter contains bile and pancreatic juice, and is sometimes very offensive. The cancer is usually of the constricting type, and the duodenum above the constriction becomes enormously distended; the dilated stomach and duodenum constricted by the pylorus resemble a bilocular stomach. Cancer sometimes arises in the middle of the transverse portion of the duodenum and the growth involves the vena cava and the superior mesenteric vessels. A constricting cancer in this part of the duodenum may be so hidden as not to be visible until the gut is opened. Rolleston has seen the channel of the gut so narrowed that its lumen in the cancerous section would only admit the passage of a pencil. I had an opportunity of operating on a man in whom the duodenum was completely obstructed by cancer. The patient, aged 56, was invalided from Burma on account of persistent vomiting and rapid emaciation. Cancer of the stomach seemed to be the most probable cause of the illness, but no lump could be felt in the stomach or its neighbourhood. The vomiting resembled that seen in the condition known as a "vicious circle" after gastro-jejunostomy; it was very offensive. At the operation the stomach was found to be contracted, and on turning it over to examine the posterior surface I found a small constricting growth in the middle of the third part of the duodenum. This hard ring of cancer completely obstructed the gut, so that the bile and pancreatic juice regurgitated into the stomach, where they mingled with the gastric juice and ingested fluids to be ejected as filthy vomit. The duodenum above the stricture was enormously dilated, and produced an appearance like a bilocular stomach. The cancer had involved the walls of the duodenum, and implicated the superior mesenteric vein; excision of the affected area of the gut was impracticable. Posterior gastro-jejunostomy was performed, and the distended section of the duodenum was also anastomosed with an adjacent coil of jejunum. The vomiting ceased after the operation, and the patient began to take food freely and assimilate it. Pain ceased, and we hoped that his life might be prolonged. Cardiac dyspnœa began to cause trouble, circulatory complications arose, and he died fourteen days after the operation. A *post-mortem* examination confirmed the opinion, formed at the time of the operation, in regard to the impracticability of removing the cancerous portion of the intestine, for it involved the pancreas extensively as well as the large blood vessels. In the infra-ampullary cases the vomit always contains bile and pancreatic juice; this is of diagnostic value. Pancreatic juice can be demonstrated by the digestion of fibrin in the filtered vomit, with the addition of a few grains of sodium bicarbonate.

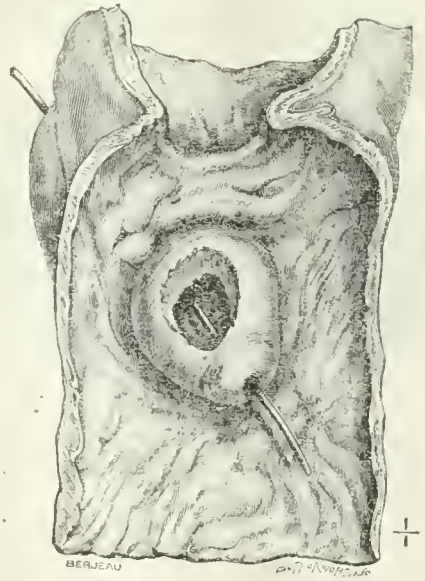


Fig. 2.—Cancer of the ampulla. The common duct contained three gall stones, and one had ulcerated through the growth. From a woman aged 58. (Museum, Royal College of Surgeons.)

Cancer of the Jejunum and Ileum.

Tumours of the jejunum and ileum are interesting pathologically and clinically. A tumour of any kind in the small intestine is rare, and those belonging to the benign group are, as a rule, pedunculated; the propulsive movements of the intestine not only affect the contents, but influence tumour formations within its walls. The simple tumours arising in the intestinal walls may be lipomas, some are described as myomas, and many as sarcomas, but, whatever the structure, the constant propulsive efforts of the intestine tend to force the tumour towards the lumen of the bowel until it projects within it covered merely by a layer of mucous membrane. The danger to be feared from such tumours is invagination, or intussusception of the gut, for the tumour, acting as a foreign body, is urged along the bowel, and being fixed to the bowel wall drags it in and produces an intussusception, which, if unrelieved by art, or the timely sloughing of the intussusceptum, ends in fatal obstruction. The peristalsis of the small intestine exercises moulding effects on deposits of cancer within its walls, as well as on benign tumours; this applies to secondary as well as primary deposits. A man with disseminated melanoma was admitted into the Middlesex Hospital with intestinal obstruction. In the face of widespread melanomatous deposits an operation for the relief of the obstruction was regarded as useless; to the astonishment of the physician, the symptoms abated and the patient passed a long slough of intestine which proved to be a piece of ileum containing a deposit of melanoma. This had led to intussusception, and the intussuscepted piece of gut sloughed and the man recovered.

The museum of the London Hospital contains a portion of ileum in a state of intussusception caused by a secondary deposit of melanocarcinoma. The specimen was obtained from a woman admitted with signs of strangulated femoral hernia; at the operation the supposed hernia proved to be an enlarged lymph node charged with black pigment. The woman died and the invaginated gut was discovered after death. The seat of the primary growth is not stated.

Cancer and Accessory Pancreatic Tissue.

A consideration of tumours of the small intestine would be incomplete without reference to the suggestion that cancer of the small intestine may arise in an accessory pancreas. Small detached masses of pancreatic tissue have been detected in the stomach near the pylorus and in the duodenum; they may be situated in the mucosa, muscularis mucosæ, or in the muscular layer of the intestine, and measure 3 or 4 cm. in diameter. An accessory pancreas is occasionally situated at the apex of a diverticulum. Although such diverticula usually arise in the duodenum they have been observed in the lower parts of the ileum, and regarded as persistent Meckelian diverticula. A pancreatic and a Meckelian diverticulum have been found in the same individual. It is possible that pancreatic diverticula are produced by traction; they are by no means harmless, and several cases have been reported in which a diverticulum, with an accessory pancreas at its apex, has invaginated into the bowel and produced intussusception. In a remarkable case reported by O'Connor an inverted diverticulum caused intussusception in a boy aged 13. On the fourth day after the attack he passed 11½ in. of gangrenous intestine with the diverticulum attached.

It is necessary to mention accessory pancreas when considering cancer of the duodenum and small intestine, because those pathologists who still believe that cancer arises in embryonic vestiges think it probable that this disease may arise in islands of pancreatic tissue. There is no evidence to support this theory, nor that which attributes duodenal cancer to morbid changes in Brunner's

glands. Like the theory attributing parotid chondromas to relics of Meckel's cartilage, they belong to the domain of fiction. Such theories indicate that pathologists, like poets, are not devoid of imagination.

Cancer at the End of the Ileum.

The frequency of ulcer and cancer at the pylorus is not repeated at the ileo-caecal valve. This part of the small

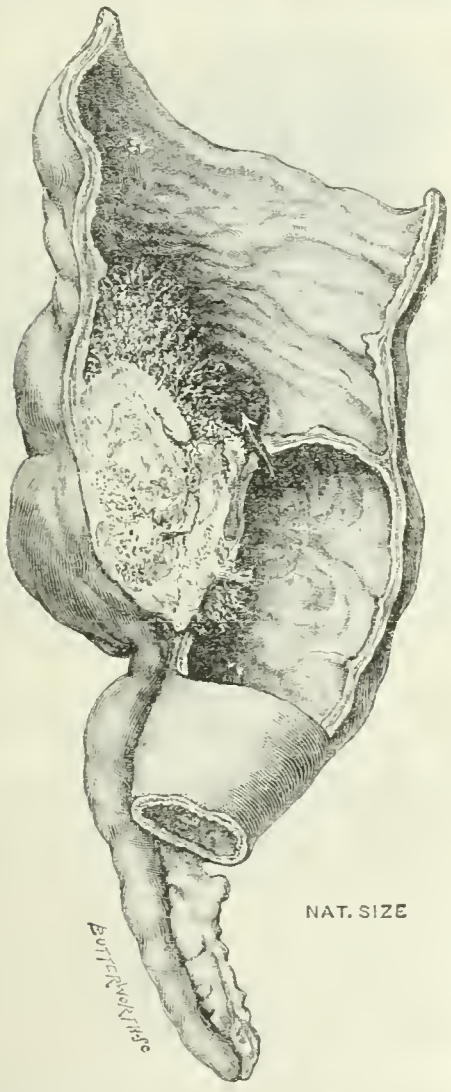

Fig. 3.—The caecum and terminal segment of the ileum. The specimen shows the manner in which cancer arising in the caecum may involve the ileum.

intestine, notwithstanding its narrowness, is rarely attacked by morbid growths, and they have been rarely the subject of critical analysis. For many years I have been interested in this question, and find obstructive growths at the valve are of four kinds:

1. Cancer arising in the ileum.
2. Cancer arising in the caecum.
3. Malignant growths in the vermiform appendix.
4. Hyperplastic tubercle of the ileum.

Cancer at the ileo-caecal junction, in the cases I have seen, has been of the circular contracting type, and leads to almost complete occlusion of the opening. The contraction is so extreme that it is necessary to make a careful search in order to detect it, and, as a rule, the disease is more easily felt than seen.

It is a remarkable thing that such inconspicuous growths give rise to widespread metastasis in the abdomen. For example, an elderly woman had a large ovarian cyst associated with frequent vomiting—two conditions forming a sinister combination, and suggestive of malignant disease of the bowel associated with the ovarian cyst.

The removal of the cysts—there were two, one as big as the patient's head, and the other the size of a turkey's egg—was easily accomplished, but the presence of much solid tissue in the walls of the cyst convinced me that the solid matter was implanted cancer. The distended condition of the small intestines led me to carefully search for an obstruction, and I found a thin, narrow hard ring of growth completely obliterating the ileo-caecal orifice. I joined the ileum to the ascending colon by a lateral anastomosis. The woman survived, and lived free from pain and able to look after her house for twelve months. In this instance the primary lesion, though contracting and atrophic, had shed cancerous cells into the general peritoneal cavity which had fallen on the walls of the ovarian cysts and converted them into large, solid, cancerous masses. The frequency with which ovaries, and ovarian cysts, are converted into solid blocks of cancer by the implantation of cells shed from a primary focus in the gastro-intestinal tract is not properly appreciated by gynaecologists, but I am glad to note that the number of converts is steadily increasing, and my scepticism in the existence of primary cancer of the ovary is intensified by further experience.

Cancer arising in the caecum does not obstruct the lumen of the bowel at such an early stage as when it arises in the colon, but there is an anatomical arrangement by which cancer arising in the caecum can obstruct the ileum. The terminal segment of the ileum rests in close contact with the wall of the caecum; if cancer, or hyperplastic tubercle, attacks the mucous membrane of the caecum immediately in relation with the terminal portion of the ileum, the intermediate tissues become infiltrated with growth, the walls of the ileum are implicated, and ultimately its lumen becomes obstructed (Fig. 3).

A study of the specimens of primary cancer of the small intestine preserved in the hospital museums in London shows that the disease presents the same characters as in

Fig. 4.—The caecum and terminal piece of the ileum. The vermiform appendix is obliterated by a new growth with the microscopic features of a sarcoma. Removed from a man aged 75. He only survived the excision of the caecum six days. (Museum, Middlesex Hospital.)

the colon. Some are of the annular contracting type, constricting the gut as if a piece of cord had been tightly tied around it. In others the disease sprouts like a cauliflower into the bowel; there is a massive form which envelops the intestine with a hard collar of new growth. An

annular constricting cancer strictly limited to the ileal aspect of the ileo-caecal valve is associated with signs of intestinal obstruction rendering accurate localization of the obstruction a matter of uncertainty. There is nothing in the signs and symptoms approaching the definiteness characteristic of a constricting cancer of the third part of the duodenum. The chief feature connected with cancer of the gastro-intestinal tract is its extreme frequency at the pylorus and its rarity at the ileo-caecal valve. The age-distribution of cancer of the small intestine agrees with that of the stomach and colon.

THE APPENDIX.

Primary Malignant Disease.

In order to show the difficulty of properly assessing the frequency of cancer at the ileo caecal valve, the following case is useful:

A man, aged 73, came under observation with symptoms of chronic intestinal obstruction, and a lump was easily detected in the region of the caecum. It was freely movable and painless. The age of the patient, the absence of fever and tenderness, the presence of a movable swelling in the right iliac fossa, accompanied with intestinal stasis and vomiting, indicated that the mass was in all probability a cancerous growth in the caecum. This view being confirmed in the course of the operation, I excised the caecum and joined the ileum by an end-to-side anastomosis in the ascending colon. The patient died suddenly six days after the operation. The caecum and exseeted portion of the ileum were preserved, and, on subsequent examination, the mass proved to be a primary tumour of the vermiform appendix which had infiltrated the adjacent walls of the ileum and caecum, including the segments of the valve (Fig. 4). Microscopically, the growth possesses the features of a sarcoma. There were no signs of dissemination and no enlarged lymph nodes were detected. Such growths in the appendix are probably rare. I have had only one

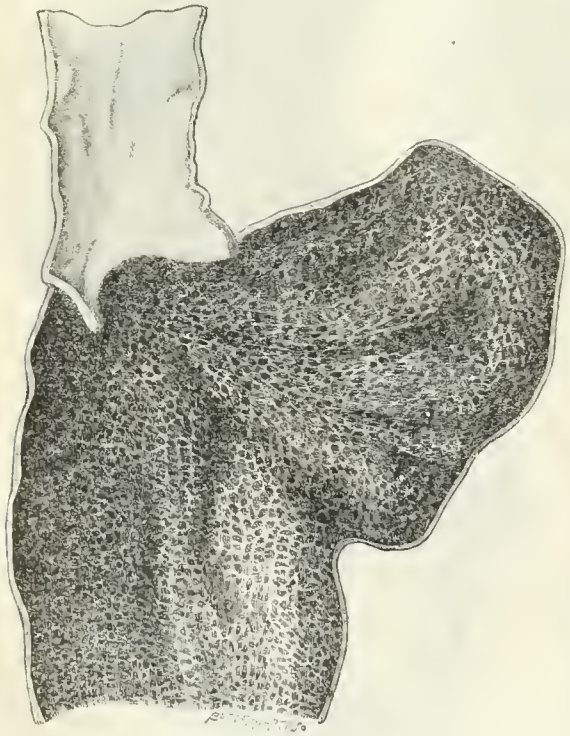

Fig. 5.—Melanosis of the mucous membrane of the colon. From a man aged 64 who died of bronchopneumonia. (After Professor Dr. Ludwig Pick.)

specimen of primary cancer of the vermiform appendix. I removed it from a spinster aged 30.

Hyperplastic Tuberculous Affections in the Neighbourhood of the Valve.

An analysis of the various growths which arise at the ileo-caecal junction makes it evident that some of the tumours in this situation labelled after operation "cancer," are in some instances tuberculous. The hyperplastic form of intestinal tuberculosis is most common in the caecum and caecal end of the ileum. It differs from other varieties of tuberculous disease in that the lesion is not destructive and leads to an increase in the bulk of the part affected. The disease begins in the submucous, or subserous, tissue, and spreads to the other coats of the bowel. The new tissue contains clumps of giant cells and sometimes calcareous deposits. Occasionally the thickened bowel is enveloped in a mass of fibro-fatty tissue such as sometimes

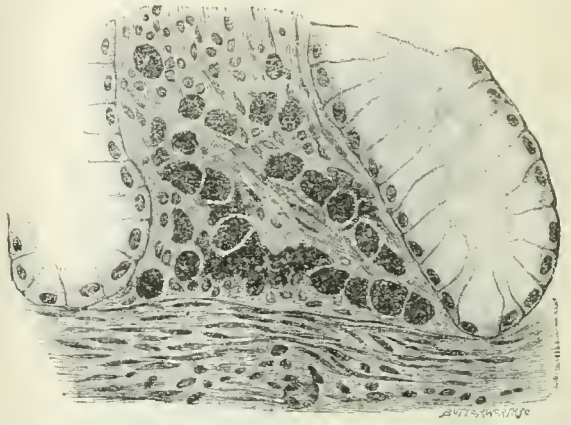

Fig. 6.—Melanosis of the colic mucous membrane showing the deposits of pigment in the stroma between the crypts. (After Ludwig Pick.)

surrounds chronic tuberculous kidneys. The cavity of the bowel is narrowed, sometimes a track no larger than a writing-quill remains, and the ileo-caecal valve is obstructed; in rare cases the disease is limited to the valve. This condition is very liable on mere naked-eye examination to be mistaken for cancer of the ileum or caecum, and it is very probable that some cases in which the caecum has been excised for a tumour casually regarded as cancer, and the patients have remained free from recurrence, the disease was hyperplastic tuberculous disease.

From the operative point of view the distinction between cancer and hyperplastic tubercle is not important, because the treatment for both conditions is the same—excision—but is a matter of great concern in regard to prognosis. Cancer and hyperplastic tubercle left to run their course end fatally, but the latter is curable by excision. Hyperplastic tubercle of the bowel was not recognized till 1891, then it received attention from Billroth, Hartmann, and Pilliet. Very little attention has been given to the disease in Britain, although there is reason to believe that tuberculous disease attacks the caecum more frequently than any other part of the gastro-intestinal tract.

MELANOSIS OF THE COLON.

Melanosis is a morbid condition of the mucous membrane of the colon that has received little attention in Great Britain. My experience is limited to one example:

A septuagenarian spinster suffered from recurring attacks of intestinal obstruction; at last colostomy was necessary, and a constricting annular cancer was excised from the iliac colon. Four months later the cut ends of the bowel were rejoined, successfully. The mucous membrane of the excised portion of the gut was of an inky blackness, but the cancer in the bowel had the microscopic structure common to primary cancer of the colon and was devoid of pigment. The blackness of the mucous membrane depended on a deposit of pigment in the connective tissue of the mucosa. I am unable to state how much of the colon was pigmented, because the patient recovered from the operation, but I examined her thoroughly with the object of finding evidence of a melanoma or an ulcerating pigmented wart, but found none. This pigmentation of the colon puzzled me. During the Christmas vacation, 1912, I visited the museum at the Friedrichshain, Berlin. There I saw a colon with the same deep pigmentation. (Fig. 5.) The intense blackness affected the colon uniformly, being sharply limited by the ileo-caecal valve and extending thence to the anus. The terminal portion of the vermiform appendix was obliterated, but the mucous membrane of its proximal unobliterated part shares in the pigmentation.

Professor Dr. Ludwig Pick has discussed in an exhaustive manner the anatomical, histological, and chemical features of this rare form of pigmentation. He also gives a useful summary of nearly a score of similar cases, beginning with one recorded by Virchow, 1847, and three described in England by C. J. Williams, 1867, G. Newton Pitt, 1891, and H. D. Rolleston, 1892. Pick states that the coloration is not due to metallic deposit—it is essentially a pigmentation of the connective tissue of the mucous membrane, and haematogenous.

Although the pigmentation begins, as a rule, at the ileo-caecal valve and extends to the anus, cases have been observed in which it does not involve the whole length of the colon. When the colic membrane is involved throughout, the pigmentation is discoverable at the anus by means of a speculum. The condition is a clinical curiosity, but if detected in the course of a clinical examination it might have undue significance attached to it. It will be useful to have some further observations on this curious pigmentation.

I selected cancer of the small intestine as the subject of the address this evening because it is a matter neglected in the ordinary works on surgery. It is intended to hold a discussion at our next meeting on the surgery of tumours of the large intestine, and we hope to have an exhibition of illustrative specimens of tumours of the small intestine as well as tumours of the caecum and colon. The council is hopeful that a series of specimens illustrating hyperplastic tuberculous disease of the caecum will be shown. This disease, often mistaken for cancer of the caecum, has not received much attention in this country, although Henri Hartmann made it the subject of the oration in 1911. The society will also be grateful for the loan of specimens illustrating primary cancer of the vermiform appendix, a disease concerning which there is much uncertainty. It will also be useful to obtain some further observations on the curious pigmentation of the colon.

PRESENT-DAY LESSONS FROM THE LIFE WORK OF MITCHELL BANKS.

Being the Third Sir William Mitchell Banks Memorial Lecture.

By SIR VICTOR HORSLEY, F.R.S., M.B., F.R.C.S.

Though the keeping bright the memory of our benefactors is a pleasant and, as in the present instance, a most honourable duty, the object and value of a memorial lecture rests equally on the fact that even a superficial consideration of the conditioning circumstances of our predecessors' work evolves a whole crowd of conclusions which are full of lessons for us.

The life work of Sir William Mitchell Banks in every aspect is not only interesting and educational but it is also a pleasant study of how much active public benefit can be secured to the community by the efforts of one of our profession, and how much can be effected by single-mindedness.

For Mitchell Banks tried to live up to Pasteur's scientific idea of what should be the inspiration of a medical practitioner, namely, that "A doctor must consider what people will say about him 100 years hence and not trouble himself about the blame or praise of to-day." Probably Banks, in his active advocacy and support of surgical and educational reforms, realized Pasteur's ideal more completely than many of his contemporaries.

Seventy-two years ago Mitchell Banks, as he was familiarly known to most of us, was born in Edinburgh (in 1842), his father being Mr. Peter S. Banks, Writer to the Signet, and his mother, Miss Ann Williamson. A student of the greatest ability, originality, and promise, he took his M.D. degree in 1864, with the highest distinction, and under the stimulating scientific influence of Goodsir, produced original work on the Wolffian bodies, which at once became the classical authority on that subject. Banks had, in fact, entered the profession at the moment when the greatest advances in medical science were being made by the anatomists owing to the development of microscopical technique. Goodsir had all John Hunter's feeling that anatomy should be pursued not only as part of natural truth to be determined for its own sake, but also always with the interpretation of function as the purpose and object of progress, and Banks's work and thought throughout his whole life exhibited this practical combination.

We have to thank the Scottish School of Medicine and its various teachers for many things, but especially the academic recognition of anatomy. For just as Goodsir was the successor to the distinguished line of Munros, so Bell made his contribution to the progress of surgical science more notable through his enforcing dissection by all his students.

But Goodsir was far more than an anatomist limited to his special subject. There was another aspect of Goodsir's influence which, perhaps, has not been so well realized outside the inner circle of the Edinburgh School fifty years ago, and yet it must have exercised a considerable effect on Banks's active intellect. I refer to Goodsir's comprehensive views of medical work in general and its bearing on social life, which led him, though in many respects a recluse, to take a part in the organization of the Edinburgh Society which was called the "Universal Brotherhood of Friends of Truth," and the principles of which were declared to be the promotion of "Fellowship, Work done, Love for the good and beautiful," and, above all, "Co-operation." Pre-eminently among Goodsir's pupils Mitchell Banks tried to carry out these principles of his teacher in his social, communal public life, as well as in his professional work.

There was thus from the first the development in him of that knowledge and sympathy for anatomy as a pure science which subsequently he so extended during his tenure of the chair of anatomy in the Medical School as to make that at first the most flourishing teaching department in University College at its foundation in 1882. And later on his work for the developing Medical School and University meant labour, not merely for medical science alone but his sympathy for social science as well, because of the inestimable benefit the University has conferred on the citizens of Liverpool.

What now of the main work of his life—his surgical achievements?

Two subjects will always be honourably associated with Mitchell Banks's name and the Liverpool School of Surgery—namely, cancer and hernia. To day they are humanity problems just as important and just as much in need of constant notice, consideration and reconsideration as they were when he began to hold up the light of surgical progress.

Both, too, are subjects respecting which his teacher Goodsir had put the true value of surgical work in words which for their scientific precision and accuracy are worthy of resuscitation here, and for their just appreciation of the possibilities and limitations of clinical work ought not to be forgotten.

> It is with methods of prevention and recovery that our profession has to do. If we make use of the terms *cure* and *remedy* we do so in their fundamental and not in their vulgar sense, for we do not profess to perform the one or to provide the other in their vulgar sense.
>
> What we undertake to provide are, *firstly*, the conditions of relief or alleviation of pain as far as these have been discovered; *secondly*, the conditions of recovery, provided these conditions can be restored; and, *thirdly*, the conditions of longevity within the limits assigned to the life of man in the present phase of his existence.

Every one who followed Mitchell Banks's work, whether in the wards or as revealed in his writings, knows that these words exactly express what he did, and no one recognized more clearly the scientific limits of the surgery of his day on the fundamental questions of "cure," "relief," "longevity," etc., which were so clearly laid down by Goodsir. No one in speaking of "results" used the word "cure" with more meticulous care, and no one weighed up more carefully in the interests of his patient the risks, especially to life, of any suggested procedure. On this last of Goodsir's points—namely, "longevity"—a word must be interpolated here, for social changes advance so unnoticed by those participating in them that the handicapping conditions under which our predecessors have worked are seldom remembered and often unknown.

The numerous risks to life caused by even a simple operation and due solely to ignorance and want of civiliza-

tion which existed only a few years ago are already forgotten in the safety of modern operative procedures.

Thus, for instance, in the year 1864, when Mitchell Banks began his career, so backward were we in civilization that a troopship crowded with sick women, children, and time-expired men took more than five months to come from Bombay to this country. And again, to quote an instance from our immediate subject—namely, the survival of patients on whom an operation designed to prolong life had been performed—let me point out that Banks, as late as 1882, stated that the death of a patient by infection was due to such shocking neglect in hospital administration that "many of the beds in the ward in which this patient lay were found to be absolutely rotten"!

And yet under similar depressing circumstances Lister—misunderstood, contemned, and cold-shouldered by his ignorant and unscientific contemporaries—had completely solved long before 1882 the principal part of the "longevity" problem—namely, how to prolong and not curtail life by an operation.

Consequently, since we have besides protection from sepsis, modern means for successfully dealing with shock, Goodsir's condition of "longevity" is now fully satisfied in both these subjects of cancer and hernia.

CANCER.

With this preface and with these rather painful memories of a by no means distant past let us take the first of these cases—namely, cancer—and we must limit ourselves to the special case of cancer of the breast.

No subject is commoner and none has been dealt with more widely by surgeons, yet at the present time there cannot be said to be either a full consensus of opinion among surgeons as to the best operative procedure for dealing with it, nor anything like a fulfilment in practice of a general acceptance of the principles on which that procedure must be based.

Mitchell Banks, at a time when pathology was only just emancipating itself from the preconceptions of clinical hypotheses, began with the fundamental fact that cancer is primarily a local disease, and must be dealt with as such. Perhaps we owe to Edinburgh teaching the idea that cancer was not a general blood dyscrasia but a parasitic disease beginning locally and only gradually invading the body. It seems to have been first taught clearly by Bell, at any rate.

But many decades passed without this all-important axiom being generally accepted. Indeed, after Mitchell Banks had begun to make true surgical principles better known, an old practitioner wrote (anonymously, of course) to the *Medical Times and Gazette*, 1870, p. 762, suggesting that all surgical treatment of cancer of the breast was useless.

It was in this sort of intellectual fog which beset the profession that Mitchell Banks began the work which became so essentially his own, for which the human race must always be indebted to him, and which, like all achievements of real scientific value, not only enhanced his reputation but also added further distinction to the School of Surgery in Liverpool.

He first published in detail the results of his work in 1877, and formulated the true position of the surgical treatment of mammary cancer by putting forward two principles:

1. That the whole of the breast tissue must be removed, because even in the parts of the gland not obviously the seat of active cancer there were, nevertheless, changes which must be regarded as pre-cancerous.*

2. That all the lymph glands in relation to the mammae should be removed, on the ground that it is impossible to determine at the time of operation,† when they appear to be normal, that they are not really infected.

Though possibly acted upon in general, these two great principles I shall show directly are not even now fulfilled in practice with scientific loyalty, though thirty-five years have elapsed since Banks promulgated them.

It might be said that these principles of operation for cancer of the breast are, after all, but the practical recognition of the truth of Bell's dictum that cancer is at first a local disease, but that is only another way of saying that all genuine advance in operative surgery is based on pathology.

Moreover, the need for Banks's teaching was indeed great, since, owing to their lack of scientific appreciation of Lister's great discovery, surgeons in 1877 did not operate to remove the disease but to palliate it. Such palliative operations were so limited in design and execution that even ten years before (in 1867) Moore had protested against what he aptly described as wholly "inadequate operations."

It was in reference to this inefficient fashion of operating in 1877 that Banks, in 1882, said in his characteristic way, "Very few people died as an immediate result of it (that is, such operation). Unfortunately, at a little later period they all died from want of a little more of it." "For it never effected a cure."

No doubt the fatal error of this incomplete operating was due in a large measure to post-operative difficulties and risks to life, which restricted the enterprise of the surgeons of that day, and which they could not or would not see were only due to their neglect of scientific facts and research.

Perhaps the best evidence of this is the fact that even in Mitchell Banks's own practice at that time (1882) the risk to life—that is, the mortality after operations for cancer of the breast—was no less than 13 per cent., a mortality which, in the hands of most modern surgeons, has now wholly disappeared from this branch of operative surgery.

Allow me to digress here for a moment on the matter of surgical terminology. I have always urged that the phrase "mortality of an operation," so commonly used, is, in fact, a false statement, and should be replaced by "mortality after an operation." For an operation *per se* is not a cause of death unless some accident occurs during its performance or unless it is unfortunately designed or executed. The fact is that cases are not adequately clinically analysed, and, as a rule, the old fallacy of *post hoc propter hoc* is allowed to prevail. Shock, for instance, is often attributed to the operative procedure in cases where it is wholly due to the condition into which the patient had been allowed to drift before operation was decided upon. Typical examples of this very common logical error in statistics are to be found in all elaborate tables and discussions of so-called operative mortality in the treatment of various diseases, and none more strikingly so than in the case of cerebral tumours, where the patient is rarely offered surgical treatment until in the last stages of the disease. Let me at the same time point out that this mistake in statistical method is not characteristic of the medical profession only, for mathematical statisticians when dealing with biological subjects also constantly omit to analyse their case material, and consequently arrive at most fantastic conclusions on all important questions of public health, such as tuberculosis, alcohol poisoning, infant mortality, housing, etc.

Leaving now the question of danger of treatment, as one now wholly without importance, we must proceed to the discussion of the chief object of Mitchell Banks's work on the treatment of cancer, namely, how to secure for the patient what Goodsir meant by "prevention" and "cure."

In the case of cancer this means the immediate extirpation of the disease while it is yet only local, and it would naturally occur to an anatomist like Mitchell Banks that such extirpation must include all the structures likely to be invaded, in the order—breast, lymph glands, pectoralis muscle.

In speaking of this anatomical order of the mode of invasion of the body by cancer beginning in the breast it is worth while drawing attention to the close parallelism between it and another parasitic disease, namely, tuberculosis.

The local lesion, the subsequent infection of the glands and later of the viscera in tuberculous inoculation of guinea-pigs, presents in a few weeks exactly the same picture that carcinoma does in years when commencing in the breast.

Early and complete extirpation of the local disease and neighbouring structures effects a cure in both conditions

* Subsequently fully confirmed by Johnson, Beadles, and others.

† In 1877 histological methods were not sufficiently advanced to permit of rapid microscopical investigation of doubtful tissues at the time of operation. But such examination, though occasionally carried out, does not meet the necessities of the case in gland infection, since time does not permit of an exhaustive search. Consequently Banks's law is as true now as in 1877, and must be fulfilled to the letter.

alike. That was Mitchell Banks's principle in respect of mammary cancer.

It might be thought that as his surgical teachers at Edinburgh were also primarily anatomists* he simply followed their inspiration, but I have not been able to find any evidence in their writings that these men had arrived at the point of intellectual evolution which marks the beginning of Mitchell Banks's original work.

One quotation will, I think, prove this. Thus Syme, his chief teacher in surgery, not only was in the habit of dismissing all cases of mammary cancer as hopelessly inoperable if he discovered any evidence of infection of the axillary glands, but also, in his last description of operating for the disease given in his *Principles of Surgery* (5th edition, 1863), he makes no mention of removing the glands as a measure of precaution.

There is certainly no evidence that the idea was present to his mind at all, and we may fairly assume that Syme represented the surgery of his day, which had not yet so freed itself from tradition as to be guided by scientific principle.

It was on this principle of making the local removal of the disease complete that Mitchell Banks advocated the clearing of the axilla, and the occasion of this lecture is the moment to consider whether we have thoroughly profited by his teaching, and to see whether the present-day operative treatment of cancer is always as complete as it should be, and as he strove to make it. In the first place, to judge by the textbooks at least, removal of the axillary glands is understood to be a *sine quâ non*, and Küster, after practising Banks's method for a few years, saw out of 95 recurrences only one occur in the axilla.

But the same statement cannot be made of excision of the supraclavicular glands; indeed, in the recent monograph on *Cancer of the Breast*, by the late Mr. Cecil Leaf, this step in the operation was distinctly discouraged.

Yet from the standpoint of surgical principle it cannot justly be omitted, for what Banks said of the axilla, "Since you cannot tell whether the glands are infected or not, remove them and dissipate the doubt," applies with equal force to the supraclavicular region.

He might have added to his terse phrase the words, "thus giving the patients the further security due to them," for Halsted, who by carrying out Mitchell Banks's principles with completeness and originality has done so much to get their truth recognized, found by a laborious and accurate investigation that cancer was present in the supraclavicular glands and tissues in 34 per cent. of the 67 cases he examined. Plainly, therefore, we owe it to our patients to clear out both fossæ.

It is not just, however, to leave the question of the design of an operation for mammary cancer at this point, for the subject has been further elucidated by subsequent investigators, notably Sampson Handley.

In his method of operating Mitchell Banks removed the skin freely, and in so far protected his patients from local recurrence, but it was from the empirical point of view of likelihood of original foci of disease being left, and this part of the scheme of operation was not put on a scientific basis until Handley's complete demonstration of the infection paths through the lymph vessels in the fascial planes.

Consideration of this point naturally brings us to the remaining one of the treatment of the pectoralis muscles. The paramount source of risk is, of course, the fascia on the pectoralis major, and the empirical practice of Volkmann in 1875, when he advocated the invariable removal of this fascia (more properly the muscle itself), unfortunately was regarded by the timorous (because septic) surgeons of the day as an extreme measure, and did not gain general acceptance until Heidenhain, many years after Banks and Volkmann, proved anatomically the widespread degree of involvement of these structures in an average case. Even then the mistaken idea of possible cripplement prevailed in the minds of some against even the realization of its necessity.

To sum up. Every operation for mammary cancer in order to fulfil all known requirements, and, by antagonizing all known avenues of the disease, really serve the interests of the patients, must include:

First, very wide removal of skin, breast, and margin of subcutaneous fat and fascia outside the gland edge, the pectoralis major, and the whole axillary contents—fat, fascia, and glands up to the edge of the first rib—in one mass; secondly, free removal of the supraclavicular fat, fascia, and glands.

So far as I know, however, this procedure is not followed in its entirety except by a few surgeons. Various explanations are often offered to justify omitting, in given cases of carcinoma, parts of the procedure, although every such omission is, for the reasons given above, a violation of surgical principle. To me such omission seems also to be a grievous wrong done to the memory of Mitchell Banks, and there we must leave it.

Hernia.

Now let us turn to the other subject which Mitchell Banks with practical prescience seized upon as a very common infliction on suffering humanity, and yet one most imperfectly treated—namely, hernia.

Prominent among the innumerable benefits which have directly issued from Lister's work is the absolute safety he conferred on the surgical treatment of hernia, and it is interesting to see what a striking diminution of its so-called clinical importance has in consequence resulted.

But hernia still remains a very considerable national evil, and one which it is the business of our profession to remove.

In view of this responsibility upon us, and the fact that hernia as a cause of death is a wholly preventable one, it is very depressing to read in the last report of the Registrar General for England and Wales—namely, for 1911—that no less than 1,569 deaths were certified in one year as due to hernia alone.

Since, as I have elsewhere shown,† our national vital statistics are extremely untrustworthy (in respect of many causes of death—for example, alcohol, syphilis, etc.—utterly so), we must be careful in endeavouring to analyse this astonishing figure, but it may be assumed to mean that a very large number of persons do really die every year directly because of their suffering from a hernia. Whether strangulation occurs or not, however important clinically as being the immediately fatal factor, is a detail quite unimportant for the present purpose, and so also is the question how many of the 1,569 patients were operated upon.

The one grave fact which stands out clearly is that our present treatment of such a very common and simple condition as hernia is exceedingly faulty, and urgently needs reconsideration, because a very large number of our fellow citizens are clearly not protected from its fatal consequences.

But there is also an equally important socio-economic reason for condemning our present methods of dealing with hernia, and that is the continual loss of national working efficiency, owing to the personal incapacity caused by hernia to the hardest worked and most industrious classes of the community.

On this part of the discussion we must determine, if possible, what proportion of the population are thus handicapped or rendered practically useless to the nation.

In his recent statistical report to the Local Government Board Dr. Basil Cook gives tables constructed from the examination of recruits which at least constitute a rough basis for a minimal estimate. From these figures we are probably justified in assuming that at any given moment 500,000 individuals of all ages are suffering to a greater or less degree from hernia in the United Kingdom. As regards total incapacity leading to social failure and poverty, Dr. Basil Cook found that, out of 3,162 paupers, nearly 2 per cent. attributed their pauperism to their being rendered incapable by a hernia.

Now if we ask why the medical profession in this matter of hernia has failed adequately to protect the community from such loss, and done so little to preserve national efficiency, the answer is simple—namely, that until quite recently the largest proportion of the profession's mode of dealing with hernia has been by means of trusses.

Unfortunately for the nation, the application of a truss to a hernia is not treatment of the evil, but merely

* The archæology of surgery is always interesting, and on this point I would like to add that not only were the Bells and Fergusson anatomists, but that Liston taught anatomy till 1833, when Syme took his place. Though followers of John Hunter, they never seem to have been drawn towards biological physiology.

† Evidence to First Report of the Royal Commission on Venereal Diseases, 1914. Also British Medical Journal, 1914, I, p. 923.

palliation. In my opinion we had drifted into this unfortunate habit of regarding a truss as treatment of hernia by following the usual path of least resistance, for the only procedure which merits the name of treatment is of course radical cure—that is, the obtaining by operation a permanent closure of the hernial defect in the abdominal wall. This being so, we have yet to explain why the profession had largely become satisfied with makeshift applications such as trusses. The explanation is not without interest, and shows that our maltreatment of hernia is due to the same causes as our inefficient operating for cancer of the breast, and therefore rightly became an object of Mitchell Banks's reforming zeal.

Seventy years ago the misdeeds of itinerant quacks and the disasters of septic infection had brought all operative treatment of hernia into such disrepute that as late as 1840 the then leader of operative surgery, Liston,[1] said, "Operations for unincarcerated (that is, without any symptoms of strangulation) hernia are not justifiable," and he added, "Those who have operated in such circumstances give a very unfavourable account of the experiment."

In fact, throughout the whole preantiseptic era no progress could be made until Lister had not only freed operative procedures from the risk of septic infection, but in this case of hernia also from the further risk of producing more functional and material injury by suppurative inflammation occurring just where most cicatricial strength was needed. On this latter point I may remind you that Denk[2] showed from his examination of the statistics in von Eiselsberg's clinic that of the cases of hernia operations in which suppuration had occurred, recurrence followed in 43 per cent. The same point had been demonstrated by Damer Harrison[3] seventeen years before.

Although Lister's work is now forty-five years old, such is the unfortunate conservative influence of tradition and custom in our profession that there still exists a certain prejudice against the radical operation, and some surgeons in consequence still speak of "treating" hernia (even in the adult) with a truss, as though this mechanical placebo was something more than a makeshift.

In fact, a truss, like "treatment" by taxis of a strangulated hernia, is one of those *reliquiae diluvianae* which will still survive in medical practice, to the detriment of the community and suffering public, until the only rational treatment by radical cure has become so habituated that operation will immediately follow diagnosis.

This custom being even now prevalent in our profession, it can easily be understood that it was not one of the least difficulties which Mitchell Banks had to contend against when he began, and even as recently as 1882 such was the prevailing darkness on the subject when he read his paper at a (Worcester) Branch meeting of the British Medical Association that Mr. Spanton, in the discussion, pointed out that in the "textbooks of surgery all operations for the cure of hernia were alluded to, only to be condemned as unnecessary and unjustifiable."

No doubt the idea that a truss deserved credit as a form of treatment arose from the number of so-called "congenital" cases in infants which are apparently cured by a rubber truss or even a figure of 8 woollen band.

All that actually happens in these circumstances is that the normal developmental process of closure of the funicular infundibular cavity occurs, and possibly more rapidly than if no support were used, but that a permanent cure is really produced in all the cases in which the hernia does not recur in adolescence there is no evidence to show. Of course these cases of so-called cure of congenital hernia are never followed up, and often the previous existence of the hernia in infancy is wholly forgotten.

Thus as lately as 1895 the principal textbook of British surgery contained the following passage:

> In young children the operation (that is, radical cure) is comparatively rarely required, for during the first few years of life herniae show a great tendency to undergo spontaneous cure.

I know of no statistics which justify the use of the word "cure" as here given. One can imagine Goodsir asking the pertinent questions—What is a cure? What was the subsequent adolescent and adult life-histories of these cases? How many relapsed soon, and how many developed herniae with advancing age?

In truth the actual clinical facts are entirely the other way, as the following analysis of the conditions which underlie the causation of hernia prove.

The old clinicians taught that the causes of hernia were manifold, but that the most important should be all grouped together under one head—namely, muscular effort and strain. That is to say, the assumption was made, and is still taught, that by muscular pressure on the abdominal contents the bowel is driven against the muscles and tissues, gradually stretching these until a sac is completely developed.

I never could bring myself to believe that a smooth soft elastic coil of intestine could be forced through the abdominal wall by violent contraction of muscles, the action of which is not in fact convergent on any spot but over the superficies of the abdomen generally. *A priori*, then, the old theory of the causation being possibly violence alone is not reasonable and moreover cannot be said to have been proved to be really operative in the way supposed.

Further, every surgeon knows that clinically in the large majority of cases a hernia is stated to have been discovered accidentally by the patient; therefore it was not suddenly produced by any such supposititious violence. Thus, Coley found that of 4,780 cases of hernia in adult males it appeared in no less than 3,102 without any known cause or violence.

Frankly, the only reasonable pathogeny is that so clearly worked out and formulated by Hamilton Russell—namely, that a preformed sac is the causal factor of hernia, the clinical converse of this pathological position being the rule first urged by Mitchell Banks, and to the discussion of which I will revert directly—namely, that no cure of a hernia is possible unless the sac is removed.

Hamilton Russell's view that all herniae are due to a primary congenital defect is further proved by the fact that the topical frequency of hernia occurs in precisely the proportion to be expected—namely, according to the regions in which congenital deficiencies and arrests and failures of development most frequently occur. For this reason inguinal hernia heads the list of herniae by such an enormous majority.

Thus all facts—anatomical, pathological, and clinical—confirm the conclusion I have put forward that so-called congenital hernia is not "cured" by trusses; that when the funnel-shaped fossa in the peritoneal surface and often part of the infundibular tube remain, and when in later life the tone of the muscles is diminished the hernia naturally becomes re-established.

The logical conclusion follows that for the good of the community—that is the State as well as the individual—every hernia must be cured by radical operation as soon as it is discovered, and such I believe is the opinion of every modern surgeon.

Mitchell Banks's share in bringing us up to this level of surgical progress was a very interesting one, because although as late as 1893 he was an advocate for the use of trusses, his scheme of real curative treatment was practically what is now universally adopted. I believe, as a radical cure, namely, the fulfilment of two principles:

(*a*) Removal of the sac with restoration of the continuous peritoneal surface (that is, abolition of the fossa).

(*b*) Protection of the hernial area by closure of the inguinal or femoral canal.

Of these two Mitchell Banks undoubtedly thought the first most important, but he always fulfilled the second by closing the canal with permanent—that is, buried—silver sutures.

(*a*) *Closure and Removal of the Hernial Sac as the Chief Step in Radical Cure.*

I have already stated the causal importance of the hernial sac as a developmental relic. If the old theory of causation by sudden violence were correct, then simple ligature of the neck of the hernial sac could not be effective as a radical cure.

Yet that it was actually so has been proved for years by the work of many surgeons, especially Professor Rushton Parker,[4] and this fundamental principle for which Mitchell

Banks contended at a time when little or no support was forthcoming is thoroughly accepted for the cure of inguinal hernia.

The anatomical conditions of inguinal hernia secure that with the closure of the neck sac there is also an abolition of any infundibular fossa, but this is not the case with femoral hernia, and I believe that some unfavourable criticism of radical cure of hernia in general has resulted in consequence of the operative treatment of femoral hernia failing to completely satisfy Mitchell Banks's first principle—namely, complete abolition of the sac. All present-day operations for the radical cure of femoral hernia which approach the sac from below and include various steps, such as closure flaps of aponeurotic tissue like the pectineal fascia, etc., are liable to failure, though a certain number succeed.

They should, in my opinion, be wholly abandoned in favour of the method of operating from above which I employed from about 1890 at University College Hospital.

It consists, first, in a 3-in. horizontal incision through the abdominal wall just above the inguinal canal, ample room being obtained by firm retraction especially of the rectus inwards. The peritoneum being exposed, traction is made upon it and the femoral hernial protrusion lifted out of its bed intact. The sac is then completely removed and the continuity of the peritoneum made normal. The upper orifice of the crural canal is then closed, preferably by a flap of periosteum and a thin scale of bone from the posterior surface of the pubic bone.

I would suggest that recurrence is impossible by this method of operating, and that it involves no more special procedures than those of approach from below, but that its chief value lies in its complete fulfilment of Mitchell Banks's principles.

Schwartschild[5] has since employed a similar procedure for the radical cure of a remarkable case of recurrent obturator hernia.

(b) Protection of the Hernial area by Closure of the Inguinal Canal.

I have already shown that Mitchell Banks fully recognized the importance of this question, but, curiously enough, he does not seem to have fully grasped the most important step of supporting an inguinal hernial defect by transplanting downwards the lower border of the internal oblique muscle and fixing it firmly to Poupart's ligament.

Perhaps the elastic value, and therefore immensely higher efficiency, of muscle tissue as compared to fascial fibrous tissue was not then realized, nor the fact that the rigidity of aponeurotic fibres not only does not prevent their slowly stretching, but also, of course, precludes any physiological elastic recoil which is essential for the support of the viscera.

Owing, unfortunately, to so many cases coming for radical cure when they have been imperfectly supported by trusses for many years until muscular atrophy has resulted, surgeons have been obliged to employ filigree or other materials to furnish a shield to the abdominal defect, and Trendelenburg indeed transplanted bone for this purpose, but no case of hernia should be allowed to sink into such a difficult and hopeless condition.

To sum up this question of hernia, the removal of which from the community is a matter of such vital importance, I would say that our plain duty is to press to their logical conclusion—namely, early and invariably operation—the principles sketched out for us by our predecessors like Mitchell Banks. Our reward will be that we have then achieved a great benefit for our people and for the State by abolishing a source of danger and suffering.

This leads me to conclude with what can only be a very brief reference to a very large share of Mitchell Banks's useful life—namely, his public work for his city, his infirmary, his university, and his profession. The help he gave to each was so great that it is impossible to do more than express our gratitude by meeting on an occasion like this.

Deeply interested in all phases of humanity and of human life, and especially in the interests and success of his fellow citizens in the city of his adoption, he emphasized in the following pungent sentences the duty of every one of us to take some active part in public affairs and assist in the development of social progress:

We must be something more than mere prescribers of physic and healers of wounds. In my youth I had it strongly recommended to me to stick to my profession and leave everything else severely alone. The life of a doctor was to see patients, do operations, order drugs, and collect fees. I thank God that I entirely repudiated this idea of my profession.

Let us show our respect for Mitchell Banks by trying to follow his example.

PINEWOOD SAWDUST AS A SURGICAL DRESSING.

By CHARLES W. CATHCART, F.R.C.S.,

SENIOR SURGEON TO THE ROYAL INFIRMARY, EDINBURGH.

SAWDUST has been used from time to time by many surgeons as a surgical dressing, but its merits do not yet seem to be appreciated as they deserve. At the present time, when an efficient, cheap, and easily prepared material is desirable, I wish to draw attention again to sawdust.

Among those who have recognized its value are the late Owen Thomas of Liverpool, the late Surgeon-Major Porter, R.A.M.C., the late Mr. Callender,[1] and the present active surgical workers in Cashmir, the brothers Neve. In a recent paper by Professor Saundby[2] reference is made to the value of pinewood sawdust as a deodorizer, which was demonstrated to him by the late Professor Vivian Poore.[3]

I have used it extensively in time past, and am using it now in Edinburgh at the Royal Infirmary and at the 2nd Scottish General Hospital at Craigleith, not only for operation wounds but also for septic cases of all sorts. It has also been much appreciated as a dressing for the shell wounds of the wounded German sailors in Edinburgh Castle, and it is very valuable for cases of incontinence of urine.

As to the wood, the sawdust from various kinds of pinewood has given good results. The softer kinds are the best, being more absorbent, while the harder kinds, although less absorbent, have the advantage of containing more resinous material. Commercial hard woods like mahogany or oak should be excluded if pinewood can be obtained. A simple method of testing the absorbent property of a sample piece of planed wood is to draw a stroke across it with a pen full of ink. If the ink spreads laterally, and dries in quickly as it would on blotting paper, the fibre of the wood is good for surgical purposes. If the ink remains on the surface, as on writing paper, the absorbent power is deficient. Apart from the wood itself, however, a good deal of absorption will take place between the individual particles of the wood.

The method of preparation I have found useful is the following:

Two large standard wire sieves are required — No. 8, that is, eight threads per inch, and No. 40, that is, forty threads per inch. In order to reject the coarse fragments the sawdust, as obtained from the sawmill, is passed through No. 8 sieve and allowed to fall on to No. 40.

It is then well shaken and rubbed on No. 40, and the very fine particles which pass through are discarded, because they would escape too readily from the prepared pads and cause an inconvenient dust. The sawdust which remains on No. 40 sieve is put into a box or sack and sent to the theatre sister.

The bags are made of butter muslin, and the sizes may be regulated according to requirement. Two sizes have, however, been found generally useful with us, and these may be shaped from a square yard of muslin as follows: Fold the square once on itself and divide the elongated double piece into three. Each of these thirds will make one large or two small bags. One end is left open, the others are closed by sewing if they do not happen to be folded. The nurse fills the bag about two-thirds full with the sifted sawdust, and then closes it with a coloured thread. The filled bags or pads are sterilized by steam in the same manner as other dressings. After use the coloured thread is withdrawn, the sawdust thrown away, and the bag washed, boiled, and dried for future use.

Besides the advantage of cheapness, and the relative

ease with which it may be obtained, sawdust is very absorbent. The pads are somewhat bulky, but this feature, with careful management, is seldom inconvenient. The discharge is so evenly distributed throughout the mass of sawdust, that the bandages and bedclothes are not soiled nearly so quickly as they are with other forms of dressing. The resin of the wood seems to act as a deodorizer, and probably also as an antiseptic.

Sawdust is well adapted for civil or stationary military hospitals. Its extensive use at the present time would save hundreds of pounds. Other materials more portable, but more expensive, might be reserved mainly for field use.

INSECTS AND WAR:

V.—*FLIES. (I) THE HOUSE-FLY (Musca domestica).*

BY A. E. SHIPLEY, Sc.D., F.R.S.,
MASTER OF CHRIST'S COLLEGE, CAMBRIDGE.

> Musca est meus pater nil potest clam illum haberi
> Nec sacrum nec tam profanum quidquam est, quin
> Ibi ilico adsit.
>
> PLAUTUS, *Mercator*.

"THE common house-fly," says Ruskin, "is the most perfectly free and republican of creatures. There is no courtesy in him; he does not care whether it is a king or clown whom he teases, and in every step of his swift mechanical march and in every pause of his resolute observation there is one and the same perfect expression of perfect egotism, perfect independence and self-confidence and conviction of the world having been made for flies. Your fly free in the air, free in the chamber, a black incarnation of caprice, wandering, investigating, fleeting, flitting, feasting at his will with rich variety of feast, from the heaped sweets in the grocer's window to those of the butcher's back yard and from the galled place on your horse's neck to the brown spot on the road from which, as the hoof disturbs him, he rises with angry republican buzz; what freedom is like his?"

The house-fly is all that Ruskin describes it to be, but it is more. It is the most cosmopolitan of insects. Wherever man is there is the fly. It is found

"From Greenland's icy mountains"
To "India's coral strand."

But it is naturally more frequent in warm climates than in cold, as the rate of its development depends very largely upon temperature.

Fig. 1.—Photograph of enlarged model of the house-fly (*Musca domestica*) in the American Museum of Natural History, New York. (From Gordon Hewitt.)

Unlike the lice and the bed-bug, the fly, like the flea, passes through a complete metamorphosis. It will breed in almost any rotten matter, whether vegetable or animal, and it breeds most successfully, as Gordon Hewitt has pointed out, when certain processes of fermentation are taking place. Probably the fermentation has a favourable effect upon the food of their larvae. Undoubtedly the place most readily selected by the female for laying her eggs is stable manure. A few years ago there was a remarkable reduction in the number of house-flies in London, and Lord Montague of Beaulieu attributed this reduction to the refreshing and antiseptic petrol vapour with which the streets were then bathed. I do not know what experiments Lord Montague had made on the subject of the insecticidal value of petrol vapour, but the ordinary man in the street attributed—and I think more correctly—the diminution of the plague of flies to the absence of the nidus in which the female fly prefers to lay her eggs. Stable-yards had been turned into garages. Flies will, indeed, breed in almost any kind of dejecta, including the human, and in rotten straw, rotten wool, cotton garments, decaying vegetables and fruits, bad meat, rotten grain, and even in spittoons; but they prefer horse-manure.

In our country flies usually begin to breed in June and July, continuing well on into October if the weather be but warm. Their greatest activity is, however, in the hotter month of August and the beginning of September. In warm stables, restaurants, and kitchens, flies are able to develop the whole winter through. A single fly will deposit at one time 100 to 150 eggs, and in the course of her summer life may produce five, or even six, batches of this size. The eggs are pearly white, elongated structures, with two converging lines, along which the egg-case will ultimately split to give exit to the larva. The eggs are laid by means of a long ovipositor a little way beneath the surface of the dung heap in a position where they will not be dried up. In favourable conditions the eggs hatch in from eight to twenty-four hours.

The first larva is legless, tapering towards the head, which bears a pair of breathing holes, or spiracles; the body is much stouter towards the hinder end. On the whole it is a white, unpleasant-looking maggot, called by freshwater fishermen a "gentle." By contracting and expanding its body it pushes its way through its moist surroundings. The skin is usually moulted some twenty-four hours later, but all these time limits depend much upon the temperature and favourable conditions. With normally high temperatures —say with 30° to 35° C.—the larva will become fully

grown in five or six days. The third and final larval stage, after the second moult or ecdysis, lasts three days, and when fully grown the maggot is now about half an inch in length. Externally twelve segments are

Fig. 2.—Mass of eggs of *M. domestica*. (From Gordon Hewitt.)

visible, but the internal anatomy shows that thirteen are really present though one is masked.

It is only during these larval stages that the insect grows, and it is never more bulky than in the third larval stage. Now it leaves the moist situation, in which it has flourished, and, crawling through the manure, seeks some dry or sheltered corner. For a time it rests, and then after an hour or two's quiescence it retracts, its anterior end assumes a barrel-shaped outline, its creamy white colour slowly changing to a mahogany brown. The larval skin forms the pupa case, and within this pupa case the body of the larva undergoes a wonderful change, far greater than even human beings undergo at the time of puberty. Many of its organs are disintegrated and re-formed, and in the course of three or four days the white, legless, repellent maggot, who "loves darkness rather than light," is changed into a lively, flying insect, seeking the sun and the companionship of man. As the Frenchman said of the pork which goes into one end of the machine in the Chicago meat factory as live pig and comes out at the other in the form of sausages, "il est diablement changé en route."

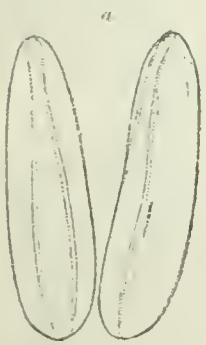

Fig. 3.—Eggs of *M. domestica*, × 40, dorsal and dorso-lateral views. *a*, Anterior end. (From Gordon Hewitt.)

In a short time after leaving the pupa case the fly has stretched her wings, the chitin of her body has hardened, and she flies away "on her several occasions."

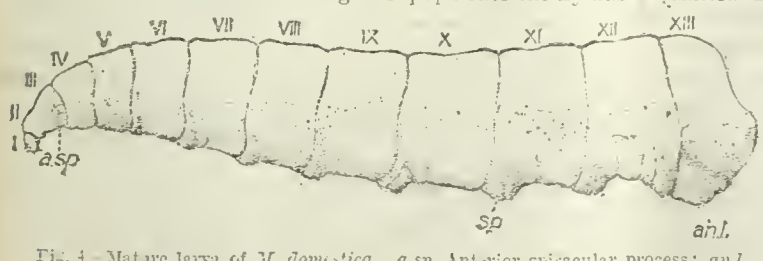

Fig. 4.—Mature larva of *M. domestica*. *a sp*, Anterior spiracular process; *anl*, anal lobe; *sp*, spiniferous pad. I-XIII, Body segments. (From Gordon Hewitt.)

Flies become sexually mature in a week or ten days, and are capable of depositing their eggs four day after mating, so that if the conditions be indeed favourable the whole development from the egg to the perfect fly may be accomplished in nine or ten days, and the second generations are able to lay their eggs ten days later. The appalling fecundity of such an insect explains the fact that in the hotter parts of the world nearly everything seems to be half covered with them.

The proboscis of a fly can only suck in liquid food, and when we see it feeding on solid substances, such as sugar, it has really dissolved the sugar by depositing some saliva on it, and is sucking up the sugary solution so produced. It not infrequently regurgitates its food in a spherical drop, which it generally reabsorbs.

As we have seen, flies are very susceptible to temperature, and with the approach of cold weather they either die or retire to hiding places in warm dwellings, and here in a state of suspended animation they pass the winter months. Many of them undoubtedly die in the autumn, as bees die, of old age; they are literally worn out. But a great number fall victims to a parasitic fungus called *Empusa*. Flies killed by this fungus are frequently to be seen in autumn, hanging dead on windows, etc., surrounded by a little whitish powdery ring of spores discharged by the fungus. Like many other insects, they are extremely difficult to keep alive in captivity, and few have succeeded in rearing them for more than a month or two. It seems probable that those flies which survive the winter are fertilized females of the younger broods. During the winter they live upon their fat bodies and their abdomen shrinks, but in the spring it very soon regains its former proportions after a meal or two.

Fig. 5.—Pupal case or puparium of *M. domestica* from which the imago has emerged, thus lifting off the anterior end or "cap" of the pupa: ventro-lateral aspect. *a.sp*, Remains of the anterior spiracular process of larva; *l.tr*, remains of the larval lateral tracheal trunk; *n.sp*, temporary spiracular process of nymph; *p.sp*, remains of the posterior spiracles of larva.

Gordon Hewitt, Copeman, Howlett and Merriman, and others have made experiments as to how far a fly can travel. Marked flies have been taken within forty-eight hours at distances ranging from 300 yards to a mile. Apparently the direction of the wind plays a considerable part in the distance they travel.

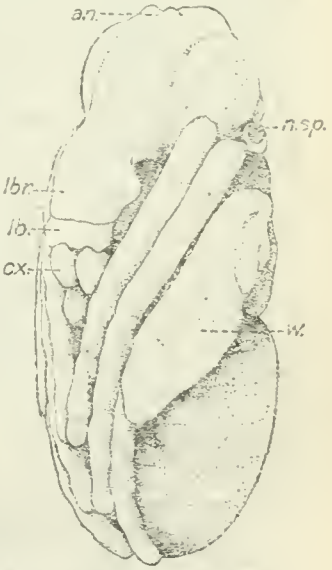

Fig. 6.—"Nymph" of *M. domestica* dissected out of pupal case about thirty hours after pupation. *an*, Swellings of nymphal sheath marking bases of antennae; *cx*, coxa of leg; *lb*, labial portion of proboscis sheath; *lbr*, labral portion of same; *n.sp*, spiracular process of nymph; *w*, wing in nymphal alar sheath. (From Gordon Hewitt.)

The house-fly has recently become of very great importance to humanity, and especially to humanity at war, as a carrier of disease, especially of bacterial disease. Moses was as great as a Principal Medical Officer as he was as a Director of Supplies, and this is shown in Deuteronomy, chapter xxiii, where he deals with the need of strict

hygiene in the camp. In the middle of last century already attention was being drawn to the fact that the house-fly and the blow-fly transmitted various diseases. But it was during the American-Spanish war and the South African war which followed shortly afterwards that the part played by these pests in conveying enteric became definitely established. Flies coming straight from the latrines with their legs and their wings and their proboscides soiled with typhoid bacilli would enter the camp and

Fig. 7.—*M. domestica* in the act of regurgitating food. × 4½. (From Gordon Hewitt.)

the tents of the soldiers and settle on their food supplies, crawling over their jam, floating in their milk. Thirty per cent. of the deaths in the Boer war were due to typhoid fever. The bacillus, as is well known, is capable of existing for a long time and of persisting alive in the alimentary canal of the insect, and Graham Smith has shown that the bacilli may remain active for six days after feeding, and that the feet of flies which have the bacillus on them are capable of infecting surfaces upon which they walk for at least two days after first coming in contact with the germs.

Faichne reared maggots in dejecta infected with typhoid bacilli, and he was able to show that the flies into which these maggots turned contained virulent typhoid germs in their intestines. There is absolutely no doubt that typhoid is largely conveyed by the agency of these insects, and as flies are perfectly controllable if the people will but have it so, it is one of the disgraces of our civilization that this disease should be so prevalent.

The protective inoculation against enteric is now almost perfect, and its value is shown by two quotations from a valuable leaflet issued by the Research Defence Society:

> Sir William Leishman, in a letter published during the present war, August 22nd, 1914, says: "The benefits of inoculation are so well recognized in the regular forces that we find little difficulty, in foreign stations, in securing volunteers for inoculation; for instance, about 93 per cent. of the British garrison of India have been protected by inoculation, and typhoid fever, which used to cost us from 300 to 600 deaths annually, was last year responsible for less than 20 deaths. Inoculation was made compulsory in the American army in 1911, and has practically abolished the disease; in 1913 there were only 3 cases and no deaths in the entire army of over 90,000 men."
>
> In Avignon, in the south of France, during the summer of 1912, typhoid fever broke out in the barracks. Of 2,053 men, 1,366 were protected and 687 were not. The non-protected had 155 cases of typhoid, of whom 21 died; the protected had not one case. In the winter of 1913 the French Senate resolved that the protective treatment should be made compulsory throughout the French army; and, in special circumstances, among the reservists.

Infantile diarrhoea, which so afflicts the crowded poorer quarters of our cities in the summer, is another disease

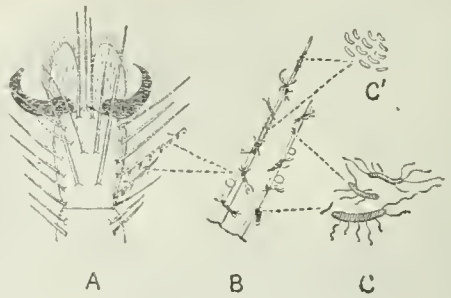

Fig. 8.—A, Foot of a fly, showing hairs bearing bacteria; B, a single hair more highly magnified; C and C', bacteria.

intimately connected with the *Musca domestica*. But that is hardly a disease likely to trouble the soldiers. The tubercle bacillus is another germ conveyed by flies. They are particularly fond of feeding on saliva, and Lord, Hayward, and Graham-Smith have obtained virulent bacilli from the intestines and dejecta of flies which had been fed on tubes containing tuberculous sputum. These experiments have been amply confirmed by other workers. Any one who has ever been in Egypt will remember the terrible sight of the flies attacking little children suffering from ophthalmia, and it is believed that the wide prevalence of this most pitiful trouble is attributable to the abundance of flies — the flies of Egypt.

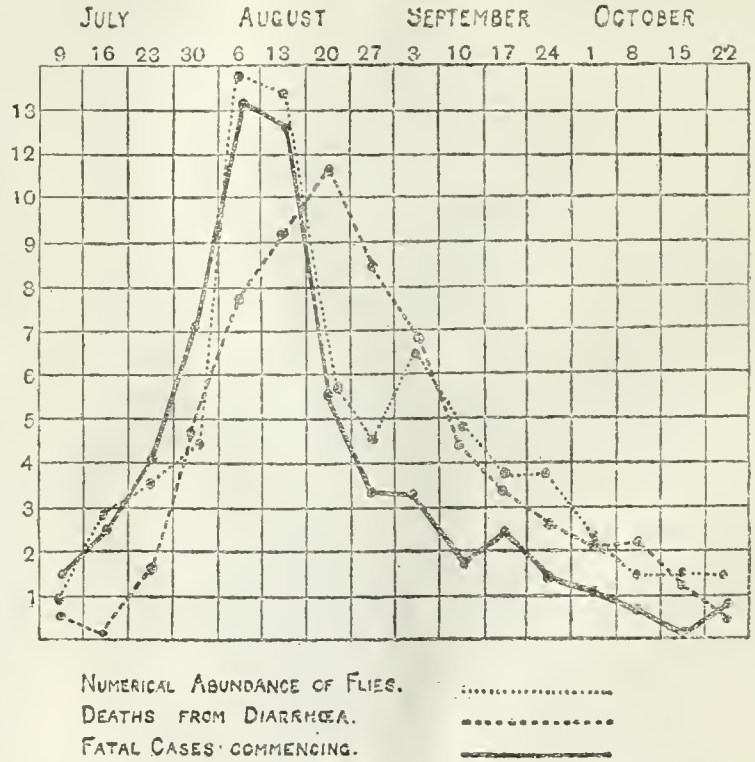

Fig. 9.—Chart illustrating the relation of the numerical abundance of house-flies to summer diarrhoea in the city of Manchester in 1904. Prepared from statistics and chart given by Niven.

Another disease—anthrax, or wool-sorter's disease—may be conveyed by the same carriers from infected cattle, and there is a good deal of epidemiological and bacteriological evidence available to show that flies play an important part in the spread of cholera, which is now becoming alarmingly prevalent in the Eastern seat of the war, and possibly in disseminating the organisms which cause yaws and tropical sore.

It will be noticed that the fly is not a necessary second host for any of these germs. They are conveyed, as if by an inoculating needle, by contact with the proboscis or the legs or other organ of the fly. Other bacilli, however, pass through the alimentary canal apparently unchanged and unharmed, and are deposited either with the regurgitated food from the fly's stomach, or with the dejecta of the insect. There is no subcutaneous inoculation such as takes place in the case of the mosquito when it conveys malaria, or in the case of the tsetse fly conveying sleeping sickness, where the disease-causing organism is injected into the human body. The action of the fly is mechanical, but none the less efficient. The poisoning of the soldiers' food supply is its chief rôle.

(To be continued.)

EIGHTY-SECOND ANNUAL MEETING
OF THE

British Medical Association.

Held in Aberdeen on July 29th, 30th, and 31st.

PROCEEDINGS OF SECTIONS.

SECTION OF MEDICINE.

F. J. SMITH, M.D., F.R.C.P., President.

THE OUTLOOK IN EPILEPSY.

By WILLIAM ALDREN TURNER, M.D., F.R.C.P.,
Physician to King's College Hospital and to the National Hospital for the Paralysed and Epileptic, Queen Square, London.

In estimating the curability of epilepsy it is necessary to define what is meant by a cured case. A cure has generally been considered to be an arrest of seizures for a certain number of years—the actual number of years varying from two or three up to ten or more. With so much elasticity in the definition of a cure, it is not unnatural that the cure of any given case of epilepsy would depend upon the interpretation, optimistic or otherwise, which the physician would place upon the arrest of seizures in his patient.

We know that cases remit for several years and then relapse sometimes into an incurable state. It is therefore desirable that some feature other than a time limit should be introduced into the definition of the cure of epilepsy. I am therefore entirely in agreement with Pierce Clark[1] and others, who hold that the mental condition of the patient is an essential factor. The cured epileptic should be able to obtain his living. If this state can be obtained without the use of sedatives so much the better, but complete withdrawal of all sedative remedies is not necessary. I have personal knowledge of a number of epileptics who are able to attend to business and carry on all the ordinary duties of life so long as they take a daily dose of bromide, but who at once lose confidence in themselves and sometimes experience a return of symptoms when bromide is withheld for a time.

It may be urged by way of criticism that those patients ought not to be regarded as cured; but my point is that the most that can reasonably be expected in epilepsy is the arrest of the fits in conjunction with a mental condition so unimpaired that the patient is able to attend to business and earn his living according to his vocation. If the sedative drug can be permanently withdrawn (and this should be done gradually) without any relapse of the seizures and with retention of good mental faculties and memory, the case belongs to the group of cured epilepsy.

The curability of any case of epilepsy depends to a large extent upon several factors, to which brief consideration may be given.

The epilepsies of infancy and early childhood form one of the most unsatisfactory of the several types of the disease. In many cases these epilepsies arise from organic focal lesions of the brain. Some of the patients also are backward in mental development, in walking, and in talking. Quite a large proportion are feeble-minded, showing restless, destructive, and often dirty tendencies. There is one point, however, which ought to be borne in mind in connexion with the early epilepsies—namely, the remarkable tendency to temporary arrest or remission of the fits which frequently takes place about the age of 4 or 5 years, a remission which may last for some years, or until puberty.

When, however, we come to consider the epilepsies of puberty and adolescence, which are the common periods for the onset of the idiopathic disease, we have as a rule a not unfavourable type of epilepsy, provided that the fits are not too frequent, too severe or of a psychical character, that the mental condition is satisfactory, and that the treatment is undertaken early and conducted persistently.

In the late epilepsies, or that form of the disease which arises after 30 or 35 years of age, we find on the whole a favourable type of epilepsy, provided that the seizures are not symptomatic of a cerebral tumour or other organic lesion of the brain and that alcoholism may be excluded.

In the greater number of cases of idiopathic epilepsy no cause of the fits is found. The origin of the disorder is attributed to the normal processes of development, growth, and maturation of the reproductive functions in those who are hereditarily disposed to nervous instability and convulsions. On the other hand, infective causes may be at work, among which scarlet fever, measles, and diphtheria may be mentioned. Psychical causes, such as fright, worry, and anxiety, are not infrequent, and injuries to the head without organic cerebral lesion are often mentioned as the exciting cause.

My own experience, and it would seem to bear out the observations of others, is that epilepsy supervening upon infective conditions, such as scarlet fever or measles, is not an unfavourable type of the disease, and should stimulate to prolonged medicinal treatment.

On the other hand, cases attributed to psychical causes have a less favourable outlook.

In a general way my experience shows that cases of epilepsy arising without exciting causes and without ascertainable heredity are less favourable for treatment and are more likely to become confirmed cases than those with both an exciting cause and a hereditary foundation.

It is in connexion with the late epilepsies that the investigation of an organic cause is important. Should an individual over 30 years of age develop epileptic or epileptiform attacks, certain possibilities should in the first place be investigated before a diagnosis of epilepsy is made. One of the commoner causes of epilepsy in later years is the onset of intracranial tumour, hence the need of careful examination of the reflexes and the optic discs in all such cases. In a like manner general paralysis of the insane may develop and its existence be eliminated only after careful examination, in which the Wassermann reaction of the cerebro-spinal fluid should play a part. The majority of cases of late epilepsy are due either to chronic alcoholism or to degenerative cardio-vascular disease. My experience of late epilepsy of vascular origin is on the whole favourable, provided that there is abstinence from alcohol and the administration of the bromides is maintained over a long period.

It is a matter of common knowledge that the major attacks (grand mal) are more readily influenced by the bromides than the minor attacks (petit mal). My statistics show that the largest number of cases of arrested epilepsy are found amongst those who suffered from major fits of relatively infrequent occurrence. The least favourable type of the disease is the true minor epilepsy or petit mal, especially when the attacks are of a psychical character with epileptic automatism as a marked feature.

Quite a favourable type of epilepsy, on the other hand, is that which is characterized by the presence of jerks or jumps frequently unattended by loss of consciousness, the "petit mal moteur" of the French writers.

A recent German writer[2] on epilepsy states that cases showing considerable motor and psychical irritability at the time of the seizures respond favourably to bromide treatment. He points out that the activity of the knee-jerks is especially valuable as a guide to the usefulness or otherwise of the bromides in any particular case.

It is, however, on the mental condition of the patient that the physician should rely largely in forming an estimate of the curability of any particular case of epilepsy.

The term "mental condition" here referred to is that which is observed during the intervals of the seizures, and may be called the permanent interparoxysmal mental state.

The mental state of epileptics varies within limits from what may be regarded as normal, on the one hand, up to a considerable degree of dementia on the other. A certain number of epileptics present no obvious mental deficiency, notwithstanding an inherited predisposition to the disease, the duration of the malady over many years, its onset in early life, and the combination of major and minor attacks, occurring at frequent intervals. Likewise the impaired mental condition found in many epileptics is not necessarily the direct consequence of the seizures, but is an expression of the same neuropathic constitution which gives rise to the fits.

There can be no doubt that the earlier the onset of the

disease, especially when under 5 years of age, the greater is the probability of mental failure—a fact which indicates a more aggravated type of the malady than that which occurs in consequence of arterio-sclerosis in later life.

It is therefore obvious that when a case of epilepsy first comes under observation certain features are present by which the outlook may be surmised. As features of a favourable character may be mentioned the commencement of the disease between the ages of 16 and 20, especially if a hereditary history is obtained, and some obvious exciting cause for the disease is present; the commencement of the disease after 40 or 45 years of age provided organic disease of the brain can be eliminated; infrequent occurrence of the seizures, and the absence of any obvious mental impairment or well-marked stigmata of degeneration.

In contradistinction to the above-mentioned type of epilepsy, or that class of case which is eminently favourable for treatment, there is the incurable, chronic, or confirmed type, which finds its way eventually into institutions for epileptics.

The general features of epileptic dementia need not be considered here, but it is revealed by all grades of mental deficiency, from a mere defect of memory, especially for recent events, up to pronounced dementia. Although an integral part of the disease it may be modified to some extent by the duration, the frequency, and the character of the seizures.

My experience shows that once the mental condition has become materially affected in the direction of dementia, the outlook as regards any real amelioration is unfavourable, although the fits may be kept in abeyance over long periods by sedative remedies.

RHEUMATOID ARTHRITIS.

By D. DURWARD BROWN, M.D.,

Harrogate.

To most medical men, and in Harrogate to all, this condition presents itself as one of the most insidious, most perplexing, and even most mysterious of the ills of our modern time. It is, if we may trust tradition, growing in the frequency of occurrence. The obvious commentary on such a statement is that it is now more readily diagnosed. It certainly has signally arrested our regard in Harrogate, where we yearly see an ever-increasing number of cases.

Before approaching the subject of treatment I must claim the benefit of your intelligence whilst I shortly run through the etiology of this disease, for treatment is but the sequel of such an understanding.

General Causes.

1. Absorption of toxic products—for example: (*a*) Pyorrhoea alveolaris, 70 per cent. of cases are due to this cause; (*b*) leucorrhoea; (*c*) local suppurations; (*d*) worry; (*e*) thyroid changes.

2. Menopausal causes: (*a*) Artificial; (*b*) natural, often premature as to time.

3. Inflammatory abdominal causes, as in a case reported by Dr. Woodcock, in which an acute abdominal crisis, apparently without suppuration, was followed in two months' time by a typical acute rheumatoid arthritis, affecting the joints universally.

The Direct Chemical Cause.

This is the abnormal fermentation products of carbohydrates. Such foods seem to form a generous nidus for the growth of micro-organisms. Men suffer less than women from this disease.

Another point I should like specially to bring to your notice is the connexion of certain spinal disorders and rheumatoid arthritis. In these cases the spine is attacked by infective inflammation, as metastatic arthritis, or a chronic cerebro-spinal toxaemia is followed or preceded by changes in the joints of the spine, the joints of which show the characteristics of rheumatoid arthritis, but the changes are not limited to the spinal bones, at least, so I find in the very many cases I have met with among visitors to Harrogate. I decidedly lean towards the theory that the changes in the joints and muscles which are characteristic of rheumatoid arthritis may be due to irritation and destructive lesions often first located by the physician as being in the spinal ganglia, and especially met with in the cervical and lumbar enlargements.

In my early cases with a history suggesting a septic cause, I find that although the main symptoms present are often stiffness of the fingers with slightly enlarged joints, yet the spine, especially at the eighth or ninth dorsal, shows a decidedly painful spot, and when the patient's attention is called to it, he or she will remember vague inconvenience at intervals which she has suffered for years.

Some authors hold that the cause is either infective or nervous, but why separate causes which are interdependent?

Treatment.

The aim of treatment in all cases must be as follows:

1. To remove the toxic cause in the digestive tract; the greatest offenders in this direction are the teeth, gums, and, to a less degree, the nose, tonsils, and stomach. The teeth must be removed or otherwise treated by antiseptics. A case I saw two years ago illustrates this:

> Miss M., aged 45, was so lame as not to be able to walk without a stick; both knees very swollen and tender; hands stiff, but no deformity. On inquiring, I found she had a full set of false teeth, and she said they were all right; but, on asking her to remove them, I discovered the teeth had been broken off, and all the stumps were left, and the mouth was in a filthy condition. I advised extraction of the teeth, which was done (two or three at a time, as, to my mind, the disease is aggravated if they are all taken out at one sitting), and within a month the knees were reduced to almost normal, and the last time I heard she was able to play the English national game, which every Scotsman knows to be golf.

The nose must also be examined and treated, if necessary.

The stomach must also be treated with care; and might I mention here that in the majority of cases of rheumatoid arthritis I find dilatation of the stomach to a greater or less degree?

Leucorrhoea and all other discharges must be inquired into and treated by the gynaecologist.

2. To encourage the elimination of the poison by the bowels, kidneys, and skin.

The Bowels.

In Harrogate we make use of the Plombières treatment, and, if thought advisable (a lot of these cases are not able to stand too drastic treatment), the sulphur water each morning for the first week at least.

If at home, Hunyadi water, or a similar water, might be given three mornings running, and after which a large enema twice a week is necessary.

Drugs.

Among the principal drugs I place creosote or guaiacol, and I certainly agree with Dr. Luff that great benefit can be got by their use. I generally order it in the form of a cachet (guaiacol carbonate grains v, guaiacol resin grains v), and if pain is severe I prescribe calcii acetosal (grains v), and with quinine sulphate (grains j), and these I give on alternate weeks with some form of iodine, and also in most of these cases thyroid extract (grain j) twice or thrice a day.

Might I point out here that[1] not only does the internal secretion of the thyroid gland promote appetite, digestion, and peristalsis, but also it neutralizes any toxic substances resulting from imperfect digestion of food, and therefore is an adjunct in the cure of rheumatoid arthritis?

All these must be continued for months or even years, and personally I have greatly rejoiced at the results of this treatment.

I have also used solution of magnesium sulphate (25 per cent. solution, use 2 c.cm.), injected into the muscles, but the results are uncertain, although in more acute cases of rheumatism the results have been brilliantly successful. I got the idea from Russell of Edinburgh and A. B. Jackson of Philadelphia, and certainly in some cases it is all that they promise.

General tonics must not be forgotten—their name is legion, and a few are good. Syr. ferri hypophos. co. will do as well as any.

Kidneys.

Hot water should be taken the last thing at night and first thing in the morning.

Electric Treatment.

Blistering the spine has been recommended by several authors,[2] and I have carried out this treatment in several cases with good results. The blisters are applied in the mid-dorsal and lumbar regions, and the wounds kept open for three weeks with savin and resin ointments, but the fault I find with this drastic treatment is that so few patients will submit to it, and, besides, why continue this when the same results can be procured from ionization? In this I always first of all treat the back, feeling very confident that the spine is the primarily affected part. The ionization is applied in the form of pads of potassium iodide and lithium—one on the dorsal and the other to the lumbar region. Later I treat the other affected parts in the same way, such as the knee, hand, foot, etc. Alternating with this treatment I give d'Arsonval or static treatment, according to whether the blood pressure is above or below normal. If there is much pain in any of the joints I also give Berthollet baths (hot steam up to 300°) to the affected parts, also "light and heat" and peat baths.

Massage and Exercises.

This is very important towards the end of the treatment, specially when the disease is complicated with fibrositis, or in some cases of panniculitis; also to give tone to the abdominal muscles and indirectly to the stomach and bowels. With these I usually advise some light exercises, especially those of resistance.

Summary.

Is rheumatoid arthritis increasing in frequency? The answer I would give would be Yes, but one reason that might disprove that assertion would be the more frequent capable diagnosis made in the disease. Then I should ask, Is it curable? Now here I give a very emphatic Yes; although we deplore almost every day how patients are told that there is no cure for rheumatoid arthritis, and practically nothing can be done for the patient. I think this is deplorable. Why should a disease so frequent be left to its fate in this stupid manner? Can you blame patients who get no assistance from their own medical men reverting to all sorts of advertised quackery?

Therefore, let us agree that the first thing is to remove all sources of infection, and especially associated with dental decay. Then, if possible, hurry the patient into a nursing home, where she will be away from any worry or alien thoughts. Keep her in bed as long as possible, up to three weeks or a month, and all this time electric massage and bathe her, and above all feed her generously well.

Do not despise suitable treatment by drugs, and at the risk of undue repetition go in manfully for electricity and massage, but above all devote the latter to the spine primarily and to the other joints secondly. This treatment can, no doubt, be best carried out at a spa, and in Harrogate, during three to six weeks' stay, a patient can be given a very good start towards complete recovery. After the period of passive movement comes the period of active movement, and many nowadays would give less bed than I have given.

SECTION OF DISEASES OF CHILDREN.

Dr. John Thomson, President.

THE TREATMENT OF TORTICOLLIS

(CONGENITAL NON-SPASMODIC WRY-NECK).

By Paul Bernard Roth, M.B., Ch.B.Aberd., F.R.C.S.Eng.,
Surgeon, Kensington General Hospital; Senior Orthopaedic Clinical Assistant, London Hospital.

This note is in the nature of a plea for the adoption of a simpler treatment than that usually employed. The present teaching is that the whole muscle, that is, the sternal and the clavicular heads, together with bands of deep fascia, must be divided by the open operation; and that retentive apparatus must then be applied over a long period subsequently. I maintain:

1. That, as a rule, division of the sternal head is sufficient; in exceptional cases division of the clavicular head is also required; but division of bands of deep fascia with the knife is never required.

2. That whether the clavicular head is divided or not the operation should always be done subcutaneously.

3. That retentive apparatus after the operation is entirely unnecessary.

The following remarks are made in support of the above propositions:—

1. In the very large majority of cases, when the sternal head is divided on the operating table, the deformity can be over-corrected without any further section. I am therefore unable to see why the surgeon should proceed to divide the clavicular head. The favourite argument advanced is that as he is operating he may as well do the job thoroughly, and so lessen the likelihood of relapse. But it is a good surgical rule never to divide a structure if it can be saved, and relapse after operation for torticollis is practically unknown. I doubt if there is anyone here who can cite a case. Exceptionally, perhaps in one case out of ten, division of the sternal head is not sufficient; in such a case, after division of the sternal head, the clavicular head rises up instantaneously into the area of operation, as if to take its place, and it also must be divided. If after section of both of these the deformity cannot be over-corrected, firm but gentle manipulation of the head while the patient is still anaesthetized will stretch or rupture any bands of deep fascia responsible; to divide these by any cutting operation is fraught with danger, owing to their close proximity to the internal jugular vein.

2. While house surgeon at the London Hospital in 1909 I divided the sterno-mastoid muscle in five patients by the open method. Since then I have always divided it subcutaneously, and the latter method appearing so vastly superior I examined the literature of the subject to find out if possible why it had been abandoned; in this, however, I was unsuccessful. The operation was first described by William Salmon, M.D., in 1685,[1] but was apparently first performed by Roonhuysen in 1670.[2] It was the standard operation for the greater part of the nineteenth century, for an open operation would have ended in suppuration. When antiseptic surgery came in there was a great tendency to abandon all old methods and do everything in a brave antiseptic manner, and this operation seems gradually to have fallen into disrepute for no other reason. At the present time the alleged danger of the operation is a formidable bogey, but that is all. In every modern manual of surgery with but one exception, one is warned of the danger of the operation, and in most of them strongly advised not to perform it. In only one book is it recommended—namely, in Calot's *Orthopédie Indispensable*.[3] Calot says: If you are set on doing it by the open method, do it by the open method; but if you have no views on the subject, take his advice and do it subcutaneously. When I tried to obtain evidence of the danger of the operation, in book after book I found it stated that accidents had occurred, but hardly ever any definite data. Erichsen[4] stated, in 1884, that he had heard of "more than one case in which from want of due precaution, abundant haemorrhage occurred, and of three in which a fatal result followed the operation." (Cause not stated.) Then Edmund Owen,[5] in 1890, described how he nearly lost a case during the operation.

This exhausts the evidence I have been able to find in books as to the danger of the method.

As for Erichsen's three cases, of which he had heard, it is not clear what they died of; a fatal result may follow any operation. They may have died of sepsis.

As for Owen's case, as recorded in the British Medical Journal,[5] a vein was divided, and the air was heard being sucked in with each breath with a hissing sound, and no attempt seems to have been made to apply a pad to the wound. If this had been done, it is unlikely there would have been any untoward symptoms to record.

I wrote to Owen in 1912 to ask if he knew of any other case of accident, and he kindly replied at some length, telling me that when he was house-surgeon to Spencer Smith the latter told him that Skey, whose pupil he was, divided the tendon subcutaneously, and that the patient—a young lady—died on the table. My comment on this case is that we do not know whether the young lady had not "status lymphaticus."

The above does not appear to me sufficient ground for regarding the operation as dangerous. On the other hand, I regard the open operation as certainly dangerous. Directly the incision is made just above the clavicle, the negative pressure at the root of the neck causes all the deeper structures, including the subcutaneous tissue, to retract so that a hollow space is formed there; and it becomes exceedingly difficult not to wound a vein. Moreover, after one has divided the tendon one feels tempted to nick at various strands of tense fascia which lie perilously near the great vessels of the neck. On five occasions when I have performed the open operation, even though I had ample assistants and a good light, I was never able to avoid wounding both the anterior jugular and external jugular veins. Owing to the formation of the negative pressure space, these veins come to occupy an abnormal position, and the tissues which should support and protect them fall away. Bradford and Lovett record a case where the internal jugular vein was wounded during the open operation. Another danger is undoubtedly that of sepsis.

Then there is the difficulty of suturing; it is very difficult to join the skin edges accurately, the reason being the negative pressure space. Even if the edges appear in good position, a day or two later they are found apart or puckered in. The result in nearly all cases is a depressed scar. This grows, as all scars grow, and when the patient, perhaps the daughter of well-to-do people, starts going out to dances, on her neck is a bad advertisement for the surgeon. I have heard of three cases in private where the scar has developed into a keloid. A writer[6] on this subject makes light of the annoyance of a resulting scar, and then describes a new incision of his own for avoiding it. Probably when the new incision has been tested by time the resulting scar will be as bad as ever. The subcutaneous operation leaves no scar at all.

Technique of Subcutaneous Tenotomy.

General anaesthetic; paint with iodine; while tendon is being made prominent by gentle traction, introduce with blade held vertically a sharp-pointed, slender-bladed tenotome immediately to inner side of sternal head, half an inch above sternum; when way clear to tendon withdraw, and insert blunt-pointed tenotome; insinuate it carefully behind tendon, turn blade at right angles to tendon, and stroke the tendon with little short strokes while the anaesthetist puts the muscle on the stretch; the tendon gradually gives way as bundle after bundle of fibres are cut through; there is no hurry; half a minute may be taken to divide the whole tendon. When divided withdraw tenotome and at once seal opening with celloidin and gauze. After division of the sternal tendon the clavicular tendon, if it require division, at once springs up into the area of operation, and appears as a tense band under the skin, just as the sternal tendon had previously done. The sharp tenotome is again taken, a vertical puncture again made at the inner side of this tendon, and the operation completed exactly as before. No attempt is made to divide deep bands of fascia. After the first pad of gauze and celloidin is set, or if both tendons have been divided, after the second pad, the surgeon takes the patient's head and firmly, but gently, twists it round till the chin is over the shoulder of the affected side; as he moves it round any bands of fascia which perhaps still retain the head in a bad position give way. Turning the head straight again, he now bends it sideways until the ear on the unaffected side can be made to touch the shoulder on that side. The head is then laid straight, a pad of wool fixed over the gauze with strapping, and the patient left till next day, when the same two movements are performed once each. On the third day the patient is allowed up.

REMARKS.

As regards the possibility of injury to veins in this operation, there are two which might be injured—the anterior jugular and the external jugular. (It is difficult to conceive of any surgeon being fearful of wounding the internal jugular, which in a case of torticollis lies ½ in. to ¾ in. deep to the posterior surface of the muscle.)

The anterior jugular can be avoided by introducing the tenotome exacting at the inner border of the sternal tendon, ½ in. above the sternum; this is outside the vein where the latter runs vertically, and above it where it runs horizontally.

The external jugular is not wounded, because by the time the tenotome gets near it the tendon is divided, and the surgeon at once ceases moving it.

Even supposing that both these veins are nicked, owing to their occupying an abnormal position, it is doubtful whether any serious bleeding could take place; for there is no artificially produced negative pressure space for them to bleed into, and the tendency is for the blood to be drawn in rather than out.

3. The question of the unnecessary use of retentive apparatus after operation was dealt with at some length in a paper[7] contributed by me to the *Lancet* in 1911; and I have only time to refer briefly to it. In that paper I showed by extracts from leading textbooks that the universal practice was to use retentive apparatus; I then gave a description of the treatment I had carried out in four cases without the use of any apparatus, and indeed without any after-treatment at all except some slight simple exercises, with excellent results; and finally suggested that the use of retentive apparatus was unnecessary in all cases.

In the next issue of the *Lancet*[8] appeared a letter from Mr. T. H. Kellock warmly endorsing my remarks, and even going further and stating that exercises and manipulations are equally unnecessary. He also stated that "relapses after operation for torticollis seem to be very rare." Since that letter was written I have slightly altered my practice. Where the case is one of simple torticollis, in a child, say, of 4 or 5, division of the muscle is all that is required, and I discard exercises; but in older children, where a secondary scoliosis has been produced, exercises after the operation are of use in hastening the assumption of a straight position, and I retain them.

I conclude this paper by a quotation from the works[9] of one whose opinion, though delivered in 1863, before the days of antiseptic surgery, and therefore before the introduction of the open operation, will certainly carry weight with you—Syme of Edinburgh:

> Every case of wry-neck that has come under my care since the one just mentioned (which was in 1831) I have treated in this manner—that is, by subcutaneous tenotomy—with invariable success. I have seldom found it necessary to divide more than the sternal portion of the muscle. . . . No . . . after-treatment of any kind is required, since the distorted parts soon regain their natural position.

Reports of Societies.

MEDICAL SOCIETY OF LONDON.

THE first ordinary meeting of the session was held on October 12th. A vote of thanks to the retiring President, Sir David Ferrier, was proposed by Dr. DE HAVILLAND HALL, seconded by Mr. WILLMOTT EVANS, and carried with acclamation. Sir DAVID FERRIER replied. Dr. WALTER BROADBENT proposed a vote of thanks to the other retiring officers. This was seconded by Dr. STEELE PERKINS, and passed unanimously. Dr. R. A. YOUNG, the retiring Honorary Secretary, replied. Sir DAVID FERRIER then introduced the new President, Sir J. Bland-Sutton, and invested him with the badge of office. Having taken the chair, Sir J. BLAND-SUTTON delivered his opening address on Cancer of the Small Intestine, which is published in full in this issue of the JOURNAL (p. 653). A vote of thanks to the President for his address was proposed by Mr. SWINFORD EDWARDS, seconded by Sir STCLAIR THOMSON, and carried unanimously.

THE second annual convention of the Cremation Association of America was held at Indianapolis on September 3rd. The President, Dr. Hugo Erichsen, of Detroit, delivered an address in which he reviewed the progress of cremation. Speaking of the obstacles which the movement had met with he said: "The apathy of the general public, the antagonism of some undertakers, the indifference of the press, the open hostility of certain cemetery and mausoleum corporations, and the inertia of some so-called cremationists—surely no reform ever had to cope with so many difficulties and obstacles as ours." Yet in face of them all he was confident of ultimate success. The Convention extended over two days, and many questions relating to cremation were discussed. Dr. Erichsen was re-elected president.

Memoranda:
MEDICAL, SURGICAL, OBSTETRICAL.

TREATMENT OF TETANUS.

Anything which may be of use to our wounded needs no apology, therefore I wish to repeat some remarks I made in the British Medical Journal of November 5th, 1910.

In the ordinary way tetanus is such a rare disease that it only occupies a small part of one's thoughts. Now this is not the case. Tetanus kills partly by the direct action of the toxin and partly by the exhausting effects of the convulsions. By the trismus and dread that taking food will bring on a convulsion, starvation is added to the horrors of the disease, and sleep is prevented by the painful muscular contractions. In treating the disease when it is manifest there are therefore the following indications:

1. To prevent further absorption of toxin by the removal of its source as far as possible.
2. To neutralize the toxin present.
3. To relax the muscles and prevent the tetanic spasms, so that the patient will escape the exhaustion and be able to take food and to sleep. Consequently he will be spared much suffering and be in the best position to fight the disease.

Of the first two indications, the necessity for removing every scrap of necrotic tissue or blood clot, the provision of the freest drainage, the great value of the prophylactic dose of antitetanus serum after suspicious wounds, and the necessity for large doses to produce effect when the disease is established, are too well known to need more than passing mention. But the use of chloretone to meet the third indication does not seem as well known as it deserves.

McClintock and Hutchings undertook an experimental study of the various drugs used for this purpose, and were convinced that chloretone was the best and least poisonous substance hitherto employed. Hutchings published 6 cases treated with chloretone, with 4 recoveries. The only case I have so treated was a severe one; the beneficial effects of the drug were immediate and striking, trismus was almost abolished and convulsions completely prevented, and the patient recovered. These cases seem to more than warrant a further trial of chloretone.

The method of using chloretone is as follows: 30 to 40 grains of chloretone in olive oil are given by the rectum; in one to two hours there should be an improvement in the muscular symptoms. When the effect passes off, the dose is repeated. Our man had an average of 80 grains a day for five days. Chloretone poisoning is by respiratory failure, so this must be looked out for. Its use is in no way to supersede antitoxin or surgical measures, but to act as a very useful ally.

Guildford. Eric W. Sheaf, M.C.Cantab.

THE ADRENALS AND URINARY SECRETION.

Mentioning the following case to Sir Berkeley Moynihan he tells me it is worthy of report. A lady of 72 was confined to bed by sheer weakness and listlessness; she complained of nothing else. Repeated medical examinations revealed no disease, but it was found that the urinary secretion was only some 10 to 12 ounces daily.

A consulting physician diagnosed pure senile debility, and prescribed strong tonics, strychnine, etc. A good deal of improvement followed, but in an early relapse these drugs failed to resume their good offices. Several medical men then saw her, but nothing prevented the gradual decrease in strength and in amount of urine. One idea occurred to me—to try adrenalin. The result was dramatic and staggering in its efficiency. In forty-eight hours the urine rose from 5 to 40 ounces; in a few days the patient was up, and in a week was out in a bath-chair.

The improvement continued after the lapse of some months, but she continues to take adrenalin, for cessation at once causes renewed debility, etc.

Sir Berkeley gave me the interesting information, and allows me to state it here, that whilst he has not paid much attention to this side of the question he has to the converse, and, having come to the conclusion that *excessive* activity of the suprarenal glands is a cause of arteriosclerosis, has already suggested surgical measures depriving the gland of its blood supply and leaving it attached to the kidney by only a few strands of tissue. One such early case has already undergone the operation, and Sir Berkeley Moynihan is on the look-out for another on which to perform the operation himself.

These two converse methods of treatment afford fascinating fields for further much-needed work, and will yield a rich harvest to the gleaner

Leeds. Ralph Hopton, M.D.Lond.

ANAESTHETICS IN EYE-WORK.

Recent correspondence in your columns on this subject reminds me of an experience which raises the question as to the depth of anaesthesia required in ophthalmic surgery.

The patient was an old man of 74, with but one eye and that blind from cataract. At the preliminary iridectomy he developed such spasm of the eyelids that I told him it would be unsafe to remove the lens. He, however, pleaded so insistently for its performance and carried out so earnestly the control exercises that I consented to do it under a general anaesthetic.

The operation, in all its steps, was completed in a few seconds and no time wasted over the toilet. No sooner was an attempt made to gently raise the speculum than it was followed by a most vicious spasm of the ocular muscles with a great loss of vitreous.

The patient was deeply under and cocaine had been previously used, yet the old habit spasm manifested itself.

Perhaps it would have been better to have used deep orbital injections of cocaine, as suggested by Dr. Traquair, or to have held the eye by means of the superior rectus. Fortunately the ultimate outcome was very good ($\frac{6}{12}$) with glasses, but the slow steady squeeze and the outpouring of vitreous was as surprising as it was unpleasant.

MEDICAL AND SURGICAL PRACTICE IN HOSPITALS AND ASYLUMS.

ROYAL EYE HOSPITAL.

BULLET WOUND OF THE EYE: LOCALIZATION BY X RAYS: EXCISION: PATHOLOGICAL REPORT.

(Under the care of Sir William Collins, K.C.V.O., M.S.Lond., F.R.C.S.)

Private A., Coldstream Guards, was engaged in the battle of the Marne at Château Thierry on September 8th. The enemy was in occupation of a farmhouse and firing a Maxim gun from an upper window. The patient was shooting from behind a boulder when a bullet ricochetted off the stone, splashing into the right side of his face. A field dressing was applied to the face two hours later and he slept in a barn that night. Next morning he was transported by motor car and ambulance train and viâ Southampton to London, arriving at Woolwich on September 15th.

He was admitted at the Royal Eye Hospital on September 16th. The face exhibited several small wounds from lead splutters from a bullet; the right eye was closed by swelling of eyelids and there was photophobia in the left. The vision of the right eye was p. l. only, the tension was slightly *plus*, there was much conjunctival injection and chemosis. There was iritis, the pupil was immobile, and the fundus unilluminable. A pigmented spot midway between the corneal margin and the equator, down and out, and some corneal abrasions suggested points of entry of fragments of the bullet. The right upper canine tooth had been smashed by the bullet, and pellets of lead could be felt under the skin of the face in several places. The left eye showed some minute fragments of lead on the cornea, which were removed, but the vision was—tells time accurately; the media were otherwise clear and the tension normal. He was suffering a good deal of pain in the right eye and side of the head.

A skiagram taken by Dr. Herbert Rhodes showed a peppering of the right side of the face; fragments, the

largest of which was not more than 3 or 4 mm. in breadth, were to be seen in the upper and lower jaw and the right orbit.

On September 24th Sir William Collins excised the right eye under chloroform, administered by Mr. F. D. Bennett. The orbit was searched by the finger for fragments, but none found. The pain was at once relieved, he made a rapid recovery, and was discharged on October 2nd with perfect vision and no photophobia in the left eye. The report on the excised eye by Mr. Chapman, the pathologist, states as follows:

Three fragments of lead have perforated the globe through the outer and lower portion of the cornea, passing through the iris and ciliary muscle but not rupturing the lens. Two fragments lie close together and one is deeply embedded in the sclerotic near the attachment of the external rectus. The third fragment was probably at first in the vitreous, but has sunk and become attached near the ora serrata by a focus of suppuration, which is becoming fibrous. The vitreous is beginning to be infiltrated with leucocytes, and in the hyaloid fossa is a collection of pus although the lens is clear. Three other minute fragments of lead lie close together, deeply embedded in the substantia propria of the cornea, just below the scar caused by the perforating fragments, and two other small pieces of lead are set in the sclera below the insertion of the external rectus, but have not penetrated.

Reviews.

ORGANIC ANALYSES.

THE eighth and final volume of the fourth edition of *Allen's Commercial Organic Analysis*[1] is devoted to proteins, albuminoids, and allied bodies. Like previous volumes of this edition, it consists of a number of sections written by different authors. To the physiologist or physiological chemist this is, perhaps, the most important and interesting volume; but the commercial analyst, for whom the book is presumably principally intended, does not appear to have been kept specially in mind in deciding on what to include and what to exclude. In some sections the amount of information supplied is rather too scanty, while in others much valuable detail is given which belongs more to the department of research than to that of commercial analysis. It is, perhaps, natural that a work produced as this has been, with the editors and other contributors divided between England and America, should be rather open to such criticism, which is not intended to detract from the valuable character of the book as a whole.

The first section of the work is devoted to enzymes, and this important and interesting class of substances is dealt with much more briefly than any of the other groups to which sections are allotted, this portion only occupying some fifteen pages. The enzymes mentioned are arranged in six divisions, but the arrangement is not adhered to: thus emulsin is classed as a glucosidoclast, but is described under the heading "sucroclasts," and lipase is classed as a lipoclast, but is described under "proteoclastic enzymes."

The second section of the book consists of a very excellent treatise on the proteins proper; their general chemical nature, the separation of the products of their hydrolysis, the quantitative determination of the proteins themselves, and the identification of the individual compounds, are very clearly described. The proteins of plants and the proteins of milk are dealt with separately in the two succeeding sections; another of considerable length is devoted to milk, and its full examination for commercial and other purposes. Cream, butter, cheese, and other milk products are dealt with by other writers in a separate section: humanized milk and other modified milks, koumiss, kephir, and the sour milk produced by the action of *Bacillus bulgaricus*, are included here.

Then follows what is by far the longest section in the book, on meat and meat products, by Dr. W. D. Richardson of Chicago. The term "meat" is treated as including poultry, eggs, and fish, while "meat products" embraces extracts, juices, etc., as well as sausages of many kinds. The composition of the various kinds of meat and their full analysis, the preservation of meats by canning, curing, and the addition of antiseptics, the nature and detection of ptomaines, etc., are among the matters discussed in detail. Other divisions of the book are devoted to the digestion-products of the proteins, haemoglobin and its derivatives, albuminoids or sclero-proteins, and fibroids. In accordance with modern usage, the term "albuminoids" is used to cover collagen, gelatin, chondrin, mucin, and similar bodies not included in the group of proteins proper; while fibroids include silk, hair, wool, chitin, etc.

There can be no question as to the great usefulness of the book, in spite of some unevenness in the treatment of the various divisions of the matter; any one concerned directly or indirectly with the analysis of nitrogenous foodstuffs will find it almost indispensable as an up-to-date compendium of present knowledge of the subject.

[1] *Allen's Commercial Organic Analysis.* Entirely rewritten and edited by W. A. Davis, B.Sc., A.C.G.I., and S. S. Sadtler, S.B. Vol. viii. Fourth edition. London: J. and A. Churchill. 1914. (Roy. 8vo, pp. 706; 60 figures. 21s. net.)

ASTHMA.

IN a small volume Dr. ADAM presents his view of the causation and treatment of *Asthma*.[2] He endeavours to prove that its main cause lies not in any local condition *per se*—as bronchial spasm or vascular engorgement—but that these depend upon a constitutional factor, which is a toxaemia secondary to imperfect protein metabolism, the result of excess of carbohydrate in the diet and of insufficient exercise; the toxaemia arising partly in the bowel and partly in the tissues generally. To prove his point he passes in review the symptoms of an acute attack, and some of the pathological conditions found in the asthmatic subject, laying particular stress upon the toxicity of the urine, and frequently quoting Bouchard and Walker Hall to substantiate his theories. From this point of view he deals with the mode of life of the asthmatic and of those suffering from allied conditions, such as the recurrent bronchitis of children, laryngeal catarrhs and spasms, angio-neurotic oedema, etc. He gives a few pages only to nasal conditions, considering them to be subsidiary factors, yet in most of the clinical cases he reports nasal abnormalities were present and were also treated. By a combination of diet, exercise, and nasal treatment he claims to have cured 76 per cent. of all cases; 16 per cent. were improved, and 8 per cent. unimproved. His contribution to the vexed question of asthma causation is useful, by drawing attention to the importance of regimen, but his conclusions can hardly be accepted in full. They do not fully explain those fairly numerous cases in which under precisely the same dietetic conditions attacks occur due to slight causes, as odours, varied climatic conditions, even change of room, and the numerous cases in which a cure—using the term as he uses it—has resulted through nasal treatment only.

[2] *Asthma and its Radical Treatment.* By James Adam, M.A., M.D., F.R.F.P.S. London: Henry Kimpton; Glasgow: A. Stenhouse. 1913. (Cr. 8vo, pp. 181; 4 illustrations. 5s. net.)

THE PHYSIOLOGY OF THE INTERNAL SECRETIONS.

ONE of the best of the papers read before the Section of Medicine at the International Congress of Medicine held in London during August, 1913, was Professor GLEY'S report on the correlation of the organs of internal secretion and their disturbances. He has rearranged and added to this report, and published it in the form of a little book.[3] He believes that our knowledge of the glands with internal secretions, as such, is due to Claude Bernard and Brown-Séquard, in reality, and sounds a warning note as to the facility and futility of the countless unfounded speculations as to the functions and disturbances of function of these organs, that are so common in the medical literature of the present day. He calls for more facts about these endocrine glands, as they are called, and fewer fancies, and gives an account of their various secretions and a classification of the glands themselves. The last twenty pages deal with the functions of these glands in health and disease. Like Dr. Noel Paton's volume recently reviewed in these pages (November 29th, 1913, p. 1438), Dr. Gley's book is a very valuable contribution to medical literature from the pen of an eminent physiologist. It is most lucidly written, and should be read by all physiologists and practitioners of medicine.

[3] *Les Sécrétions internes. Principes Physiologiques, Applications à la Pathologie.* Par Professor Dr. E. Gley. Paris: J. B. Baillière et Fils. 1914. (Cr. 8vo, pp. 96. Fr. 1.50.)

THE RESTRICTION OF BIRTHS.

There has been a steady increase in the number of scientific works dealing with the social phenomena of the falling birth-rate and of the voluntary restriction of families published in Germany. Needless to say, the interest in the subject has not been lessened of recent years by the fact that the German birth-rate itself has begun to descend. Dr. Max Hirsch's book upon abortion and the prevention of conception in their relation to the fall in the birth-rate, which was reviewed in these pages not so long ago (vide Journal for February 28th, 1914, p. 486), was written from the viewpoint of gynaecology; Professor A. Grotjahn, a teacher of hygiene in the University of Berlin, has since issued a work [4] on the falling birth-rate and the restriction of births, in which these matters are discussed from the side of individual and social hygiene.

Setting out to prove the main proposition that the falling birth-rate is peculiarly the central problem of social hygiene at the present time, Professor Grotjahn passes lightly over the contrast between natural and rational propagation in ancient and modern times and comes straight to the problem itself as it began to attract notice in the last three decades of the nineteenth century. The first part of his book deals with the possibility of restricting the birth-rate. He refers to the high development of the art of prevention in relation to conception, to the hiding of the falling birth-rate by the coetaneously falling death-rate, and to the appearance in all civilized lands of this decrease in the size of families. Then he touches upon some false and upon some insufficient explanations of the falling rate, showing that natural fertility has not altered, that the number of marriages has not lessened, and that neither the fall in infant mortality nor the increase in wealth are to be blamed for the smaller number of births. The immensely improved means of preventing births is the true cause of the fall. Preventive measures may be placed in four groups: there are the so called natural means, such as lactation, complete abstinence, partial abstinence at fixed periods, and interrupted cohabitation; these it is said are uncertain or little practised. There are the means which act by destruction of tissue, such as criminal abortion and artificial sterilization by surgical operation, and by the Roentgen rays. There are the chemical means, such as vaginal douches and suppositories and the great army of "Lady's Friends," "Lady's Doctors," "Comfort Douches," "Pneumatiks," "Lätitias," "Spermathanatons," "Semori-tabletten," "Steriloform-tabletten," "Paris Safety-sponges," etc. Finally, there are the mechanical means, such as the various types of occlusive pessaries and rubber condoms.

The second part of Professor Grotjahn's book deals with the right to restrict births, and touches upon the many vexed questions of prevention of conception and stoppage of pregnancy in such diseases as syphilis and gonorrhoea, in such complications of pregnancy as tuberculosis, kidney disease, nervous maladies, and heart troubles, in connexion with the propaganda of eugenics and race hygiene, and in circumstances where the births in a family are either too numerous or are following upon each other too quickly, or where a campaign is being waged against an excessive infantile or child mortality. In all these cases it is evident that the medical man has a part to play; he cannot avoid playing it, and he must be prepared to meet each set of circumstances as it arises. The great problem is the inevitable conflict between the interests of the individual family and the good of the whole community.

The third part of the work concerns itself with the dangers of the falling birth-rate, from race-suicide down to the more selfish matters between neighbouring States and even between rival towns. The author looks at the risks as they exist among the Jews, the French, the Anglo-Saxons, the Dutch and the Germans. The really valuable and in many ways novel part of this section of the book is the statistical light which it throws upon the falling birth-rate in Germany. The great danger anticipated there would appear to be an inflowing of Slavs.

The fourth section takes up the consideration of how the falling birth-rate and its dangers are to be counteracted or adjusted, and deals with many complicated and intricate problems, such as the legal questions connected with the preventives and abortive agents, the moralities involved, neo-Malthusianism and the two-child system, the three-child minimum system, the desire for offspring, and a great many other socio-political and hygienic questions, such as housing and food supply, which can only be described as likely to be very pressing long before the twentieth century has reached the end of its first quarter. Professor Grotjahn's book may be confidently consulted by any one in search of information on the various matters alluded to above.

[4] *Geburten-Rückgang und Geburten-Regelung. Im Lichte der individuellen und der sozialen Hygiene.* Von Prof. Dr. med. A. Grotjahn. Berlin: L. Marcus. 1914. (Med. 8vo. pp. 385. Brosch. Mk. 6.00.)

NOTES ON BOOKS.

Old age should be attainable by every one who will keep to the road which leads to it. Failure to reach the goal is generally traceable to neglect of warnings by the way. The significance of these warnings is well shown by Dr. T. B. Scott of Bournemouth in a little series of essays, lay and medical, collected into a small volume indicating *The Road to a Healthy Old Age.*[5] Dealing for the most part with high arterial tension, its causes, effects, and treatment, the medical element largely preponderates over the lay, but a great deal of sound advice as to personal hygiene may be noted which should appeal to all who are growing old, and can recognize in themselves the symptoms about which they may read. It is the fashion of modern times to attribute everything to microbes, but it is probable that the microbes would make but little headway if the ordinary rules of hygiene were followed, and the soil for their development kept in physiological health. Dr. Scott holds very definite views as to the results of certain drugs in lowering blood pressure and so prolonging life. He follows the teaching of Dr. Oliver in the use of hippurates of lithium and ammonium as depressors, but he also extols the value of adrenalin and suprarenal extracts in the same direction. Deeply impressed with the importance of vaccines in the treatment of diseases of the lungs of bacterial origin, he appends a chapter dealing with vaccines in general from the pen of Surgeon G. B. Scott, R.N.

Dr. Hyvert of Pougues has written a little volume on pathology and diagnosis [6] for the benefit of general practitioners of medicine, in the form of a dictionary of the chief signs, symptoms, and diseases. Having reached the second edition, the book has clearly met with a success for which the author, as he says, had not hoped. Nothing in the inevitable summary and superficial character of its contents explains this success; one would have thought that few practitioners would be benefited by entries such as the following—Hogdson, disease of; Variety of syphilitic aortitis, with marked arterial pulsation—which may serve not unfairly as a type of many.

MEDICINAL AND DIETETIC PREPARATIONS.

Sweet Whey Powder.

We have received from Casein, Limited (Culvert Works, Battersea, S.W.), a sample of their sweet whey powder, which is put forward for the preparation of foods for infants and invalids. It is claimed for this that it is prepared in such a way that the enzymes are not destroyed, and that the protein contained in it consists chiefly of lactalbumen, and not casein. It is a fine, cream-coloured powder, which readily dissolves in water to a cloudy solution having a very pleasant taste. Our analysis showed it to contain:

Proteins	14.4 per cent.
Milk sugar	75.1 ,,
Mineral matter	8.5 ,,

It will, no doubt, prove a very useful preparation in the feeding of convalescents, infants, and the aged.

Mr. Sydney Stephenson has been appointed master of the Oxford Ophthalmological Congress vice Mr. R. W. Doyne nominated as past-master. Mr. P. H. Adams has become deputy-master and Mr. Bernard Cridland secretary. Colonel R. H. Elliot has been elected a member of the Council.

THE BRITISH PHARMACOPOEIA, 1914.

(Continued from page 635.)

ADDITIONS TO THE PHARMACOPOEIA.

SYNTHETIC ORGANIC CHEMICALS.

OF the many organic chemical substances prepared artificially which have come into use in medicine since 1898, only seven are included in the new *Pharmacopoeia;* for four of these new names have been coined. The following is a list of the seven substances, the terms in brackets being the names by which they have hitherto commonly been known:

Acetylsalicylic acid (aspirin).
Barbitone (veronal).
Benzamine lactate (beta-eucaine lactate).
Chloral formamide or chloralamide.
Diamorphine hydrochloride (heroin hydrochloride).
Hexamine (urotropine, hexamethylene-tetramine).
Phenolphthalein (purgen, laxoin).

Other artificial organic chemicals of less recent introduction, now made official for the first time, are picric acid, ethyl chloride, guaiacol and guaiacol carbonate, formaldehyde (solution), methyl salicylate, methylsulphonal (trional), and resorcin.

It will be seen that the principle of not admitting to the *Pharmacopoeia* names which are the registered trade marks of particular firms, has been adhered to; but it is to be regretted that new names have been introduced for those substances for which non-proprietary short names are already in use. Thus the body known under the trade names veronal, malonal, and hypnogen, and by the descriptive chemical names diethyl-malonyl urea and diethyl-barbituric acid, was introduced into the *British Pharmaceutical Codex* in 1907 under the name malourea; the new name barbitone appears to possess no advantage over this, and introduces fresh possibilities of confusion. Betacaine was the name given in the *Codex* to beta-eucaine; the name benzocaine was given to para-amino-benzoic ethyl ester (known under the trade name anaesthesine), and the new name benzamine may easily be confused with this. A useful principle adopted in the *Codex* was that of giving all local anaesthetics names ending in "caine," but the name "benzamine" does not conform to this. It would be a reasonable contraction for the chemical name "benzylamine," which is a totally different body, and confusion may thus arise. Again, acetomorphine (the *Codex* name for diacetylmorphine or heroin) is more descriptive, and scarcely any longer than diamorphine. However, the new names, being official will of course have to be used, whatever their intrinsic merits, and whatever temporary confusion may ensue from the multitude of synonymous terms.

Certainly no fault will be found with the inclusion of the substances mentioned above, since all of them are in frequent use. But it would not be difficult to name a good many more which are probably quite as much used and which have not been included.

Coming now to the consideration of the substances now included, the following points may be noted:

Acetylsalicylic Acid.—A test is ordered for the detection of free salicylic acid, which is required to be absent. Maximum limits are fixed for lead and arsenic respectively of ten and two parts per million. The purity of the substance is to some extent safeguarded by the melting point, given as 133° C. to 135° C., but no quantitative test to prove the presence of a definite proportion (for example, 98 or 99 per cent.) of true acetylsalicylic acid is given.

Barbitone.—The melting point is given as 191° C., and certain identity tests are described; there is no test for purity except the melting point, the absence of ash, and the general characters.

Benzamine Lactate.—No doubt this salt has been adopted, and not the hydrochloride, because of the greater solubility of the lactate, which makes it much more useful. Certain identity tests, especially for distinguishing it from cocaine and alpha-eucaine, are described. No quantitative test is given and no melting point.

Chloral Formamide.—The commoner name "chloralamide" is mentioned as a synonym. The melting point (114° to 115° C.) and tests for "certain organic impurities" and "certain decomposition products" are given. There is no quantitative test.

Diamorphine Hydrochloride.—This is described as "the hydrochloride of an alkaloid obtainable by the action of acetic anhydride on morphine; the formula represents it as containing one molecule of water ($C_{21}H_{23}NO_5HClH_2O$), but in the *Codex* it is represented as anhydrous. The melting point is given as 231° C. to 232° C., which is a little higher than is usually assigned. The "characters and tests" given are chiefly identity tests, but there is a test for the absence of morphine. No quantitative test is given.

Hexamine.—This is required to contain not less than 98 per cent. of real hexamethylene-tetramine, and a quantitative test, depending on its decomposition by means of dilute acid, is ordered.

Phenolphthalein.—The melting point is given as 250° to 253°, and no appreciable ash is to remain on ignition. A quantitative test for its sensitiveness to alkali is ordered, which indicates the absence of any serious quantity of the objectionable impurity, fluorane.

Picric Acid.—Purity of 99 per cent. is required. The melting point is given as 122° C., and titration with caustic soda is ordered to prove the presence of 99 per cent. of real trinitrophenol.

Ethyl Chloride.—This is permitted to be made from ethyl alcohol or from industrial methylated spirit; in the latter case (as is pointed out in the text) it will contain a small proportion of methyl chloride. A range of specific gravity—at 0° C.—of from 0.920 to 0.960 is allowed. Several qualitative tests for impurities are ordered, and a quantitative test by hydrolyzing a weighed quantity with potash and titrating back with standard acid; the result is required to correspond to not less than 99.5 per cent. of esters calculated as ethyl chloride.

Guaiacol.—This may be prepared synthetically or from creosote. Certain tests for impurities are directed.

Guaiacol Carbonate.—The melting point is given as 85° C. to 88° C. There is no quantitative test.

Formaldehyde Solution.—This is required to be from 36 to 38 per cent. strength, weight in volume. The strength is determined by adding caustic soda and hydrogen peroxide, and after allowing a sufficient amount of heating on a water bath titrating the excess of soda. A solution of formaldehyde with soap is also made official; this contains 20 per cent. by volume of formaldehyde solution with soft soap and some alcohol.

Methyl Salicylate.—Oil of gaultheria (wintergreen) contains about 99 per cent. of methyl salicylate. The article introduced under the name "methyl salicylate" is made artificially, and is required to contain not less than 98 per cent. of the pure substance, but no method is given for its quantitative determination.

Methylsulphonal.—The melting-point is given as 76° C. to 76.5° C., and certain tests for identity and purity are specified.

Resorcin.—The melting-point is given as 110° C. to 111° C., and certain tests for identity and purity are specified.

ACTIVE PRINCIPLES AND THEIR PREPARATIONS.

The additions under this head include adrenalin and liquor adrenalini hydrochloricus, cantharidin and acetum, emplastrum, tinctura, and unguentum cantharidini, injectio strychninae hypodermica, pelletierinae tannas, and theobrominae et sodii salicylas. The following points may be noted:

Adrenalin.—It is stated that this "may be obtained from the suprarenal glands of animals"; this does not specifically exclude the synthetic article, and none of the characters and tests given would do so. But the chemical name which is given, laevo-methylamino-ethanol-catechol, is properly only applicable to the natural substance, which is laevorotary, while the synthetic is optically inactive unless special means are taken to eliminate the dextro-modification. It is an arguable question, in view of this fact, whether the artificial substance would be considered to be included or not.

Liquor Adrenalini Hydrochloricus.—This is a 1 in 1,000 solution, containing also 0.3 per mille of real hydrochloric acid, 9 per mille of sodium chloride, and 5 per mille by measure of chloroform.

Cantharidin and Preparations.—These are introduced to take the place of the preparations of cantharides, which are omitted; the latter were by no means of uniform strength in active principle, and the cantharidin preparations have the additional advantage of being cleaner. The Chinese fly *Mylabris* and its preparations were in the Indian and Colonial *Addendum;* these are also now dropped and replaced by the cantharidin preparations. The strengths of the new preparations are: Acetum, 1 in 2,000; emplastrum, 0.2 per cent.; tinctura, 1 in 10,000; unguentum, 1 in 3,000. In addition, the formula of emplastrum calefaciens is altered to contain 0.02 per cent. of cantharidin, instead of being made with cantharides. Tincture of cantharidin is approximately of the same strength as an average sample of the present tincture of cantharides, and therefore only about one-seventh of the strength of the tinctura cantharidis of the international agreement. Unguentum cantharidini is of approximately two-thirds of the strength of the unguentum cantharidis which it replaces.

Injectio Strychninae Hypodermica.—This is a simple solution of strychnine hydrochloride containing 0.75 per cent., or $\frac{3}{4}$ grain in 110 minims.

Pelletierine Tannate.—This is a mixture of the tannates of the alkaloids of pomegranate bark; the bark itself and the decoction are now omitted. The name "pelletierine" has been given to one of these alkaloids, but the pelletierine tannate of commerce usually consists of the tannates of the total alkaloids, and this practice now receives official sanction.

Theobromine and Sodium Salicylate.—This is the substance known by the trade-mark name "diuretin." The formula is given as $Na_2C_{14}H_{12}N_4O_5$, and the method of preparation mentioned is "by combining sodium hydroxide, theobromine, and sodium salicylate in molecular proportions"; such a compound would contain 49.7 per cent. of theobromine and 38.1 per cent. of salicylic acid, but the official requirement is that 40 per cent. of theobromine and 35 per cent. of salicylic acid shall be yielded by the test which is described. Some loss of theobromine occurs in the test, but when this is allowed for, the 40 per cent. only represents 46.5 per cent. present in the compound, so that the standard is certainly not unduly strict.

Metallic Salts.

The new metallic salts are calcii lactas, ferri phosphas saccharatus, sodii phosphas acidus, strontii bromidum, and zinci oleostearas. The following points may be noted:

Calcium Lactate.—This is required to contain not less than 93 per cent. of the hydrated salt $Ca(C_3H_5O_3)_2$, $5H_2O$, the percentage of calcium being determined gravimetrically. The salt is described as "slowly soluble in 18.5 parts of water, forming a clear, colourless solution"; it is required to be free from alkalinity, and a limit is fixed for acidity. The limit for lead is 10 parts, and for arsenic 5 parts, per million.

Saccharated Iron Phosphate.—This is a mixture of ferrous phosphate with glucose, and takes the place of plain ferrous phosphate, which is omitted. By an improved method of precipitation the percentage of ferrous salt in the product is increased; it is required to contain not less than 60 per cent. of ferrous compounds calculated as hydrated ferrous phosphate, $Fe_3(PO_4)_2.8H_2O$, against the present minimum of 47 per cent. The limit for arsenic is 5 parts per million.

Acid Sodium Phosphate.—This is required to contain not less than 70 per cent. of the anhydrous salt NaH_2PO_4. The limit for lead is 5 parts, and for arsenic 2 parts per million.

Strontium Bromide.—This is required to contain not less than 97 per cent. of the hydrated salt $SrBr_2.6H_2O$. A volumetric test for the bromine, and a gravimetric test for the strontium are given, and a special test to ensure absence of barium. The limit for lead is 20 parts, and for arsenic 5 parts, per million.

Zinc Oleostearate.—This is made by precipitation from zinc sulphate and a mixture of hard soap and curd soap, and consists therefore chiefly of a mixture of zinc oleate and stearate. It is a white amorphous powder, insoluble in water, alcohol, or ether.

Other Additions.

Other additions to the *Pharmacopoeia* are the following:

Acetone.—Not less than 95 per cent. is required to distil between 55° C. and 57° C., the boiling-point of pure acetone being 56.5° C.

Dilute Hydriodic Acid.—This contains 10 per cent. of real hydriodic acid, and 1 per cent. of real hypophosphorous acid as a preservative.

Syrup of Hydriodic Acid.—Contains 10 per cent. (weight in volume) of the dilute acid.

Cassia Fruit.—Introduced as the source of cassia pulp, used in confection of senna.

Cresol.—Not less than 90 per cent. is required to distil between 195° C. and 205° C.; the boiling points of the three isomeric cresols which may be present are 188° C., 198° C., and 202° C. Phenol is required to be absent, and a limit test is given for hydrocarbon oils.

Liquor Cresol Saponatus.—This is a disinfectant of the type of the proprietary article lysol. It contains 50 per cent. (weight in volume) of cresol and differs from the liquor cresolis saponatus of the *British Pharmacopoeia Codex* in being made with castor oil soap instead of linseed oil soap, and in containing no glycerine except what is produced in the saponification; the *Codex* preparation contains 50 per cent. of cresol by weight.

Glucose.—The syrupy variety, containing about 80 per cent. of solids, is adopted. It is introduced principally for use as an adjunct to ferrous carbonate and phosphate. The limit for arsenic is two parts per million.

Ipomoea Root.—This is usually known as Mexican scammony, or Orizaba jalap. It is introduced as a source of scammony resin, which has been commercially prepared from it for some time. It has been shown, however, that the resin so obtained is not identical with that from true scammony.

Senna Fruit.—The well-known senna pods, which have been in general use for a considerable time.

Benzoated Suet.—Introduced for use in India in place of benzoated lard.

Unguentum Lanae Compositum. Compound Wool Fat Ointment.—A mixture of lard, wool fat, hard and soft paraffins, and beeswax.

Unguentum Plumbi Subacetatis.—A mixture of strong solution of lead subacetate with a base of wool fat and hard and soft paraffins. It takes the place of the present lead acetate ointment, which is dropped.

The next article will deal with changes in the name and composition of preparations.

(*To be continued.*)

THE ORIGIN AND DEVELOPMENT OF THE RED CROSS.

(*Continued from page 634.*)

The Geneva Convention.

The following is a list of the Powers which originally signed the "Convention for the Amelioration of the Condition of the Wounded and Sick in Armies in the Field," and of those which subsequently acceded to it: Argentine Republic, Austria, Baden, Bavaria, Belgium, Bolivia, Brazil, Bulgaria, Chile, China, Colombia, Congo, Corea, Cuba, Denmark, Dominican Republic, Ecuador, France, Germany, Great Britain, Greece, Guatemala, Hayti, Hesse-Darmstadt, Honduras, Italy, Japan, Luxemburg, Mecklenburg-Schwerin, Mexico, Montenegro, Netherlands, Nicaragua, Panama, Paraguay, Persia, Peru, the Pope, Portugal, Prussia, Rumania, Russia, Salvador, Saxony, Servia, Siam, Spain, Sweden and Norway, Switzerland, Turkey, United States, Uruguay, Venezuela, Würtemberg.

From time to time various additions and modifications were considered and in 1906 (June 11th to July 6th) a conference was held at Geneva for the revision of the original Convention. A full account of its proceedings will be found in *Sick and Wounded: Papers relating to the Geneva Convention, 1906.*[1] The Convention of 1864 contained ten articles; that drawn up by the Conference of 1906 is divided into eight chapters and general provisions containing in all thirty-three articles. As charges of abuse of the Red Cross on the part of the Germans in the course of the present war have been so frequent that it has been suggested that the use of that emblem of mercy has rather added to than diminished the horrors of war, and as our own Territorial Forces may not have had the

[1] Presented to both Houses of Parliament by command of His Majesty. Eyre and Spottiswoode. 1908.

opportunity of studying the provisions of the Convention, it may be well to give the essential clauses of the text as it was settled in 1906:

CHAPTER I.—*The Wounded and Sick.*

Art. 1.—Officers and soldiers, and other persons officially attached to armies, shall be respected and taken care of when wounded or sick, by the belligerent in whose power they may be, without distinction of nationality.

Nevertheless, a belligerent who is compelled to abandon sick or wounded to the enemy shall, as far as military exigencies permit, leave with them a portion of his medical personnel and matériel to contribute to the care of them.

Art. 2.—Except as regards the treatment to be provided for them in virtue of the preceding Article, the wounded and sick of an army who fall into the hands of the enemy are prisoners of war, and the general provisions of international law concerning prisoners are applicable to them.

Belligerents are, however, free to arrange with one another such exceptions and mitigations with reference to sick and wounded prisoners as they may judge expedient; in particular, they will be at liberty to agree:

To restore to one another the wounded left on the field after a battle;

To repatriate any wounded and sick whom they do not wish to retain as prisoners, after rendering them fit for removal or after recovery;

To hand over to a neutral State, with the latter's consent, the enemy's wounded and sick to be interned by the neutral State until the end of hostilities.

Art. 3.—After each engagement the commander in possession of the field shall take measures to search for the wounded, and to ensure protection against pillage and maltreatment, both for the wounded and for the dead.

He shall arrange that a careful examination of the bodies is made before the dead are buried or cremated.

Art. 4.—As early as possible each belligerent shall send to the authorities of the country or army to which they belong the military identification marks or tokens found on the dead, and a nominal roll of the wounded or sick who have been collected. The belligerents shall keep each other mutually informed of any internments and changes, as well as the admissions into hospital and deaths, among the wounded and sick in their hands. They shall collect all the articles of personal use, valuables, letters, etc., which are found on the field of battle, or left by the wounded or sick who have died in the medical establishments or units, in order that such objects may be transmitted to the persons interested by the authorities of their own country.

Art. 5.—A competent military authority may appeal to the charitable zeal of the inhabitants to collect and take care of, under his direction, the wounded or sick of armies, granting to those who respond to the appeal special protection and certain immunities.

CHAPTER II.—*Medical Units and Establishments.*

Art. 6.—Mobile medical units—that is to say, those which are intended to accompany armies into the field—and the fixed establishments of the medical service will be respected and protected by the belligerents.

Art 7.—The protection to which medical units and establishments are entitled ceases if they are made use of to commit acts harmful to the enemy.

Art. 8.—The following facts are not considered to be of a nature to deprive a medical unit or establishment of the protection guaranteed to it by Article 6:

(1) That the personnel of the unit or of the establishment is armed, and that it uses its arms for its own defence or for that of the sick and wounded under its charge.

(2) That in default of armed orderlies the unit or establishment is guarded by a piquet or by sentinels, furnished with an authority in due form.

(3) That weapons and cartridges taken from the wounded and not yet handed over to the proper department are found in the unit or establishment.

CHAPTER III.—*Personnel.*

Art. 9.—The personnel engaged exclusively in the collection, transport, and treatment of the wounded and the sick, as well as in the administration of medical units and establishments, and the chaplains attached to armies, shall be respected and protected under all circumstances. If they fall into the hands of the enemy they are not to be treated as prisoners of war.

These provisions apply to the guard of medical units and establishments mentioned in Article 8 (2).

Art. 10.—The personnel of Voluntary Aid Societies, duly recognized and authorized by their Government, who may be employed in the medical units and establishments of the armies, is placed on the same footing as the personnel referred to in the preceding article, provided always that the first-mentioned personnel shall be subject to military law and regulations.

Each State shall notify to the other, either in time of peace or at the commencement of or during the course of hostilities, but in every case before actually employing them, the names of the societies which it has authorized, under State responsibility, to render assistance to the regular medical service of its armies.

Art. 11.—A recognized society of a neutral country can only afford the assistance of its medical personnel and units to a belligerent with the previous consent of its own Government and the authorization of the belligerent concerned.

A belligerent who accepts such assistance is bound to notify the fact to his adversary before making any use of it.

Art. 12.—The persons designated in Articles 9, 10, and 11, after they have fallen into the hands of the enemy, shall continue to carry on their duties under his direction.

When their assistance is no longer indispensable, they shall be sent back to their army or to their country at such time and by such route as may be compatible with military exigencies.

They shall then take with them such effects, instruments, arms, and horses as are their private property.

Art. 13.—The enemy shall secure to the persons mentioned in Article 9, while in his hands, the same allowances and the same pay as are granted to the persons holding the same rank in his own army.

CHAPTER IV.—*Matériel.*

Art. 14.—If mobile medical units fall into the hands of the enemy they shall retain their matériel, including their teams, irrespectively of the means of transport and the drivers employed.

Nevertheless, the competent military authority shall be free to use the matériel for the treatment of the wounded and sick. It shall be restored under the conditions laid down for the medical personnel, and, so far as possible, at the same time.

Art. 15.—The buildings and matériel of fixed establishments remain subject to the laws of war, but may not be diverted from their purpose so long as they are necessary for the wounded and the sick.

Nevertheless, the commanders of troops in the field may dispose of them in case of urgent military necessity, provided they make previous arrangements for the welfare of the wounded and sick found there.

Art. 16.—The matériel of Voluntary Aid Societies which are admitted to the privileges of the Convention under the conditions laid down therein is considered private property and, as such, will be respected under all circumstances, saving only the right of requisition recognized for belligerents in accordance with the laws and customs of war.

CHAPTER V.—*Convoys of Evacuation.*

Art. 17.—Convoys of evacuation shall be treated like mobile medical units, subject to the following special provisions:

1. A belligerent intercepting a convoy may break it up if military exigencies demand, provided he takes charge of the sick and wounded in it.

2. In this case, the obligation to send back the medical personnel, provided for in Article 12, shall be extended to the whole of the military personnel detailed for the purposes of transport or guard of the convoy, and furnished with authority in due form to that effect.

The obligation to restore the medical matériel, provided for in Article 14, shall apply to railway trains, and boats used in internal navigation, which are specially arranged for evacuations, as well as to the matérial belonging to the medical service for fitting up ordinary vehicles, trains, and boats.

Military vehicles, other than those of the medical service, may be captured with their teams.

The civilian personnel and the various means of transport obtained by requisition, including railway matériel and boats used for convoys, shall be subject to the general rules of international law.

CHAPTER VI.—*The Distinctive Emblem.*

Art. 18.—As a compliment to Switzerland, the heraldic emblem of the red cross on a white ground, formed by reversing the Federal colours, is retained as the sign and distinctive emblem of the medical service of armies.

Art. 19.—With the permission of the competent military authority this emblem shall be shown on the flags and armlets (brassards) as well as on all the matériel belonging to the medical service.

Art. 20.—The personnel protected in pursuance of Articles 9 (paragraph 1), 10, and 11 shall wear, fixed to the left arm, an armlet (brassard) with a red cross on a white ground, delivered and stamped by the competent military authority, and accompanied by a certificate of identity in the case of persons who have not a military uniform, and who are attached to the medical service of armies.

Art. 21.—The distinctive flag of the Convention shall not be hoisted except over those medical units and establishments which are entitled to be respected under the Articles of the Convention, and except with the consent of the military authorities. It must be accompanied by the national flag of the belligerent to whom the unit or establishment belongs.

Nevertheless, medical units which have fallen into the hands of the enemy, so long as they are in that situation, shall not fly any other flag than that of the red cross.

Art. 22.—The medical units belonging to neutral countries which may be authorized to afford their services under the conditions laid down in Article 11 shall fly, along with the flag of the Convention, the national flag of the belligerent to which they belong.

The provisions of the second paragraph of the preceding Article are applicable to them.

Art. 23.—The emblem of the red cross on a white ground and the words "Red Cross" or "Geneva Cross" shall not be used, either in time of peace or in time of war, except to protect or to indicate the medical units and establishments and the personnel and matériel protected by the Convention.

CHAPTER VII.—*Application and Carrying out of the Convention.*

Art. 24.—The provisions of the present Convention are only obligatory for the contracting Powers in the case of war

between two or more of them. These provisions shall cease to be obligatory from the moment when one of the belligerent powers is no longer a party to the Convention.

Art. 25.—The Commanders-in-Chief of the belligerent armies shall arrange the details for the execution of the preceding Articles, as well as for cases not provided for, in accordance with the instructions of their respective Governments and in conformity with the general principles of the present Convention.

Art. 26.—The signatory Governments will take the necessary measures to instruct their troops, especially the personnel protected, with regard to the provisions of the present Convention, and to bring them to the notice of the civil population.

CHAPTER VIII.—*Prevention of Abuses and Infractions.*

Art. 27.—The signatory Governments, in countries the legislation of which is not at present adequate for the purpose, undertake to adopt or to propose to their legislative bodies such measures as may be necessary to prevent at all times the employment of the emblem or the name of Red Cross or Geneva Cross, by private individuals or by societies other than those which are entitled to do so under the present Convention, and in particular for commercial purposes as a trade mark or trading mark. The prohibition of the employment of the emblem or the names in question shall come into operation from the date fixed by each Legislature, and at the latest five years after the present Convention comes into force. From that date it shall no longer be legal to adopt a trade mark or trading mark contrary to this prohibition.

Art. 28.—The signatory Governments also undertake to adopt, or to propose to their legislative bodies, should their military law be insufficient for the purpose, the measures necessary for the repression in time of war of individual acts of pillage and maltreatment of the wounded and sick of armies, as well as for the punishment, as an unlawful employment of military insignia, of the improper use of the Red Cross flag and armlet (brassard) by officers and soldiers and private individuals not protected by the present Convention.

They will communicate to one another, through the Swiss Federal Council, the provisions relative to these preventive measures at the latest within five years from the ratification of the present Convention.

The following States ratified the Convention on the dates appended to the several names: Siam (January 29th, 1907), United States of America (February 9th, 1907), Russia (February 9th, 1907), Italy (March 9th, 1907), Switzerland (April 16th, 1907), Congo (April 16th, 1907), German Empire (May 27th, 1907), Mexico (June 4th, 1907), Denmark (June 11th, 1907), Brazil (June 18th, 1907), Belgium (August 27th, 1907), Luxemburg (August 27th, 1907), Spain (October 11th, 1907), Austria-Hungary (March 27th, 1908). The following States have acceded to the Convention: Nicaragua (June 17th, 1907), Venezuela (July 8th, 1907), Turkey, with reservation that emblem of Red Crescent will be employed (August 4th, 1907), Colombia (October 28th, 1907).

The delegates appointed by the British Government for the revision of the Convention were Major General Sir John Ardagh, K.C.M.G., K.C.I.E., C.B ; Sir John Furley, C.B., J.P., D.L.; Professor T. E. Holland, K.C., D.C.L., and Lieutenant-Colonel W. G. Macpherson, C.M.G., Royal Army Medical Corps.

The revised Convention of 1906 completed the work initiated by Henry Dunant. As Sir Thomas Longmore, speaking of the original Convention in a lecture delivered at the Royal United Service Institution on March 16th, 1866, truly said:[2]

> This is a remarkable instance of a general treaty brought about by the exertions of an individual in private life; at the same time, without the active support and operation of the International Committee of Geneva, but, above all, without an advanced philanthropy inducing a strong general desire for lessening, as much as practicable, the evils of war to individual soldiers, who, after all, have no personal feelings in the conflicts in which they are engaged, who only act as instruments; without these aids, it is more than probable that the benevolent efforts of Monsieur Dunant would never have achieved the work they at last accomplished.

It is gratifying to be able to add to this testimony that Dunant's work was recognized in his later years before the award of the Nobel Prize showed that his name had not wholly faded from the memory of the world. On December 30th, 1897, the Swiss Federal Council awarded him the highest prize in its gift—that known by the name of Binet-Fendt (about £73) as "founder of the Red Cross and initiator of the Geneva Convention of August 22nd, 1864." The twelfth International Congress, held at Moscow in 1897, also awarded him the prize of the Municipal Council of the City of Moscow (£200) "for the eminent services rendered by him to suffering humanity."

[2] *Help for Sick and Wounded.* London. 1870. P. 373.

PARLIAMENTARY GRANTS, 1914-15.

DETAILS of the Votes in Supply with regard to insurance and public health matters (with the exception of that which forms part of the Education Vote) passed by the House of Commons without discussion, in view of the national crisis, on August 4th, were not reported at that time, but the details may now be interesting.

The vote to the Royal Society for scientific investigations was increased by £4,000, the total now being £29,550. A special grant for defective children in Scotland amounted to £4,139.

The grants passed in respect of National Insurance were as follows:

G.—*Administration of Medical Benefit, etc. Grant in Aid).* (£35,100.)—The special grants in aid of the administration of medical benefit for the year 1914 (Class VIII, Vote 9, 1913-4) were subject to the condition that the grants therefrom to Insurance Committees should not exceed the rate of 1½d. for each insured person. Experience has shown that the cost of administration of Insurance Committees per head of insured population varies with the number of insured persons in the area, and that a flat rate of grant is inappropriate. It is proposed, therefore, to apply a sum not exceeding £21,000 out of this vote in payments to certain Insurance Committees for the year 1914 in excess of the rate of 1½d. per insured person. As, however, there will be balances in the special accounts estimated at £20,900, which will be available towards the grants to be made for the year 1915, the net additional sum required to bring up the amount available in respect of the latter year to a sum equal to 1½d. per insured person is £100. Provision is also made for grants to Insurance Committees, in addition to those above mentioned, but not exceeding £15,000 in all, in respect of the special initial expenses in connexion with the administration of medical benefit in the year 1914, so far as those expenses have created a deficiency in the administration account of any committee. It is also proposed to apply a sum not exceeding £20,000 in grants to Insurance Committees in the United Kingdom towards the cost of health lectures and the publication of information on questions of health (National Insurance Act, 1911, section 60 (1) (*b*)).

K.—*Arrears of Contributions (Grant in Aid).* (£80,000.)—For grants to approved societies to be applied by them towards discharging the "penalty arrears" of their members incurred while out of work (so far as such arrears may exceed six in the case of a man and five in the case of a woman), including a contribution towards the expenses incurred by those societies in administering the grants.

L.—*Sickness Benefit (Women) (Grant in Aid).* (£500,000.)—For grants towards the cost of sickness benefit, including loss of contributions, incurred since the commencement of the Act by approved societies having women members on a basis calculated with reference to the relative incidence of incapacity during pregnancy among such members.

M.—*Medical Referee-Consultants, etc.* (£50,000.)—Remuneration and expenses of Medical Referees and Consultants, travelling expenses of insured persons presenting themselves for examination, and other expenses for the purpose of Referee and Consultant services. (Any payments made by approved societies in respect of the services of Medical Referees will be paid into the Exchequer.)

N.—*Supplementary Medical Services (Great Britain).* (£50,000.) —For grants to Insurance Committees in respect of the provision of specialist consultations in connexion with the treatment of insured persons and in aid of the equipment and maintenance of clinics for the use of panel practitioners.

O.—*Nursing Grants.* (£100,000.) For grants to Insurance Committees towards the provision of nursing.

P.—*Sanatorium Benefit.* (£100,000.—For grants to Insurance Committees for the purpose of supplementing the funds available for sanatorium benefit under the National Insurance Act, 1911, on a basis calculated with reference, *inter alia*, to the relative incidence of tuberculosis in various areas.

Q.—*Medical Attendance, etc., of Aged and Disabled Members of Societies (1913).* (£28,000.)—For grants towards the cost of medical attendance of aged and disabled members of societies to whom Section 15 (2) (*c*) of the Act of 1911, as amended by Section 10 (2) of the Act of 1913, applies, at a rate not exceeding 2s. 6d. for each such person. The grants will be paid in respect of expenses incurred in the year 1913, provision having been made in the original estimate in respect of the year 1914 only.

The grant for pathological laboratories for the portion of the current year is £50,000, and is described as follows:

Pathological Laboratories. (£50,000.)—The money will be allocated by the Treasury to the English, Scottish, and Irish Local Government Boards for the purpose of distribution, with the approval of the Treasury, as grants to local authorities willing to provide or arrange for the provision of laboratory facilities with a view to the prevention, diagnosis, and treatment of disease, and who submit schemes for that purpose not later than December 31st, 1914. If in any area the local authority is unwilling to provide or arrange accordingly, a share of the grants will be allocated to the National Insurance Joint Committee for distribution to the Insurance Committee of that area towards the provision of such facilities and aids. Balances remaining in hand at the close of the financial year will not be subject to surrender to the Exchequer.

British Medical Journal.

SATURDAY, OCTOBER 17TH, 1914.

THE MEDICAL SITUATION IN FRANCE.

WE received this week a number of communications from a correspondent in France; some of them will be found elsewhere in this issue, and the rest we regard as not intended for publication. The writer is a medical man who has had experience of men and affairs in many parts of the world, and, besides taking part in more than one great war, has had as a private practitioner to deal with cases of sickness and injury in conditions unfamiliar to the great majority of his colleagues. On the strength of what he says we are prepared to take a much more cheerful view of medical matters in France than seemed reasonable a week or two ago.

At that time, and even more recently, there were rumours which seemed to be almost equivalent to a statement that the medical arrangements, both of the British and French authorities, were ill-devised and had already broken down. It was, indeed, a charge of this character launched against the French Government by M. Clemenceau—a medical man by education, but best known as a politician, and nicknamed at times the "breaker of Ministries"—that led to the suppression of his paper, *l'Homme Libre*. He promptly brought out another journal, under the title of *l'Homme Enchaîné*, and in the second issue of this publication, which appeared last week, though he did not actually recant, he made a statement which was practically equivalent to a confession of error. He explained that he had not intended to assert that there had been gross neglect of the wounded and lack of foresight in regard to them, but merely that there had been great delay in getting them from the advanced hospitals where they had received efficient first-aid treatment, to the base hospitals at which it was intended that they should be submitted to any operations necessary, and remain until convalescent.

With the views of M. Clemenceau we are not directly concerned, but they are of some interest as being probably based on the rumours which have been current both in France and in this country. There has been a tendency to believe that the death-rate in France from tetanus and so called gas gangrene is gigantic, that any officer or man reported to be wounded who does not shortly arrive in this country is in a hopeless condition, that the authorities are being negligent because they have been obliged to correct with some frequency the statements made by themselves in regard to casualties, and that the extent of the mortality and suffering have been gravely increased by avoidable causes.

We do not propose to consider all these rumours, as to some of which statements will be found in the notes already mentioned, but may remark that our correspondent's communications make it clear that a large proportion of all the wounded officers and men who have not been sent home are in a condition which is anything but hopeless, that he is strongly impressed by the comprehensiveness of the arrangements made for the care of the wounded and prevention of disease, by the extent to which the very latest scientific knowledge is being utilized, and by the width of the view which has been taken by the medical department of the British War Office of the needs of the situation, past, present, and future.

One of his notes affords an explanation, which may console some of them, of the fact that the friends of missing officers sometimes find it difficult to ascertain anything of them and as to why the casualty lists have often needed correction. Comparatively early in the war the French War Office issued permits to go to the front to a very large number of persons possessed of motor cars and extemporized ambulances. These benevolent folk picked up wounded men who had been removed from the firing line by regimental bearer parties to await the arrival of field ambulances, and took them off for treatment either in their own homes or in hospitals in towns more or less distant from the seat of operations. Like steps were frequently taken by the inhabitants of towns and villages near the front: they rarely reported what they had done, and the result was that the authorities altogether lost sight of many men, and could not be certain whether they were prisoners or wounded, or alive or dead. They merely knew they were missing.

He thinks it is true that until recently there has been an unhappy amount of delay in securing for the wounded conditions in which final treatment could be undertaken, but points out that the circumstances of the war have rendered this entirely unavoidable. Apart from the fact that the absolute necessity of keeping the armies supplied with food, ammunition, and reinforcements has necessarily tended to prevent free circulation of trains on the railway lines, no one could have foreseen that the operations would be extended over so wide a range of country as to make it impossible for the horsed ambulances of each divisional ambulance unit to collect the wounded promptly from the multiplicity of regimental dressing stations. He tells us that he has conversed with a great many privates, some of whom had quitted the firing line only a few hours previously, that all were loud in praise of the gallantry and devotion exhibited by the officers and men of the Royal Army Medical Corps, and agreed that at times it would have been absolute folly to attempt to withdraw the wounded from the firing line except by night. In this connexion it will at once occur to our readers that in a large proportion of cases—especially those in which large vessels or the cavities of the body have been wounded—it must be decidedly advantageous from a medical point of view that the patients should not be subjected to any kind of movement for at least some hours after the first aid dressings, which every soldier carries, have been applied either by the patients themselves or the men in their immediate vicinity.

Another subject on which our correspondent dwells is the immense strain to which the medical arrangements of our own army were subjected almost as soon as they came into operation. As every one knows, the army after the battle of Mons commenced a rapid retirement to the south, which lasted several days and ended in an equally rapid advance in a north-easterly direction. During the first part of this procedure it was quite impossible to afford adequate treatment to all the wounded; large quantities of stores were left behind, some ambulance units lost practically the whole of their officers and men, and regimental medical officers had to be replaced in some instances several times in succession. After the

turning point had been reached the fighting was even heavier than before and the advance rapid; hence convoys of wounded inevitably made slow progress towards the various bases. As things are, the operation of the medical arrangements seems to him to be daily improving; the blockage of the railway lines is diminishing, the rolling stock used for ambulance work is being improved, the ambulance trains fully staffed and equipped, and the greatly increased supply of volunteer automobile ambulance workers organized on a proper footing.

On the whole, therefore, it seems to us that, so far as medical foresight and unstinting utilization of the resources of medical science can diminish the mortality and suffering inevitable in any war, the outlook is favourable. We feel, in short, very little doubt that when the end at length comes the Army Medical Staff and the Royal Army Medical Corps will both be congratulated on the way in which they have done their work.

SCHOOLS FOR MOTHERS, AND MATERNITY CENTRES.

Towards the end of July the Board of Education issued regulations under which it was prepared to make grants to Schools for Mothers in England and Wales during the financial year ending March 31st, 1915. The regulations were accompanied by a memorandum in which it was pointed out that one of the results of medical inspection had been to show that a large number of children on first admission to public elementary schools were already suffering from ailments and defects attributable to a great extent to insufficient knowledge of the simple rules of health on the part of the mothers. A School for Mothers was defined as primarily an educational institution providing training and instruction for mothers in the care and management of infants and little children. Such a school would impart instruction by systematic classes, by home visiting, and by infant consultations, but any provision of medical and surgical advice and treatment should only be incidental. A School for Mothers was to be distinguished from a baby clinic or infant dispensary, which is an institution primarily concerned in giving medical and surgical advice and treatment for infants and little children, and in which any instruction of the mother was only incidental. A number of schools for mothers have for some time received grants under the regulations of the Board of Education for technical schools, but the grants were payable only in respect of organized class instruction, and the amounts paid have in consequence been small. The new regulations permit the Board to take account of the whole of the activities of schools for mothers, and in future where the work is efficient the amount may be increased and brought into closer relation with its cost. To earn the grant, which may amount to fifty per cent. of the approved expenditure, the syllabus of instruction in the systematic course must be approved by the Board, and must be of a simple character, including practical work. It is contemplated that each institution would have a superintendent, who would be present at the infant consultations conducted by a medical officer on the staff of the institution. The infant consultations, the Board laid down, should be held not less often than once a fortnight, and wherever practicable once a week or oftener. Home visiting would be carried out under the supervision of the superintendent, who might need one or more nurses to assist her, though this would depend to a large extent on the number of voluntary helpers available. In places where there are several institutions concerned in various ways with the welfare of infants and young children the Board suggested that a representative local committee should be formed to prevent overlapping, and that on this committee the local education authority and the sanitary authority should be invited to appoint its medical officer as one of its representatives. The memorandum also pointed out that the co-ordination of such institutions with the school medical service, and with the work of the sanitary authority would need careful consideration.

The plan of the Board of Education, it will be seen, was a modest proposal to extend and consolidate schemes which had done good work, and had commanded, we believe, the sympathy of the medical profession.

A little later the Local Government Board published a very much more ambitious scheme which it had in contemplation, and for the initiation of which it had obtained from Parliament at the end of the session a grant of £12,000 in the supplementary estimates passed during the rapid conduct of business in the House of Commons at the beginning of the war. The grant was for the administration of maternity and child welfare centres, but a memorandum[1] issued by the Board set out that a complete scheme would comprise a number of elements, each "organized in its direct bearing on infantile health." These elements included arrangements for the local supervision of midwives; for an antenatal clinic for expectant mothers; for home visiting; for maternity hospitals; for attendance during confinement at home; for the treatment of complications arising after parturition, whether in the mother or infant; for the provision of systematic advice and treatment of infants at a baby clinic or infant dispensary; for the continuance of these clinics and dispensaries so as to be available for children up to school age; and for the systematic home visiting of such infants and children. This explanatory memorandum shows that the scheme in view, if carried out, would overlap or replace many existing institutions and schemes, and would indeed involve something like a complete revolution in present methods.

Before such a scheme could command its sympathy and support it would have to be very carefully considered in all its bearings by the medical profession. At present it seems to be very much in the air, and the respective spheres of the Board of Education and the Local Government Board are not well defined. The Prime Minister was questioned upon the subject on July 20th, and we must confess that his answer was not as illuminating as most of his utterances. "Any funds available for grants to institutions of the nature of baby clinics and infant dispensaries, whose primary object is to provide medical and surgical advice and treatment for infants and little children, will," he said, "be administered by the Local Government Board. Grants to institutions of the nature of schools for mothers, the object of which is primarily educational, which provide training and instruction for mothers in the care and management of infants and little children, and which may include systematic classes, or home visiting, or infant consultations (the provision of specific medical and surgical advice, the treatment, if any, being only incidental), will be administered by the Board of Education. Any cases of doubt or difficulty will be investigated by a joint committee of

[1] See British Medical Journal, August 22nd, p. 382.

officers of the two Boards, which will include women medical officers."

In the stress of the last two months the matter has been rather lost sight of, but the time has come when the Ministers responsible should make a clear statement on the subject, and should publicly indicate their desire to consult the medical profession upon matters which so nearly concern it.

THE DIRECTION OF THE ARMY MEDICAL SERVICES.

It has been decided that at the present juncture it is desirable to duplicate the office of Director-General of the Army Medical Services. Sir Alfred Keogh, K.C.B., who was Director-General from 1904 to 1909, and has recently been Chief Commissioner of the British Red Cross Society in France, has been called to London, where he will be in charge of the office of Director-General at home. Sir Arthur Sloggett will become Director General of the Expeditionary Force, and will shortly leave for France. He will be accompanied by Colonel Burtchaell, R.A.M.C., as staff officer. This decision has been taken partly on the score of the enormous amount of work connected with the Expeditionary Force on the one hand, and the home force and new recruits on the other, and partly because it is felt to be essential that the officer acting as Director-General in this country should have had personal experience of the local conditions with the Expeditionary Force. This Sir Alfred Keogh has gained during the last two months, when he was Chief Commissioner of the British Red Cross Society. Sir Arthur Sloggett has been appointed Chief Commissioner in France both of the British Red Cross Society and the St. John Ambulance Association; he will thus be in a position to co-ordinate the work of the Royal Army Medical Corps with the two voluntary organizations, and in this way to increase the efficiency of the combined service by obviating any overlapping.

THE PREVENTION OF EPIDEMIC DISEASE IN THE EXPEDITIONARY FORCE.

The War Office has appointed Sir John Rose Bradford, physician to University College Hospital, Sir Wilmot Herringham, physician to St. Bartholomew's Hospital, and Sir Almroth Wright, director of the Department of Therapeutic Inoculation, St. Mary's Hospital, London, to be consulting physicians with the Expeditionary Force. Like the consulting surgeons previously appointed, they will have the rank of colonel, and draw the pay and allowances of that rank. They will leave England next week, and will be accompanied by three expert bacteriologists of junior standing. The Minister for War has also decided to appoint a special Army Sanitary Committee to advise the Army Council on all matters connected with the health of the troops at home and abroad. It will be a mixed committee, presided over probably by a general officer of the Engineers, and comprising officers of the Royal Army Medical Corps and members of the civilian public health service. This announcement will be received with great satisfaction by the medical profession, which is well acquainted with the risks from epidemic disease that must arise both with the Expeditionary Force and in this country. We can only trust that full use will be made of this committee, and that the results of its labours will be seen in the thorough organization of a medical and sanitary service which will safeguard the health of the new recruits and at the same time reinforce the efforts of the medical service of the Territorial Force. There has been no official confirmation of the reports to the effect that a considerable number of cases of cholera have occurred in the Austrian army and that several Austrian provinces, as well as part of Hungary, are infected, but the Austro-Hungarian Government has not been profuse in official statements, and the announcement that the University of Vienna has been asked to supply large quantities of anticholera vaccine is very categorical and may well be true. During July the disease was epidemic in Podolia,[1] the Russian province immediately east of Galicia, through which the railway from Odessa to Lemberg and Przemysl runs, so that there is nothing inherently improbable in the reports that the Austrian army has become infected. The health of the British force in France during the earliest stages of the war was very good, and down to ten days ago, at any rate, there had been little sickness. There had been cases of pneumonia, and also of diarrhœa and bowel complaints, some of which have been spoken of as dysentery. This comparative immunity from disease may, we hope, be in a large measure attributed to the efficacy of the antityphoid inoculations which a large majority of the men in most units underwent before leaving this country. But the history of previous campaigns seems to suggest that it may be in some measure due to the fact that troops were not during the early part of the campaign long encamped in one place, for it is known that enteric fever and dysentery do not, as a rule, become prevalent until troops have been in camp in one place for three or four weeks. During the last few weeks the conditions have materially altered, and it is very positively stated that the German forces in their entrenched positions have suffered from enteric, and that the services of bacteriological experts have been called into requisition.

TREATMENT OF TETANUS.

Mr. Sheaf, of Guildford, has done well to recall attention to the use of chloretone in the treatment of tetanus at the present time, when we hear of a good many cases occurring among the wounded both in the French and British forces. At one time chloral hydrate was a good deal used in the treatment of the rare cases of tetanus which occur in civil life. More recently chloretone has been used with success, a striking instance of which was reported in the JOURNAL of April 24th, 1909, as occurring in the practice of Dr. Peterson, of Ann Arbor, Michigan. Dr. Peterson called in consultation Dr. W. H. Hutchings, of Detroit, who had then successfully treated five cases of tetanus with this drug. An enema of 60 grains of chloretone dissolved in hot olive oil was administered, and followed by 1,500 units of antitetanic serum. The patient improved, but a recurrence of symptoms took place next day, and both the chloretone and the serum were repeated; after this convalescence was uninterrupted. In the JOURNAL of November 5th, 1910, Mr. Hobbs and Mr. Sheaf reported the case to which the latter refers at page 669, and in that also antitetanic serum was used, but for reasons indicated last week (page 636) it is doubtful whether the serum had much to do with the fortunate result in any of the cases. Chloretone is a trade name for trichlor-tertiary butyl alcohol—$CCl_3C(CH_3)_2OH$—also known as chlorbutanol or chlorbutol, the latter being the name by which it is described in the *British Pharmaceutical Codex*, and under which it is now in fairly general use. It is produced by the reaction of acetone and chloroform, and has been named acetone-chloroform, but this name is misleading and should not be employed. Chlorbutol is a crystalline substance with camphoraceous odour and taste, nearly insoluble in water, but soluble in alcohol and several other organic solvents; when given internally it is usually administered in cachets or capsules in doses of 5 to 20 grains; it has a local anæsthetic action on the stomach, and has been somewhat widely used for seasickness, with varying success, and to some extent as an analgesic and

[1] *Bulletin: Office International d'Hygiène Publique*, August, 1914.

hypnotic. In the treatment of tetanus it seems usually to have been administered in the manner stated by Mr. Sheaf—namely, in olive oil by rectal injection.

THE PLAGUE OF LICE IN THE CRIMEA.

The *Guy's Hospital Gazette* of October 10th contains some interesting letters written by Sir Thomas Longmore when he was a regimental surgeon in the Crimea. One of them, addressed (March 25th, 1855) to Edmund Birkett, who was a contemporary of his at Guy's, describes the plague of lice from which our men suffered in the Crimea, and is of special interest in relation to Dr. Shipley's article on that "minor discomfort" of an army in the field which was published in the Journal of September 19th, p. 497. Longmore tells his correspondent that he has sent him two packages of the "veritable Crimean Pediculi." He thought that if they survived the voyage they might be of some interest as evidence before Mr. Roebuck's Committee. These parasites had been much talked about, and an old Peninsular officer told Longmore they were of the same family as those which infested the troops in Spain and Portugal. They "seemed to thrive nearly as well on the ground for some time as on the clothes, and the officers, who had to lie down in the trenches, where also the men were in the habit of lying, got them in this way in considerable numbers every time they went on duty in the trenches. They multiplied with marvellous rapidity in the clothes and persons of men, who became anaemiated and much debilitated, and the increase of vermin and increase of debility, by mutual co-action, went on at least at geometrical ratio until death carried off the man. Putting wet flannels for a couple of days in snow destroyed the lice, but not the ova, and it was very difficult to get rid of them, as we had no means of boiling or baking the clothes. The larger lice burst from the effect of the cold when placed in snow, others became shrivelled up." In another letter Longmore complains bitterly of the ineptitude of the superior medical officers. Everything was tied fast in red tape, and hardly any medicines could be got. When the hospitals were full of "frost bite, scorbutic dysentery, and general emaciation and cachexia from overwork, want of food and clothing, and all kinds of exposure," the regimental surgeon who applied for remedies was told to "try charcoal"! An instance of the attitude of the generals of that day to any suggestion of sanitary improvement is afforded by Sir George Brown, a first-rate fighting man, but, according to Kinglake, "the most unbending opponent of innovations." On his return to duty after recovery from a wound he inspected the regiment and almost the first question he asked the commanding officer was whether he had any pipe-clay. The major replied that he had not, and that there was none to be got at Balaklava. "Then," said the General, "it must be got from England; get your belts clean, then the men will think themselves clean"! Longmore goes on: "Not a word about the *means of ablution* and *personal cleanliness*, one of our greatest difficulties. Our only water is got from very small streams issuing out of springs in the ravines. The men bring, with great labour, enough for cooking up to camp. From only one set of flannels having been issued to the men until lately, when a second set was given, from their constant labour, utter fatigue and prostration, and always lying on the muddy ground, their underclothing became infested with a species of vermin, different in some respects from the ordinary pediculus: they multiplied in immense numbers, and the more anaemiated and prostrate the man the greater the increase of the parasites. We have done all we could to arrest the evil, but without washing tubs, bathing place, drying place, with snow on the ground and no protection but a tent, it has been impossible to prevent it altogether. Men threw away their flannels, abandoning all hope of ridding them of their swarms. You would not credit if I were to describe what living tissues I have seen some of these woollens become. Very few officers were at one time, before we got our baggage from the transports, free from some of these companions; and even at this moment no means are arranged for washing even our hospital blankets. I long since suggested the conversion of two houses or sheds at Balaklava, one into an ablution, the other into a drying house, for hospital blankets, etc., but nothing was done. One of our great difficulties is still to obtain for the men the time and means of personal cleanliness. Sir George Brown proposes to effect this object by pipeclaying the belts and *appearing clean*—perhaps the reality of cleanliness may follow."

TEUTONIC CULTURE AND SCIENCE.

We have heard so much of German culture for many years past, and of the debt which the world owes to those who are regarded as its prophets, that not a few allowed themselves to be persuaded that it was all true. Especially was this the case in the province of science. At the beginning of the war a group of Cambridge "intellectuals" issued a sort of manifesto to the effect that to fight against Germany was a crime against human progress. The eyes of most of these superior persons have been opened by subsequent events to the true character of the civilizing agency in favour of which apparently they were willing to let considerations of national honour go to the winds. One by one they have withdrawn their adhesion to the unfortunate proclamation which they signed, and some of them are now among the fiercest denouncers of the "Huns." We who have never taken German culture or science at the valuation of their professors may be allowed to feel a little amusement at the suddenness of a conversion which has been brought about by a rude contact with reality. Nietzsche, the preacher of the gospel of the "Superman," from whom the powers that guide the destinies of modern Germany seem to derive their inspiration, was under no illusion as to the mentality of his fellow-countrymen and the real tendency of the doctrines of their teachers; he said that wherever Germany extends her sway, she ruins culture. In this he echoed Heine. Education seems but to make the natural Teuton more potent for mischief. It is stated in the papers that the other day a German who had lived for years near the Bibliothèque Nationale came flying over Paris and tried to drop a bomb exactly over the manuscript room of that famous library; this attempt failed only because of his indifferent aim. This kind of thing is war, not against an enemy, but against civilization. A still more characteristic example of this same spirit is related in Vallery-Radot's *Life of Pasteur*. The famous physicist, Regnault, was at Geneva when the war of 1870 broke out. He had left his laboratory apparatus in his rooms at the Sèvres porcelain manufactory, of which he was the manager. On his return everything was apparently left in the same place, not a window was broken, no locks forced; but a Prussian, evidently an expert, had been there. "Nothing seemed changed," writes J. B. Dumas, "in that abode of science, and yet everything was destroyed; the glass tubes of barometers, thermometers, etc., were broken; scales and other similar instruments had been carefully knocked out of shape with a hammer." In a corner was a heap of ashes; they were the registers, notes, manuscripts, all Regnault's work of the last ten years. "Such cruelty," exclaimed J. B. Dumas, "is unexampled in history. The Roman soldier who butchered Archimedes in the heat of the onslaught may be excused—he did not know him; but with what sacrilegious meanness could such a work of destruction as this be accomplished!" The deliberate cruelty of this calculated piece of "cultured" spite shows that the descendants of the men of 1870 are worthy of their forefathers.

THE THERAPEUTIC APPLICATION OF RADIUM.

In a lecture to post-graduate students at the School of Physic, Trinity College, Dublin, on October 2nd, Professor John Joly, Sc.D., F.R.S., said that a radio-active treatment, whether by use of radium or of the emanation of radium, owed its value mainly to the properties of one particular derivative of these elements—the substance RaC. This body gives off very penetrating alpha, beta, and gamma rays. The alpha ray was not of use in general, seeing that the atomic particles of which it was constituted did not penetrate an appreciable depth into soft tissues. The more minute material particles (electrons) of which the beta ray was composed, penetrated distances which might amount to as much as one centimetre of soft tissues. The ethereal vibrations making the gamma rays of RaC were very penetrating—the most penetrating gamma rays known. The gamma ray was identical with the light ray, but of much shorter wave length; to this it owed its more penetrating properties. Photo-electric phenomena had established that electrons were expelled or liberated from matter exposed to light vibrations. Similarly, investigation had shown that the x ray caused the liberation of a beta ray (which was a fast-moving electron) from matter. The x ray was similar in properties to the gamma ray, but of longer wave length. Finally, the gamma ray caused the expulsion of a beta ray of very high velocity. All these facts bore out a law established by photo-electric investigations—namely, that the velocity of the expelled electron increased as the wave-length of the vibration concerned in its expulsion diminished. It was evident that the physical effects of all three sorts of vibration—(1) spectral vibrations, (2) x-ray vibrations, and (3) gamma-ray vibrations—were of the same nature, only differing in intensity. The therapeutic effects of the gamma ray were with very great probability to be ascribed to ionization, which was mainly not a direct result of the gamma ray. As already stated, however, this ray gave rise to beta rays of very high velocity—in the case of the gamma rays of RaC approaching that of light. Now the beta ray was a powerful ioniser. Hence the therapeutic value of all radiations seemed to depend either on the direct application of high-speed beta rays or on the secondary creation of these by gamma, x, or light rays. The first agent was much the most vigorous source of secondary beta rays. Direct chemical effects due to ionization had been established by the break-up of H_2O, HCl, NH_3, CO_2, etc., under the rays from radio-active bodies. That the growing cell should be profoundly affected by such rays was not to be wondered at. It could, in fact, be either stimulated in its natural functions or over-stimulated to its destruction. The object of the physician was to secure, as far as possible, uniform illumination of the tissues being radiated. This result was best to be obtained by exposing them to radiation from several points of feeble radiation. Results obtained in Dublin hospitals showed very beneficial effects by the use of emanation contained in very fine capillary tubes and enclosed in fine exploring needles. They were inserted in surface tumours, many at a time, and in such positions as best to irradiate the tissues. The method was extremely economical, as the smallness of the dose—5 to 10 millicuries in each needle—rendered lead-screening unnecessary. Professor Joly concluded by discussing the advantages of using the emanation in place of the parent substance radium. At the conclusion of the lecture Dr. Walter C. Stevenson demonstrated the use of the capillary emanation tubes obtained from the Radium Institute of the Royal Dublin Society, and showed a series of photographs of patients in various stages of treatment.

NOTIFICATION IN NEW YORK.

By a recent order of the New York Board of Health the number of diseases notifiable within twenty-four hours of the time when the case was first seen is now twenty-nine. The following is the list: Anthrax, Asiatic cholera, diphtheria (croup), dysentery (epidemic), epidemic cerebro-spinal meningitis, glanders, gonorrhoeal ophthalmia, hookworm disease, leprosy, malarial fever, measles, mumps, paratyphoid, plague, acute anterior poliomyelitis (infantile paralysis), pulmonary tuberculosis, rabies, rubella (German measles), scarlet fever, septic sore throat, small-pox, tetanus, trachoma, tuberculous meningitis, typhoid fever, typhus, varicella, whooping-cough, and yellow fever.

THE TOTAL NUMBER OF INSURED PERSONS.

THE Insurance Commissioners have announced that the total number of names on the index registers throughout the country is considerably more than the total of insured persons. The conclusion drawn was that there must be many duplications on the index registers, and it is stated the Commissioners have announced that the number of persons for whom medical fees shall be paid must be reduced pro rata throughout the country. The matter came up at the recent meeting of the Sheffield Insurance Committee, when the chairman stated that the number of insured persons on the index registers of the societies in Sheffield was 172,000, whereas the number estimated by the Commissioners was only 148,000. Dr. Forbes contended that there was no evidence that in Sheffield the index registers were anything but correct, and that in fact it was possible that the total number might prove to be in excess of the higher of the two numbers. It was urged that it would be unfair to penalize a district where the lists were accurately kept because in other districts there had been incompetence. It was decided that a conference should be held between the Panel and Finance Committees with a view to submitting a case to the Commissioners. Clearly the Commissioners cannot be expected to pay medical fees for more insured persons than exist, and no doubt accuracy is difficult to attain, but we feel sure that this way of cutting the Gordian knot by doing injustice in some districts because there has been incompetence in others will cause very great dissatisfaction. It would seem that it ought to be possible to ascertain the facts in each district and to allocate the money accordingly.

WINTER COMFORTS FOR THE R.A.M.C.

WITH the approval of the War Office, Mrs. C. K. Morgan, wife of Major Morgan, Instructor in the Training School at Aldershot, is making an appeal for winter comforts to dispatch to the medical units who are succouring the wounded at the front. She will be glad to receive shirts, socks, flannel belts, mufflers, coloured handkerchiefs, tobacco, pipes, cigarettes, pipe-lighters, etc., or money for the purchase of the same. Communications may be addressed to her at Oakdene, Alexandra Road, South Farnborough. We understand that it may probably be found advisable to extend the organization and to form a committee for the purpose, but meanwhile those who are disposed to respond to this appeal may feel certain that anything sent to Mrs. Morgan will be well used. The need of the men of the corps for such comforts is quite as great as that of any other force in the army.

AT the meeting of the Royal Anthropological Institute on Tuesday next, at 8.15 p.m., Mr. D. MacRitchie will give a demonstration on the double-walled towers of Scotland. The meeting will be held at 50, Great Russell Street, W.C., instead of at the rooms of the Medical Society of London.

AT the meeting of the Council of the University College of South Wales and Monmouthshire, held at Cardiff on October 9th, it was announced that the anonymous donor whose munificent offer to erect and present to the college a school of preventive medicine and medical school buildings was accepted in May last, had promised a further £10,000 towards the building fund for the completion of the medical school.

THE WAR.

MEDICAL MATTERS IN FRANCE.

(From a Special Correspondent in Paris.)

RED CROSS WORK IN PARIS.

The British Red Cross.

The ensign of Paris at the present time is the Red Cross. Automobile cars bearing it are constantly flitting through the streets, and commonly at a pace which would horrify a London policeman. They are to be seen at every hour of the day, and seem in some quarters almost as numerous as taxi's. The latter never dominate the streets of Paris to the same extent as those of London, and at the present time they are much fewer than usual. In most streets, too, the Red Cross is again in evidence either at the head of some printed notice relating to the French Red Cross Association, or over the doorway of some house in which an ambulance has been established. But the Red Cross ensign is in effect neither Parisian nor national. It is distinctly international, for no one could be many hours in Paris without becoming aware that the French Red Cross Association has a compeer in the matter of benevolent activity. Last week (on Friday), for instance, the traffic on the main boulevards was temporarily blocked during the passage of a large convoy of British Red Cross ambulances, lorries, and automobiles on their way up country, and one meets from time to time officers and orderlies obviously in the employ either of the British Red Cross Society itself or of the St. John Ambulance Association, which is working in conjunction with it and under its control.

The Society has established its French head quarters in the Avenue de Iena, the actual building used being a large modern hotel of that name. Even a casual stroll through its rooms conveys a good idea of the vastness of the work that the Society has undertaken, and a trained observer would probably conclude that its general organization was sound. The personnel is adequate, and the whole administrative machinery is under the control of Sir Savile Crossley, who was for many years one of the honorary secretaries of an equally successful organization, King Edward's Hospital Fund for London, and of Colonel E. St. A. Wake, a retired officer of the Indian army. The work is being done in the closest co-operation with the army medical authorities, both British and French, and in its character seems to fall under three main headings—ambulance work, hospital work, and supply work.

Ambulance Work.

To the ambulance work reference has already been made. The plan upon which it is to be done in future has been arranged in all its details, and is already partly in operation. Its merits, however, still have to be tested, and for this and for other reasons details of the systematized operations in view are for the moment better omitted. Let it suffice, therefore, to say that the term "ambulance" is here used in its restricted English sense, and that if no hitches occur the work done under this heading is likely at least to equal in importance and utility the other two branches of the Society's work. It may be added, however, that the work hitherto done has lain in two main directions—the provision and working of true ambulance convoys operating under the control of an officer of the Army Medical Corps, and the provision and maintenance of small flying convoys charged with the duty of exploring all villages and townships where it is thought likely that wounded British officers and men may be found under French care.

Hospitals.

The Society has been asked by the War Office to maintain at Paris for the present an aggregate of 500 beds. This it is doing, and in addition is maintaining an officers' hospital at Rouen, and has two other hospitals outside Paris under its control. One of these is near Chantilly, at Château Laversine, the property of Baron Robert de Rothschild, now on General French's staff. Besides generously placing this beautiful chateau at the disposal of the Society, he has fully equipped it as a 65-bed hospital, expansible to 200, and provides all the funds necessary for its maintenance. The other is still further north, near Compiègne, and a comparatively short distance from the front. It is established at the Château d'Annell, the country residence of Mrs. Depew, an American lady, who personally takes a part in all its work. The 500 beds of which mention has been made are distributed among four institutions, all of which are working under the aegis of the Society, though some of them draw part of their maintenance funds from private sources. The largest is the Astoria Hospital, with 180 beds, expansible to 300, the other three ranging in capacity from 25 beds upwards. All of them are fully equipped, and do their work under the general superintendence of an officer of the Royal Army Medical Corps. Their staffs consist of a varying number of medical officers, a matron, a number of trained nurses, a number of dressers, and a number of orderlies. The cooking work is done by locally engaged labour, but each hospital unit is prepared, I understand, to do its cooking for itself if occasion requires.

At the present time none of these institutions is working nearly to its full capacity. The actual number of daily casualties at the front seems to be less than it was, and in addition the diminished stream of wounded and sick is to some extent being diverted from Paris. Consequently the needs of the situation, so far as the Society is concerned, are fully met by its present arrangements and it is well able to carry out its principle of keeping at least one complete hospital unit ready packed up and in a position to start, at an hour's notice, for any place where the army medical authorities desire to see a Red Cross hospital established. The present waiting units are the Duchess of Westminster's hospital and that which works under the name of Lady Dudley. The former of these, which is under the command of Major Douglas, V.C., who has Mr. C. Gordon Watson as his surgeon-in chief, will probably have been dispatched to a station outside Paris before this letter reaches home.

Supplies.

In regard to the third heading under which the work of the British Red Cross in Paris has here been classified, the aim kept in view is double. The hospitals working under the control of the Society have to be maintained fully equipped in the matter of personnel, furniture, drugs, medical comforts, and general stores, and there are likewise the needs of the Army Medical Service to be considered. Hence it need scarcely be said that this part of the Society's work entails a great amount of labour and forethought. The great bulk of its supplies are kept separately stored, but it maintains an emergency supply at head quarters ready for immediate dispatch, and it is there, too, that such members of the executive personnel as are not already posted attend daily for orders. The scene, therefore, is one of constant and considerable animation, though the extent of the visible work naturally varies from time to time. It is superfluous to give a list of the goods that are kept in stock, but it may be said generally that the Society is in a position to supply on the briefest notice anything from a tin of vaseline to a bottle of chloroform or a tube of tetanus antitoxin, from a pair of list slippers to a hat, from a pair of pyjamas to an outdoor set of clothes, whether for an officer or a private, from a pair of surgical scissors to a sterilizer, from a bed-rest to a bed, from a light novel to a packet of chocolate or cigarettes, from a male orderly to a clergyman of the Church of England or a chaplain of any other denomination, from a surgical safety-pin to a completely equipped 300 bed hospital. All this is apart from the maintenance of a staff of surgeons and nurses to meet any probable emergency.

It is indubitable, therefore, that the British Red Cross Society is finding plenty of use for the money placed at its disposal by the British public. The task with which its officers in France have had to grapple would in any case have been very great, and its difficulty has been materially increased by the fact that the course the war has taken has made it necessary for the Society to change the base of its operations on at least four occasions. So far as concerns its Paris branch, which has now become its French head quarters branch, it is much indebted both to Dr. Leonard Robinson, physician to the British Embassy, and Dr. C. J. Jarvis, physician to the Hertford British Hospital. The former was authorized some time ago to establish a local branch of the Society at Paris, and is now its president, and the two, acting together, have co-operated in establishing the various

hospitals of which mention has been made, and, helped by Mr. Stanhope, the Secretary of the Society, have organized the ambulance convoys which, besides bringing back a considerable number of wounded, have taken out supplementary supplies of medical stores and comforts to the army medical establishments at the front.

Rest Camps.

Work corresponding in kind to that described under the heading "Railway Canteens," but of a more comprehensive character, has already been undertaken by the British Red Cross Society. At various times and at various stations on the railway lines leading from various bases towards the front it has established "rest camps," these being in the nature of what the French would term auxiliary ambulances. They are staffed by surgeons, dressers, nurses, and orderlies, and, last but not least, by cooks, and their purpose is to supply suitable hot meals to the occupants of ambulance and other trains containing sick or wounded that stop at the stations where these rest camps are established, to remove from them any cases which may seem too bad to continue their journeys, and to supply other patients with any deficiencies noted in the matter of warm clothing and other comforts. How much work of this order is now going on I am unable to state, but the undertaking of it when required seems to be one of the definite aims that the British Red Cross Society in Paris has in view.

Nursing Costume.

The military governor has drawn attention this week to a Government order issued a fortnight ago relative to ambulance workers. This forbade all ladies executively connected with red cross or other associations to wear nursing costumes or red crosses or anything else likely to suggest their occupation while going about the town. They must wear them only when actually within the confines of the different hospitals or of ambulance posts at the stations and elsewhere, unless given an order which necessarily takes them into further places in circumstances which render a return to plain clothes impossible for the moment. Furthermore, every woman ambulance worker must always have with her some means by which her status can be proved, the proper evidence being a kind of descriptive passport and a photograph of herself. Hitherto breaches of this order have been frequent, but the military governor intends now rigorously to enforce it. The reason is that it was found that many women were sailing under false colours, their objects including those which have led, I understand, many of the great hospitals in London to cease to issue outdoor uniforms to their nurses. Practically none of the many English nurses now working in France have brought with them anything in the way of plain clothes, and therefore must perforce, while working in Paris or waiting for orders, go about in uniforms. Consequently the order of the military governor might be expected to put them in a position of great difficulty. The governor, however, must necessarily depend for the execution of his order on the *gens d'armes* and other Paris police, and these, like their analogues in London, usually bring to their work a vast amount of common sense. No English nurse, therefore, seems likely to be embarrassed by the regulation in question.

The French Red Cross.

Often one sees references, both in the English and foreign press, to the French Red Cross Society, but the statements made with regard to it usually relate in reality to one of the three societies—La Société de Secours aux Blessés Militaires, L'Union des Femmes de France, and L'Association des Femmes Françaises, the first named being much the oldest and richest of the three. Nominally they form one common body known as La Croix Rouge Française, but there is considerable rivalry between them, and, practically speaking, their strongest bond of union seems to be the fact that they are all subject to the jurisdiction of the French War Office. The latter leaves them quite free so far as their internal management and the work they undertake are concerned. The character of their work indeed varies widely, but when it comes to actually dealing with individual soldiers the control exercised is effective. No hospital, however small, can be utilized by any of these societies for the purpose of receiving soldiers until it has been sanctioned by the French War Office; once this sanction has been given the hospital becomes in effect an integral part of the French army medical department itself, doing its work under the title of "Ambulance Auxiliaire," a term which covers all institutions for the reception of sick and wounded soldiers other than those which exist in times of peace as well as of war.

The Ambulances Auxiliaires.

The number of these auxiliary hospitals is very large; in Paris alone there must be upwards of a hundred of them. They vary greatly in size and the completeness of their equipment, in the way in which they are staffed, and, to some extent, in the general character of the treatment afforded. Some possess only nine or ten beds, and are in charge of a single medical officer and half a dozen amateur nurses, and the patients are mainly wounded soldiers arrived at a semi-convalescent stage. Some, not very much larger, depend entirely on trained assistance so far as the work of the wards is concerned, and others are quite large hospitals which, although extemporized, are complete in every respect, and deal mainly with cases requiring very active surgical interference. The character of the buildings occupied by them also presents great variety; the largest of all, that known as the Hôpital Buffon, occupies a very large school of that name in the neighbourhood of Les Invalides. The home of another is the Théâtre Français at the Palais Royal. A third enjoys the distinction of doing its work in some rooms at the Louvre itself—namely, the State and the highly decorated apartments of the Minister of Finance. Others have been established in business premises for which their owners have no present use, or in private houses, or have had placed at their disposition the whole or part of some modern hotel. There are instances, in fact, in which hospital work and ordinary hotel work are going on under the same roof. These auxiliary ambulances are to be found all over Paris, but are more numerous right in central Paris than elsewhere. They work quite independently of one another, and the fact that there is already a hospital established in one particular area does not seem to be regarded as a reason for not opening another a few hundred yards away. As to the character of the work they perform and the efficiency of the attention that the French wounded soldier receives it would be easy to draw false conclusions. There is a vast difference between French and English ideas on almost every subject, and an almost equally large difference between English and French standards of medical comfort and hospital routine and discipline. Some of the things done in French hospitals would certainly horrify an English nurse, and others would probably set a whole ward grumbling; there are sometimes, too, conditions which to a physician or surgeon trained on purely English lines might seem calculated to militate seriously against successful treatment. But how far all these differences are of any real importance so far as obtaining good results is concerned is quite another question. The only thing that is certain is that while the French—an exceptionally logical race—recognize very fully the value of trained nursing, they could not possibly meet the needs of the present situation if they excluded all but trained workers from their hospitals. It is to be remembered, too, that French women are very adaptable, and that though it is easy to detect the society lady under her uniform, she brings to her work a high degree of intelligence and readiness to learn, takes much pride in making herself efficient, and is prepared to devote herself heart and soul to her duties. I am speaking now rather of the smaller institutions than of the one or two larger places attendance whereat is apt to be regarded as a mark of social distinction. The general rule as to hours of work seems to be twelve hours on and twelve hours off, the nurses living out of doors and providing their own meals. But every ambulance has its own laws on this subject. It is not alone French ladies who are co-operating in the work of these auxiliary hospitals; practically all of them have on their staffs a greater or smaller number of men who for varying reasons have been held exempt from ordinary military service. They act as porters and clerks, and in other capacities, some devoting their whole day to their duties, others dividing their time between their ambulance and their ordinary occupation.

Railway Canteens.

An organization which is to bear the title "L'oeuvre des trains de blessés" has just come into existence at the suggestion of the authorities. The object in view is to establish at various points on the railways leading to the front a number of canteens for the benefit of the wounded. They are always to be prepared to serve out hot liquid and other suitable food to the wounded on their passage through these stations, and will, whenever possible, be warned in advance that a train containing wounded men is coming down. A canteen of this kind was established some little time ago at Aubervilliers by the Union of Women of France—one of the three bodies which form the French Red Cross Society. It was found to be of such utility that a desire was expressed that the work should be greatly extended, many more canteens being established, and some of them placed at stations as near the front as military considerations may render permissible. The initial organization of the new work is in the hands of the Syndicat of the Paris Press, 37, Rue de Chateaudun.

The Calm of Paris.

How far the medical arrangements at Paris would stand a really severe strain is a little doubtful. So far none of the hospitals have had to work up to the full extent of their normal capacity in the matter of beds, and the cases treated have been mainly of a surgical character. Up to the present the military governor of Paris has discountenanced the bringing of many wounded into the city, though he has raised no objection to the opening of hospitals; the result is that at the present time the total number of French wounded under treatment at Paris seems to be not more than about 3,000. In allowing hospitals to be opened freely the Governor has acted very wisely, for, whether the auxiliary hospitals do much work or little work, they afford occupation and usefully divert the thoughts of a very large number of persons. Why the military governor of Paris is keeping down the number of wounded is a matter as to which there is considerable difference of opinion. That he should have done so a few weeks ago when there was a prospect of Paris being invested was easy to understand; possibly he is afraid of the effect of the presence of large numbers of wounded on the city's *moral*, but, if so, I venture to believe that his fears are groundless. No one who has known Paris in peace times can fail to be struck by its profound calm. If I had to choose for a neurotic patient either Paris or London as a residence, I should certainly opt for the former. The difference between their moral atmospheres is very great. A day in London, with its crowded streets, its dangerous crossings, unlimited special editions with flaring posters, and alternating waves of depression and buoyancy, throws a much greater strain on the nerves than a week in Paris, with its occasional bombs, 75 per cent. of closed shops, no theatres, and total closure of cafés and restaurants after 9 p.m. Weekday Paris of to-day is early Sunday morning Paris of three months ago. No one seems to have any doubt as to the ultimate result, and news, whether good or bad, is received with calm. The women that one sees in the streets and elsewhere are very quietly dressed, mourning is not uncommon, and a large proportion of the whole male population carries a brassard, or a band of some kind or other, such as is worn in London by special police on the left arm. But the whole tone is one of cheerful resolution. The news of more bombs is not followed by the slightest sign of excitement, and a stranger to France might be disposed, from his experience of Paris and its surroundings, to write down the French as a phlegmatic race.

Tetanus and Gangrene.

Two diseases which modern surgery has almost abolished from civil life are to be seen in Paris at the present moment. They are tetanus and emphysematous traumatic gangrene, which is commonly going by the name of "gas gangrene." The wildest rumours have been current in regard to both of them, and until the end of the war it will be practically impossible to form any satisfactory estimate of the extent to which they have contributed to the gross mortality. At present the views expressed even by those who are really in a position to form an opinion vary very greatly; each man judges according to his personal experience in his own hospital, or from the figures relating to one or more hospitals which have come under his official or other observation.

Some seem disposed to see a direct and essential connexion between the two diseases, a slight attack of gas gangrene reducing the oxygen content of the tissues and making it possible for the tetanus bacillus to multiply in the system. One knows, of course, that the tetanus germ is quite common, and experience gained in the early days of injections of quinine in cases of malarial fever showed that quite small reductions of the local resistance of any given part of the body, such as those caused by injections of quinine sulphate, might suffice at times to allow a tetanus bacillus to develop. It is credible, therefore, that there has been in many cases a direct connexion between a patch of gangrene and a subsequent attack of tetanus. I have, however, seen some cases in which tetanus came on in men admitted to hospital within forty-eight hours of being wounded, and in whom there was no evidence whatever of any gangrenous or other septic infection.

Some observers, on the other hand, assert that the prevalence of tetanus has been purely due to the character of the country in which the greater part of the battles during the past month have been taking place. They assert that the soil in the Aisne valley has long been well known to contain many more tetanus bacilli than does most soil. They support this view by citing numbers of cases of apparently identical lesions, some of which developed tetanus and some did not, and by showing that those attacked were wounded when fighting in certain areas. Another view which is favoured by many persons may be described as the "stackyard" view; they hold that it explains the existence both of tetanus and gas gangrene. According to this view, the wounded men have been infected sometimes with tetanus, sometimes with gas gangrene, by having been laid down in farmyards on beds of straw, or by straw being placed in the wagons used for the transport of the wounded.

Antitetanic Serum.

It is not very profitable, however, to consider all these various views; much more satisfactory is it to be able to state that the military authorities both of Great Britain and of France seem very fully alive to the needs of the situation. The occurrence of tetanus, indeed, seems to have been one of those possibilities which our own medical department foresaw from the beginning. In any case, it sent out supplies of antitetanic serum at the beginning, and this serum is now being used prophylactically as well as therapeutically very freely indeed. Its use was at first restricted to cases in which tetanus had either already developed or in which for some reason or other its onset was deemed likely, but it is now being used prophylactically in a more general way. An experienced serum worker is stationed at the railhead with instructions to give a prophylactic injection to every wounded man, and in order to avoid any case being overlooked the surgeons lower down the line are directed to inquire as to whether an injection has been made, and if not to make one themselves. At the French hospitals it appears to be the rule now to give a prophylactic injection as soon as a patient arrives. Should any operation be undertaken a lumbar injection of antitetanic serum appears to be part of the ordinary routine.

The reports as to the therapeutic value of antitetanic serum are not very satisfactory, but there is reason to believe that its prophylactic use is of considerable value; at all events, the authorities of the Buffon Hospital, which is the largest of the extemporized military hospitals now at work in Paris, were able to assure me that since they had commenced the prophylactic use of antitetanic serum the proportion of cases in which tetanus developed had materially diminished. At one hospital I was told of a case in which a patient whose condition was previously exceedingly bad lost all symptoms for four whole days, but then died suddenly. The earliest date of onset of which I have hitherto heard is fifty-four hours after the time of the reception of the wound, the latest fifteen days. The patient in the first of these cases died within twelve hours.

Last week there was a rumour that the supplies of antitetanic serum were running short, but it would seem to be baseless. Apart from the supplies obtainable from England the Pasteur Institute in Paris appears to have in

use for the production of antitetanic serum some sixty horses, each of which is capable of furnishing some 1,500 doses of serum a month. It is also credited with having had a very large stock in hand at the beginning of the war, and to have been hard at work in its production ever since. The rumour, in short, may be considered to have been based on an order issued last week by the Minister of War. It directed the Pasteur Institute to refer to himself all applicants for serum. The order gave rise to a good deal of irritation, as the Minister of War, in common with all the other Ministers, has moved to Bordeaux, and Bordeaux at the present time is, for all practical purposes, twice as far away from Paris as in normal times.

"Gas Gangrene."

As for "gas gangrene," the impression left upon my mind is that the extent to which this has prevailed has been considerably exaggerated; on the other hand, there is no doubt whatever that a large proportion of wounds are septic. It would be strange if it were otherwise, seeing that shell wounds which commonly cause large breaches of surface predominate, and that many of the men have been wounded while wearing under-clothing which they have not changed for days and weeks, and a large proportion of them after standing or sitting in wet trenches for many hours. Moreover, the fact that there has often been considerable, but inevitable, delay in getting down the wounded from the front to a base hospital may have counted for something. I put things in this way because in the public mind this delay accounts for everything—that is to say, both for tetanus and for gas gangrene. It could not account for tetanus, and it could hardly account entirely either for septicity or gas gangrene. In any case, I have seen patients whose wounds have healed almost by first intention, though they have assured me that their first-aid bandages were soaked through and through with blood, and remained so for days before they were changed. On the other hand, I have been given an account of a case in which signs of septic infection were noted by a skilled observer as early as ten hours after the receipt of the wound.

Septic Wounds.

In regard to the treatment of ordinary septic wounds, free irrigation appears to be the general rule, while in the case of large breaches of surface treatment by vaporized tincture of iodine appears to be favoured by many. Hydrogen peroxide is also being employed. I have heard of no treatment for gas gangrene which seems to be markedly effective. Driving streams of oxygenated air over the wounds has been proposed, but I have not yet had an opportunity of noting its effect, if any. One or two cases have created in my mind an impression that the experience of civilian hospitals is perhaps influencing treatment somewhat unduly; in other words, I have seen attempts made to treat on conservative principles fractures so extensive in themselves, and accompanied by such serious lesions of soft parts, that only a few years ago they would have been treated by amputation without the slightest hesitation. They were quite fresh cases—that is to say, they had reached a base hospital within forty-eight hours of the receipt of the wounds.

The Paris Hospitals and Schools.

The Dental School of Paris (Rue de la Tour d'Auvergne) is to recommence lectures and classes on the first Tuesday in November. Practically, however, it has been at work for many weeks past, for at the beginning of the war arrangements were made by it for the treatment of injuries coming within the field of dental surgery. The Medical Faculty of the University of Paris still remains closed, and it seems doubtful whether it will be open for some little time to come. Despite the absence of a considerable proportion of the general population of Paris the civil hospitals seem to have plenty to do, and most of those who compose their staffs are engaged on work connected with the war. Many of them, indeed, are absent from Paris altogether on military duty. Much the same considerations apply also to junior members of the staffs of the civil hospitals and to the young fellows who in the natural course of events would be pursuing their studies in the medical schools. On the other hand, some of the faculties of the University of Paris have opened their doors for the winter session as usual, the Faculty of Science being one of them. Still, the conditions in which they are doing their work are scarcely normal; one friend of mine, for instance, who is a professor in this particular faculty, rushes off to do radiography at one of the larger Red Cross hospitals as soon as he has got through any work that his position as a professor imposes upon him.

The Academies of Medicine and of Science.

The Academy of Medicine held its opening meeting for the session 1914–15 on October 6th, and the general character of the proceedings was what might be expected at the present time. A large proportion of all those present were in uniform, and the patients in all cases brought forward were soldiers. The chief address was delivered by M. Capitan, who wore the uniform of a principal medical officer in the army, and dealt with the subject of bullet wounds of the chest.

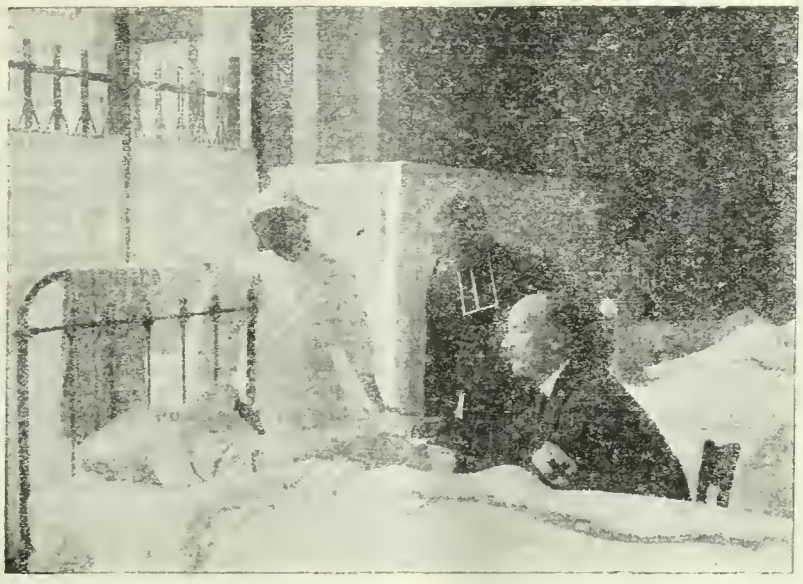
Dr. Capitan said that his experience with ten patients, all of whom had been wounded on one of two consecutive days, indicated that complete recovery from a bullet wound of the chest might be expected in from fifteen to twenty-one days, provided that the wound was caused by a bullet travelling at a sufficient rate to pass right through the chest, and it wounded neither the heart nor any great vessel. If, however, many ribs were broken, or portions of clothing were carried in, the consequences were less benign. A soldier struck by a bullet in the chest was usually able to march for some little time, his only abnormal sensation being a pricking feeling, accompanied in some cases by a slight feeling of oppression. Pure blood, or blood mixed with air, jetted from the wound, and some of the men said they coughed up a little frothy blood. After a lapse of between twelve and twenty-four hours or so nearly all of them experienced a varying degree of dyspnœa. Most of the patients had remained free from fever from beginning to end.

The Academy of Science held one of its ordinary meetings last week (October 5th), the proceedings including a paper by M. Laveran. Subsequently it held a private meeting for the purpose of considering what steps, if any, should be taken in regard to a question which has been giving rise to a good deal of difference of opinion. This is as to whether corresponding members of French scientific societies who are of German and Austrian nationality should be expelled, on the ground that they have made no protest against the atrocities perpetrated by the German army. The Academy is understood to have decided that no step should be taken by itself except as a sequence of any decision that may be reached at a meeting of all the academics composing the Institute of France. Whether any such meeting will ever be held remains to be seen; in any case none has yet been summoned.

The Entente Cordiale.

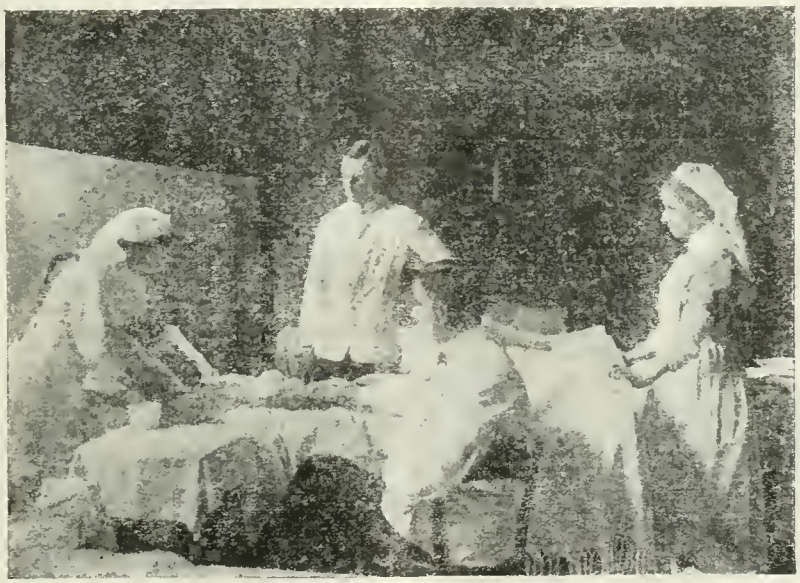
One of the most interesting of the many hospitals now at work in Paris is that established at the Hôtel Majestic, near the Arc de Triomphe. Apart from the fact that it owes its existence entirely to the generosity of a member of the English medical profession, none other perhaps so fully represents the incorporated spirit of the Entente Cordiale. English in point of origin, it is for administrative purposes French; generally known as The Majestic, its proper title is Hôpital Auxiliaire, No. 160 (Union des Femmes de France). Nominally staffed purely by English people, its personnel is, in effect, mixed in the matter of nationality, and equally mixed in the same respect are the occupants of its eighty beds. By way of evidence of this I send a couple of snapshots of a bedside scene. The figure in nursing uniform at the head of the bed is that of a French lady, the figure at the foot that of an English trained nurse; the figures on each side of the bed are in one picture English, in the other French; one patient is an Algerian Turco, the other a Highland piper. The building occupied is the ground floor of one of the newest and vastest of Parisian caravansaries; this, thanks to the width of the corridors, the excellent sanitary arrangements of the cloak rooms, and the size of the various reception rooms, lends itself very well to hospital work. Between two of the largest rooms there is a balcony broader than that of

any sanatorium I have ever seen, and the highly decorated walls and ceilings of the principal wards present a curious contrast to the hospital beds placed against them. The cloak room used for a theatre lends itself so well to its present purpose that one could almost imagine that it had been built to meet it. The same might be said of the radiography annexe and photographic dark room. Curiously enough, one of the first patients admitted was a man who had helped to gild one of the ceilings. In a semi-torpid condition when he arrived, he was much puzzled on coming to himself to account for finding himself in a room which had recently been so familiar to him in quite another connexion. This hospital is being provisioned by the branch of the French Red Cross Society under whose aegis it works, but its lavish equipment was provided by Dr. Kirby, who still furnishes the funds required to meet the outlay entailed by its maintenance. The undertaking was organized on his behalf by Dr. Haden Guest; the latter is still the official representative of the hospital so far as the French authorities are concerned, but at the time of my visit last week he had gone south to see to the establishment of a second unit, which Dr. Kirby wishes to see constituted on the same basis at Limoges.



The professional staff of the hospital consists of three English surgeons, one of whom is an expert radiographer; of twenty-five fully-trained English nurses, a house-surgeon, and four dressers drawn from London hospitals. Besides these, there are eight or nine persons who, although amateurs, play an important part in the hospital's work; there are, for instance, four men—one an old English resident in Paris, another a Frenchman usually an inhabitant of London, and all of good social position, who act as *brancardiers*, or stretcher-bearers; they move patients about the hospital when required, go out with the ambulance to meet the hospital trains, and do a great many odd jobs in the way of cleaning up and sweeping. There are also several ladies, some French, some English, whose services are equally valuable. They act as interpreters for the nurses and staff when required, write letters for patients, and assist in various other small but highly useful ways. One of them, for instance, knows shorthand well, and, attending at all operations, takes down a dictated note as to the work done. Another of these volunteers—a lady to be seen in one of the pictures—plays a still more important part in the work of the hospital. Practically every night the ambulance wagon attached to the hospital goes out to Aubervilliers, where all hospital trains bound southwards stop for an hour or two, and returns in the morning sometimes empty, sometimes full. She always goes out with it, and it is largely owing to her tact and energy that the staff of the hospital is gaining so much experience of military surgery. At any rate, I fancy that they are getting placed in their charge a larger proportion of cases requiring immediate operative interference than are most of the British surgeons now at work in Paris. On two evenings that I visited the hospital I was present during the performance of six or seven operations, and can testify to the high standard of the work done. The staff was also lucky in being sent out from Paris soon after the battle of Meaux to a station where several trains of wounded had accumulated. It was there that they met the French lady who has been mentioned; she had been helping some local doctors for several days and eventually attached herself to the Majestic party.

I have dwelt upon the work of this hospital and of that done by the volunteers attached to it at some length, for it illustrates more or less aptly much of the work that is being done by all Paris hospitals, including those of the British Red Cross. It also illustrates what I have elsewhere said as to the adaptability of French women in the amount of zeal they bring to their voluntary work. The two specifically mentioned, for instance, though both in their early twenties, and certainly entire strangers to hospital work of any kind until a month or two ago, are as professional in their manner and ways when on duty as if they had been in hospitals for years.



It may be as well also to supplement what has been said in regard to Aubervilliers and Limoges. The French system is to send all military patients for treatment, if possible, in the territorial areas of their regiments; this is why the French wounded and sick are to be found distributed all over France, from north to south, from east to west, and one reason why the Paris hospitals have some difficulty in obtaining a sufficient number of patients to keep them reasonably busy, and why a hospital so far away from the front as Limoges is likely to be useful.

THE BRITISH RED CROSS SOCIETY.

Motor Ambulances.

THE work of the Society has proceeded during the week without unusual incident. An encouraging feature has been the large number of motor ambulances subscribed for or promised, and the squares near the head quarters in Pall Mall are lined with ambulances or motor vehicles which have been converted for that purpose. The Sydney branch of the Society has sent a donation of £5,000, of which £1,000 is to be allotted for ambulances. The number promised now exceeds 200. There is still need for a large hospital train.

Hospitals in Paris.

The personnel of a 50-bed hospital in Paris provided by the Scottish branch of the Society which left Scotland recently has now reached its destination. The hospital is located in the upper floor of the Red Cross Hospital at the Hotel Astoria. In view of the fact that many British wounded have been treated there, the British Red Cross Society has made a grant of £1,000 towards the American Hospital at Neuilly. A party of six surgeons and ten nurses was ready this week to go to Ostend, but owing to the change in the military situation they are awaiting fresh instructions.

Hospitals for the Indian Troops.

Orleans is the hospital base of the Indian contingent, and in connexion with it a hospital of 500 beds is being established at Alexandria in order that the recovery of the wounded may be facilitated by a suitable climate. A smaller hospital has been established at Marseilles, to serve mainly as a rest station.

The Society and French Wounded.

Urgent appeals have been received from many of the coast towns of France begging for assistance for wounded French soldiers. It has not been possible to give more than temporary help, because if the British Society were to satisfy all the French appeals for stores, for example, its own stock would be utterly depleted. The Society has been compelled, however regretfully, to adhere to the principle of attending to British demands first. An enormous extension of the work would be necessary if the requirements of the French wounded were to be met by the British Red Cross Society.

A Gift from America.

A handsome gift has been received from America of £800 worth of chloroform. With every surgeon is being sent out an ample supply of antitetanic serum.

Help for Servia.

An offer by the British Red Cross Society and the St. John Ambulance Association to send medical stores to Servia has been gratefully accepted. As land transport would be difficult at the present time, the Society is in need of a yacht to take out the consignment.

THE HOME HOSPITALS AND THE WAR.

THE 3RD AND 4TH SCOTTISH HOSPITALS AT GLASGOW.

THE 3rd and 4th Scottish Hospitals are established in the Glasgow Parish Council's large new hospital at Stobhill, which is situated on high ground in the northern part of the city. Stobhill Hospital is practically in the country, and extensive views of country districts are obtained from the wards. It is particularly well suited for the purpose of a military hospital; its wards are ample and spacious, and there is a large space of ground around it, while a very important additional convenience is found in a railway siding with a temporary platform, so that hospital trains can be run directly into the hospital grounds and patients transported with a minimum of trouble and suffering to themselves.

The 3rd Scottish Hospital.

Our representative was favoured with an interview by Lieutenant-Colonel Archibald G. Hay, M.D., the officer commanding the Third Scottish Hospital. Associated with him are Major Brownlow Riddell, M.D., who is acting as Registrar, and Major and Quartermaster Lee of the regular forces. The following is the medical and surgical staff which was mobilized immediately on declaration of war: Lieutenant-Colonel Professor Robert Muir, M.D., Lieutenant Colonel T. K. Dalziel, M.D., Majors Henry Rutherfurd, M.B., James H. Nicoll, M.B., Professor W. K. Hunter, M.D., John M. Cowan, M.D.; Captains R. B. Ness, M.B., J. McC. Johnstone, M.D., James Carslaw, M.D., Alfred A. Young, M.B., John Morton, M.B., W. W. Christie, M.D., Alexander McLennan, M.B., A. H. Edwards, F.R.C.S.Edin., Logan Taylor, M.B., E. G. Fortune, M.B., John Gracie, M.B.

The hospital accommodates 500 privates and 20 officers. The numbers at present in residence are 314, of whom 168 belong to the Territorial Forces, and 146 to the Expeditionary Force. Four trains have been received, the latest to arrive being on October 13th. To this date 400 members of the Expeditionary Force had been in residence, of whom 145 have been discharged, some on sick furlough and others to various convalescent homes throughout the country. A notable feature of the admissions has been that the first lot of wounded had the cleanest wounds—the degree of sepsis has been increasing with every train. There has been, so far, only one death—a man suffering from septic compound fracture. There is at present one case of tetanus in the hospital. The cases amongst the Territorial soldiers were appendicitis, varicose veins, varicocele and hernia, and amongst the medical cases phthisis, rheumatism, bronchitis, bronchial asthma; the nature of some of these indicated that the examination by the recruiting medical officer had been conducted with some laxity. Amongst the Territorials there have been two cases of amputation of the knee, required on account of gunshot wounds; each of those cases illustrates the truth pointed out by Mr. F. C. Selous in a recent letter to the *Times*. The rifle in each case was fired at short range, in one case the muzzle was held against the man's leg, and in the other the shooting took place within the barrack room; in each case the limb was completely shattered, the calf muscles in one case being absolutely burst asunder. On examination of one of the bullets it was found that the point was intact, but that the coating of the after-part of the bullet had spread out like an umbrella.

The 4th Scottish Hospital.

Lieutenant-Colonel Napier, M.D., is in command of the 4th Scottish Hospital in which Captain Hugh Walker, M.B., is registrar. The following officers have been mobilized: Lieutenant-Colonel Renton, Lieutenant-Colonel Middleton, Majors J. H. Pringle, F.R.C.S., R. H. Parry, F.R.C.S.E., Professor T. K. Monro, M.D., J. Grant Andrew, M.D.; Captains A. N. McGregor, M.B., J. Brown Kelly, M.B., Farquhar Macrae, M.B., J. A. C. Macewen, M.B., David Fyfe, M.B., J. D. Holmes, M.B., Robert Carslaw, M.B., James McLean, M.B., Goodwin Tomkinson, M.D., Douglas Russell, M.B., David Lamb, M.B. Dr. Otto McGregor, Superintendent of the Victoria Infirmary, had been appointed Registrar, but an unfortunate accident has compelled him to go on sick furlough for a considerable time. The total number of patients in the 4th Hospital is 347, of whom 187 belong to the Expeditionary Force and 160 to the Territorials. There has been a fatal case of tetanus in this hospital.

GLASGOW ROYAL INFIRMARY AND THE WOUNDED.

Immediately on the outbreak of war the managers placed a certain number of beds at the disposal of the War Office. The offer was made possible by the fact that, having still intact six wards of the old infirmary—the new building opened by His Majesty on July 7th being now fully occupied—there was no likelihood of the needs of the civilian population being neglected. The medical and surgical staff had also willingly agreed to undertake the treatment of cases sent in, while the nursing staff was fully equipped in spite of the departure of many nurses on military service. On October 9th a hospital trainload of 100 men of the Expeditionary Force was received. The train arrived at Queen Street Station from Southampton in the early hours of the morning, and a fleet of motor ambulances was in readiness to transport the men to the infirmary. The arrangements for admission made by Dr. J. Maxtone Thom, superintendent, and Miss Melrose, matron, worked with admirable smoothness and celerity, so that in seventy-five minutes every case was comfortably established in bed. The number of

serious cases is not large in spite of the fact that most of the men were wounded a month ago at Soissons and on the Aisne. The injuries are almost entirely of the limbs. There are 28 medical cases, of whom at least 2 suffer from dysentery. There are 2 cases of tetanus.

2nd Eastern General Hospital, Brighton.

Two further convoys of wounded men from the front, numbering together about 200, have been received into the 2nd General Eastern Hospital, Brighton. Most of them received their wounds at the battle of the Marne, some at the battle of the Aisne. They were landed at Southampton and travelled by ambulance train to Brighton; having been in many instances a week altogether on their journey from the front they were thoroughly tired out on arrival. The wounds were distinctly more severe in nature than in those previously admitted. Shrapnel wounds were most numerous and the cause of nearly all the more serious injuries.

A short account of some of the graver cases will be interesting.

Shrapnel Bullet embedded in the Head of the Tibia.

This patient was struck by a shrapnel bullet in front of the knee. Examination by *x* rays showed the piece of lead embedded in the head of the tibia, close to the posterior surface of the bone, and just over the popliteal artery. There was a sinus in front of the upper part of the tibia. The upper end of the bone was exposed, and a sinus found in it leading to an abscess cavity in the head of the bone. The sinus was enlarged by chiselling, the bullet extracted, and the abscess cavity drained. The patient is making good progress towards recovery. If the bullet had struck him ½ in. higher up, he would have had a suppurating knee-joint, and would probably have lost his leg.

Shrapnel Wound of Buttock.

This patient had a large portion of the buttock blown away, and was admitted with a big sloughing wound. Under treatment with hydrogen peroxide and iodoform it is rapidly clearing and healing up. Although only the soft parts were touched in this instance, it is a good example of the disability caused by an extensive superficial shrapnel wound. The patient will be disabled for at least two or three months.

Bullet Wound of the Pelvis.

A shrapnel bullet struck this man in the lower part of the abdomen, passed through the pelvis, just missing the bladder, and finally lodged high up in the femur. Some considerable difficulty was experienced in removing the lead, but it was finally extracted, and the patient is doing well.

Bullet Wound of the Liver.

This man was shot through the upper part of the abdomen, the bullet passing through his liver. On admission he was passing blood by the rectum, and there was a fair-sized swelling in the abdomen. This was incised, found to be full of pus, and drained. The man did well, and the bleeding by the rectum ceased. After about a month he was suddenly attacked with signs of commencing intestinal obstruction—persistent vomiting and constipation. The abdomen was opened, and it was found that the intestines were matted in many places by recent adhesions, causing acute intestinal obstruction by constriction and kinking. The adhesions were broken down as far as possible, but the obstruction could not be completely relieved in this way. The distended small intestine was anastomosed to a piece of large intestine and the wound sewn up. Unfortunately death ensued in forty-eight hours.

Bullet Wound of Thigh and Pelvis, causing Concussion of the Spine.

This man's history is most interesting. He had marched and fought for two days practically without food, when he was struck in the upper part of the left thigh, the bullet passing upwards, traversing the abdomen, and lodging under the skin of the right ribs. He lay on the ground under shell fire for forty-eight hours, his legs completely paralysed, and with no sensation, unable to pass water. All the time he was without anything to eat or drink, and rain fell heavily. At the end of two days our men drove the Germans back three miles, and the patient was picked up by an ambulance. A catheter was passed at once. He was for seven days in the train and boat, during which time the bullet was extracted. He is now improving; he has regained almost all the power in his legs, and sensation is commencing to return, but, so far, the bladder and rectum are completely paralysed. There could not have been any actual mechanical lesion of the spine, as many of the chief symptoms have disappeared rapidly. The case was one of concussion of the cord—a quite well-known effect of a bullet passing with velocity in the immediate neighbourhood of nerve tissue. The prognosis is good, for there is every probability that the bladder and rectal signs will soon clear up.

Bullet Wounds of the Skull.

The first patient was struck by a bullet on the vertex of the skull; on admission there was a wound of this part opening up the brain case. He was trephined, and several pieces of loose bone were removed from deep in the brain, in which there was an abscess. No trace of a bullet was found, nor did an *x*-ray examination reveal any. Probably the bullet struck at such an angle that it drove the pieces of bone into the brain without itself entering, though there remains the possibility that it may be embedded deeply in the base of the skull. The man is doing well.

The second patient was struck by a bullet on the left side of the vertex of the skull. He was left lying in the trenches, half full of water, for forty hours, and when picked up he was found to be suffering from paralysis of the right leg. On admission, examination with the *x* rays showed a punctured wound of the skull, with small pieces of loose bone just beneath. The bullet could not be located, though it is undoubtedly in the skull. The man is very fit, and the paralysis of the leg has quite cleared up. The lesion here was clearly an injury, slight in nature, of the cortical leg centre on the left side.

There are a good many cases of wounds of large joints, some of them very serious indeed. So far no amputations have been performed, though there is little doubt that eventually some of the limbs will have to be removed. But every possible effort is being made to save them.

Bullet Wound of Knee.

In this man the bullet was found wedged between the patella and the lower end of the femur, and removed. There is very marked synovitis of the knee-joint, but so far no pus, so the prospect of saving the leg is good.

In another case of injured knee-joint the lower end of the femur and the upper end of the tibia are smashed, and the joint is full of blood and totally disintegrated. Even here an attempt is being made to save the limb, but probably amputation will have to be resorted to.

Shrapnel Wound of the Humerus causing Compound Fracture of the Joint: Secondary Haemorrhage: Ligature of the subclavian Artery.

This man received a bullet wound of the upper part of the arm which fractured the humerus. Soon after admission, and about ten days after he had been shot, there suddenly appeared a large subcutaneous swelling over the pectoral muscles, and the man became very blanched. It was obvious that there was some excessive bleeding going on under the skin. The swelling was incised, the blood clot turned out, and attempts made to find the bleeding vessel. This could not be done, and the subclavian artery was therefore ligatured. This stopped the main haemorrhage, but there was still a good deal of blood being lost; this was controlled by plugging with gauze. All went well for about two weeks, when on the separation of some sloughs very free bleeding again came on. Pressure stopped this, but the same thing occurred again a week or so later, and the man is in a precarious condition, with the chance of having his arm amputated.

There were also a good many compound fractures of bones not affecting joints, such as one of the femur, in which the bone was extensively comminuted; as many as thirty pieces of bone were removed; the wound was full of pus. In all cases, including this, attempts are being made to save the limb.

Up to the present, among over 500 cases admitted to the hospital, there have only been four deaths, one each from bullet wound of the brain, bullet wound of the liver, enteric, and meningitis following otitis—a very satisfactory record.

1st London Territorial Hospital.

Colonel Sir Wilmot Herringham, M.D., is temporarily in charge of the 1st London Territorial Hospital owing to the indisposition of the commanding officer, Lieutenant-Colonel W. A. Atkinson, M.D. The buildings which have been adapted for their present purpose consist of St. Gabriel's Training College, situate in a quiet, residential part of Camberwell, and a large London County Council school adjoining. Both premises are of modern construction and overlook a public open space called Myatt's Fields. St. Gabriel's College, which forms the principal block, is four or five stories high and has a considerable frontage, though comparatively little depth. The proportion of window space is therefore high and the class-rooms are exceptionally airy and well lighted; in fact, Sir Wilmot Herringham expressed the opinion that in this respect the buildings were superior to those of most hospitals. There are twelve wards in the college block, providing 206 beds, also quarters for 20 sick officers. The council school affords accommodation for 318 more patients. After the fittings had been removed the class-rooms required very little adaptation to render them suitable for hospital wards, but it was necessary to construct extensive sanitary annexes of every kind and to instal two lifts which involved a considerable amount of constructional work. An art studio in the roof was

easily adapted as an excellent operating theatre, but to serve it one of the lifts had to be extended beyond the roof of the building. The college building also contains the administrative offices. In the playground of the school wooden buildings have been constructed to provide quarters for the staff attached to the hospital, sleeping, dining, and washing accommodation, sleeping quarters for the night orderlies, and a large cook-house to serve that portion of the hospital located in the Council school. Existing sheds have been adapted as a storehouse and a mortuary and *post-mortem* room. A disinfector, sterilizer, and incinerator for the destruction of refuse have also been installed in the playground. The remaining principal constructional work is the erection of a covered way between the two hospital buildings.

The administrative staff consists of Lieutenant Colonel W. A. Atkinson, commanding officer, Captain R. J. W. Oswald, registrar, and Hon. Major H. E. L. Purcell, quartermaster. The whole of the medical and surgical staff is drawn from St. Bartholomew's Hospital, and the nursing staff has been trained there. A section of the hospital is also established at St. Bartholomew's, affording accommodation, when necessity arises, for 198 additional patients. At present these beds have not been used.

The first convoy of wounded was received on September 29th and numbered 67. Another convoy of 117 was received on October 3rd. Amongst the first contingent were men suffering from very bad shell wounds, but the second convoy had been treated for some time in a hospital in France and were well on the way to recovery. Amongst them also were some very slight cases. There are between twenty and thirty medical cases, including one of diarrhœa and several of pneumonia and rheumatism. There are no cases of enteric or of tetanus. A few members of the Territorial Force are under treatment: one of them has mumps. One or two of the personnel of the hospital are ill.

MEDICAL SUPERVISION OF CAMPS AND BILLETS.

IN the JOURNAL of September 12th a note was published from a correspondent who had been civil surgeon during the South African war, in which, after regretting that he had received no special instruction beforehand, he made the observation that he had been for several months in medical charge of a regiment before he learnt that one of his duties was to inspect the cooking utensils and see that they were kept clean.

A medical officer of a Territorial regiment now mobilized and in billets, whose attention has been attracted by this note, has sent us the following interesting observations bearing on the subject:

There are a hundred and one ways in which a regimental officer can see that the men of a regiment are comfortable, and it is only by experience that a man can learn these things. A medical man has to be up and down the billets constantly keeping his eyes open. For example, when making my rounds with the sanitary sergeant I saw a butcher coming out of the stable with a brush; I made a mental note and visited the butcher's store shortly afterwards, to find him brushing it out. I asked where he got the brush, and was told that, as he had lost his own, he was using that used to brush out the stable. Then we wonder why men get diarrhœa! We had a good deal of diarrhœa at first, and I found that nearly every man who came sick from that cause had had fried chips and potatoes at some of the Italian shops. I communicated with the medical officer of health for the county, and the police were instructed to tell these people I would call and inspect their premises. I had no powers, but called and asked if they objected to my having a look round. I said we did not wish to interfere with their trade, but I had the commanding officer's authority to say that if they did not consent their shops would be marked "Out of bounds." I then made a minute inspection of their shops, and recommended that all towels used to dry glasses in which ices were served should be boiled twice a week at least; that the cages in which the fish was fried should be boiled regularly; and that fish not used the one night was not to be kept over and used next day; that unless they could detach the knives on the potato cutters and boil them they must use ordinary knives to pare and cut the potatoes. I think the Italians have made every effort to carry out my suggestions. Probably many regimental medical officers do not recognize that this is part of their duty. In our case we have had practically no diarrhœa since we started this inspection. A district order has recently been issued recommending such inspection. So far in my experience no objection has been made.

It might be a help if in the various Division areas an experienced officer was appointed as a medical inspector under the Assistant Director of Medical Services, to go round and assist the regimental officers to follow out a uniform system of dealing with the sick and regimental sanitary duties.

In spite of the fact that in many instances medical officers of the Territorial Force found themselves suddenly placed on mobilization in positions which called upon them to do surgical or sanitary work quite outside any recent experience, our correspondent thinks that a very efficient medical service for the Territorials is being evolved. So far as the sick and injured are concerned, they are being very well looked after, and the other duties are being learnt. When the war is over, he says, most medical officers will have suggestions to make, and, by taking stock, a Territorial medical service which will be much better fitted to meet any future emergency will be evolved. Our correspondent thinks it a defect in the present organization that the medical officers in charge of field ambulances have in most cases not previously acted as regimental medical officers; such officers have had no personal experience of the routine life in a regiment, and consequently there has sometimes been a certain amount of working at cross purposes, but this difficulty also is being adjusted as experience is being gained.

NOTES.

THE OVERSEAS DOMINIONS.

Canadian Red Cross Society.

COLONEL JEFFERY HALE BURLAND, who has been appointed Commissioner in charge of the Canadian Red Cross both in England and at the front, left Montreal on September 28th. He will take complete charge of the work during the war. Colonel Burland has been closely connected with the work of the Canadian Red Cross Society for years, and in 1912 organized the Quebec Province branch of the society. Mrs. Burland accompanied her husband. She will remain in England and will direct the work there while Colonel Burland is at the front. In appreciation of the interest taken by Colonel Burland in the work of the Red Cross Society, His Majesty the King recently made him a Knight of Grace of the Order of St. John of Jerusalem.

The Canadian Contingent and its Hospitals.

By the time these lines are published the first contingent of 30,000 Canadian troops, which left Valcartier, Canada, early this month, as already noted in the JOURNAL, will probably have landed in this country.

In addition to field hospitals it is intended to establish base hospitals, one on the French coast and one at Folkestone, to serve Canadian sick and wounded. The hospital at Folkestone is already in being, but at the request of the War Office it is nearly filled at present with serious cases from the front, principally Belgian soldiers, whose condition was so grave that further travelling was most undesirable. A telephone message received in London on the morning of October 14th from Mr. Donald Armour, F.R.C.S., who is at Folkestone, stated that the surgeons had been operating all through the night, and that the loss of several cases was feared. The Canadian Contingent Aid Association has taken offices at the Westminster Palace Hotel, Victoria Street, London, S.W.

When the war broke out, the women of Canada offered the French Government a fully-equipped hospital with a complete personnel of doctors and nurses drawn from the French-speaking towns of Canada. The hospital was to be placed in any part of France that the Government desired, and the cost of maintenance for one year was guaranteed. The offer has now been accepted by the French Government.

IRELAND.

Untrained Nurses for the Front.

The request of several of the holders of the certificates of the St. John Ambulance Association and of the Red

Cross to be allowed to obtain practical experience in the Royal Victoria Hospital, Belfast, has led to a very full and careful consideration of the whole question by the board of management of that institution. The Principal of the Technical Institute of Belfast has also made a similar application on behalf of classes on first aid and nursing which are being held in the institute.

Great sympathy with the movement is felt by every one, but it was pointed out that the Royal Victoria Hospital is one of the teaching hospitals in Belfast, and has upward of 150 students in the winter session; in addition there are about 50 probationers. To allow any more raw material in for training would exceed the powers of the responsible heads and tend to lower the standard of attention to the patient. Besides, to allow a number of young women into the hospital in a more or less irresponsible position would put a strain upon its discipline, and these women would, when they had obtained their month's or three months' or six months' certificates, in many cases arrogate to themselves the title of sick nurse, and by the public would be looked upon as sick nurses, and so the high standard demanded now by the three years' training would be lowered. Would such a short training really equip a woman for active and responsible duty in a hospital where terrific strain is suddenly thrown upon the officers of all classes, or in the field, where the personal initiative and responsibility is so great?

But the whole discussion seems to be futile in the light of the declaration of the War Office that they will not send any but fully-trained nurses to the front, and that they have a reserve of some 1,500 of such on their list. The British Red Cross also states that the reserve of fully-trained nurses is large. The board of management of the Royal Victoria Hospital, after a most sympathetic discussion of the matter, announced that on account of the difficulties surrounding the question, it could not accede to the request, but agreed that, in case the War Office thought that a serious emergency had arisen demanding the engagement of such a type of trained nurse, it would, along with other authorities, accede to the request.

Dublin Hospitals and the War.

During last week six nurses were called up by the War Office from Steevens's Hospital, Dublin, and four from the Royal City of Dublin Hospital; in both cases this is the second detachment that has been sent, and in the case of the latter hospital there is a further number waiting for orders to go. A second class of temporary probationers has been started this month at the Royal City of Dublin Hospital; most of the other Dublin hospitals are also holding these classes, and the numbers wishing to join are so great that in one, at any rate, the waiting list contains close on 200 names. Most of the classes of lectures in first aid have now finished and the examinations have been held; classes for instruction in home nursing are being attended by large numbers. Already two convalescent homes, each containing about thirty beds, have been established within a few miles of Dublin to accommodate the wounded soldiers when they are well enough to be discharged from the hospitals, but so far none have been sent to any of the Dublin general hospitals.

The Condition of the Wounded from France.

A surgeon on active duty at one of the London base hospitals, Territorial Force, has given us some details of the wounded from the front who have come under his care. The general impression which he has formed is that the condition of the wounded when they arrived was extraordinarily good, bearing in mind the difficulties of transport. The total number of men from the front that this surgeon has had under his care is between 100 and 130, and of these there were not more than ten admitted with discharging wounds. The cases have been mostly caused by shrapnel shell; the bullet wounds were few. The latter have done very well, and in one case in which the patella was smashed by a bullet, and another in which the bullet had passed through the knee-joint and lodged in the internal condyle of the femur, there is every hope of saving the joint. The vast majority of the cases came with wounds well scabbed over, excellently dressed and apparently free from infection. In one case, however—that of a very severe shell wound, tetanus had already supervened.

So far as could be gathered the men's wounds had been dressed at proper intervals during the long journey from the front, and they were well and regularly supplied with food. The general condition of those who were sent from the battles of the Marne and Aisne was much superior to those who came from Mons. This is doubtless to be explained by the fact that the former had been fighting in an advance, while the latter had been retreating.

French Wounded at Lyons.

Dr. Alexis Carrel, who in 1912 was awarded the Nobel Prize for his researches on the transplantation of organs, and who is now serving as a medical officer with the French army, says in a letter written to a friend from Lyons: "I am in my own city. Mobilized, naturally. I am in the Hôtel-Dieu in the Department of Surgery. I have more than a thousand wounded to look after. My patients are the first who came under fire. They are those who in Haute Alsace completed with the bayonet the work of the mitrailleuse. Fortunately the wounds are not very serious. In all, the wounded in Lyons are about 12,000, distributed among forty-two hospitals; in the district there are 25,000 more. Having regard to the tremendous number of combatants, the number of wounded up to the present is not, so far as our army is concerned, very heavy, and the mortality is very low. In my hospital of 2,000 men hardly 20 have died of their wounds. Besides, our wounded go back in great numbers to the front, and thus our army goes on acquiring as time goes on soldiers who know what taking cover under fire means."

Midwifery in the Fire Zone.

A medical officer of the Special Reserve, R.A.M.C., sends us the following graphic little story in an envelope endorsed "No military information":

Imagine a very small village situated in the shadow of a wooded ridge of hill, and above the village limestone caves, and above the caves reserve trenches, then trenches and wire entanglements, then the dead whom neither side could remove, and then the Germans, the latter, of course, crowning their slope of the hill as we do ours.

Within two hundred yards of our most advanced trenches, and continually under shell fire, what remains of the civil life of the village goes on day by day. In the caves are our dressing stations and our wounded. The officers live in a farmhouse near the caves—or did until three days ago, when shell fire sent us back to the caves to sleep. And in the village some houses are wrecked—a few—and most are stripped of furniture and valuables. These the inhabitants have taken down to large underground refuges—half cellar and half cave.

Standing by the caves one day—a quiet day, with little firing since one big bombardment at about 7 a.m.—a message was brought me by a sergeant that "a lady wanted a doctor to see some one who had been hurt in the village." Putting on a haversack which contained most things necessary for the ordinary casualties of war, I went with the guides—"two ladies." They led me to a cellar with one door and no other light. On the left of the door was a space reaching the depth of the cave, and cut off by wire netting. In this were chickens. On the extreme right was inky darkness. Nearer to me on the right was a woman in bed. Beyond her another mattress on the floor, at her feet two children asleep. In front of me as I entered was a pile of household goods, and, as in our own country, there were not wanting neighbours.

My servant had followed me, although not at my suggestion, but on perceiving an obviously newly-born babe I sent him away. The babe had been born the night before, was very neatly and cleanly wrapped up, and should be a credit to its country.

The trouble was that the placenta had not appeared. As the uterus was well contracted and not unduly large, it required little erudition to locate the placenta in the vagina. Lysol (made into a thick but soluble form, and put up in flexible screw-top tubes) was available and water. Thus the placenta was soon removed.

The people then brought soap and water and placed them before me, and, after ablutions, I withdrew, while all the inhabitants shouted "Merci, Monsieur," and similar phrases.

I should have mentioned that they showed me money, and seemed desirous of paying on the spot—a practice not without merit but out of place in the circumstances. I was living in the house of one of the attendant neighbours.

An hour or two later—an hour of terror for the chickens—my servant was given what appeared to be a fine chicken. Alas! it proved later to be uncommonly tough. Even so I was amply rewarded by the mere sight of roast chicken. (Is it roast, or is the process as applied to fowls called by some other name? I forget.) The few inhabitants left in this village live largely on our bully beef, eggs when the chickens are obliging, and field produce. There is no bread or milk.

Next day I visited my patient and gathered that medicine was required. I assumed that castor oil was what they wanted, and gave an eggcupful to be taken in two parts, the second only if required. Also the mother not only had no milk then, but from the condition of her breasts was not preparing any. I cannot say why this should have been. She was a woman of about 30, and seemed healthy. Anyway, I gave her from His Majesty's stores two tins of condensed milk. This being made by Nestlé's had instructions on the cover. I hope these made it plain how much the circumstances required, but from a cursory inspection I fear that the gift may have led to a violation of the principles of infant feeding as laid down by eminent authorities.

We were relieved next day, and I did not see my patient again, but possibly the whole incident may interest you as a picture of things as they are in one small spot of the great battle line.

THE MEDICAL SERVICE OF THE GERMAN NAVY.

An Italian newspaper quoted by *Il Policlinico* says that the experiences of recent naval warfare shows that the number of killed in modern sea fights is 5 per cent. and that of wounded about 15 per cent. The sailors of the German navy are trained not only in the transport of wounded men, but also in first aid, for which at various stations sterilized bandages and dressings are provided. The appliances include light splints for fractured limbs and elastic bandages for the arrest of profuse haemorrhage. The sailors are also trained in the performance of artificial respiration. There is a service of carriers of wounded attached to the hospitals. In smaller ships with only one surgeon there is a ward for first dressing and immediate treatment, whilst a second ward is kept in reserve in case the other is destroyed. Battleships carry three surgeons, who give immediate attention to all cases. Only the most urgent operations, such as the arrest of haemorrhage, necessary amputations, and tracheotomy, are done on the battleships, though to this list laparotomy is added. All wounded men in a condition to be transported are sent as soon as possible to the hospital ship.

FIRST AID USE OF ANAESTHETICS.

Lieutenant-Colonel E. LAWRIE, I.M.S. (ret.), Hove, writes: The method of anaesthesia in the field advocated by Professor Schleich (BRITISH MEDICAL JOURNAL, October 10th, p. 639) is clumsy, wasteful, and impracticable. For use to relieve pain, in the field, the anaesthetic *par excellence* is chloroform, given by means of a Junker's inhaler which the wounded soldier can, if necessary, work himself. I first saw this plan employed in midwifery by Dr. G. F. Blacker several years ago. Directly the patient becomes unconscious he can no longer squeeze the ball of the inhaler, the further administration of the anaesthetic ceases automatically, and whether he is lying on his back or not there is no danger whatever in entrusting pure or methylated chloroform to a wounded man to administer to himself in this way. At present an enormous amount of pain goes unrelieved on the field of battle owing to ignorance of the advantages of Dr. Blacker's method of auto-administration of chloroform. . . .

THE 5TH K.O.S.B.

The medical profession, and particularly the British Medical Association, may be proud of the contribution of officers it has made to the 5th (Dumfries and Galloway) Battalion of the King's Own Scottish Borderers. The battalion is commanded by Dr. P. M. Kerr of Dumfries; Dr. Ford of Castle Douglas and Dr. Anderson of Dalbeattie are captains, and another captain is Dr. J. J. Dykes, who practises as a dentist in Dumfries. The medical officers are Major G. R. Livingston, honorary secretary, Scottish Committee, and formerly honorary secretary and treasurer of the Border Counties Branch of the British Medical Association, and Lieutenant John Saffley, M.B., of Annan.

VACANCIES FOR MEDICAL OFFICERS.

1st (Home Service) North Midland Field Ambulance.

Five medical men are urgently required as officers to complete the establishment of the 1st (Home Service) North Midland Field Ambulance, R.A.M.C. Engagement for the period of the war, home or foreign service. Applications should be made to the Commanding Officer, Captain H. G. W. Dawson, M.B., at the Head Quarters, 91, Siddals Road, Derby.

FURTHER CASUALTIES IN THE MEDICAL SERVICE.

Prisoners of War: Previously Reported Missing.

Graham, Captain J. H., R.A.M.C.
Kelly, Captain H. B., R.A.M.C.
Kempthorne, Captain G. A., R.A.M.C. (wounded).
Long, Major H. W., R.A.M.C.
Preston, Lieutenant A., R.A.M.C.
Stevenson, Captain G. H., R.A.M.C.
Thomson, Colonel H. N., A.M.S.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

LEEDS.

UNIVERSITY OF LEEDS: OPENING OF MEDICAL SESSION.

In respect of the serious situation of European affairs the winter session of the School of Medicine was opened very quietly on October 1st. In spite of the fact that a good many of the members of the staff were on duty at the Second Northern Hospital, near Leeds, and that others of the staff and students were prevented by having undertaken various duties from being present, there was a good attendance at the opening address, which was delivered by Professor Arthur Keith, curator of the Royal College of Surgeons Museum. He took as his subject the "Making of a Surgeon," and illustrated his theme by references to the life of Sir James Paget. With singular charm of manner Professor Keith dealt with the various phases of Sir James's character and the influence his early training in natural history had in strengthening his powers of independent observation. Speaking of his eloquence and of the beauty of his language Professor Keith attributed much of this to the orderliness of his mind and to the beauty and uprightness and purity of his spirit. A cordial vote of thanks was accorded to Professor Keith on the motion of Sir Berkeley Moynihan. The motion was seconded by Mr. Stephen Hey, the warden of the dental department of the school, and this served to mark in a quiet way the recent complete amalgamation of the school of dentistry with the University.

It has for many years been the habit for the profession of Leeds and district to celebrate the opening of the winter session by holding a dinner at which the orator is entertained as the chief guest. No one would have received a more cordial welcome in that capacity than Professor Keith, but it was felt on all hands that such a function would not be in keeping with the feelings in the hearts of the members of the school and of the profession at large.

MEMORIAL TO THE LATE DR. E. F. TREVELYAN.

At a largely attended meeting of the colleagues and friends of the late Dr. Trevelyan, who died in December, 1911, a portrait bust was unveiled at the General Infirmary to commemorate his valuable services to that institution, and in recognition of his other activities in Leeds. The bust, which is executed in bronze, is the work of Mr. Wyon, and has been placed in the entrance hall of the infirmary. The presentation, which was made by Dr. Barrs on behalf of the subscribers, was followed by the unveiling by Mrs. Hicks, wife of the Bishop of Lincoln and a sister of Dr. Trevelyan, and, on behalf of the infirmary, Mr. Charles Lupton accepted the memorial and undertook its custody. In making the presentation Dr. Barrs referred to the work of Dr. Trevelyan, to the affection in which he was held by all his colleagues, and to

the high standard of his scientific attainments. But, as Dr. Barrs rightly said, there was something more than all this. "It is not," he said, "the mere record of service that makes us offer you this memorial. We are swayed by our remembrance of Edmond Trevelyan's personality. He was always an English gentleman, brave and true to the last, never more so than when he was suffering from his last painful illness." These were true words, and the members of the staff and the other subscribers to the memorial were fortunate in having their feelings so adequately expressed as they were by Dr. Barrs.

Ireland.

[*FROM OUR SPECIAL CORRESPONDENTS.*]

Royal Academy of Medicine in Ireland.

At the annual general meeting of the Royal Academy of Medicine in Ireland, held in the Royal College of Physicians on October 9th, the following officers were elected for the coming year: President, Walter G. Smith; General Secretary, J. Alfred Scott; Secretary for Foreign Correspondence, Sir John Moore; Presidents of Sections—Medical, J. A. Lindsay; Pathological, J. B. Coleman; Surgical, F. Conway Dwyer; Anatomy and Physiology, E. J. Evatt; Obstetrical, M. J. Gibson; State Medicine, T. P. C. Kirkpatrick.

St. John Ambulance Association.

The sixth of a series of lectures arranged by the Dublin centre of St. John Ambulance Association was delivered last week in the Lecture Theatre of the Royal Dublin Society by Sir Charles Cameron. He dealt with Water: its danger and methods of purification. The importance of water might, he said, be inferred from the fact that a person should drink a quart of it every day, and that water entered very largely into the constituents of food. The Vartry water was very soft, and it contained only 4½ grains of solids per gallon. The danger of contamination of wells by surface water was pointed out, and attention was drawn to the fact that whereas the Vartry water was usually slightly coloured, at present, owing to the fact that the only water going into the reservoir was spring water, it was perfectly colourless. Having spoken of the diseases which are usually attributed to water infection, Sir Charles Cameron emphasized his points by performing a number of experiments.

Meals for School Children.

Up to the present the work of providing meals for hungry school children in Dublin has been left to private benevolence, but now some of the provisions of the English Act have been extended to Ireland. The new Irish Act has many disadvantages, it confines municipal expenditure to a very narrow rate, and is only applicable to schools that come under the jurisdiction of the Board of National Education, but it is better than nothing in that it enables a beginning to be made. Last week the Corporation of Dublin decided to put the Act into effect. There are 158 schools under the National Board in Dublin, and the halfpenny rate will realize only £2,000, or about 5s. a week for every school. It is clear, therefore, that the scheme will only succeed if it secures the support of all classes of the citizens, and is conducted efficiently and economically. There can be no doubt about the necessity of meals for the hungry children of our slums, and there ought to be no delay in getting the machinery of the scheme into full working order. The provision of meals should be dissociated from school work and school buildings, and parents should be required to contribute, as far as may be possible, to the cost of their children's meals; but no public difference should be made between children for whom this contribution is available and those who pay nothing.

Political Ferment and Lunacy.

Dr. M. J. Nolan, the resident medical superintendent of the Down District Lunatic Asylum, in his annual report, speaks of the admissions during the year, and goes on to discuss the predisposing causes which led to some of them. It is noteworthy, he says, and it cannot be too often emphasized, that the conditions of modern life tend enormously to increase the predisposing and exciting causes which make for the production of insanity, and it is interesting that passing events influence very largely the manner in which current insanity manifests itself. During the past year contemporary insanity in his district had been deeply tinged by many stirring though more or less ephemeral occurrences. This is in contrast to the monotonous continuity of "voices," "vague fears," and "unknown enemies" which were previously the uniform complaint in the majority of cases of delusional insanity. The "voices" are now definite commands of opposing factions of political and sectarian strife; the "vague fears" are the acute terrors of "civil war"; the "unknown enemies" are "Orangemen" or "Hibernians," as the case may be. The stimulation of the public mind of the district by political ferment has had the natural result of influencing the direction of the aberrant minds of the community. In some cases, undoubtedly, this strain was the exciting cause of the breakdown: in others it unquestionably shaped the form of the attacks which would have occurred in any event. So it is. Dr. Nolan says, at all periods of exceptional popular emotional waves the lunatics of the period reflect in their delusions the prevailing ideas, but the reflection is the grotesque of a mirror which distorts.

Canada.

[*FROM OUR SPECIAL CORRESPONDENTS.*]

Saskatchewan Medical Association.

The eighth annual meeting of the Saskatchewan Medical Association, which took place on August 18th, 19th, and 20th, was the most successful convention in its history, and Dr. Peterson (the president) and Dr. MacKay (the secretary) are to be congratulated. Perhaps the most important matter dealt with was that of public health. A schedule of questions had previously been sent to the secretary of each rural municipality in the province, and the replies were considered by a committee appointed for that purpose. The following recommendations were prepared and will be forwarded to the Minister in charge of public health at Regina:

> Resolved that the province of Saskatchewan be divided into four or more health districts, each under the supervision of a fully qualified health officer, under the direction of the provincial public health department; that the above officers be required to devote their entire time to the health matters within their respective districts, and that at least one nurse be engaged for each district under the supervision of the district medical health officer.

At present there is a lack of uniformity in matters pertaining to public health; in some instances the officers are not specially trained for the work, and, as a rule, they only devote a small portion of their time to it. In many of the rural districts of the province there are no medical practitioners for miles, and in cases of emergency it is impossible to get prompt aid. Consideration was also given to the matter of claims for overcharge against members of the medical profession. Instances have occurred in which such claims have received the support of the Grain Growers' Association, and Mr. W. J. Thompson, a director of this latter association, had been invited to address the meeting. After some discussion, it was arranged that the President of the Medical Council should appoint an official representative whose duty it should be to attend each meeting of the Grain Growers' Association, so that matters of common interest could be discussed and amicably settled. Some interesting papers were read and discussed. The association will meet next year at Moose Jaw on the last Tuesday in July. The president is Dr. G. P. Bawden, of Moose Jaw, and the secretary-treasurer is Dr. C. G. Sutherland, also of Moose Jaw.

Huron Medical Association.

The meeting of the Huron Medical Association at Goderich, Ontario, on September 9th was well attended, and some interesting papers were read. It was decided that members of the association should give their professional services free to the families of privates who have volunteered for military service during the present war.

TUBERCULOSIS IN NOVA SCOTIA.

An able address was given at the recent meeting of the Municipalities Union, which took place at Halifax, by Dr. W. H. Hattie, the provincial health officer for Nova Scotia. Dr. Hattie reminded his hearers that each year more than a quarter of a million dollars are expended by the public treasury of Nova Scotia in the prevention of tuberculosis. According to the provisions of the Act passed last year, the province will be divided into five districts, in each of which a sanatorium will be established by the provincial government. The local government will provide two dollars a week towards the maintenance of each patient in those sanatoriums. Clinics will be established in each county, and nurses will be appointed to take charge of them. These clinics will serve as bureaux of information and as places of consultation for local physicians, and they will be visited from time to time by a provincial officer appointed for that purpose. The nurses' duties will include visits to the homes of patients. Thus the work of prevention will extend throughout the province, each town council assuming its share of the burden. The system, as a piece of legislation, is most complete, and if carried out properly should be productive of great results. There is room for improvement, for last year there were 471 deaths from tuberculosis in the province, which has a total population of some 500,000.

WATERWORKS AND SEWAGE DISPOSAL.

Regulations concerning the preparation of plans for the installation and extension of waterworks, sewerage, and sewage disposal systems in Saskatchewan are now in force. They provide that information must be supplied to the Bureau of Public Health concerning every point that would be taken into consideration by a competent consulting or municipal engineer, and that, unless this information is satisfactory, the construction of the works in question cannot be commenced. In the past general information has been supplied to the bureau, but the details of construction have been left in the hands of the engineer in charge, and cases have occurred in which the mistakes made have proved extremely costly to all parties concerned.

CONSERVATION OF LIFE.

The Commission of Conservation has recently enlarged its sphere of activity. In the past its efforts have been devoted principally to the conservation of the natural resources of the country; in future the conservation of health will constitute a special branch of its work. A monthly publication, entitled *Conservation of Life*, will be issued, and an effort will be made to "disseminate light on the one subject which vitally affects every human being." The problems which confront the health officer and the sanitary engineer will be treated, and information, stated simply and concisely, will be placed at the disposal of the man who is too busy to gather it from books for himself. Research will also be undertaken. The first number of this publication, which appeared in August, deals with such questions as the maternal nursing of infants, infectivity of tuberculosis, prevention of occupational diseases, and the first Canadian town-planning regulations; Halifax is the first Canadian city to adopt such regulations.

THE PREVALENCE OF CANCER.

During the year 1913 there were in Canada, with its 7 million people, 7,000 deaths from cancer. From 80 to 90 per cent. of the cases occurred in persons over 45 years of age. When it is remembered that a large percentage of these cases could have been cured had they been operated upon in time, it behoves the medical profession to impress upon the public the extreme necessity of early attention to any symptoms which might suggest the disease. In the August number of the *Health Bulletin* issued by the Toronto Department of Public Health this is done and information is given which should be of material assistance to readers. In the United States and Canada more than 80,000 persons die each year from this disease.

GIFT TO MCGILL UNIVERSITY.

The late H. H. Lyman, who lost his life in the *Empress of Ireland* disaster, bequeathed his entomological collection and library and the sum of twenty thousand dollars to McGill University.

Correspondence.

INSECTS AND WAR: FLEAS.

SIR,—In the very interesting and instructive paper of Dr. Shipley in your issue of October 3rd he says: "Plastering a floor with cow-dung, which is a common practice in South Africa, is said to be a very efficacious means of keeping down fleas." This was certainly not my experience, for I have a very lively recollection of a dwelling in Natal, during the Boer war of 1880 and 1881, the earthen floor of which had a plastering of cow-dung which was simply swarming with fleas, due, I have no doubt, to the excellent breeding nature of such primitive floor covering in a semi-tropical climate.

I have found Keating's powder most effective in keeping down these little pests.—I am, etc.,

Dublin, Oct. 10th. TREVOR N. SMITH.

NUTRITION AND MEAT EXTRACTS.

SIR,—In a letter appearing in your issue of September 26th, Professor W. H. Thompson, referring to my book, *Nutrition, a Guide to Food and Dieting*, reviewed by you recently, disclaims an economical ration attributed to him.

I can only express regret if, inadvertently, he was given credit for that to which he lays no claim. He protests also, and at some length, against my suggestion that retention of water might explain the increases in weight observed in certain dogs when meat extract was added to their diet.

He agrees that there was retention of water, and when we refer to the original paper (BRITISH MEDICAL JOURNAL, September 16th, 1911) and find (p. 616) him admitting that retention of water "probably accounted largely for" the increase in weight, he really seems to have very little to complain of, and the matter might almost be left there, but an examination of his data will show that even his claim for gains in weight after administration of meat extract are by no means so free from doubt as they might be. A few examples will illustrate this:

DOG VI.—*Period 5: no extract.* Weights from day to day in kilos: 10.67, 10.64, 10.7, 10.64, 10.64, 10.67, 10.75, 10.73, 10.75. This dog is now a little heavier without meat extract than he was just after the meat extract period, when he weighed 10.69; he is also heavier than at the end of an earlier meat extract period. *Period 7; no extract:* 10.75, 10.77, 10.8. A further slight rise; in fact, *this dog shows a general tendency to increase in weight on the diet given, whether meat extract be added to it or not.*

DOG VII.—*Period 1; no extract.* Weights in kilos: 6.41, 6.41, 6.42: trifling rise. *Period 2; with extract:* 6.48, 6.475, 6.44, 6.42, 6.42, 6.44. The extract ceases to have any weight-raising effect after the second day; in fact, there is a fall after the first day. *Period 5; no extract:* 6.41, 6.445, 6.6, 6.575. Note, first, that on the first day of this period, following seven days with extract, he is no heavier than at the commencement of the experiments, and, secondly, that there is a greater rise without extract than with it. This dog continued to increase in weight during the next period without extract.

Coming to the human subjects, we meet with similar results; "C," for instance, rose from 61.020 to 61.465 after five days with extract, but weighed 61.690 at the end of the period during which he had no extract.

These differences are small, and Professor Thompson is doubtless perfectly right in not attaching so much importance to weight changes, but, if so, how unfortunate that he should have allowed a startling and, as I hold, misleading conception of the effects of meat extract to be spread broadcast among the general public with all the semblance of his authority.—I am, etc.,

London, N., Oct. 3rd. CHARLES E. SOHN.

THE WORKING POWER OF THE WHITE MAN IN THE TROPICS.

SIR,—At a recent meeting in Darwin of the medical officers of the Northern Territory of Australia, who are members of the British Medical Association, the article by Professor Leonard Hill on "The working power of the white man in the tropics and the electric fan" (BRITISH MEDICAL JOURNAL, February 7th, 1914) was discussed, and it was agreed that the arguments brought forward against the White Australia policy as regards the Northern Territory, although they may appear plausible in theory, are quite opposed to what is found to be the case in actual practice.

It was with amusement that we found a letter from Mr. F. Allen, Mayor of East Fremantle, referred to as supporting these arguments. As a matter of fact, Mr. Allen spent less than forty-eight hours in Darwin, and during that time interviewed, as far as we can gather, chiefly dissatisfied men who were on strike for higher wages, and most of whom had been but a few weeks or months in Darwin, and were unacquainted with the territory. He sought no information from departments, or from departmental records, of climatic conditions. This, added to his personal ignorance of these conditions, even as regards Darwin, let alone the Northern Territory, renders his views hardly worthy of attention.

As regards the working power of whites in the Northern Territory, we find in actual practice that the white man who spends his whole existence in the open air, exposed to the full force of climatic conditions, is capable of as good a day's work as are the men working in more temperate climates, and retains his strength and vigour unimpaired after many years of residence in the territory. These men take no precaution to protect themselves against actinic rays, their working costume often consisting merely of boots, breeches, and felt hat.

On the other hand, "the white man who takes refuge under umbrellas, in verandahs, etc., screening himself from the sunlight," is less healthy and less capable of severe exertion.

In the case of women also, it is found that those who take sufficient open-air exercise enjoy excellent health. As an example of this fact we find that women who live on the bush stations are capable of as great a degree of endurance as the men themselves. Recently two women who had spent more than four years on a bush station in what is considered the least agreeable part of the territory from a climatic point of view—namely, the coastal belt—journeyed to Darwin, spending five consecutive days in the saddle, and on the last day rode from 7 a.m. till 9 p.m., with but an hour's halt at midday.

Children in the territory show no evidence of deterioration, physical or mental, and the infantile mortality is lower than in any other part of Australia.

Turning to the black aboriginal races we find that their capacity for work is far below that of the white man, and apparently they feel the influence of climatic conditions more severely.

We have been struck with the general healthiness of the white race in the Northern Territory, and attribute it to the comparative absence of the diseases usually prevalent in other tropical countries. It seems to us that the great bar to the settlement and development of the tropics by the white race is the presence of these diseases, and not climatic unsuitability. The diseases can be eradicated.

The real drawback to the settlement of the Northern Territory by a white population is not climatic, but is due to the lack of communication with, and the distance from trade centres, a journey to Sydney meaning a fortnight's voyage. This difficulty will be overcome when railway communication is increased and Darwin is linked up with Adelaide and other State capitals.—We are, etc.,

FRANK HOWSON,
Government Medical Officer, Darwin; late Lecturer in Physiology, Sydney University,
MARTYN J. HOLMES, M.B., B.S.Melb.,
Chief Health Officer, N.T.A.
PHILIP A. MAPLESTONE, M.B., B.S.Melb.,
Darwin, Aug. 17th. G.M.O., Pine Creek, N.T.

LUMBAGO AND GREEN PEAS.

SIR,—I am interested in Dr. Haig's treatment of lumbago as described in the JOURNAL of September 26th (p. 539), by manipulation and active movement. Lumbago was one of the first ailments I had; I had repeated attacks, and generally was laid up for three days. Three years ago I was studying the physiological action of green peas, and to my astonishment I had an attack of lumbago, to which I had long been a stranger. It did not cripple me as it used to do, and I did not lay up, but exercised rather more than usual, having discovered that exercise was the best cure. Having met a young healthy farmer, I told him I was suffering from lumbago from eating green peas. "What," he said, "I have lumbago, and I have been indulging largely in green peas!" I was glad to have my observation corroborated by a healthy young man. Now, on looking back to my first attack, and knowing that it occurred at Whitsuntide, when green peas are to be had, and of which I have always been fond, I have little doubt that they would be the primary cause of the lumbago, which came on after the unusual exercise of cutting a terrace with a lawn mower, and getting a good sweat.

This spring I hesitated as to sowing peas, knowing that in spite of my knowledge of their action, I might indulge in them. I did sow them, however, and had an extra good crop. I was eating them, and without any other cause that I could think of, the old symptoms showed themselves. I gave the peas to a lady of my acquaintance, and she also had similar symptoms. The reason why Dr. Haig succeeded in relieving his patients by exercise, is no doubt the fact that lumbago, and indeed every ache and pain we have, is due to reflex action from the intestinal tract, and flatulence is probably the secondary cause. Massage and exercise no doubt act as stimulants of the circulation, and by causing increased elimination are useful in any disease, but specially so in lumbago, which is a sort of hybrid between rheumatism and a sprain in the sacro-iliac region, on a spot which the point of the finger can cover. Cramp, which is akin to lumbago, I can cause by eating green vegetables, such as cabbage; and when the physiological action of foods is studied, it will be found that the physician of to-day is causing more disease by the food he prescribes than all he can cure by drugs. Dr. Haultain, in the same journal, gives five cases of eclampsia treated by veratrone; the patients were fed on milk, the strongest of all foods, and a poison in such a disease. In reading the cases, no one can help being struck with the fact that improvement followed sickness. Whether the drug caused the sickness or not, there can be no doubt that the sickness would relieve the system, and allow elimination to occur, as it did, most markedly, by the kidneys. Such cases, if left without any food, would get well quicker than if fed and treated by any drug, but it is time the physician realized that his aim ought to be to find out a diet suitable for the sick, which Hippocrates, "The Father of Medicine," said it should be.—I am, etc.,

Hawick, Sept. 27th. JOHN HADDON, M.D.

BELGIAN REFUGEES.

SIR,—There are many medical men among the thousands of Belgian refugees. Surely we can show them some hospitality during their enforced residence amongst us.—I am, etc.,

London, W., Oct. 14th. H. FLEMING BROWNE, M.B.

*** The arrangements for the reception of Belgian refugees are in the hands of the War Refugees Committee. Lord Hugh Cecil is the chairman of the executive, and the honorary treasurer is Viscount Gladstone. Offers of hospitality should be addressed to Mr. F. A. Hirst, Hospitality Department, War Refugees Committee General Buildings, Aldwych, W.C.

Obituary.

LIEUTENANT J. F. O'CONNELL, M.B., B.S.Lond., ROYAL ARMY MEDICAL CORPS.

THE death in action at the battle of the Aisne on September 20th of Lieutenant John Forbes O'Connell, M.B., B.S.Lond., R.A.M.C., was briefly announced a fortnight ago.

He was born at Neemuch, Central India, on February 18th, 1889, where his father, Lieutenant-Colonel D. V. O'Connell, R.A.M.C., was then serving. He was the great-grandson of Dr. James Forbes, Inspector-General of the Forces, who served with distinction in the Peninsular War, and was the founder of the Army Medical Mess at Fort Pete, Chatham, which was moved to Netley in 1860.

He was educated at Epsom College, where he gained an entrance scholarship in 1902. After passing the preliminary scientific examination of the London University in 1907 he proceeded to St. Mary's Hospital, where he had a brilliant career. He became L.M.S.S.A.Lond. in January 1912, was house-physician at St. Mary's for six months and subsequently assistant resident medical officer at Hanwell Lunatic Asylum for nearly six months.

In November, 1912, he graduated M.B., B.S.Lond., and in the following January joined the R.A.M.C., gaining the fifth place at the entrance examination. He was stationed at the Connaught Hospital, Aldershot, till he went in medical charge of the 2nd Highland Light Infantry with the British Expeditionary Force on August 14th.

He was an ardent Rugby footballer, gaining his first XV cap at school, was twice captain of his hospital team, and played also for the London Welsh and London Irish; of the former he was vice-captain in 1913.

He was a very general favourite with every one who knew him, his frank and generous nature and sunny disposition gaining him friends wherever he went. An old school friend of his at Epsom writes to his father on hearing of his death:

For several years at Epsom and afterwards it was my privilege to know him intimately, and I shall always look back upon his friendship as one of the most delightful and valued possessions of my life. None who knew him could have failed to respect his frank and generous nature, or to love him for his warm and genial sentiments. It is indeed sad that so promising a life should so soon be cut off, and I am sure that all who had the honour of his friendship will suffer an irreparable loss. The loss to you of so splendid and gallant a son must be a great blow, but you have the consolation of knowing that he died nobly in the service of his country, unselfishly laying down his life that others through him might live—a fine end to a fine life. I shall always remember him as a genial, kind-hearted comrade—one of the very best.

Colonel Wolfe Murray, commanding the Highland Light Infantry, in announcing the sad news of his death to his wife, to whom he was married only a few months, writes:

He was shot dead in the trenches while attending Lieutenant Fergusson, H.L.I., who had been very seriously wounded, and who himself died later in the day. We all feel his loss most acutely. He performed his duties as a medical officer most efficiently, and was a general favourite with us all. I have never seen any one pluckier; he was just as cool under fire as he was at any other time, and the act which cost him his life was characteristic of him.

LIEUT.-COL. HERBERT WILSON PILGRIM, M.B., F.R.C.S.,

LATE SURGEON-SUPERINTENDENT, EUROPEAN GENERAL HOSPITAL, CALCUTTA.

LIEUTENANT-COLONEL HERBERT WILSON PILGRIM, Bengal Medical service (retired), died suddenly at Brighton on October 1st. He was born on October 10th, 1858, at Barbados, the son of Mr. Henry Pilgrim, a planter in that island, and was educated at Cheltenham College, and afterwards at University College, London, St. Bartholomew's, and Edinburgh University. He took the diplomas of L.S.A. and M.R.C.S. in 1884, and the degree of M.B.Lond. in 1885; in 1902 he became F.R.C.S.Eng. His first commission as surgeon was dated September 30th, 1886, when he passed into the I.M.S. second of a very large batch. He became major on September 30th, 1898, lieutenant-colonel on September 30th, 1906, and was placed on the selected list from December 25th, 1911. In April, 1912, he took two years' furlough, at the expiration of which he retired from the service on May 11th, 1914. He served on the North-East frontier of India in the Lushai campaign of 1889, receiving the frontier medal with a clasp. Most of his service, however, was spent in civil employ in Bengal. He was posted to that province in June, 1890, and, after two years as civil surgeon of the Nadiya district, was appointed second resident surgeon of the Presidency European General Hospital, Calcutta, and in it, with the exception of two short intervals of acting as civil surgeon of the 24 Parganas, he spent the remaining twenty-four years of his service. In 1896 he became first resident surgeon. When the late Lieutenant-Colonel Alexander Crombie, surgeon-superintendent of that hospital, retired, in the spring of 1898, his post was not filled for some months. Finally, in June, 1898, Pilgrim was appointed to succeed him, though he still only held the rank of surgeon-captain, and the post has usually been held by one of the senior members of the service. He was the most junior officer ever appointed to this post, one of the most important, professionally, in the whole service. How well he discharged the duties of the post, and how thoroughly he justified his selection—which was the subject of much comment at the time—is well known to all who have served or lived in Calcutta during the last sixteen years.

He was not only a first-class man all round in his profession, both as physician and as surgeon, but during his tenure of office he showed great business ability. The hospital, the most important in Eastern India, had fallen somewhat behind the times, and it was Colonel Pilgrim's lot to supervise, as well as partly to plan, the construction of an entirely new and up-to-date hospital, which has been constructed at a very large expense, by the Government of Bengal. The whole hospital, as it stood when he was appointed, has been dismantled block by block, and new and greatly improved buildings, thoroughly equipped on the most modern lines, have taken the place of those in which many of the senior members of the service have studied or worked. The only buildings which remain as they were at the date of his appointment are those of the block used as quarters by the resident surgeons. His epitaph, like that of Sir Christopher Wren, might well be, *Si monumentum quaeris, circumspice.*

THE HON. G. H. BUTLER, M.R.C.S., L.R.C.P.,

CONSULTING MEDICAL OFFICER, HOBART GENERAL HOSPITAL; FORMERLY CHIEF SECRETARY OF STATE.

THE HONOURABLE GAMALIEL HENRY BUTLER died on July 15th of cerebral apoplexy after a few hours' illness. He was born in June, 1854, the son of the late Hon. Henry Butler, F.R.C.S.Eng., who had settled in Tasmania in the Forties. After attending the Hobart High School he became a student at the Westminster Hospital, and took the diplomas of L.R.C.P. and M.R.C.S.Eng. in 1879. On his return to Tasmania Dr. Butler settled in Hobart, and became an honorary medical officer to the General Hospital. At the time of his death he was honorary consulting surgeon, with rank of major, to the Military Forces of Tasmania, president of the Medical Defence Association, chief medical officer to the Australian Mutual Provident Society, member of the Medical Council and Dental Board, president of the Australian Trained Nurses' Association, vice president and chairman of the council of the Royal Society. He was a member of the Tasmanian Branch of the British Medical Association, and in 1902 was president of the Intercolonial Medical Congress which met in Hobart. Dr. Butler became a member of the legislative council of Tasmania in 1896, and was Chief Secretary from 1909 to June, 1912; he held the same office under the Solomon Ministry until March of this year. Some eighteen months ago his health broke down, and he made a visit to England. He returned last November much improved in health, and resumed his many duties, so that his sudden death was a great shock to his relatives and friends. He was a genial, kind-hearted man, a keen observer, and sound reasoner. The *Medical Journal of Australia* says that he never lost a friend, but often won over a would-be enemy.

The funeral was attended by representatives of all classes. Dr. Butler leaves a widow, two daughters and four sons, one of whom, Dr. Nairn Butler, is engaged in practice in Hobart.

DR. ROBERT ARTHUR FRYER died on September 25th, at Southbourne, Hants, after a lingering illness. He was born at Warwick in 1869, and educated at the King's School in the same town. He received his medical education at Edinburgh, and graduated M.B. and C.M. In 1891 he began practice in partnership with Dr. John Davies, J.P., at Hoxton, and for nearly twenty years was one of the district medical officers of St. Leonard, Shoreditch, and carried on an extensive practice in the North of London. He was essentially a worker, and the whole of his life was given to the practical work of his profession. It is to be feared that his premature death was not a little due to his untiring energy and the self-denying way in which he laboured to promote the welfare of his numerous patients. Never of a robust constitution, the long hours, irregular meals, and constant nightwork slowly undermined his health. In January, 1912, he had an attack of what appeared to be acute rheumatism, but accompanied by some pulmonary symptoms, and tubercle bacilli were discovered in the sputum. He was a patient at several sanatoriums, but in spite of everything that medical science could suggest, the disease slowly progressed, and finally culminated in a fatal haemorrhage. Dr. Fryer possessed a most delightful

personality that endeared him to all who came in contact with him. If ever a man could be said to be without an enemy, he might have afforded an example, and his loss will be keenly regretted by all that knew him. He was fond of music, for which he had an excellent ear. He was also a keen sportsman, and the only relaxation from his arduous professional duties that he indulged in was a few weeks' holiday in the summer, which were invariably devoted to fishing and shooting. He leaves a widow, but no children.

We regret to announce the death, on September 6th, as the result of a cycle accident, of Dr. Horace Mansell Maybury. Dr. Maybury, who was in his 67th year, was the third son of the late William Augustus Maybury, surgeon of Frimley, Surrey. He was born in London on June 8th, 1848, and entered the City of London School. His medical training was received at St. Thomas's, London, and Queen's College, Belfast. He was M.D., M.Ch., and L.M. of the Royal University in Ireland, and held also the diplomas of M.R.C.S.Eng. and L.S.A. Dr. Maybury, as a young man of 24, became resident medical officer of the Islington Dispensary, an appointment he retained until shortly after his marriage in 1890, when he started in practice in Almeida Street. He was one of the oldest practitioners in Islington, and was held in the highest respect and affection by all who knew him. He was of a very genial, kind disposition, and his many good deeds and gratuitous medical services to those who needed his help will never be forgotten by many of his patients and friends. He was an adept cyclist, and his devotion to the wheel dated back to the old boneshaker machine. He had twice ridden from Land's End to John o' Groats. He had often gone 100 to 150 miles in one day, even in recent years. The funeral took place on September 12th at Frimley churchyard, and he was laid to rest with his late wife, who died in 1909.

Dr. Alfred Hegar, professor of obstetrics and gynaecology at Freiburg in Baden from 1864 till 1904, died on August 6th. He was the author of numerous writings extending over the whole field of gynaecology. He was the founder of the *Beiträge zur Geburtshilfe und Gynäkologie*.

Dr. W. J. Branch, of Basseterre, St. Kitts, W.I., who died recently, in his 76th year, was born in Barbados, and graduated M.D.Edin. in 1860. He had resided in St. Kitts for fifty years, and in announcing his death the *St. Kitts Daily Express* said that he had stood for all that was good and worthy in the community. "As a surgeon, a physician, a man of learning, and a friend of the poor his place will be hard, if not impossible, to fill." He had held the appointments of medical officer to the Cunningham Hospital and to the St. Kitts Hospital and analyser of vital statistics and health officer of St. Kitts, Nevis, and Anguilla. He was a member of the Leeward Isles Branch of the British Medical Association. For some years he had lived in retirement.

Deaths in the Profession Abroad.—Among the members of the medical profession in foreign countries who have recently died are Dr. Hasket Derby, one of the founders of the American Ophthalmological Society and a pioneer in the speciality of eye disease, aged 79; Dr. Gutierrez, Director of the Rubio Institute, Madrid, and Senator of Spain, aged 63; Dr. Alexander S. Leverty, clinical instructor in medicine, Department of Neurology, Cornell University Medical College, New York, aged 48; Dr. Martin Hayward Post, a prominent ophthalmic surgeon of St. Louis, aged 63; Dr. Paul Reclus, surgeon to the Hôtel-Dieu, Paris, and professor of clinical surgery, aged 67; and Dr. G. B. H. Swayne, one of the founders and first dean of the faculty of the Medico-Chirurgical College of Philadelphia, aged 81.

William Blackborne Clapham, M.R.C.S., L.S.A., aged 87, of Eastholme, Great Dunmow, Essex, left estate valued at £41,969.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following candidates have been approved at the examinations indicated:

First M.B. *Part I (Chemistry).*—J. C. Ainsworth Davis, H. Barbash, R. H. O. Betham Robinson, A. M. Broad, E. J. Crisp, E. C. Curwen, H. V. Edwards, A. C. Halliwell, A. T. Hawley, M. S. Thomson, J. S. Williams, R. L. Williams, D. W. Winnicott. *Part II (Physics).*—J. C. Ainsworth Davis, H. S. Allen, H. Fariba h, R. H. O. Betham Robinson, A. M. Broad, E. J. Crisp, E. C. Curwen, H. V. Edwards, A. C. Halliwell, A. T. Hawley, H. J. H. Hendley, R. Hilton, R. P. Lloyd-Williams, A. S. Rediero, M. S. Thomson, R. L. Williams. *Part III (Elementary Biology).*—R. H. O. Betham Robinson, A. M. Broad, H. V. Edwards, M. S. Thomson, J. S. Williams, R. H. White.

Second M.B. *Part II (Pharmacology and General Pathology).*—F. H. R. Altounyan, D. J. Batterham, W. H. Blackburn, R. S. Corbett, E. H. Dendy, J. M. Downie, J. R. Earp, J. S. Ellis, H. W. Featherstone, L. P. L. Firman-Edwards, H. Gardiner-Hill, E. A. Gibb, C. C. Goodhall, E. A. Green, F. H. S. Greenish, J. Hale, F. E. Higgins, G. M. Kendall, C. C. Kerby, E. A. Leak, W. J. MacCombie, G. L. Maule, T. D. Morgan, D. M. Muir, E. S. Orme, P. E. D. Pank, D. W. B. Richardson, J. Rickman, G. B. Sellwood, W. J. D. Smyth, N. S. Tirard, F. H. Vey, R. C. P. Whitcombe, H. G. E. Williams.

NATIONAL UNIVERSITY OF IRELAND.

A meeting of the university was held at University College, Dublin, on Saturday, October 10th, when the following degrees and diploma were conferred:

M.B., B.Ch., B.A.O.—J. B. Magennis, B.A., B.Sc., †P. J. Smyth, †J. I. Enright, W. O'Neill, P. Carney, C. I. Hannigan, B.A., M. Heenan, R. M'Grath, J. J. Moonan, E. J. O'Keeffe, B.Sc., F. C. Ward.

M.D.—J. Reidy, D.P.H. *(in absentiâ).*

Diploma in Public Health.—P. Steen, M.B., B.Ch., B.A.O. *in absentiâ).*

* With first class honours. † With second class honours.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS, IRELAND.

The following have passed the autumn examination for the Conjoint Diploma in Public Health:

Donal Mahony Barry (honours), M.B., R.U.I.; Rutherford Cramb, M.B.Glasg.; Hugh Reynolds McKay Fergusson, M.B.Dubl.; Percy Ernest Harrison, L.R.C.P.and S.I.; Alexander Frederick Kennedy, M.B., R.U.I.; Augustus Charles Lorena, L.R.C.P.Edin.; Robert Joseph May, L.R.C.P.and S.I.; Charles Gregg Sherlock, M.D.Dubl.

CONJOINT BOARD IN ENGLAND.

The following candidates have been approved at the examination indicated:

Anatomy and Physiology.—K. N. G. Bailey, T. B. Bailey, H. F. G. Berncastle, K. H. Bhat, B. Bishara, L. G. Blackmore, C. J. L. Blair, J. B. Brash, A. W. A. Davies, F. G. L. Dawson, Saad el Din Ahmed El Daab, Abdel Aziz Hassan El Zeneiny, J. H. Ewen, E. F. Fernando, J. T. T. Forbes, A. R. Hart, Mahdy Sayed Hashish, T. L. Heath, H. S. Hensman, E. B. Hickson, S. R. Johnston, G. Mallya, R. S. Millar, A. Mishriky, B. Mitra, V. S. R. Pandit, W. D. Pearman, A. W. Pearis, W. E. Powell, H. L. Pridham, E. Rau, R. J. Rhys, A. Rodd, H. H. Silley, M. O. Simpson, R. S. S. Smith, V. R. Smith, E. L. Stephenson, A. A. Thiel, E. S. Toogood, S. K. Vaidya, L. R. Woods, W. Yeoman.

First Examination *(Part I, Chemistry, and Part II, Physics).*—Y. Abdel-Massiah, †G. W. Almeyda, †J. F. E. Burns, C. J. C. de Silva, †M. A. El Dardari, †M. A. El Hennawy, †A. H. El Rakshi, †M. W. M. Hassan'ally, Elisabeth Esther McCulloch, †A. R. Neckle, A. B. Olamuyiwa, F. Y. Pearson, †M. C. Sarkies, †Gladys Mary Thurlow Williams, S. Wolff, V. D. Wyborn. *Part III, Elementary Biology.*—H. L. Vickers.

† Passed in Part I only. ‡ Passed in Part II only.

CONJOINT BOARD IN SCOTLAND.

The following candidates, having passed the requisite examinations, have been admitted Diplomates in Public Health:

Hira Singh Anand, M.B., Ch.B.Edin.; C. Gamble, M.B., Ch.B.Edin.; J. W. Edington, M.B., Ch.B.Edin.; S. B. Rao, F.R.C.S.Edin., etc.; Lakshmi Prasad Chaliha, F.R.F.P.and S.G., etc.; and J. H. Boag, M.B., Ch.B.Edin.

SOCIETY OF APOTHECARIES OF LONDON.

The following candidates at the Primary Examination passed in:

Biology.—C. E. Clarke.

Materia Medica and Pharmacy.—A. M. Berman, C. H. Philips, A. J. A. Wilson.

Anatomy.—A. M. Berman, J. M. Forbes, C. Gilroy-Jones, E. M. Gooda, F. J. Harrington, D. E. Hearn, R. F. Jarrett, H. D. L. Jones, S. Mikhail, J. B. Thomas, L. J. Vincent.

Physiology.—E. V. Beaumont, A. M. Berman, R. F. Jarrett, S. Mikhail, T. F. Reason, J. B. Thomas, L. J. Vincent.

Medical News.

THE sixth International Congress of Thalassotherapy will, as at present arranged, be held at San Remo in 1916.

DR. F. S. LEACH and Dr. John Todd were among the justices of the peace sworn in at Gateshead police court on October 7th.

AT a recent meeting of the Mississippi State Board of Health it was decided to procure a supply of vaccines, antitoxins, and serums, to be distributed to the public at cost.

A CHAIR of clinical tropical medicine has been founded in the University of Naples. The sum allocated for its maintenance is £548 a year, in addition to an annual subsidy of £120.

ONE case of plague and one death from the disease were reported at Hong Kong in the week ending September 26th, while on October 5th the colony was reported free from the infection. Seven cases of plague and seven deaths were reported at Mauritius in the week ending September 24th.

THE Council of the National Institute for the Blind, Great Portland Street, London, W., have undertaken to help, as far as practicable, all men who lose their sight while serving their country in the present war. Names and addresses of those who desire to avail themselves of this offer should be forwarded to the secretary-general of the institute.

A HOSPITAL with accommodation for 140 non-paying and 50 paying patients for the benefit of Italians has been founded at Jerusalem. It is said to be the best equipped hospital in the Levant. The operating theatres are fitted up with every modern appliance. It has isolation pavilions for contagious diseases.

THE proprietors of the Droitwich Brine Baths have undertaken to give facilities for the use of the baths to officers and men who have been invalided in the course of the war. They believe that such treatment will be specially beneficial in the case of those who have suffered from exposure. Soldiers and sailors who may therefore have been invalided home, and for whom the baths may be prescribed, may have their use free of charge.

ACCORDING to the *Medical Record* of September 26th Dr. N. T. Moore, formerly secretary of El Paso County Medical Society, is being kept a prisoner at Culician, Sinaloa, Mexico, because he performed an operation upon a resident of that city which resulted in his death. From this it would seem that the practice of operative surgery is almost as dangerous in Mexico as it was in some parts of Europe in the Middle Ages. Even in Italy, then the most civilized country in the world, we read that a famous surgeon before performing a critical operation insisted on being protected by a bond of indemnity signed by all the patient's friends.

THE rubber flooring for the Stephen Ward of Guy's Hospital was formally presented on behalf of the Rubber Growers' Association by Lady French on October 6th. Mr. McEwan, chairman of the Rubber Growers' Association, stated that some 170 of the producing companies had contributed. Mr. Cosmo Bonsor accepted the gift on behalf of the governors of the hospital. Particulars of a similar gift to the Edinburgh Royal Infirmary were published in the BRITISH MEDICAL JOURNAL of September 12th, p. 488. The rubber flooring lately laid in the consulting room of the out-patients' department of the Hospital for Sick Children, Great Ormond Street, was also the gift of the Rubber Growers' Association. The association had also voted a gift of 1,000 hot-water bottles, made from plantation rubber, to the British Red Cross Society.

AMONG the books to be published this autumn by the Cambridge University Press are *The House-fly: Musca domestica (Linn.); Its Structure, Habits, Development, Relation to Disease and Control*, by C. Gordon Hewitt, D.Sc.; *The Chemical Examination of Water, Sewage, Foods, and other Substances*, by J. E. Purvis, M.A., and T. R. Hodgson, M.A. The publications of the University of Chicago Press are sold in Great Britain and the British Empire (except Canada) by the Cambridge University Press. Among those announced are the following: *Water Reptiles of the Past and Present*, by Samuel W. Williston; *The Osteology of Some American Permian Vertebrates*, by Samuel W. Williston (Contributions from Walker Museum, vol. i, No. 8); *The Evolution of Sex in Plants*, by J. M. Coulter; and *Proceedings of the American Sociological Society*, vol. viii (Problems of Social Assimilation).

Letters, Notes, and Answers.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Aitiology, Westrand, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*.

TELEPHONE (National):—
2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

☞ *Queries, answers, and communications relating to subjects to which special departments of the* BRITISH MEDICAL JOURNAL *are devoted will be found under their respective headings.*

QUERIES.

CROWN DERBY asks for hints in building a surgery and waiting room.

INDIAN will be much obliged for information as to the suitability or otherwise of Alpine mountain resorts in winter for a person subject to chronic and subacute attacks of pneumococcal bronchitis in cold wet weather.

ANSWERS.

E.G.H.W.—A small household destructor for refuse, which would be suitable for a hospital of thirty beds, is made by Messrs. Horsfalls, the Station Works, Pershore, near Worcester.

LETTERS, NOTES, ETC.

THE PRACTITIONER AND THE NEW "PHARMACOPOEIA."

DR. J. C. MCWALTER (Dublin) writes: Allow me to make a vigorous protest against the meddling with the strength of the preparations of our most potent drugs—which is exhibited in the new *Pharmacopoeia*.

Take nux vomica, which is now being taken by literally millions of people. The new *British Pharmacopoeia* reduces the strength of the tincture to one-half. This means that practitioners no longer get the beneficial results they anticipate—for the dosage is suddenly cut down to half.

On the other hand, strophanthus—a most potent poison—is increased to four times its strength. Your heart patient, for whom you have prescribed a fairly liberal dose of the present *British Pharmacopoeia* tincture, will wander round the country in imminent danger of sudden death, when the conscientious chemist, after previous cogitation, insists on dispensing a tincture four times as strong as you contemplated.

Laudanum is also juggled with. It is made 25 per cent. stronger. Thus, when with fear and trembling you order a 20-minim dose, the equivalent of 25 minims will be given.

On the other hand, your syphilitic patient will be defrauded of his due dose of mercury. Liq. hydrargyri perchloridi is made weaker, and ungt. hydrargyri, used for inunction, suddenly drops to 60 per cent. of its former strength.

Surely to Heaven, digitalis should not be meddled with—but it is. The strength of the tincture is reduced 20 per cent.

There is a sudden drop in the strength of white precipitate ointment; it is reduced to half potency.

Belladonna is also altered. The tincture, formerly made from the leaves, and in the *British Pharmacopoeia* (1898) ordered to be made from the root—is now twisted back to the leaves again. Worse than that, its strength is reduced 30 per cent.

Another objectionable thing in the new *British Pharmacopoeia* is the introduction of abbreviations. We all write illegibly, but imagine sanctioning the use of "æth." when you want to prescribe ether, or "lin. sap." when you want to order soap liniment.

This extraordinary juggling with the strength of potent drugs should meet with stern reprobation.

THE INFLUENCE OF ENFORCED DOGMATISM IN MEDICINE.

Being the Presidential Address of the Birmingham and Midland Institute.

By SIR FREDERICK TREVES, Bart., G.C.V.O., LL.D.,
serjeant surgeon to h.m. the king.

In the study of the rise and development of any science certain common features are met with which might be presupposed, before even that study is entered upon. There are the inevitable void of the unknown, the many doubts, the wanderings from the predestined track, the delusions passing as solid truth, and the fumbling over strange things picked up in the dark. Most curious of all, we find associated with much progress a varying amount of actual fiction the origin and intention of which are not always easy to determine.

The old geographer, for example, fashioned a map to the best of his knowledge, but often finished it to the best of his belief. He added fictitious lands and peopled them with such beings as are found only in children's story books. Certain of these essays which came, in later days, to be ridiculed have been proved to be undeserving of the slight. There was, for example, a period when it was confidently believed that the centre of Africa was occupied by an arid desert. It was then that the map of Claudius Ptolemaeus, drawn some time in the second century, was condemned as an unworthy document, since it showed great lakes about the equator as well as mountains covered with snow. In the fullness of time, however, when Speke had discovered the Victoria Nyanza, and when Rebman had sighted the snow peaks of Kilimanjaro it was allowed that Ptolemy's belittled map was nearer to the truth than any design the cartographer had produced in the intervening centuries.

Then again, in the history of chemistry the labours of the alchemist occupy a prominent place. These patient, earnest men worked blindly on with crucible and alembic, striving to attain an object, not by the way of reason or induction, but by the means of preternatural accident. Their prime purpose was the transmutation of metals and the discovery of that Philosopher's Stone which was to change base things into gold. Incidentally they strove to find, by the process of a fantastic pharmacy, the Elixir of Life. The alchemist lived at a time when every tale of wonder was believed; when miracles were common; when the relics of saints could turn the unswerving course of nature. He was occasionally stoned to death as a magician, or was thrown into prison as a common rogue. From about the eighth to the eighteenth century he struggled on, mixing his essences, going blind over his furnaces, until Lavoisier came upon the scene and raised chemistry to the status of an exact science.

The alchemist, although he made fools of many and was himself the wildest gambler, yet did great good. He kept alive the spark of chemical research, advanced that science without intention, and discovered, without concern, important chemical compounds and valuable drugs. To the seeker after the Elixir of Life we owe phosphorus, the compounds of antimony, some of the chief acids, as well as such humbler substances as nitrate of silver and calomel.

It may be asked, in view of what follows in connexion with medicine, if the fiction upon which the alchemist founded his work was entirely without reason. In a sense it was not. Sure it is that none will ever drink of the Elixir of Life, and that the Philosopher's Stone as an object for research may be ranked with the Golden Fleece or the Holy Grail. On the other hand, there were grounds for the idea of the transmutation of metals. The alchemist, in his very earliest essays, had seen strange changes take place in metals under the influence of heat and certain reagents. In fusing argentiferous lead ore he had found—after the baser metal had been got rid of—a globule of silver. If silver could come forth from lead, why not gold from iron? At the time when the atom was the ultimate and unalterable particle, the alchemist's belief in the transmutation of metals was regarded as the sorriest nonsense. It is curious that now, at this late hour of the day—in this the twentieth century—the alchemist's belief should be shown to have some basis in fact. The transmutation of metals is an accepted item in the modern scientific creed. Indeed, the evolution of the atom from uranium to lead through a series of intervening stages can be said to be allowed. The alchemist may now rest in his grave with a better repute than he has enjoyed since the last of his number was thrown out of the market place as an impudent impostor.

The history of medicine tells a like story. It records long centuries of sound and patient work. It tells also of error and of false conclusions. But what is most remarkable, in the evolution of the science, is the daring amount of pure fiction with which its progress is associated—a fiction for which no such excuse as has just been offered is available. Some grounds may be found for the fantasies of the alchemist, but none for those of the mediaeval physician. In no branch of learning does the element of absolute fabrication form so large a part in the early structure of a science as it does in the case of medicine. For years—nay, for centuries—the system upon which the practice of physic was founded was a system devoid of both reason and of truth, being little more, indeed, than a jumble of elaborate nonsense.

I trust to make it evident that this vast body of fiction was the product of no natural stage in the progress of research, but was compelled by a phase of public opinion, and was imposed upon the plastic science of medicine to satisfy a demand of the people.

In order to make clear this relation of cause to effect it is necessary to imagine the dawn of the medical art and the position of the physician at a time when his knowledge was without form and void.

In the days of the primitive community the sick or wounded man would invoke the aid of someone in the settlement who, by reason of length of years, was assumed to have experience of human troubles. This was probably an aged woman, for I think that the first doctor was a lady doctor. If the ministrations of the knowledgeable person were successful, the same were no doubt rewarded by gifts of meat, bone needles or flint implements. These primitive fees would in time excite the cupidity of stay-at-home men, who would profess an understanding of bodily ills in order to reap what appeared to be an easy harvest. The self-elected practitioner would sooner or later meet with failure and would, in consequence, be beaten with a club. Indeed, I fancy that the solitary neolithic man who wandered away from the tribe and discovered new lands was often an unsuccessful medical practitioner still sore from the blows of his last patient's friends.

It is obvious, therefore, that one of the first efforts of the primitive doctor would be to find means to protect himself, and in this endeavour he deserves sympathy. He must needs shift the responsibility for his failures upon shoulders that could not be belaboured with heavy sticks. It is not surprising that in his theory of medicine diseases were due to deities and demons and that his treatment consisted largely in either propitiating or in exorcising ill-disposed spirits. From little more than this rose the crude practices of the medicine man, with his mummery, his incantations and his immoderate antics. If he failed, the patient had had at least a little for his money, and the practitioner, while yet perspiring from his efforts and with his sorry trumpery still jingling about him, would explain that the ill result was due not to the art of medicine but to the obstinate malignancy of the powers of the air.

Throughout the early history of medicine punishment for failure was a prominent feature in the evolution of the practitioner. Even in the enlightened days of Rome and Athens unsuccessful physicians were apt to be severely handled, to be driven into exile or stripped of their possessions. This abiding dread of punishment was not conducive to the welfare of the science. It did not encourage high thinking, it fostered the art of making excuse, it promoted deceit, and made a certain amount of fabrication a necessity.

As civilization advanced and as the rag-bedecked demons of the savage faded away there streamed into the blue heaven, in stately and superb procession, the gods of ancient Egypt, Greece, and Rome. A wondrous and dazzling company they were, in whose laps lay the fate of all who were sick or afflicted. The practice of medicine

was transferred from the forest glade to these stupendous temples which are still the wonder of the world. The sick man, who crept along the pillared colonnade to fall before the statue of the god, learnt little more than the naked savage knew. The gods were offended, propitiation must be made, the greed of priests must be satisfied, and beyond that were little but a reverential hope and an aphorism to ponder over.

In fullness of time the gods failed, and man was once more brought face to face with man, as in the days when the world was young. The sick or wounded looked to his fellow and not to a petulant deity to help him in his distress.

We now begin to notice two lines of development proceeding side by side. On the one hand was the true science of Medicine, built up, fragment by fragment, with infinite labour, fact being added to fact with prodigious patience; until by slow degrees there appeared the elements of a practice of Physic based upon accurate observation and sound reasoning. On the other hand there sprang up, like the beanstalk in the nursery legend, a monstrous fabric purporting to be a system of healing, but lacking any foundation in either actual knowledge or experience—a work of fancy which assumed all the authority of an inspired revelation and which was as poor a simulacrum of the truth as was the tragic mask of an actor on the Athenian stage. This travesty of a science dominated Medicine for many centuries. It served no doubt a certain end, but it hampered progress and blinded the eyes of those who were seeking for the truth. It owed its origin, as I have already said, not to misdirected research but to a popular demand, and it is with this phase of its development that I propose alone to deal.

This imagined science of Medicine took upon itself several aspects. Its earliest, most conspicuous, and most abiding form is that known as the Humoral Pathology. This fiction had its origin about the days of Hippocrates, and to a very large extent dominated Medicine for some twenty centuries.

It was varied from time to time to meet the public taste and to satisfy new requirements, but its principal features were as follows: The body was occupied by, and was to a degree composed of, four cardinal humours—namely, blood, phlegm, yellow bile, and black bile, the two latter being also known respectively as choler and melancholy. The equipoise and proper adjustment of these humours constituted the state of health. The loss of this balance, or an unpropitious blending of the humours, was the cause of disease. The humours, which in substance were described as "humedious and vaporative," were allied with, or were expression of, certain distempers, complexions, or states of the body. Blood was associated with a hot condition or distemper, phlegm with cold, and black bile with melancholy. In like manner certain foods and medicines were heating, others were cooling, while a third variety was melancholic.

Very detailed accounts of these purely fictitious fluids were provided for all who demanded dogmatism in medicine. Phlegm, for example, was bred in the liver, and had most puissance in winter, from October 8th until March 9th, and from the third hour of the night until the ninth of the said night. Melancholy, in the language of the seventeenth century, "is a humour imperfectly concoct which hath his mansion and abiding in the spleen. It reigneth in harvest from September 18th until October 8th, and hath dominion from the ninth houre of the day until the third houre of the night." What more could a man want to know?

In applying these data to practice it would appear that cancer—as an instance—was due to a collection of black bile, produced by a hot distemper of the liver. Its medical treatment, therefore, was obvious. The patient must avoid all melancholy meats, must take cooling medicines together with such remedies as were soothing to the liver. Drugs with these reputed powers were forthcoming, and consequently the medical treatment of cancer was as undoubted as were its causes. Here, then, was a system of medicine for popular contemplation, complete in every particular, and one that not only explained the nature of all diseases, but, at the same time, indicated their intelligible treatment.

It is interesting to inquire how a science of medicine so elaborate and yet so devoid of any element of truth came into existence and remained dominant and satisfying for so many centuries. Ignorance rendered its acceptance possible, but not its fabrication, for ignorance is merely the state of not knowing, while this was a carefully invented and finished scheme. The explanation is, I think, the following: In matters involving special knowledge the layman is indulgent of hesitating statements. In a legal issue he will not complain if the opinion of his lawyer is indefinite as to the outcome of a pleading or as to the value attaching to this evidence or to that. He himself acknowledges that the law is uncertain. When he questions the mariner, too, as to the coming weather, he is satisfied with a dubious reply. The morrow will probably be fine, but, on the other hand, there may be rain. Now in all matters connected with personal health, as in all matters concerned with personal religion, the layman demands absolute dogmatism. There must be no uncertain reply to any inquiry. The very suggestion of doubt is abhorrent, and, indeed, insupportable. Both the pastor and the physician must be dogmatic, must be sure of their views and be free from any shadow of vacillation.

The true science of Medicine was slow of growth. In the early days of which we are speaking the sum of actual knowledge it presented was negligible. What the physician did not know would have filled many volumes, while what he did know would fall within the compass of a page. At the same time it was from the many volumes unhappily that the sick man sought his questions and expected, in reply, a firm answer. What could the man of Medicine do? If he stood in a Palace of Truth he would speak to his patient in this wise—"I believe that the disease from which you suffer is called cancer. As to the causes of the malady I know nothing; as to the nature of the malady I also know nothing. I only know with regret that the disease is fatal. Certain remedies are employed empirically in such a case as yours, but I cannot say how they act, nor am I sure that they have any effect at all. The surgeon may do something for you, but I nothing." As surgery in early days involved substantial terrors it is not to be supposed that the sick man would suffer the truth-speaking physician kindly. He demanded something more comforting than the bare truth.

Some such invention, some such plausible fiction as the humoral pathology became a necessity. Agnosticism in Medicine, however honest, the sick man would not and could not tolerate. Some satisfying tale was as much needed to maintain the status of the physician as it was to furnish consolation to the patient. The humoral pathology enabled the doctor to answer with promptness and confidence every problem placed before him and to convey his answer with the dogmatism that the afflicted man required.

The general trend of the humoral pathology was little more—as I shall hope to show—than a reflex of the untutored mind on the great subjects of health and disease, while its unfaltering array of reputed facts was needed to maintain that infallibility with which alone these problems could be discussed. The intellectual simplicity of those who derived comfort from this fiction and the ingenuity of the imposture are revealed by a very little study of the details.

The body of the sick man was the seat of turmoil. Humours flying in various directions were making great havoc. They were pursued by the physician with the same alacrity as would be displayed in chasing rats about a barn. Some humours had to be driven out; others had to be coaxed from their hiding place, for these humours, while sometimes very shy and often very bold, were always fickle and uncertain. Culpepper says that when in a fever the eruption fails it signifies "the retirement of the humour inwards." He speaks also of the obsequiousness of a morbid humour and of its contumacy and sulkiness. He tells, too, how they become numbed by cold and excited by heat. The activity and malignancy of the humours were marvellous. They could fly from the feet to the head like a soaring bird or drop from the brain to the ankle like a stone. They would gather together in unsuspected places like conspirators, or slink out of the body as do thieves in the night.

Every person in these days had a temperament, just as now many have a constitution. Those with a hot temperament grew quickly, as does a plant in a warm atmosphere,

their teeth appeared early, and the growth of their hair was luxuriant. The man of dry temperament was like an ill-watered shrub, scraggy and thin, while his hair, like the leaves, soon fell off.

These temperaments or complexions are very fully described in works on medicine of the time, and by no writer more vividly than by John Fage of Midhurst in his work, *The Sick-mans Glasse*, which was published in 1638, and sold at the shop of William Lugger on Tower Hill near to the Postern Gate.

The man of choleric temperament, John Fage tells us, was short of stature, with a florid complexion and red or "alborne" hair. He was quick witted and bold, but also unshamefaced, hasty, and fraudulent. He was eloquent, but, at the same time, graceless as well as a mocker and one apt to leasings. He of a melancholic constitution was slender and had dusky or flaxen hair. He was a self-lover and covetous, fearful without cause, vexed with dolours of the mind, ambitious and very majestical in behaviour, yet slovenly and inhumanious. The sanguine individual was well built and had brown hair. He was merry, liberal, courteous and bold, a man of good behaviour with apparently no other fault than that grief stuck but lightly to his heart. Every possible combination of temperament was described and among them the very modern person may be interested to find the sanguine-phlegmatic man who was noteworthy because of his proneness to dream of flying in the air.

Each of the organs had also a temperament. For example, a warm heart was associated with a large pulse, but also with "boldness and maniacal ferocity." The cold heart went with a small pulse and a "timid and spiritless disposition." With the dry heart the pulse was hard and the passions ungovernable, while the pulse of the humid heart was soft and the subject dull and lethargic.

The compounds produced were endless, so that one can conceive the physician sucking his gold-headed cane while he pondered a regimen for a man with a dry heart and a cold stomach or a hot liver and a humid lung.

Many of the characteristics ascribed to food and drugs appealed easily to the imagination of the layman. Some of them were arbitrary, and had to be accepted without question. A few have survived, for certain people still speak of cooling medicines, although what they mean is not now known. Meat was heating, and even to this day one hears of a mother who thinks that beef is too heating for a child, although her expression is no longer intelligible. The dryest meat was that of a wood-pigeon. The meat of the turtle dove was dry and hot, and had "a wonderful effect in sharpening the understanding." Fish, of course, was cold. Geese and ducks produced humid food, because they dabble about so much in water. Prunes were cooling and dates were heating, but the explanation of these properties I cannot discover. The lettuce, the gourd, and the cucumber were obviously cold foods. Lentils, for some reason, were melancholy. Sweet apples were heating, but sour apples were cooling, and "cut the humours in the stomach." Even now there is a domestic remedy in use for coughs which contains vinegar, the acid being of value—the wise women say—in cutting the phlegm. The radish, needless to say, was hot; while the penetrating onion could pierce with ease the thickest humour. Barley was decided to be cold, so barley water was given in fever, and is, I believe, still employed by some in the ceremonial treatment of that condition. Borage "imparted gladness to the soul," and for that reason, and so far as I know for no other, is still used in the compounding of claret-cup and like beverages, when gladness of soul is desired.

Wine, of course, was heating, although, as a matter of fact, it lessens heat production. Thick wines were assumed to make thick blood, and so to this day the sick man's friends prefer burgundy to claret. Red wine made red blood, and was therefore prescribed in anaemia. This ancient fancy still persists, for port wine is given to the pallid apparently on the ground that the wine is red and the patient is white. To give such a sufferer a white wine would be a heresy. I am under the impression—in this connexion—that stout is given to the weak because the word "stout," as defined in the dictionary, means "physically strong."

The number of medicines at the disposal of the practitioner was prodigious. The idea that any disease could be treated without medicine was inconceivable. This system embodied the great fundamental article of faith that if a person was sick he must take medicine. No man could expect to get well without going through this drear observance. He was taught to associate ill-health with drugs, or more probably he determined for himself that every one who was sick must take medicine in some form. The belief still lingers with many folk. The out-patient, for example, leaves the hospital with a sense of being wronged unless he takes with him something in a bottle. If a child has measles, there are parents still who demand that the child shall have medicine, and, if the physic be not forthcoming, they seek what they term "higher advice." Their argument is the old one. The child has measles; measles is a disease; therefore the child must have medicine.

Among the many hundreds of drugs which figured in the old antidotaries of, say, the sixteenth century, scarcely one is in use at the present day. These reputed remedies were obtained from all the realms of Nature. The majority were derived from herbs by complex and uncanny processes, such as attend the making of a broth in a witch's kitchen. Some of the plants the doctor gathered for himself in the fields and woods, more especially at the full of the moon. Others he grew in his garden, while many came across the seas from wonder-abounding lands. The botanical preparations were at least cleanly, but many of the remedies obtained from the animal kingdom were loathsome. Certain forms of physic were purely fanciful, for there was special power in an elder leaf upon which the sun had never shone, and sterling virtue in a powder made from the sail of a wrecked ship. A few items in the materia medica were almost poetical. For example, the heart of a nightingale was given as a cure for loss of memory. There is a pretty conceit in this, for the song of the nightingale is so long sustained, is so infinitely varied, and yet so well remembered, that the heart of the singer should bring back the recollection of all bygone things.

Every drug had its function, so that if a patient asked why a medicine was given, the physician had an answer ready. The doctor seldom trusted to one remedy; he rarely drew one bow at a venture, but rather sent a flight of arrows into the dark. If one bolt happened to hit the mark he proceeded to prove that it was aimed with a purpose. We find that one very popular draught of the time—the *aqua coelestis*—contained (as the *London Pharmacopoeia* of 1682 assures us) 45 ingredients, while that excellent electuary, Venice treacle, was composed of no less than 65 carefully selected drugs. The action of the drugs had, with one or two exceptions, not the slenderest foundation in fact. They belonged to a materia medica of pure fiction. The therapeutic effect of the much vaunted plants had no more scientific basis than has the "Language of Flowers." To assert that rue warmed the blood or that raisins strengthened the liver ranked in value with the pleasing conception that rosemary stood for remembrance.

As the properties of drugs were invented primarily to meet the demand of the patient for dogmatic assurance about his ailments it will be noted that the effect ascribed to many remedies was such as the lay mind could understand. I might take some of the simplest instances. The juice of the pomegranate was advised for undue pallor of the complexion, because that fruit itself is of the deepest red. To preserve the face from wrinkles a preparation was used composed of ivory shavings, frankincense, and isinglass. "Why?" asked the lady who buys the cosmetic. Because ivory is itself perfectly smooth and free from wrinkles; because frankincense is employed in embalming and can prevent the ravages of decay, and because isinglass is soft, glossy, and readily moulded. For threatened baldness bear's grease must be applied. But why bear's grease above all other forms of grease? Because the bear has the thickest coating of hair of any animal. By another plan—not yet quite abandoned—the hair was treated as an agricultural crop, and was supplied with fertilizers, just as, at the present day, one applies basic slag or nitrates to a bare or patchy lawn.

If, when a child was cutting teeth, the teeth were slow to come through the gum, the gum was rubbed with the brain of a hare, because the hare is so quick in its exits, and, at the same time, sweet oil was poured into the ear.

The mother could understand this latter measure well, for she must often have poured oil into a rusty lock when the bolt was hard to come through.

As the sick man demanded a scheme of therapeutics that would meet every malady and every symptom to which the human body was prone, he was supplied with the most lavish materia medica the world has ever seen. He asked for bread and was given not a stone but a magic mountain worthy of the *Arabian Nights*. The whole of this system of treatment has vanished, leaving no trace behind except in the form of a few valued drugs still in use, together with copious reminiscences embodied in the folk-lore of the country and in the literature of the modern quack.

The domestic use of linseed tea, of liquorice, of horehound, of coltsfoot, of cooling powders and of elder wine, all belong to the vanished Aladdin's Palace of Medicine. The hardiest survivor is, perhaps, the tonic. The tonic is a medicine the taking of which gives strength. The pretence is as ridiculous as would be the assurance that there was a drug the swallowing of which gave wealth or the power of speaking the truth. We have still in our chemists' shops some decoctions, some syrups, and some electuaries, but where are the lohochs and the necsings, the masticatories and the lambitives, the vapours and the fumes, the alexipharmicks, and the epithems?

It must be confessed that with the disappearance of this fool's paradise a great deal of the picturesqueness of the sick-room has also passed away. Think of the prettily named remedies that stood by the solemn four-post bedstead, or that were taken from the gracious Tudor cupboard or from the still-room chest! Where are the julep of wild poppies, the conserve of tamarisk flowers, the syrup of sweet smelling apples, the succory water and the oil of lilies? It was almost worth while to be ill if one could be treated with a potion made from "the four great cold seeds," while how poor a thing is the modern tabloid by the side of "one pugil of the great celandine"! Who could decline an ointment made of spikenard and black hellebore, or a draught of marjoram mixed with fleabane, or an apozem made by moonlight from so prettily named a simple as the pellitory of the wall?

There was nothing these remedies could not do. They could harden the heart or soften the brain, and make the pores of the skin to open or shut as easily as if they were the ventilators in a railway carriage. By his demand for dogmatism and a remedy for every symptom the sick man and his household laid up much trouble for themselves. The effect of their requirements upon the inventive powers of the physician may be illustrated by the treatment of a child for measles as given in a textbook written in the year 1668.

The room is very warm, because the pores of the skin must be kept open and the humours thereby afforded every opportunity to escape. It is also very close, since a cold air might drive a chilly humour back again, just as it was leaving the body. The coverings of the bed are crimson, because, as Culpepper says, that colour entices the boiling blood to the external parts. Lying actually on the bed is a live sheep, not tethered there to amuse the child but "because these creatures," as the writer states, "are easily infected and draw the venom to themselves, by which means some ease may happen to the sick person."

The wretched child has been already bled, to its infinite terror, and has already drunk a decoction of barley and figs in order to coax the humour to the skin. It has probably swallowed a quantity of gum, for whenever the humour is thin it must be thickened by gum and like substances. The little patient would now be in a position to take medicine. This might be either in the form of a julep of turnip seeds, fennel roots, and scabious leaves, or a lohoch of a nature equally uninviting. Gargles and vapours, as well as protective syrups for the lung, would be added as occasion offered.

Another example of the penalty the irrational patient brought upon himself is afforded by the procedure adopted in dealing with a common cold. The catarrh is due, the physician said when an explanation was demanded, to the defluxion of an excrementitious humour from the head to the parts below. The brain is the seat of the trouble, for are there not headache and great heaviness in the head? The brain is large; a cold distemper causes the nourishment brought to it to be excessive and ill concocted. The superfluous supply drains away in the form of phlegm, and so there is at once explained the streaming eyes, the nasal catarrh, the trouble in the throat, and, later on, the expectoration from the lung. The brain, in fact, is a kind of sponge which has become over-saturated. The rest is a mere question of gravity.

Cold feet may cause a catarrh? the patient asks. Assuredly they may, because—as Culpepper affirms—the cold distemper is conveyed to the brain from the feet "by the chiefest nerves that come through the marrow of the back bone." Hence incidentally is also explained the aching often felt about the spine. Could any pathology be more simple?

The treatment of the cold must follow the lines indicated by the pathology of the disease. The humour must be got rid of, and the dripping brain must be dried up. What a terrible process it was, and what horrors it added to a malady already melancholy enough! Picture the miserable man sitting in an armchair in a stifling room. He has been bled. He has been cupped on the neck and shoulders, and has had an issue applied behind each ear, for the humour must at all costs be drawn out. He could not feel more sore if he had been ridden over by a cart. He takes medicated snuff at one moment, and inhales the pungent fumes of burnt linen the next. He sniffs at powders that make him sneeze, or chews an acrid substance that causes his mouth to water. In this fashion the brain is, as it were, drained. In any interval that may occur he drinks medicine, such as marjoram water, betony juice, a mess made of nutmegs, or that gallant remedy for all cold distempers, coloquintida, which figures in so many "magistrall receipts."

This, however, is not all. The great medical event in the cure of a cold is the drying up of the brain. The fore part of the head is shaved and the supposed fluid in the sodden brain is mopped up, as it were, by applying bags of bran or of sage leaves to the scalp. Such is the procedure for the day; but at night the head is covered with a drying powder composed of eleven absorbent substances, which same powder is combed off, like so much clay, in the morning.

It is a dreadful picture. But for the folly of insisting upon a knowledge that none possessed the patient may have been sitting quietly in his room with an interesting romance and have recovered in half the time without a shaven head, without the scars of two issues behind the ears, without a long abiding nausea and the debility consequent upon loss of blood.

These measures belong not to science but to the cult of the story teller and the mime. The afflicted man called for a story—for any story—that would satisfy his anxiety, just as a frightened child demands from its nurse an explanation of the thunder and lightning which fills it with dread. The story furnished was dogmatic and detailed, and adapted to the intelligence of the inquirer. That it was pure fiction was immaterial. It fulfilled its intention. It satisfied the patient as it did the child.

It may be asked how remedies so utterly ineffectual came to be accepted by the world as of sovereign value even if the patient himself was unknowingly the instigator of their invention. Such measures were tolerated and were even held in esteem, for the same reason that secures some modicum of success to every quack. The reason is simple. The very great majority of sick people recover and the patient is always more ready to ascribe success to medicine than to nature. Moreover, as Stuart Mill has observed, "Faith in delusions is quite capable of holding out against a great multitude of failures, provided that it be nourished by a reasonable number of casual coincidences between the prediction and the event."

Here, then, is a science of medicine founded upon pure nonsense, or rather upon the fables evolved to satisfy the demand of the public for dogmatism in all that related to ill health. In this extraordinary product the physician himself believed. The tale had come to be accepted as true; it was a matter of sober study; it formed the basis of the education of every medical man, while its ridiculous gibberish became the speech of the cultured physician.

The true science of medicine, the science based upon assured facts, was proceeding side by side with this phantasm, but its influence was slight and its movement almost imperceptible. The course of medical progress had been diverted from the firm road into a shaking quagmire

where men stumbled to and fro, talking, so far as the ears of truth were concerned, in unknown tongues. The people insisted upon a complete, infallible system of medicine where was neither doubt nor wavering, and they obtained in response to their impossible demand a fabric of fiction which is unique in history by reason of its magnitude, its detail, its audacity and the completeness with which it satisfied the demand that called it into existence. This vast work of invention had no more concern with the living science of Medicine than has the cocoon with the living butterfly. It was the people who were the leaders of early Medicine. That they led it utterly astray does not alter the fact that they led. The physician had to adapt what little he knew or professed to know to the attitude of mind they displayed. The channels available for the expansion of Medicine were channels directed by the people's needs and expectations, while the very details of the art had to conform to the popular understanding.

In conclusion, it is needless to observe that the whole of this spurious science has long been swept away. Medicine is now an exact science founded upon well tested facts; its speculations are directed by reason and justified by experience. While its confines have been enormously extended, while its ramifications have become almost bewildering and its potentialities amazing to contemplate, its principles have been consolidated, simplified, and reduced to a few great propositions.

Medicine, or at least the elements of Medicine, are now for the first time "understanded of the people."

No longer are medical topics obscured by a mystic verbiage which was deliberately intended to hide ignorance and give the appearance of learning to sorry inventions. The educated person of the present day can inform himself of the foundations upon which medical practice is based; he finds himself dealing with facts and not with mysteries; he is enabled to appreciate the physician's difficulties, to share in his doubts, and yet to obtain, in well proven truths, that dogmatism which, while the world lasts, the sick man will never fail to demand.

NOTE ON THE USE OF "DUM-DUM" AND EXPLOSIVE BULLETS IN WAR.

By SURGEON-GENERAL W. F. STEVENSON, C.B., K.H.S.

History again repeats itself! and surgeons at the front, and especially young civilian surgeons inexperienced in bullet wounds, on both sides, are accusing their enemies in this war of using "Dum-Dum" and explosive small-arm bullets, a practice which, as regards the latter, is contrary to an agreement entered into by the principal European Powers in 1868, by which they bound themselves not to use explosive projectiles under 14 oz. in weight.

Dum-Dum and Other Kinds of Easily Deformed Bullets.

The Dum-Dum bullet is so named after the place near Calcutta at which it was first made. It is precisely similar to the Lee-Enfield bullet, except that the cupro-nickel envelope ends near the shoulder, about ⅜ in. from the point, leaving the leaden core exposed for that distance. Other forms of this class of missile have a hollow, or dimple, in the fore-end which is uncovered by envelope, or cross-cuts made with a saw in the direction of the long axis of the bullet; but in all of them the same object is desired—that they should readily break up on contact or, at all events, on striking bone; and this result has certainly been achieved. They do break up very frequently in the tissues, and almost always when they meet with hard bone at a fairly high rate of velocity. No doubt the injuries produced by them are severe; pieces of the core and jagged strips of the envelope are scattered widely through the part struck, remaining lodged in the part to set up surgical complications later on, and important structures may be torn by pieces of the envelope. But, on the other hand, they suffer much damage themselves by being so broken and distorted, and thus a good deal of the energy they possess, on which their capability of destructive effect entirely depends, is expended in causing the distortion and fragmentation they undergo, and therefore less remains to be spent on comminuting the bone and injuring the soft parts. These projectiles were invented for the purpose of obtaining greater "stopping power" than the service bullet possessed against Ghazis and other fanatic savages, and, no doubt, when they implicate any of the large cavities of the body, the destruction of which they are capable is extreme. But the ordinary service bullet is, as we shall see later on, capable of causing more severe wounds in the limbs when they traverse compact bone at high rates of velocity.

The mere fact of finding bullets broken into numerous fragments in wounds is no proof that this type of missile is being used by the enemy. The ordinary service bullet sometimes parts with its envelope, which may be torn into jagged and twisted strips of metal, while the leaden core is broken into slug-like pieces, with the result that the destructive effect on the soft parts of the limb is greatly increased. The only certain evidence of their employment is the finding of bullets of this kind or fragments of them in the patients during their surgical treatment or in the positions recently evacuated by the enemy. The recognized customs of war and all ideas of humanity are against the use of projectiles of this kind among civilized nations, and it is improbable that they are used to any great extent.

Explosive Small-arm Missiles.

The employment of explosive small-arm bullets in warfare comes under another category altogether. It is not only against the customs of war and opposed to all notions of humanity, but it is contrary, as already mentioned, to the conference held in St. Petersburg in 1868. But agreements of this kind do not always exclude the evils they are intended to prevent—as witnessed notably in this year of 1914—and the matter must be considered from the point of view of the evidence for and against the truth of statements made on the question.

Army surgeons and civil surgeons employed on a campaign meet with a fairly large number of wounds the entrance apertures of which are clean-cut, circular holes of about the size of the end of an ordinary cedar-wood pencil, while the exit wounds are of great superficial area and accompanied by bone fractures of great severity and extensive comminution, together with widespread destruction of the soft parts. That injuries of this class could be due to the passage of a solid bullet of quite small calibre appears to those who see them for the first time to be impossible, and the ready explanation is immediately proclaimed that the enemy is using explosive bullets other than those for artillery guns—that he is using small-arm bullets containing bursting charges within them which explode on contact with the object hit. These cases have been met with, similar views have been held and similar reports made regarding them since small-arms of the more powerful kinds were first employed in warfare—the Snider, Martini-Henry, Lee-Enfield, Mauser, Lebel, etc.—and practically in every war for the last fifty years each side has accused the other of using these explosive small-arm bullets; whereas, in fact, they have not been used at all. This is the phase of the war which surgeons are going through just now, and it depends on a want of knowledge of the capabilities of the ordinary service small-bore bullet under certain conditions.

I was present and had to report on a long series of experiments carried out at Woolwich when small-bore rifles (Lee-Metford and Lee-Enfield) were first adopted in the British army, for the purpose of ascertaining the probable effects of their projectiles on men in actual war. The results obtained in these experiments showed that at short ranges the Lee-Enfield bullet produced wounds on the exit side, in a large number of cases, which, from their extent and extreme severity, it was difficult to recognize as being the results of solid bullets of 0.311 in. calibre; they looked as if they must have been produced by explosions within the tissues. It soon, however, became evident that two conditions as regards the bullet were invariably present in these cases—(1) short range and therefore high velocity, and (2) that it had passed through structures offering great resistance to it; in these circumstances only was the "explosive effect" produced.

M. Delorme, the French army surgeon, has reported this class of injury to have occurred when only strong tendinous soft parts had been traversed by the bullet, but in the experiments, and as actually experienced in South Africa, the implication of compact bone in the bullet track is necessary for their production in their really typical character. Injuries of this class were caused by the Snider and Martini-Henry bullets of as great severity as those resulting from small-bore bullets, but not so frequently, because the former did not retain a sufficiently high velocity over as long ranges as the latter. The older bullets produced them up to 100 or 150 yards' range, whereas the Lee-Enfield, Lebel, and Mauser bullets produced them up to about 400 yards. The cause of the great destructive effect seen on the exit side is the violent displacement of the fragments representing the comminution which occurs in the compact bone tissue, due to the great energy still inherent in the bullet at the ranges mentioned. The result is that the bone fragments, large and small, are driven forward through the soft parts and out at the exit side, producing the exit wound of the enormous size sometimes met with in specially severe cases, and when the exit side happens to be on the inner side of the limb large nerve and vascular trunks are very liable to be torn.

If injuries of this class are seen to result from solid small-arm bullets in experimental work, why should we immediately accuse the enemy of using explosive bullets when we meet with them in actual warfare, as we did in the Boer war, and as surgeons at the front are doing now? If small-arm shells were used in war, almost every bullet wound seen would be of the explosive type (the only exceptions being the few cases in which the bullets failed to explode), and they would not be confined to men hit at 400 yards and under, but would be experienced at all ranges, and whether bone had been implicated or not. Range and velocity and the structures traversed would, in fact, have nothing to do with the amount of damage done. But "explosive effect," experimentally and practically, is seen to result only under the conditions mentioned above; naturally, in these circumstances, we must admit the relation of cause and effect in this case. Surgeons who uphold the explosive bullet theory talk freely of the enemy's use of these projectiles. Why do they never produce one in proof of their contention? In every trench, or defended position, which has been evacuated by the fighting line, hundreds, perhaps thousands, of unused cartridges are to be picked up by any person who wishes; yet apparently nobody has ever found one with an explosive bullet in it. We accuse the Germans of using these missiles, and they accuse us of doing so. This kind of thing is just a phase common to the early days of all campaigns, and is equally untrue of all. The Germans carry on war in barbarous fashion, but they have not yet adopted this particular barbarity, probably because it would be of no advantage to them, for solid small-bore bullets do all they desire of them, and small-arm shells are not required.

I have seen references to the new sharp-pointed bullet first used in the German army as being more "humane" than those of other small-bore rifles. If humane in this connexion means less fatal, I believe that it will not prove, on actual experience, to deserve this character. Its centre of gravity, owing to its long and tapering shoulder and point, is situated unusually near its base. This gives it a marked tendency to turn over on meeting with even slight resistance, thus causing it to spin on its shorter axis during its passage through the part traversed by it, the result of which is certain to be increased damage to the contents of the head, chest and abdomen when these cavities have been traversed by it. Professor Fessler of Munich made experiments with this bullet when it was first introduced into the German army, and reported to the above effect.

THE Buxton Council have resolved "that all officers, soldiers, and sailors of the Allied Forces invalided to Buxton be granted the Buxton mineral water treatment free of cost, such treatment to be prescribed by a medical practitioner." It is believed that the waters of Buxton combined with the dry bracing air will prove an excellent remedy for the cases of rheumatism contracted by our army and allies whilst in the trenches.

THE SOLDIERS' FEET AND FOOTGEAR.

BY

CECIL WEBB-JOHNSON, M.B., CH.B.,

CAPTAIN R.A.M.C.(T.F.),

HONORARY SECRETARY OF NAVAL AND MILITARY MEDICINE AND SURGERY SECTION, ANNUAL MEETING, BRITISH MEDICAL ASSOCIATION, 1914.

THE lexicographer might have said, "The question of feet comprises in itself a subject of no inconsiderable magnitude." The importance of soldiers having well formed and normal feet cannot be exaggerated, for an army lasts only as long as the feet of its infantryman. Feet to the soldier are what tyres are to the motor, wings to the bird. In fairy lore, classical literature, and mythology, the means of locomotion given to man and beast have engaged the attention of the greatest writers of the centuries. Children love to hear of the magic boots of the giant whose every stride covered a mile, while the tales of Cinderella and her slipper, and of the children who lived in a shoe have become immortal. The people of Abarimon, a district of Scythia, we are told, could only live in their native air, and their feet had toes behind their heels. Mythology tells us that Mercury, the son of Jupiter, had wings to his feet which enabled him to transport himself from place to place with lightning velocity. Amongst his many exploits he is said to have robbed Venus of her girdle, and Mars of his sword; nor must we forget Achilles, who was plunged by his mother in the Styx, and rendered invulnerable except in his heel. His life was one long day of deeds of valour until he met his death at the hands of Paris, who wounded him with an arrow in his vulnerable heel. Like Achilles, armies have proved themselves invulnerable except in their feet, and have suffered the humiliation of seeing victory snatched from their grasp on account of inability to march any further. When once the ambulatory power of a force breaks down, its *moral* and spirit suffer, and its attributes of pertinacity of purpose and celerity of movement are lost. This has been recognized by all the armies in the field to-day, and every endeavour is being made to cope with the question from a military and a medical standpoint. No one has shown more solicitude for the soldiers' feet than our King, who, when visiting the wounded, made anxious inquiries about their feet and footgear. The letters from soldiers at the front, published in the daily papers, constantly contain complaints about their feet, and may be well summed up in the sentence of Private F. Burton, of the Bedfords, who writes: "Sore feet are the great trouble, most of us being a bit lame." Brave as a man may be, it is a physical impossibility for him to march far with blistered and sore feet, and he becomes a drag on his comrades. In this respect one cannot help calling to mind how Captain Oates walked out of the tent into the Antarctic blizzard with his poor maimed feet tortured with frostbite, his one thought being to save his comrades who refused to proceed to "One-ton Camp" until he could accompany them.

No army in the world is better provided with good serviceable footgear than our own, and the Government, recognizing this to be of the utmost importance, are making strenuous efforts to keep this efficiency constant and lasting. The British "Tommy" has a special affection for his boots, for he knows that, in war time, they are his best friends, and a striking example of this is related by Sir Frederick Treves in his interesting book *The Tale of a Field Hospital*, in which he says: "Amongst other traits, one notices that the soldier clings with great pertinacity to his few possessions, and especially to his boots. There was one poor man at Spearman's who was in great distress because, just as he was being sent down to the base, he had lost his solitary boot. He said it contained a puttie, a tin of jam, two shillings in money, and a bullet that had been taken out of him."

The evolution of the human foot is of great interest. Man is the only animal whose thighs and trunk are in a straight line when standing, for even anthropoid apes have their lower limbs bent towards the belly at the hips, and flexed at the knees, when walking. To have gained our present erect posture has taken millions of years, for there is no bone, muscle, or organ in the body, which has not been changed. Although the ordinary monkey runs on all fours, the gibbon, or small anthropoid ape, runs along the

branches of a tree on its legs in an erect posture, only using its long arms to seize overhanging twigs to help it on its way, or to swing from bough to bough, or tree to tree, when pursued or in a hurry. In the gorilla the legs are comparatively stronger, and fashioned to bear the weight of the whole body, and in consequence have lost some of the features which make the monkey's foot chiefly a grasping organ. *Pithecanthropus*, the earliest human-like fossil discovered, had in all probability a foot like our own, for no human foot has ever been seen with the great toe separated like a thumb, as is the case in all anthropoids. To the scientific mind, however, there is little doubt that the great toe was once set like a thumb, and that the foot was used as a grasping organ. Wire walkers and the native artisans of the East use the great toe to steady and balance themselves and their work, causing the muscles of this organ to be well developed. The human foot was evolved, as far as one can say, in the Miocene period, and the upright posture of man appeared with the evolution of the gibbons. The chief changes which have taken place in the lower limb are:

(*a*) The straightening of the limb into a line with the trunk when standing.
(*b*) The stiffening of the mid-tarsal joint.
(*c*) The lowering of the heel until it reached the ground when standing or walking.
(*d*) The disappearance of the thumb and the substitution of the great toe.

The two diagrams below show roughly the position of the lower limb in the pronograde dog-like monkey and in the anthropoid ape.

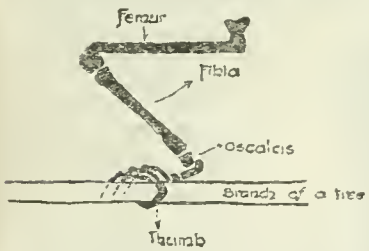


Fig. 1.—Diagram of the foot of a pronograde dog-like monkey grasping a branch of a tree. The heel is bent up and does not touch the branch; mid-tarsal joint is flexible.

In the former the limb is bent towards the belly, and flexed at the knee, while the mid-tarsal joint is very flexible, and the heel is a long way from the ground; while, in the latter, the limb is getting nearer the straight line, the mid-tarsal joint is becoming less flexible, and the heel is approaching the ground. The human foot, having to bear the whole weight of the body, is provided by nature with natural arches, which are recognized by engineers to be the strongest in existence. The hollow bony arches of the foot give it the necessary strength and elasticity, and, in addition, protect delicate structures (blood vessels and nerves), from pressure and injury.

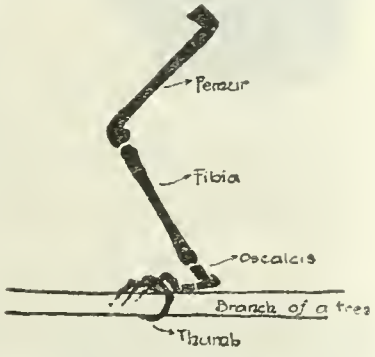

Fig. 2.—Diagram of the foot of an anthropoid ape. The heel is not bent so much, and nearly touches the branch; mid-tarsal joint is less flexible.

In man, the arch of the foot was evolved by:

(*a*) Development of a tonic and tetanic condition of the muscles of the toe and the flexors.
(*b*) The stiffening of the mid-tarsal joint.
(*c*) The approximation of the metatarsals 2, 3, 4, 5, to metatarsal 1, and not the opposite, as is usually supposed.

From within outwards, the longitudinal arch is dependent upon:

(*a*) The way in which the bones are fitted together to form an arch.
(*b*) The way in which the bones are held together by ligaments, especially the inferior calcaneo-scaphoid ligament, supporting the head of the astragalus.
(*c*) The tendons running round the inner ankle inverting the foot and flexing the toe, all tending to strengthen and maintain the arch, especially the tibialis posticus.
(*d*) The small muscles of the foot.
(*e*) The plantar fascia and the skin.

In walking or standing the maintenance of the arch depends on muscular action, and if, from strain or overwork, the muscles or tendons lose their power of bracing up the arches of the foot and this task is left to the ligaments, which may themselves give way, either rapidly by rupturing or gradually by stretching—the result is what is known as flat-foot. It follows from this that the weight of the body should be distributed so as to cause least burden on the muscles of the arch, and should fall just in front of the transverse arch.

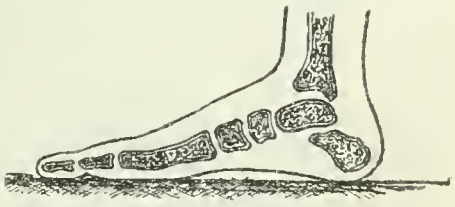

Fig. 3.—Diagram of section of a foot lengthways, showing bones of longitudinal arch.

Fig. 4.—Section of a foot crossways, showing bones of transverse arch.

The skin of the sole of the foot is composed of three layers, the most superficial of which varies in thickness and hardness according to the amount of friction and pressure it is subjected to. The middle or mucous layer is intimately connected with the other two layers, and, although it contains no blood vessels, it may allow fluid from those in the deeper layer to pass through it. This exuded fluid, not being able to pass the hard horny layer, separates the first and second layers, and forms a blister. The third layer, or true skin, is composed of dense elastic tissue containing blood vessels, nerve endings, sweat glands, etc., and this is the layer which is affected when men complain of sore feet.

Having briefly touched on the morphology, anatomy, and physiology of the human foot, we must next consider how it is protected from injury by artificial means. The custom of wearing something to cover and protect the foot is of great antiquity, and in the British Museum there are specimens of Egyptian shoes and sandals dating back some three thousand years. Sandals of plaited papyrus and other materials were used by the ancient Egyptians, Greeks, and Romans, and are worn to this day in the East. They persisted, in Europe, until the fourteenth and fifteenth centuries, when the *poulaines* became the fashion. On account of their length, which sometimes reached several feet, the poulaines were found inconvenient, and gave way about the end of the fifteenth century to the *souliers camus*. In turn the narrow and broad shoes came, and were followed by various forms of boots, the chief fault of which was that there was little or no difference in the two feet. Gradually the patten, which was used for outdoor wear, was superseded by the heel, and each foot was properly fitted with its own boot. The sandal, being correctly shaped to the normal foot, with a straight inner edge, caused little deformity, and the two straps, the latchet and the forestrap, which kept it in position, helped to maintain the proper adducted position of the great toe in walking and standing. Ancient writers, about the time of Christ, in spite of this, have left on record descriptions of deformities caused by ill-fitting sandals and shoes. When, in Europe, the sandal was discarded in favour of the shoe, the tendency amongst the fashionable set was to have it smart and pointed, though in the reign of Henry VIII it was considered more fashionable to have a shoe wide and broad.

We must next review the steps taken by the Government to provide soldiers with suitable footgear. On joining the Regular Army each soldier is given two pairs of army boots and three pairs of socks, free

of cost. They are kept in stock sizes, and it is the duty of the officer to make quite sure that the correct sizes are issued, for if the soldiers are allowed to choose their own boots without official supervision, they are apt to let "vanity override wisdom," and choose too narrow or too small a boot. This is known in the army as "fitting the eye instead of the foot," and even after the proper sized boots have been issued, the soldier will often have them altered in shape at his own expense to make them look smarter. This should never be allowed, and, if discovered, should be severely dealt with. It may happen that no stock size will fit, in which case a man is permitted to have his boots specially made for him. The fact must not, however, be overlooked that such a man may prove a menace to his unit in a long campaign, for when his boots are worn out he will find it extremely difficult, or impossible, to get another pair to fit him. In every battalion there is a shoemaker's shop, where the boots are repaired at a fixed rate. The army socks are made of grey worsted and are of regulation sizes, and it is the duty of the soldier to see that they are kept clean and in proper repair. Periodically a kit inspection is held, when it is decided whether the boots and socks are in a satisfactory condition, and if the company officer is not satisfied that such is the case he either orders them to be repaired or new ones purchased. Every soldier has a clothing allowance, out of which new kit is purchased. If, at the end of a certain period, there is a surplus, the money is added to his regular pay, but if there is a deficit it is subtracted. By this means every soldier is encouraged to be careful and economical, and if he is careless and extravagant he has to pay for such weaknesses out of his own pocket.

When the British army is mobilized every soldier should possess two pairs of boots and two pairs of socks. If these are not in good condition the Government supply new boots in place of those not considered fit for active service. On reaching a foreign country, in order not to hamper the soldier when marching, his kit-bag containing his spare kit is left in charge of the company storeman at the Infantry Base Depôt. Amongst the other articles in this spare kit are one pair of boots and one pair of worsted socks, which can be forwarded from the base when it is considered convenient or necessary. On active service the British soldier does not carry a spare pair of boots with him, but fifty pairs of shoes and thirty pairs of ankle boots or Highland shoes for each infantry battalion are carried in the regimental transport. There should always be supplies at the base for replacements. The Territorial in peace is not supplied with either boots or socks by the Government, so that the oddest assortment of both are often seen. The county associations, however, usually make a grant to men who are in possession of suitable boots for the annual camp, and on embodiment every Territorial is given 10s. by the Government if his kit is considered satisfactory by his company officer. It would make for more uniformity and efficiency if the Government could see its way to provide both boots and socks free of cost to every Territorial on embodiment. Every Reserve man has his mobilization equipment, including his boots and socks, kept ready for him at the mobilization stores.

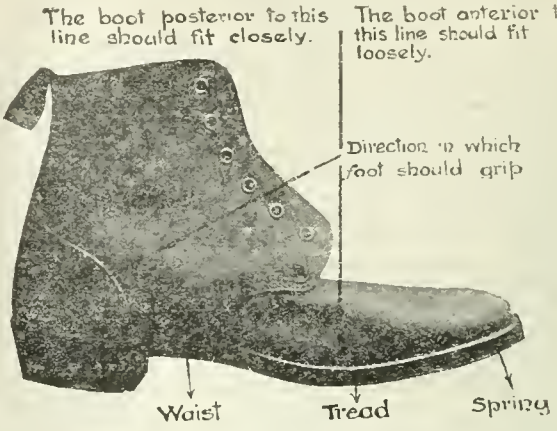
THE ARMY BOOT.

Photographs of the army boot are given in three positions. Made of stout leather, it consists of the following parts:

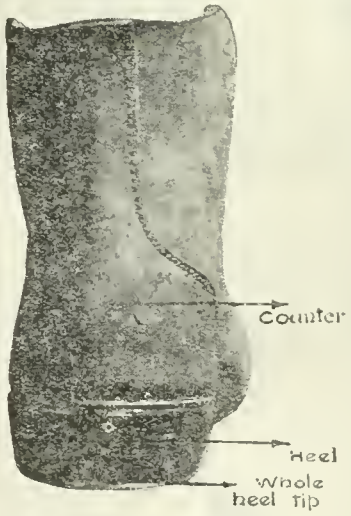
The Sole is composed of two stout layers of leather sewn together with or without a central filling. To add to its durability and to prevent slipping on wet ground, nails are inserted into it, and the sole is said to be "billed."

The Waist being the narrowest part of the sole is apt to "give" too much, and for this reason a piece of stout leather is usually inserted between the two layers, from the heel to the tread.

The Heel consists of stout leather, and is "whole-tipped" in order to prevent it wearing out too quickly, and to act



as a protection from stones and other objects when marching. Generally speaking, the lower the heel the better, for if too high, it tends to throw the weight of the body on to the toes and strain the arch of the foot and the ligaments of the ankle, especially when marching downhill.



The Vamp, or front portion of the boot, is made of a softer leather, and is rounded over the toes. It covers the toes and instep and is continued up in front of the ankle into the *tongue*, which reaches well to the top of the boot.

The Quarter, or back part of the boot, covers the ankle-joint and the heel, and is pliant over the former and stiff over the latter. It is composed of two halves seamed together with the edges of the seams turned outwards. It is stitched to the vamp in front and the "*counter*" behind, and is pierced with eyelet-holes for lacing. The laces are made of strong leather.

Fitting the Boot.

It may seem a matter of small importance to insist that the boots fit the feet properly, but it must not be forgotten that ill-fitting boots are the cause of bunions, corns, hallux valgus, metatarsalgia, ingrowing toenails, hammer toes, bromidrosis, and hyperidrosis.

The fitting of ready-made boots is no easy matter, and many things have to be considered before the right pair is finally selected. Not only the length and breadth of the foot, but also the height of the instep, must be taken account of, and for this reason *magnitude* as well as *size* must be allowed for. The size and magnitude are stamped on the inside of the boot for future reference, the former being placed below the latter—for example, $\frac{7}{2}$.

On standing or walking the whole weight of the body is thrown on the feet, and two changes take place in them—namely: (*a*) The whole foot spreads out and increases in length and breadth. (*b*) The great toe is drawn to the middle line of the body, although its alignment is seldom that of the first metatarsal bone, as it should be. For these reasons it is necessary to make the soldier stand and walk in the boots to see if they are comfortable and roomy

enough in front. It is important to remember that the foot swells when heated and fatigued, and that a boot which fits perfectly over a thin sock, may be very uncomfortable over a thick one.

An ideal boot should protect the foot from cold, wet, and external injury, and support it when necessary without hind r ig any of its normal movements or causing any undue pressure upon any part of it. It should fit tightly round the heel and as far forward as the middle of the metatarsus, but should be roomy in front of this to allow for the spread of the foot, the adduction of the great toe, and the free use of the metatarso-phalangeal joints. The sole of the boot should have a good projecting welt, be straight on the inner edge, and be pliant so as to ease the toes and the tread when marching. If the front part of the sole is not pliant it bends up and forms a curve called the "*spring*" of the boot, and gets fixed in this position. Although some soldiers say that such a boot facilitates marching by enabling them to use their feet simply as rockers with minimum muscular effort, sooner or later troubles will arise, such as corns in the sole of the feet, with pain and inflammation around the metatarso-phalangeal joints. The vamp of the boot should be pliable, especially near the roots of the toes, so as to allow free movement to the "natural hinge" of the foot, and should be boxed up and rounded over the toes to prevent pressure or friction. The quarters should not interfere with the bending of the ankle, nor should they quite meet in front, otherwise it will be impossible to lace them so as to apply firm pressure. If the quarters are too high the soldier will be tempted to leave one or two of the upper holes of the lacing undone to give more movement to the ankle.

I would insist upon the following details being carried out in fitting a soldier with boots:

1. Fit the boot *after* a march, when the foot is fatigued and swollen.
2. Fit the boot over the thickest sock.
3. Have both boots properly laced, to see that the quarters are not too high and that the ankle-joint is free.
4. Fit each boot separately.
5. Make the soldier stand and walk in his boots before deciding which pair to give him.
6. If no ready-made pair fit, insist upon a special pair being made.
7. Give full instructions about the preparation and subsequent care of the boots.
8. Give a boot that is too large rather than one that is too small, for leather, when wet, shrinks.

On handing a recruit a new pair of boots he should be told to soften them *before* wearing them, and this is best done by well soaking them, inside and outside, with crude castor oil. It is important to keep the uppers supple by the constant use of oil or dubbing, and especially is this necessary when the boot is thoroughly wet. If this is not done regularly the leather becomes hard and brittle, and one of the commonest mistakes a soldier makes is to place his wet boots near a fire. It is on record that during the first winter in the Crimean war our soldiers suffered from their boots getting soaked through, and many were in the trenches without either boots or socks, as the leather of the boots shrank so much from the constant wetting that when once they were taken off it was impossible to get them on again.

In the Balkan war the result of the men being in wet trenches for twelve to twenty-four hours on end was seen in various forms. Many suffered from cholera and dysentery, but it is also stated that gangrene of the foot was not an uncommon occurrence, beginning in a painless way with mere discoloured blistering over one or two toes, to death *en masse* of the leg as high as the knee (Max Page). Depage considers that many of these cases were caused by the pressure of damp boots and putties shrinking as they dried. It is probable that a vasomotor disturbance very similar to this occurred in the Crimean war, and was classified in the statistics as frost-bite.

It is true that, *Cucullus non facit monachum*, but the boot *may* make the soldier, and no trouble can be considered too great which not only provides him with a sound and perfectly-fitting boot but also with the knowledge of how to keep it supple and in an efficient state for the hardship of war.

The Army Socks.

The question of the soldiers' socks, although not so important as his boots, is one which requires most careful attention. Some years ago the Germans did away with socks, and kept the soldiers' feet well greased. It was reported to have been successful, not only from the point of view of economy, but it was maintained that the men marched more easily, and that the feet showed fewer blisters than when socks were worn. That this plan had its disadvantages is proved by the fact that the Germans are provided with socks at the present time. The socks should be properly shrunk before being worn, and should be a little on the large size. If too small, they will cramp the foot and compress the toes, and be liable to wear into holes very quickly. If too large, they are liable to cause blisters and sore feet from wrinkling. Unshrunken socks should be at least two or three sizes larger than the foot, otherwise, after several washings, the heels will be pulled down under the soles, and cause trouble. The army socks are made of grey absorbent worsted, and must be kept clean, or they become hard and non-absorbent, and cause sore and offensive feet. Each soldier should be taught to darn his socks evenly, so as to leave no ridges or imperfections, and on no account should he be permitted to wear socks with undarned holes. As thousands of socks are being made by patriotic ladies all over the country at the present time, the following particulars may be useful:

The socks are made with heels and toes of the usual kind, and should be woven or hand-knitted with No. 13 needles, and 4-ply superfingering or wheeling in grey, Lovat's mixture, or natural colour. The lengths of foot asked for are 10 in., 10½ in., 11 in., and 11½ in.; the largest number required are those measuring 10½ in. and 11 in. in length. For sizes 1 and 2, 64 stitches should be cast on in the first instance, and for sizes 2 and 3, 68 stitches.

A substitute has been tried for socks in the shape of foot-cloths, which can be more easily washed and dried, as they are simply wrapped round the feet. It is a matter of small consequence if they shrink, but, even with these advantages, good, well-fitting woollen socks have proved to be more efficacious.

(To be continued.

INSECTS AND WAR:

VI.—*FLIES* (Part II).

By A. E. SHIPLEY, Sc.D., F.R.S.,
Master of Christ's College, Cambridge.

Who fills our butchers' shops with large blue flies?
Rejected Addresses.

But there are other flies, first amongst which may be mentioned *Fannia canicularis* and *F. scalaris*. These belong to the family known as Anthomyidae, and are distinguished from the house-fly by being smaller in size and by many other small details in the imago stage hardly to be appreciated except by trained dipterologists. For a short time at the beginning of the summer during May and June *F. canicularis* is more abundant than *M. domestica*, and, as watched on the window panes of our living rooms, are apt to be thought by the uninformed to be young specimens of the latter. But, as has been said in a previous article, flies when they are once flies do not grow; all the growing they do is done in the larval stage. But as the days lengthen the common house-fly becomes vastly more common than *F. canicularis*, the "lesser house-fly," and the latter now tend to aggregate in those rooms of our houses not devoted to cooking, and may frequently be noticed flying in a jerky and disconcerting manner around the chandeliers or bedposts in unfrequented living- or bed-rooms. The relative proportion of these two genera now varies in different localities. Roughly speaking, out of 100 flies collected in a house there is something between 90 and 99 per cent. of *M. domestica*, but the numbers not only vary with locality but with temperature.

On the other hand, there is a curious disproportion between the number of the sexes found "at home" in the lesser house-fly. For every 100 *F. canicularis* taken indoors 70 to 75 are males, the numbers being evened by an equal preponderance of females who have remained out of doors. The larva of *Fannia* is a flattened-looking

grub with distinct segments, decorated by numerous feathery processes. It lives amongst decaying vegetation and fruit, and also amongst fermenting animal matter and dejecta. Sometimes they are found in rotting grass. As we shall see later, they frequently pass into the human alimentary canal. *F. scalaris*, usually known as the "latrine fly," is even commoner than its congener, and the external structural differences are minute. As its name indicates, it is found as a rule breeding in human dejecta, and is therefore, as a typhoid carrier, much more dangerous than *F. canicularis*. Its larva is also more commonly found in the human intestine.

Fig. 1. Latrine fly, *Fannia scalaris*, male (× 3). Antenna. Head of female, dorsal view. Natural size, resting position.

Then there are two species of large flies known as blue-bottles or blow-flies—*Calliphora erythrocephala* and *C. vomitoria*. The former of these is the more common. The sides of its face are golden yellow, set with black hair; whereas in *C. vomitoria* the sides of the face are black, but the hair is golden. Both are handsome, sturdy looking diptera, with bluish-black thoraces and abdomens of a dark metallic, gun-metal sort of colour.

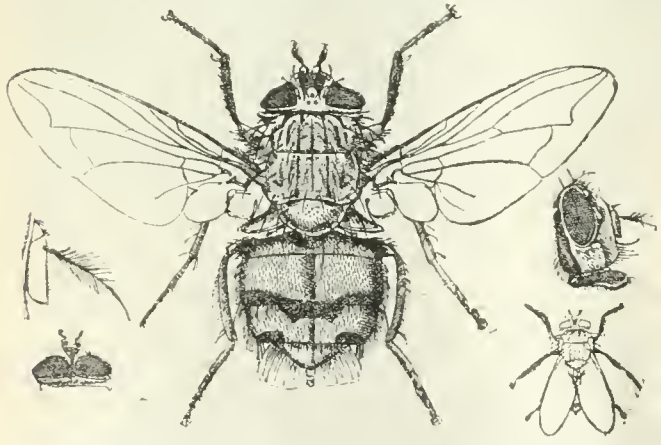


Fig. 2.—Blow-fly or blue-bottle, *Calliphora erythrocephala*, female (× 3). Antenna. Male head, dorsal view. Side view of head. Natural size, resting position.

Blow-flies deposit their eggs on fresh or decaying meat, and this is one of the great sources of trouble to the officers of the Army Service Corps. But they are not content with killed flesh. They will lay their eggs on any living flesh which is exposed, or in sores or tumours, and here their larvae will thrive. Dr. Graham-Smith tells us he once found the exposed muscles of the broken leg of a living rabbit seething with a mass of small blow-fly larvae, which were nourishing themselves upon the living flesh. The eggs of the blow-fly hatch out in from ten to twenty hours in normal British temperatures; the larval life, in its three stages, lasts from seven to eight and a half days; the pupa state lasts a fortnight, so that the total development extends a day or two over three weeks. These maggots are unusually voracious, and Linnaeus used to say that the progeny of three blow-flies will dispose of a dead horse as quickly as three lions.

C. erythrocephala is essentially an outdoor fly and enters houses only in search of a nidus on which to deposit its eggs. *C. vomitoria* resembles its congener in size and habits, but it is not so abundant. Occasionally its eggs have been known to be deposited in the nostrils of animals and men.

But there are:

> All species of resplendent flies,
> Some with green bodies and green eyes,
> Pricking like pins' heads from their holes
> Like tiny incandescent coals.—*Anon.*

One of these, *Lucilia caesar*, is a marked nuisance to those responsible for victualling a camp. This green-bottle fly, like the *Calliphora* and the house-fly, belongs to the family Muscidae, and its larvae are said to be indistinguishable from those of blue-bottles. Some species of *Lucilia* deposit their eggs in great quantities amongst the wool of sheep when the sheep are ill-kept, and they do much damage. But as far as war is concerned the harm that *Lucilia* does is laying its eggs upon dead animals. It does this on all sorts of meat stores, but in times of peace it especially infests stale fish, which the issuing larva very soon eat clean to the bone. When feeding upon a dead fish lying upon the beach they burrow down in the sand below their food. They descend some 2 to 6 in., and for the most part remain deep in the sand during the daytime, coming up to feed at night. They also have a habit of migrating from one fish to another. This fly has also been known to lay its eggs in the neglected wounds of human beings.

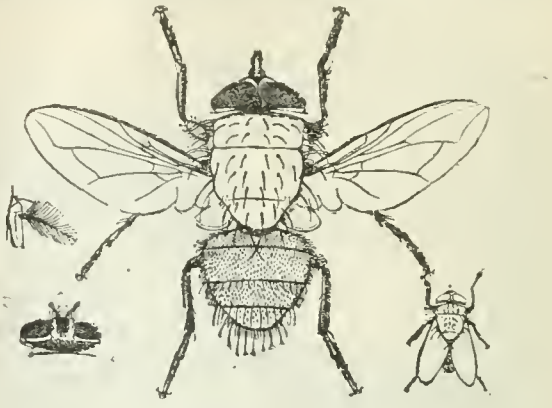

Fig. 3.—Green-bottle, *Lucilia caesar*, male (× 3). Antenna. Female head, dorsal view. Natural size, resting position.

Sarcophaga carnaria is another species which occasionally infests human sores, and which enters houses in search of filth or carrion on which to lay its eggs; it is viviparous and produces not eggs but live larvae. One female can give birth to 20,000 young, and Redi states that the larvae of flesh-flies will in twenty-four hours devour so much food and grow so quickly that they increase their weight two-hundred fold.

Finally, there is a group of flies whose larvae penetrate under the skin of human beings and give rise to definite subcutaneous troubles. But fortunately these are with few exceptions confined to the warmer regions of the earth, and there is very little risk of their causing real trouble in Northern or Central Europe.

The troubles or diseases caused by the presence of fly larvae in the body are grouped in medical language under the term "myiasis," which Graham-Smith defines as follows:

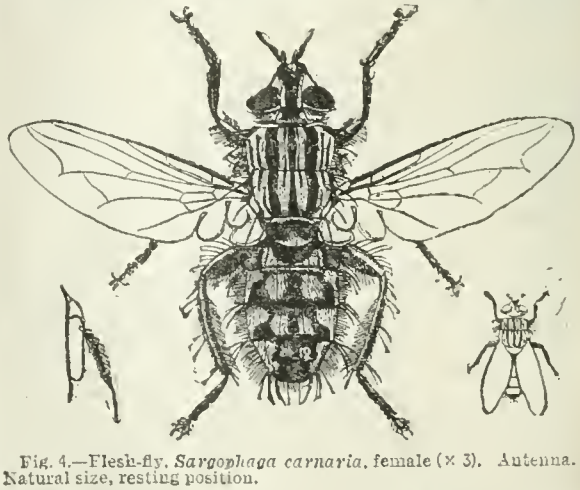

Fig. 4.—Flesh-fly, *Sarcophaga carnaria*, female (× 3). Antenna. Natural size, resting position.

> The term "myiasis" signifies the presence of dipterous larvae in the living body, whether of man or animals, as

well as the disorders, whether accompanied or not by the destruction of tissue, caused thereby. Though not strictly coming within this definition the sucking of blood by larvae through punctures of the skin, which they themselves

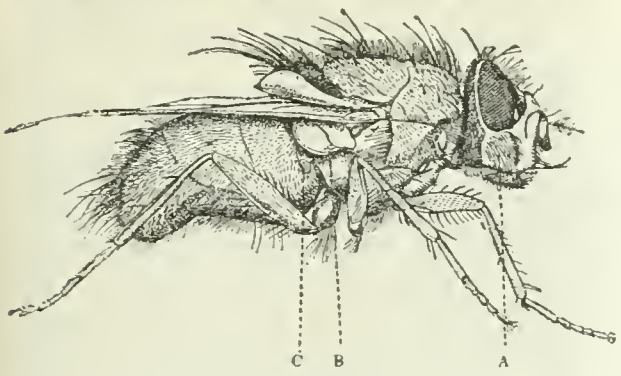

Fig. 5. Side view of blow-fly (*Calliphora erythrocephala*) (× 5). A, Cheek (jowl); B, squama; C, halter.

produce, may be included for the sake of convenience in classification.

Myiasis in man may be produced by dipterous larvae—

(*a*) Sucking blood through punctures in the skin (*Auchmeromyia luteola*).

(*b*) Deposited in natural cavities of the body (*Chrysomyia, Lucilia, Sarcophaga, Calliphora, Oestrus*).

(*c*) Deposited in neglected wounds (*Chrysomyia, Lucilia, Sarcophaga, Calliphora*).

(*d*) Living in subcutaneous tissue (*Cordylobia, Dermatobia, Bengalia* (?), *Hypoderma*).

(*e*) Passing through the alimentary canal (*Fannia, Musca, Eristalis, Syrphus, Gastrophilus*).

In the above list only the more common genera producing myiasis are mentioned. In England Type (*c*) is fairly common, and Types (*b*) and (*c*) are occasionally observed.

We may now consider in detail, but very shortly, the categories set forth by Dr. Graham-Smith:

(*a*) The very peculiar blood-sucking maggot known as the Congo floor maggot, the larva of *Auchmeromyia luteola*, fortunately does not spread beyond tropical and subtropical Africa. It chiefly affects the natives who sleep on mats.

(*b*) The flies which deposit their ova and larvae in the cavities of the body are again mostly foreign. The worst of all is the screw-worm, *Chrysomyia macellaria*, of the Southern States, Central and South America. Although it extends to Canada it is not troublesome north of Texas.

Occasionally blow-flies in Great Britain deposit their ova in the human nose or ear. They very rapidly hatch and cause great inflammation and necrosis until they can be discharged or removed. They have even been found in the anterior chamber of the eye, and I have some microscopic sections showing the presence of these larvae in that chamber, whither they had probably proceeded from the nasal sinuses. But on the whole, cases of this sort are comparatively rare, and cause but little trouble.

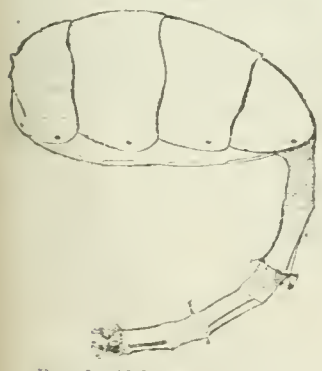

Fig. 6.—Abdomen of female house-fly, showing the extended ovipositor.

(*c*) The real difficulty, and one which has already proved a serious trouble to our army in the field, are the cases in which maggots are found in neglected wounds. Here, however, we may take some comfort in the fact that the trouble is fortunately much greater in the tropical and subtropical regions than in more temperate climates, and is likely to diminish as the cold weather draws on. Still, during the hot weeks of August there were cases of wounded soldiers left lying on the fields for two or three days who were found to be suffering in this way. One almost hesitates to offer suggestions to our heroes in such cruel conditions, *but whenever and wherever it can be done wounds should as far as possible be kept covered.* Not only are neglected wounds affected, but tumours and ulcers are often attacked. But, as I have said, the danger is much greater in warmer climates. We know that Herod Agrippa "was eaten of worms, and gave up the ghost"; a fact which recalls the translation given by an unhappy undergraduate who when in difficulties with the Acts of the Apostles in the "Little-Go" translated καὶ γενόμενος σκωληκόβρωτος ἐξέψυξεν "He became a skolekobrote, and died in the enjoyment of that Office."

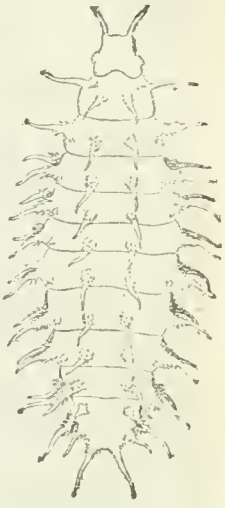

Fig. 7.—Larva of *P. canicularis*. (From Hewitt. Report to Local Government Board, 1912; reduced by one-half.)

(*d*) Flies burrowing in the subcutaneous tissues are again very much commoner in tropical climates than in Northern Europe, and the cases quoted in our country are comparatively rare.

(*e*) The presence of larvae in the alimentary canal of man is by no means uncommon. Both the larvae of *Musca* and *Fannia* are not infrequently found, and over a thousand of the latter have been passed by a highly infected individual at one time. They probably make their way into the body with over-ripe fruit. In some cases they give rise to no symptoms, but in others violent pains are felt and a certain dizziness, and the digestive functions are interfered with. The presence of these larvae in the urinary passages are even more difficult to explain, but they undoubtedly are at times found in these channels.

A few years ago an elaborate investigation was carried on by Mr. W. Nicol, for the Local Government Board, on the part played by flies in the dispersal of the eggs of parasitic worms. He showed quite definitely that the ova of certain human parasites are taken into the fly and pass through its body undigested. Should these be deposited on the food of man, there is great risk of his becoming infected. As I have said before, flies take only liquid food, and it is only when the ova of the parasites are very small that they can pass into the alimentary canal. Some eggs are too large for the fly to swallow. Eggs of parasitic worms have also been shown to be carried on the legs and proboscides of flies, and these are deposited on the spot where the fly next cleans itself. Probably, however, in the end little harm is really done by flies in disseminating parasitic worms, but it is a possibility which must not be disregarded.

The remedial measures for the control of flies are fully dealt with in Graham-Smith's admirable book, *Flies in Relation to Disease*, from which I have ventured to borrow many figures; and again by Dr. Gordon Hewitt, in his work on *House-flies*, which has had such a wonderful success in stimulating our North American cousins to decrease one of the gravest enemies to mankind.

It has been shown over and over again that we can control the mosquito; the building of the Panama Canal alone proves this. We could equally control the "Infinite Torment of Flies." The Canadians and Americans are doing their best, but are we? The knowledgeable world has at least discovered the reason why Beelzebub was called "the lord of flies."

A COURSE of lectures on infant care for voluntary health workers, mothers, nurses, etc., has been arranged by the Association for the Prevention of Infant Mortality and for the Welfare of Infancy. The lectures began on October 19th. Further particulars can be obtained on application to the Secretary, 4, Tavistock Square, W.C.

SOON after the war broke out the Lancaster Medical Book Club, one of the oldest medical societies in the country, which now includes every medical man in the town, held a special meeting at which arrangements were made to undertake the work of every medical man called up or volunteering for military service, and to safeguard the integrity of their practices. The balance of funds in hand, amounting to between £30 and £40, was voted to the Prince of Wales's Relief Fund.

EIGHTY-SECOND ANNUAL MEETING
OF THE
British Medical Association.

Held in Aberdeen on July 29th, 30th, and 31st.

PROCEEDINGS OF SECTIONS.

SECTION OF PATHOLOGY AND BACTERIOLOGY.

W. S. Lazarus-Barlow, M.D., F.R.C.P., President.

DISCUSSION ON THE ACTION OF RADIATIONS ON CELLS AND FLUIDS.

OPENING PAPER.

By W. S. Lazarus-Barlow, M.D., F.R.C.P.

(*Abstract.*)

In a desire to investigate certain differences in the behaviour of different varieties of malignant new growth to radium radiations I determined to examine the effects of these radiations upon normal cells of the rat, notably the dry squamous epithelium of the tail, the moist squamous epithelium within the sphincter ani, and the columnar epithelium of the rectum. By inserting the upper part of a tube containing $RaBr_2$ into the rectum and allowing the lower part to protrude through the anus, I was able to ensure that each of these varieties of epithelial cell should be brought under the direct action of a constant source of radiations for a definite length of time. At various times after the irradiation the rats were killed and examination was made for histological change.

Two distinct varieties of radium exposure were made the subject of investigation. In the one a tube of platinum 0.3 mm. thick and 25 mm. long by 2 mm. wide contained 38 mg. $RaBr_2 2H_2O$. In the other a tube of platinum 0.5 mm. thick and 18 mm. long by 3½ mm. wide contained 92 mg. $RaBr_2 2H_2O$. Experiments showed that after due correction the total ionization of the 38 mg. tube for 30 minutes was represented in the case of the 92 mg. tube by 13½ minutes. One series of rats was therefore subjected to 38 mg. for 30 minutes, another series to 92 mg. for 13½ minutes. Rats of each series were killed on the first, second, third, seventh, eighth, and ninth days after irradiation.

Various points of difference between the irradiated and the normal epithelial cells and between the subcutaneous and submucous tissue in irradiated and in normal animals were noted, but I shall only advert here to the numbers of mitotic figures present in the epithelial cells and the number of cells presenting deeply-stained red cytoplasm with Pappenheim's stain ("plasma cells.") The number of "plasma cells" I regard as rough evidence of the degree of inflammatory reaction present in the subepithelial tissue; the number of mitotic figures is clearly evidence of the reproductive activity of the epithelial cells.

In the annexed table the mean values for the days 1–3 and 7–9 under the two conditions of irradiation are expressed as multiples or submultiples of the corresponding mean normal values, and it appears that the effects of a single application of radium are different (*a*) according to the type of epithelial cell under consideration, (*b*) according to the arrangement of the "quantity × time" factors which go to make up the single application of radium.

Thus 38 mg. for 30 minutes acting directly on columnar cells reduces mitosis 32 per cent. during days 1–3, but stimulates mitosis 33 per cent. during days 7–9 after irradiation, whereas it reduces the mitosis of dry squamous cells 85 per cent. during days 1–3 and further reduces it during days 7–9 after irradiation. Hence the dry squamous cell of the rat's tail is more vulnerable under these conditions of irradiation than the columnar cell of the intestine. On the other hand, the same total amount of irradiation, but distributed in the form of 92 mg. for 13½ minutes, reduces the mitosis of columnar cells in contact with the radium tube by 87 per cent. during the first three days after irradiation, while the mitosis of dry squamous cells is only reduced 43 per cent. Under these conditions, therefore, the columnar cell is more vulnerable than the dry squamous cell.

A similar difference is observable in the effects of radium at a distance ("high" columnar epithelium), 38 mg. for 30 minutes leading to a five-fold multiplication of the number of mitoses, 92 mg. for 13½ minutes only leading to a doubling of the number of mitoses.

One of the most striking points of difference brought out by the experiments concerns the two varieties of squamous epithelium. Histologically, one might possibly assume that the moist and the dry varieties only differ in respect of the amount of water they severally contain. But it is seen from the table that the two varieties behave differently under irradiation, although they have points of similarity. Whether early or late periods after irradiation be considered, the dry squamous cell is seen to be more vulnerable than the moist, while both varieties are more injured by 38 mg. for 30 minutes than by 92 mg. for 13½ minutes.

If attention be turned to the submucous and the subcutaneous tissues differences in behaviour under irradiation are equally observed. Whether the irradiation be by means of 38 mg. for 30 minutes or 92 mg. for 13½ minutes, subsquamous tissue shows no alteration. On the other hand, subcolumnar tissue shows an inflammatory reaction as indicated by the number of plasma cells present. But the two types of irradiation are not equally effective in this respect, even as regards subcolumnar tissue, for it is clear that 38 mg. for 30 minutes calls forth a greater inflammatory reaction than 92 mg. for 13½ minutes during the 1–3 days after irradiation (whether "low" or "high" epithelium be considered). During the 7–9 days this greater efficiency of 38 mg. for 30 minutes in invoking inflammatory reaction is seen in the case of "high" columnar subepithelial tissue—that is, tissue which has not been in direct apposition with the radium tube, but in the case of "low" columnar subepithelial tissue there apparently occurs a delayed inflammatory reaction.

If one consider columnar cells with submucous tissue and squamous cells with subcutaneous tissue as complexes that must necessarily be dealt with in matters of treatment with radium (for example, columnar cell carcinoma and squamous cell carcinoma), it would appear from the

Tube of $RaBr_2$	Days after Radium:	Days 1–3. 38 mg. for 30 min.	Days 1–3. 92 mg. for 13½ min.	Indication for Treatment.	Days 7–9. 38 mg. for 30 min.	Days 7–9. 92 mg. for 13½ min.	Indication for Treatment.
	(High) columnar—						
	Mitoses	× 4.8	× 1.9	92 mg. for 13½ minutes	× 4.1	× 4.5	Nil.
	Plasma cells	× 2.2	× 1.1	92 mg. for 13½ minutes	× 3.8	× 2.2	92 mg. for 13½ minutes.
	(Low) columnar—						
	Mitoses	× 0.68	× 0.13	92 mg. for 13½ minutes	× 1.33	× 1.3	Nil.
	Plasma cells	× 2.4	× 0.8	92 mg. for 13½ minutes	× 1.9	× 2.5	38 mg. for 30 minutes.
	Moist squamous—						
	Mitoses	× 0.5	× 1.04	38 mg. for 30 minutes	× 0.8	× 2.2	38 mg. for 30 minutes.
	Plasma cells	Negligible			Negligible		
	Dry squamous—						
	Mitoses	× 0.15	× 0.57	38 mg. for 30 minutes	× 0.1	× 1.0	38 mg. for 30 minutes.
	Plasma cells	Negligible			Negligible		

experiments that in order to produce the maximum injury to epithelial cells and minimum damage to subepithelial tissues different procedures must be adopted. If the quantity of radium be x, and the time of exposure be y, which produces the optimum results in the case of a carcinoma of dry squamous surface, x must be increased and y must be diminished in order to produce the optimum results in the case of a carcinoma of columnar epithelium. In the contrasted cases of squamous carcinoma affecting *a*, a dry surface, and *b*, a moist surface, the indications are not quite clear. So far as concerns the epithelial cells themselves of a carcinoma originating in a moist squamous surface, probably the quantity factor x might remain constant, the time factor y being prolonged, but it must be remembered that a carcinoma of a moist squamous surface is in close relation with submucous tissue upon which increase of the time factor acts injuriously. Hence the indications differ according to the size and situation of the growth. If the growth be small and submucous tissue be in close relation, the *time factor* should probably be kept as low as possible and the quantity factor should be high, whereas if the growth be large and submucous tissue be relatively at a distance, the *quantity factor* should be kept as low as possible and the time factor should be raised.

[The full paper upon which the preceding abstract is based will appear in the Archives of the Middlesex Hospital, Thirteenth Cancer Report.]

DISCUSSION.

Dr. J. O. Wakelin Barratt (London) said that of the appearances produced by irradiation those which were perhaps the least easy to interpret were caused by the formation of darkly staining material, sometimes in relatively abundant amount, in the cell nucleus. At first sight the impression was obtained that this represented paraplastic material, but no conclusive evidence existed that the cell nucleus stored up substances destined for its own use or for that of the body generally, nor was it possible to assign any other structural or functional significance to this darkly staining intranuclear substance. In the cytoplasm changes might occur which were capable of interpretation as evidence of functional disturbance. When such changes, however, were of rapid onset as the result of irradiation another interpretation appeared to be permissible—namely, that the changes in question did not represent a disturbance of function of the cell in the strict sense of the term, but indicated a process following upon death of the cell such as might conceivably be impossible of occurrence during the life of the cell, or it might be that if a similar end result obtained during life the mechanism of its production might be different from that taking place after death of the cell. Thus, in the few cases in which the appearances presented by cells after irradiation appeared capable of interpretation as due to disturbance of cell function, there might arise the difficult problem of ascertaining whether these changes really arose during the life of the cell or only came into being when the cell was no longer living. A further important inquiry was the extent to which acute or subacute changes, following upon irradiation, represented not functional disturbances nor events occurring after cell death, total or partial, but disordered processes of cell growth, or indicated disturbance of processes which were incidental to cell reproduction. The consideration of problems of this character was, however, unfortunately, as yet, in the absence of fuller knowledge of the nature and significance of developmental and reproductive cell changes, of necessity speculative or conjectural. In this connexion it was of considerable interest to recall the circumstance that in the case of mouse carcinoma the rate of growth of the tumour might be profoundly modified as the result of irradiation.

Dr. Henry Beckton (London) said that, in view of Morson's findings, it was of special importance to inquire whether the action of radium on cells was direct or indirect—that is, whether it was independent of, or dependent upon, the action of tissue fluids when these were present. With regard to beta and gamma radiations, the speaker's own work confirmed the observations of those who had found no effect to be produced by these radiations. He had used quantities of radium, varying from 25 to 100 mg., and for periods varying from one to three hours, and from one to three days. On fixing the radiated tissues (liver, kidney, and spleen) in formol-Müller (2 c.cm. formalin, 98 c.cm. Müller's fluid) for a week and embedding in paraffin he had found that the cells showed no constant differences from those of appropriate control pieces of tissue, either on staining with haematoxylin as regards nuclear detail, or on staining with aniline acid-fuchsin and differentiating with picric-acid alcohol as regards Altmann's granules. Moreover, he had allowed both experimental and control tissues to undergo autolysis for further periods of from one to three days, and had still observed no constant differences. With regard to alpha radiations, the matter was different, for Russ and the speaker found several years ago that these radiations produced marked changes both in nuclei and in Altmann's granules, the former showing diffusion of chromatin and the latter a very marked, or even complete, disappearance in most cell spaces worked with—namely, the cells occurring in liver, kidney, and spleen. Further, on irradiation of small tadpoles with beta and gamma radiations from 25 mg. of radium up to the moment of death, and similarly of infusoria (vorticella, etc.) with beta and gamma radiations from 3 mg., the speaker had found no histologically recognizable changes to be produced. It thus appeared that beta and gamma radiations acted upon living cells, even up to the point of killing them, without producing any histological changes as yet recognizable, and did not produce such changes in excised tissues when acting upon them even for prolonged periods. Hence it followed that the marked histological effects observed by Morson in the treatment of malignant disease by radium in tubes were dependent on the intervention of the tissue fluids of the living body.

Dr. S. Russ (London) drew attention to another aspect of radium dosage—namely, if when one type of radiation was used to cause a definite effect on two types of cells and the factor of relative sensibility was found, was this same factor found when one passed to another type of ray? Preliminary observations on these lines indicate that this was not so. He had made a comparison between the cells of Jensen rat sarcoma and *Staphylococcus pyogenes aureus* as regards their susceptibility to the alpha, beta, and gamma rays of radium. When submitted to the alpha rays the cells of the rat sarcoma appeared to be about four times as sensitive as the staphylococci; on passing to the beta rays, this factor was about six, and with the gamma rays it was reduced to about twelve.

Dr. Penfold (London) asked if the dose of the different rays from radium were adjusted so as to cause the death of the Jensen tumour tissue in constant time, would the differences of ratios he described still obtain, or was it not possible that the differences in the ratios of the lethal doses were due simply to the fact that different doses of the different rays were used, these doses being judged by the lethal action on either type of the cells under discussion?

Dr. Price Jones (London) said that he and Dr Mottram had made some observations on the influence of radium on *in vitro* cultures of mouse carcinoma and rat sarcoma. The technique employed in the preparation of the plasma cultures was practically identical with that described by Carrel and other workers. Beta and gamma rays from a capsule containing 7 mg. radium bromide were applied to the tumours for different periods of time before preparing the plasma cultures, a number of control non-radiated cultures being made at the same time from the same tumour. For purposes of examining the details of the growth, the cultures were fixed in Carnoy's fluid, and after treatment with alcohol were stained for twenty-four hours in dilute (1 in 100) Ehrlich's haematoxylin. This gave excellent results, and was much to be preferred to the use of strong stain for short time. It was found that in the different series of preparations the number of "takes" was variable. By "takes" was meant the presence after twenty-four hours of an appearance usually referred to as "growth"—that is, a spreading of the area of the original culture mass by the extrusion of cells possessing long, often branched, amoeboid processes. Out of 79 radiated cultures, including both mouse carcinoma and rat sarcoma, there were 58, or 73.4 per

cent., of takes; and of 193 control non-radiated cultures there were 135, or 69.9 per cent., of takes. From this it might be concluded that the exposure of the tissue to the 7 mg. capsule of radium bromide had no inhibiting effect on the "growth" of the culture expressed by the extension of cells. It should be noted that the minimum "radium dose" employed was more than enough to completely prevent the tissue from growing after transplantation into mice or rats. In the 25 radiated cultures that were stained, with two possible exceptions, mitosis was never observed; of these two exceptions, one culture showed 2 cells, the other 1 cell in which there was an appearance of mitosis, but of a very abnormal type the chromosomes being scattered and not arranged in any regular order. Of the control non-radiated specimens, 63 were stained; mitosis was observed in 18, and 307 cells in mitosis were counted. From this it seemed that exposure of the tissue to the 7 mg. capsule of radium bromide had a very remarkable inhibiting effect on mitosis of cells. They concluded that growth of *in vitro* cultures consisted of two processes: (*a*) Spreading of area of the original mass by extrusion of cells; (*b*) division of cells by mitosis. They concluded, further, that the spreading might occur quite independently of the mitosis, spreading being uninfluenced, mitosis being profoundly influenced by beta and gamma radiations. It also seemed to them that an increase in superficial area observed in an *in vitro* culture must not necessarily be regarded as growth in the sense of a multiplication of cells by mitosis.

Dr. Gaskell referred to experiments made some years ago on the development of hen's eggs under a daily dosage of *x* rays. The indications of these experiments tended to show that any radiation first caused a stimulation, then a diminution, finally followed by a compensatory stimulation.

DISCUSSION ON VARIABILITY AMONG BACTERIA AND ITS BEARING ON DIAGNOSIS.

OPENING PAPERS.

I.—W. J. Penfold, M.B., C.M.Edin., D.P.H.Durh.,

Assistant Bacteriologist, Lister Institute.

Since 1904, when Hiss described variations in fermentation power occurring in members of the dysentery group, much work has been done on the subject. A large series of variations have been described and fully established. From recent studies it emerges that not only fermentation power but also culture and serum reactions hitherto applied in the classification of bacteria are subject to variation.

The idea of obtaining, apart from the power to produce the disease, single infallible tests to recognize pathogenic organisms has now been almost entirely abandoned.

This variation and selection are going on in nature; they have been shown to occur within the body in the course of infection, while in the laboratory the precise factors in the environment effecting the selection have been individually examined. The facts hitherto established on the subject affect:

(*a*) Bacterial classification; (*b*) the recognition of bacteria, the standards adopted by the hygienist, epidemiologist, and the clinical bacteriologist; (*c*) the vaccinist, whether he be engaged in immunizing patients or in producing serums for passive immunization.

The streptococci have been *classified* by various workers by means of their morphology, pathogenicity, fermentation power and by their action on blood agar. All these characters, however, have been shown to be very variable and names which have hitherto been used to designate varieties are now used to designate rather phases of growth of the individual strains.

Identification.—B. coli in water, food, etc., is recognized, amongst other tests, by its power to ferment lactose with gas formation. Recent work has shown that a large group of intestinal organisms take on, by processes of variation and selection, the power to ferment lactose and that this group passes insensibly into the lactose-fermenters proper. Moreover, it has been shown that the gas-producing power of the coliform organisms can be removed at will, under laboratory conditions, by various methods; it varies also within the body, so that these characters taken individually have less value in identification than has been hitherto supposed.

Recently it has been laid down by a well known practical worker in cholera prophylaxis that any vibrio, whether agglutinating with a specific serum or not, isolated from the excreta of a person coming from an infected country, must be looked upon as suspect.

In examining clinical material it is no longer sufficient to apply forthwith agglutination tests to the isolated organisms, since it has been shown that this particular, so called specific, character is frequently temporarily suppressed in the case of specific organisms as isolated from the body, and is restored by suitable selection.

It has been recently shown that vaccination with a plague strain grown on agar will protect rats against itself, but not against the same strain grown on serum. Here we have a clear demonstration that it is not sufficient to vaccinate with the homologous strain, but we must use the homologous strain in a particular condition. The aim of the vaccinist must be to use as a vaccine the particular strain infecting the patient in its most virulent phase or phases.

The result of all the work done recently on this important subject has added additional difficulty to the work of the bacteriologist. It has become necessary to obtain a larger number of tests to define the specific organisms so that their recognition can be effected with reasonable confidence, in spite of the temporary presence of atypical characters; further, it becomes necessary to establish the relative degree of variability to which each character is subject, and to apply the information so obtained in helping further to define the species. It has been shown recently that the power to vary easily in particular directions is frequently highly specific.

II.—M. C. W. Young, M.B., Ch.B.

(*Abstract.*)

This paper was intended to supplement a demonstration of modified bacteria in the Pathological Museum and to give a general account of the hypothesis from which the work had started and the methods which had been employed in the transformation of the bacteria. This hypothesis was that all bacteria formed merely stages in the history of a group of organisms with an extremely complicated life-cycle, part of which was protozoal in character and often, possibly always, parasitic.

The connexion between the bacterial and protozoal aspects could, the speaker said, frequently be demonstrated by examining with the dark ground illuminator perfectly clear and apparently sterile serum which had been incubated for some time. The serum chiefly used for study was taken from subjects with rheumatic affections or arterial disease. In it there might only be seen a few dancing granules, but more frequent and characteristic was a further stage of bright flocculent masses apparently made up of tiny amoebulae. In these masses nucleated bodies about the size of red corpuscles made their appearance later—the sporoblasts. These could develop microbes of various kinds. The one almost invariably met with—the sporozoite, in fact—was a bacillus of the *subtilis* type. This bacillus, in young growths, usually passed on in a few hours to the protist stage without giving any indication of its presence to the naked eye, and the serum again became apparently sterile to subculture. This cycle, with appearance and disappearance of the bacillus, might take place several times, but eventually, with the exhaustion of the medium for the protozoal phases, the bacillus came to stay. It, however, might be present for some days only in small numbers if any of the other stages were present which had not completed their evolution. It then grew, usually as a wrinkled film on the surface, and formed spores. A single cycle appeared in many cases to take about a fortnight, but several overlapping cycles were usually present.

Other bacteria which had been seen to develop from these sporoblasts were a drumstick bacillus in symbiosis with a coccus. These were seen to emerge from the sporoblasts of a moribund patient after a fortnight's incubation. A streptococcus arising from similar but larger sporoblasts was shown under the microscope.

These latter sporoblasts, subcultured from the serum of a rheumatic case, appeared as a solitary hard colony on agar on the eighth day, the streptococcus developing from them two days later. A staphylococcus had also been seen to develop from similar sporoblasts on an agar slope.

The spores of this *subtilis* bacillus had been transformed into the protozoal stages by growing them on agar at 60° and then in 10 per cent. unfiltered peptone solution acidulated with metaphosphoric acid at 37°. The transition to the protist was complete in about twelve hours,

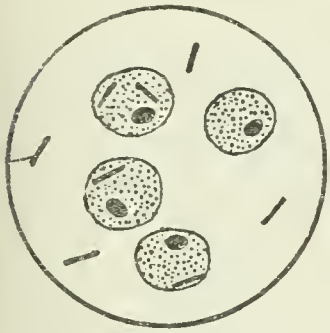

Fig. 1.—Sporoblasts and bacteria.

Fig. 2.—Passage from coccus into bacterium.

when the subcultures were negative. A couple of days later there appeared the nucleated sporoblasts. Unfortunately, the medium had apparently not been suitable for the repetition of the cycle, and the bacterium which developed from them did not disappear, but grew on and formed spores.

Every type of bacterium which had been tried—and the attempt had been made with a considerable number of non-pathogenic ones—had been transformed into this *subtilis* type with more or less ease, usually by growth in broths of varying alkalinity, ½ c.cm., 1 c.cm., or more of a 5 per cent. solution of sodium hydrate being added and the cultures kept at the required temperature, the optimum for many being about 42°. The cultures passed through the protist stage to the sporoblast, from which the usual sporing bacillus developed. The longest time taken was about four days. Some bacteria changed much more rapidly.

The bacteria resulting from this transformation resembled each other very closely, both microscopically and in culture, while, on the other hand, a large variety of types of growth could be obtained from each bacterium, by, for example, heating the spores to temperatures not sufficient to kill them. Each bacillus might occur also in a motile and non-motile form. There was shown a motile bacillus turned into a non-motile by growth at 60° in glycerine broth. Non-motile forms, on the other hand, tended to pass spontaneously into the motile, especially on media containing lactose.

It had been necessary, therefore, for identification to try to obtain as many other stages of each life-history as was possible. The preferable method would have been to have obtained the sporoblast as described above, and then to have brought about the development from it of the other phases. This method had to be given up for the time, owing to the difficulty of getting the bacteria to grow at the required temperature. It had been found, however, in the course of the experiments on the modification of the macroscopic appearance of the cultures, that on heating the spores for longer than the time which had apparently sufficed to kill them, the bacillus sometimes reappeared. The spores were therefore heated for still longer times and in various solutions, and other types of microbe were occasionally obtained.

Many of the sporing bacteria from the blood and saprophytic bacteria were used as well as those from the anthrax and tubercle bacilli.

The *subtilis* spores from anthrax were got by heating a two and a half months old culture and from the subculture in lactose broth of a five months old culture, which grew a wrinkled film, the broth below being clear and alkaline, while the other test broths gave typical cultures of the anthrax bacillus. The temperature for transforming the spores was, as a rule, 110°, the heating medium salt solution with or without alkali, and the time, for anthrax, at most five minutes. Slight variations in the process and even in the age of the spores used often affected the result materially. At best, 10 per cent. of the subcultures on one medium or another gave positive results (agar with various sugars was used). The microbes obtained included four apparently different staphylococci. A pink coccus, shown under the microscope, could be seen to transform itself directly into a bacillus on certain media, especially glucose agar, reverting to the coccal form when put back on plain agar. It was possible that such direct transformations were comparatively frequent. A diphtheroid and various cocco-bacilli and diplo-bacilli were also got.

Of the tubercle bacillus, both human and bovine types, and the Arloing Courment bacillus were used. It required a good deal of care to get positive results. The temperature was 41½°. The human bacillus turned five times out of six in ½ c.cm. alkaline broth and the sixth time in 1 c.cm. The bovine turned in the 1 c.cm., and the Arloing-Courment in the 1 c.cm. and 3 c.cm. broths. Often a bacillus which gave negative results would give positive if tried a week or so later. Parallel cultures from different media such as egg and glycerine agar would also give different results.

The sporing bacteria corresponding to the tubercle bacilli differed from all those hitherto worked with in being more readily killed by heat. Five minutes' boiling sufficed when first obtained, whereas most resisted for one and a half hours, the anthrax ones for over an hour, and one from a rheumatic blood for about six hours. Their upper limit of growth and spore formation were, when first got, about 10° higher than those of the *subtilis* type from anthrax.

The microbes got from overheating these tubercle spores were chiefly cocci. The temperature used was not higher than 105° for two to five minutes. With more or less similar conditions the same coccus, if any, appeared. Two sets of cocci from the bovine bacillus were shown. Those from the spores heated to 105° (ten in number) were white and grew at 37°; those from the steamed spores were orange, and did not grow at 37°, but scarcely above 20°. The cocci from the tubercle bacilli appeared on the agar in from two to four days, while those from anthrax took from seven to ten days, and the pink coccus mentioned above five weeks (one week being at 37°, and the heating solution 5 per cent. metaphosphoric acid). Cocco-bacilli, diplo-bacilli, and anthracoids were also got from this tubercle, as from most of the other spores, and a yeast and torula apiece from the human and bovine bacilli. The anthracoid from the human bacillus was remarkable for the extremely waved, almost spirochaetal, appearance of its filaments by the third day, spore formation having been arrested.

The above record gave very little idea of the extreme complexity of the results. The account of methods was to be regarded more as indicating the direction in which further results might be obtained than as a definite guide. Each bacterium presented to some extent new problems.

DISCUSSION.

Dr. W. S. Lazarus-Barlow (London) called attention to the fact that minute quantities of radium might exist in normal tissues, and he had found experimentally that ordinary laboratory broth sometimes contained an appreciable amount of the element. In view of the pronounced agglutination that Russ and Chambers noted in cultures of *B. diphtheriae* exposed to radium emanation, the speaker thought the possible effect of variations in the radium content of the culture medium in bringing about some of the bacterial variability ought to be borne in mind.

Dr. E. C. Hort (London) drew attention to the necessity for abandoning artificial media for the preparation of vaccines for purposes of treatment. The great point was to approximate as near as possible to the natural media of the body in order to imitate the natural processes of cure of infections. For this purpose Dr. Hort and Dr. Ingram had been using in numerous diseases whole normal human blood as medium of growth, and the results had been full of encouragement.

Dr. Wilson (Belfast) mentioned some cases of bacterial variation coming under his observation. In examining

the fermentative characters of strains of *B. coli* isolated from the urine in cases of cystitis and pyelitis he had found a number of colon bacilli, which in most cases were unable to form gas from sugars and alcohols, but a few of them were able to produce gas from alcohols but not from sugars. These "anaërogenes" strains occurring naturally were very similar to strains produced artificially by Penfold by growing *B. coli* on sodium monochloracetate media. He had also observed a *B. coli* which was able to ferment lactose at room temperature but which had no action on the sugar at body temperature. As regards morphological alterations, he had observed that the *Streptococcus faecalis*, when grown on the Drigalski-Conradi medium, attained a very large size and became distinctly ovoid in shape. Some experiments showed that this alteration was due to the action of the lactose and crystal violet in the medium. Recently he had isolated a bacillus of the *proteus* group from a subcutaneous abscess. This micro organism grew profusely at 37° C., and had the usual morphological and staining characters. When grown at 39° C. the growth was scanty, and the culture, when stained by Neisser's method, showed very well marked metachromatic granules. This bacillus was Gram-negative, and was in no way related to the *B. diphtheriae*, yet the appearance of the films was indistinguishable from that prepared with the Klebs-Loeffler bacillus. In an outbreak of cerebro-spinal fever in Belfast in 1907–8 out of some seventy strains examined all except five fermented maltose and glucose, but a few failed to ferment both these sugars. In other respects the cocci resembled the diplococcus of Weichselbaum. At the same time Houston and Rankin showed that the opsonins for the cocci isolated from cerebro-spinal fever cases had little effect on cocci obtained from cases of posterior basic meningitis. In the course of time the meningococci suddenly acquired the character of readily absorbing opsonins and agglutinins from a normal serum, whereas, at the start, it required a specific serum to produce an opsonic or agglutinative effect.

Dr. BENHAM said that the bacteriologist had this advantage over other observers in that he was able to watch the process of evolution in miniature. The rapidity with which micro-organisms subdivided, as shown by the researches of Dr. Thiele, was so great, that it was easy to understand how rapidly these extraordinary variations in type could occur. If this discussion bore no other result, he hoped it would lead bacteriologists to pay great attention to the nature of the medium on which their strains were grown, and he suggested to bacteriologists the desirability of trying their strains of bacteria on media prepared in other laboratories as well as their own, in order to see whether they had the same characteristics under these circumstances. From the point of view of immunization the discussion certainly emphasized the need for the use of media which approximated as nearly as possible to the tissues of the human body, and also the necessity for using the first subculture for immunizing purposes, a point which had been known by vaccine therapists as a rule of thumb for some years. The observations of both Dr. Penfold and Miss Young were of such importance that he hoped their papers would be read by bacteriologists throughout the world.

Dr. JOHN H. TEACHER (Glasgow) discussed variation in a diphtheroid organism. The original cultures were obtained from the uteri or placentae of guinea-pigs which had aborted. The first cultures, whether on agar or serum agar, were quite characteristic to naked eye and microscopical examination. The culture looked like diphtheria, but by the second day the colonies spread out in thin delicate crenated margins with white pointed centres. They were discrete and hard and rubbed off solidly from the agar, breaking up with difficulty. The bacilli were like *B. diphtheriae* but more septate, and on staining by Neisser's method they were less abundantly beaded. In subculture some of the cultures remained fairly constant, but in the majority the colonies lost their sharply defined characters and hardness, the result being a diffuse soft "mucusy" growth. The organisms might be coliform or even coccoid in character. But on inoculation of guinea-pigs the original characters constantly reappeared in the first culture. This process had been observed repeatedly in experiments extending over many months.

THE PRESENCE AND SIGNIFICANCE OF NITRITES IN URINE.

BY

JOHN CRUICKSHANK, M.D.,

Pathologist and Clinical Pathologist, Crichton Royal Institution, Dumfries,

AND

JOHN MURRAY MOYES, M.B., Ch.B., D.P.M.,

Assistant Physician, Crichton Royal Institution, Dumfries.

(Abridged.)

THE presence of nitrite and nitrate in urine was first observed in 1864 by Schönbein.[1] In 1895 Richter[2] found nitrites in the fresh urine of certain cases of acute gastric and intestinal catarrh, and regarded this occurrence as of pathological significance in these conditions. The fresh urine of cases of sulphaemoglobinaemia may also contain nitrites in considerable amount, and this, together with the blood changes, is regarded as an indication of the presence in the blood of an active reducing agent (a hydroxylamine derivative, vide Mackenzie Wallis[3]). Normal fresh urine, however, does not contain nitrites. In urine which is allowed to stand exposed to the air nitrites make their appearance, generally within a comparatively short time, before the urine becomes distinctly alkaline in reaction. It is also stated that the presence of nitrites in drinking water may cause nitrites to appear in the urine.

During an investigation of urine for another purpose it was found by us that the occurrence of nitrites in the freshly passed urine of mental patients was not uncommon, and as the knowledge of the phenomena connected with "nitrituria" seemed to be incomplete, we have examined in some detail a large number of normal and pathological urines for the presence of nitrites.

The presence of nitrite in urine or other fluid can be readily detected by the use of various reagents. We have generally employed the Griess Ilosvay test. Two solutions are made up, one containing 0.5 gram of sulphanilic acid, the other 0.1 gram of alpha-naphthylamine, each in 150 c.cm. of 5 per cent. acetic acid. A mixture of these in equal proportions is used for the test. It is advisable to keep the two reagents in separate bottles, and to mix the required amount just before use, as the mixture readily absorbs nitrite from the air. To 20 c.cm. of fresh urine 10 c.cm. of the alpha-naphthylamine-sulphanilic acid mixture are added. If nitrite is present a pink or red colour rapidly develops. This reagent is capable of detecting very minute traces of nitrite. A potassium iodide-starch mixture may also be used. A few drops of 10 per cent. potassium iodide solution and 5 c.cm. of dilute boiled starch solution are added to 20 c.cm. of urine, and a few drops of dilute sulphuric acid added. In the presence of nitrite iodine is liberated, and combines with the starch to give a blue compound. It is of importance, in testing for nitrite in urine, that the urine should be fresh, and that the vessel into which it is passed should be thoroughly clean. Where any doubt exists some of the reagent should be placed in the vessel, and the urine then passed directly into this. In our earlier experiments a number of urines were found to give positive nitrite reactions which on subsequent examinations always gave negative results. These reactions were readily traced to contamination of the specimens with a trace of old urine. In our later experiments the greatest care was taken to ensure that the urines were passed into perfectly clean vessels and tested immediately. Where possible, catheter specimens have been used.

About 600 specimens of urine have been tested. Out of 150 urines from healthy subjects two only gave positive results, and the possibility of contamination in these two cases could not be excluded, as further examinations of the urine of these two individuals always gave negative results. The statement that nitrites do not occur in normal urines has therefore been substantiated. Very different results, however, were obtained with the urines of patients suffering from mental and other diseases. Nitrites were found to be present in about 12 per cent. of the patients in the Crichton Royal Institution, a larger number of positive results being obtained with the urines of female patients than with those of male patients. Nitrites were found to occur in urines which were markedly acid, neutral, or

faintly alkaline, and there appeared to be no relationship between the amount of nitrite and the reaction of the urine. The amount of nitrite present differed considerably in different cases and even in different samples of the urine of the same individual. Colorimetric comparisons with known amounts of nitrite showed that the amount of nitrite being excreted per day varied from 0.01 gram to 0.08 gram, reckoned as sodium nitrite. No relationship could be traced between the occurrence of positive results and the type of mental illness, nor could we detect any physical condition which could be regarded as a possible cause of the condition. Diet and drugs were also considered, but no connexion between either of these and the "nitrituria" could be established. Careful examination of the urine for the presence of other abnormal products (albumin, sugar, blood, etc.) gave negative results. Bacteriological examination showed that in all the positive urines Gram-negative bacilli were present in varying amount. Catheter specimens from a number of cases were examined, and from all these samples cultures of coliform organisms were readily obtained. Morphologically and culturally the organisms isolated from the different cases differed considerably, and we have been unable to find any one organism common to all the cases. In no case did a nitrite-containing urine prove to be sterile. The numbers of bacilli present in particular samples of urine were frequently small and at first sight it seemed improbable that such slight infections of the urine could be regarded as the etiological factor of the condition. It was also difficult to explain on the basis of a bacteriological infection the great variations in the amount of nitrite which occurred from day to day in many of the cases. Nevertheless, we are of opinion that it was to the bacilluria that the presence of the nitrite in all our cases was to be referred. In support of this certain experiments were performed. Fresh normal urine free from nitrite was sterilized in a number of tubes. These were inoculated with a series of common laboratory organisms and with the organisms isolated from the nitrite-containing urines. The tubes were then incubated at 37° C. and tested from time to time for the presence of nitrite. It was found generally that the urinary organisms were much more active in causing the production of nitrite than were the majority of the control organisms. Distinct reactions for nitrite could be obtained in many cases after two to three hours' incubation. It was apparent from these experiments that although urine is normally retained in the bladder only for short periods such periods are ample for the production of nitrite by certain organisms of the *B. coli* type. Observations have been made over a period of about a year, and it has been found that in the majority of the cases the "nitrituria" has persisted. In certain cases every sample of urine examined during the year has shown the presence of considerable amounts of nitrite, and bacteriological examinations have always shown the presence of some degree of bacilluria. It is worthy of note that in only a very few cases has the bacilluria been accompanied by the presence of pus cells, and these only in small amount. Further, the patients showing persistent bacilluria have not appeared to suffer in any way from the condition. No symptoms referable to long-continued nitrite absorption have been observed and no nitrite has been found in the blood.

We have also examined a number of urines from patients in the medical and surgical wards of various hospitals. It was not possible to personally supervise the taking of the specimens and only a few catheter samples could be got. The results of much of the work had to be discarded owing to the possibility of contamination of the specimens. As a result we have been unable to come to any definite conclusions regarding the occurrence of nitrites in medical and surgical cases. One or two facts are, however, worthy of note. After abdominal operations nitrites not infrequently appeared in the urine as a transitory phenomenon within a few days of the operation, although the patients were apparently making an excellent recovery. This has been particularly noticeable after operations for hernia. In certain of these cases the appearance of nitrites in the urine was of short duration and was succeeded by a period in which the urine was markedly alkaline from the presence of ammonium carbonate and gave no nitrite reaction.

The administration of urotropine in doses of 10 grains three times a day was tested on two patients excreting nitrite, with the result that the nitrite rapidly diminished and ultimately disappeared.

A number of observations have also been made on the changes which urine undergoes on standing exposed to the air so far as these alterations affect the presence of nitrite. As a general rule, in the case of the normal urines, there was no trace of nitrite until the third or fourth day, but considerable variation was found in particular samples kept apparently under exactly similar conditions. The more acid the initial reaction of the urine the longer was the time before nitrite appeared. In all cases nitrite appeared while the urine was still acid to litmus. As the urine became alkaline the amount of nitrite rapidly diminished. It is important to note that the urine of cases of well-marked cystitis, in which the urine was markedly ammoniacal, gave negative nitrite reactions. In the case of urines which gave a positive nitrite reaction in the fresh state, it was frequently found that the amount of nitrite rapidly diminished on standing and ultimately disappeared, but that after a further period nitrite again made its appearance, the reaction of the urine still being faintly acid or neutral.

In regard to the statement that the presence of nitrite in drinking water may cause nitrites to appear in the urine we have found that the administration of sodium nitrite (6 grains per day for several days) was not associated with any excretion of nitrite in the urine.

As a result of these investigations we are of opinion that the most common cause of nitrituria is an associated urinary infection, and that the presence of bacilluria should be sought for in all cases. The organisms generally belong to the *coli* group and possess in marked degree the power to split the nitrate of urine into nitrite.

The test for nitrite in the urine affords a simple and fairly reliable method of detecting cases of urinary infection without the use of the microscope, provided that the infection is not of such degree as to render the urine markedly alkaline.

THE RECOGNITION OF HAEMIC INFECTIONS OF THE URINE: ITS CLINICAL AND EXPERIMENTAL VALUE.

By Edward C. Hort, F.R.C.P.Edin.

(*Abstract.*)

It is a familiar and annoying experience that bacteriological examination of the blood frequently gives negative results in cases in which the presence of continued fever makes it practically certain that pathogenic organisms, whether as primary or secondary invaders, are circulating in the blood stream. This inability to discover the organisms responsible for the fever is often an absolute bar not only to diagnosis but to the preparation of efficient vaccines, or to the use of an appropriate serum.

One of many reasons for failure in these cases appears to be the high bactericidal power of the blood. The bactericidal power of the urine, on the other hand, is relatively small, and a study of the comparative value of bacteriological examinations of the two fluids has convinced me that from this point of view the urine is often incomparably the better medium of the two.

Although haemic infection of the urine has long been known to occur in relapsing fever, Malta fever, plague, infective endocarditis and typhoid fever, and although the passage of pathogenic organisms from the blood stream to the urine has often been demonstrated in animals, the principle thus established does not appear to have been much used for clinical purposes, except for the detection of carriers. For example, no systematic attempt appears to have been recorded to show how far it can be applied to the early diagnosis of such common infections as influenza, epidemic catarrh, the pneumonias, the secondary infections of tuberculosis, or to the diagnosis of other diseases in which the causative organisms are well known. And in these numerous infective diseases in which the *causa causans* is still unknown, and in which fever is a

prominent symptom, the possibility that bacteriological examination of the urine might reveal the nature of the infective agent has been practically ignored.

In a communication such as this it is not possible to bring forward all the evidence with which my own practice has supplied me as to the clinical value of studying haemic infection of the urine, both for purposes of diagnosis and of treatment. In such diverse diseases as tuberculosis with its secondary infections, purpura septica, lobar pneumonia, bronchopneumonia, meningitis, appendicitis, infective cholecystitis, acute gastric and duodenal ulcer, acute rheumatic fever, and acute phlebitis, the results have been full of interest and promise, as they have also been in investigating the etiology of mumps and typhus, and in numerous cases of obscure fever in which physical signs were conspicuously absent. In many of the latter class of case a correct diagnosis has been only ultimately arrived at by a thorough bacteriological examination of a haemic infection of the urine. On this occasion I can only take as illustrations two diseases which I and my friend, Dr. Ingram, have been studying together for several months—lobar pneumonia and typhus fever. I have chosen the first because it is a type of infection in which the causal organisms are well known, the second because it is a type of disease in which the infective agent has not yet been discovered. It should be premised that in all cases the most scrupulous care is needed to exclude extraneous infection from the urine it is proposed to examine, and to establish the pathogenicity of the organisms cultivated. These are by no means easy matters, as may be judged from the numerous control observations we have been obliged to carry out on the sterility of normal urine. These will be shortly published elsewhere. It should also be noted that it is a mistake, if the urine is clear on passage, to rely on inoculation of artificial media with fresh urine or its centrifuged deposit. And this is especially true of solid media. In all cases in which the urine does not contain organisms in sufficient numbers to be readily recognized by the microscope immediately after discharge, as well as in cases in which large numbers are present, the use of the urine itself as the medium of growth will frequently reveal an unsuspected haemic infection. I have repeatedly found by this method that in many cases pathogenic organisms can be shown to be present in enormous numbers after a few hours' incubation of this fluid. When once firmly established in urine they will usually multiply with readiness on the ordinary artificial media. As a result of this observation I have often found that specimens of urine, rich in blood-derived organisms, can be easily obtained by allowing incubation to take place within the bladder.

Haemic Infections of the Urine in Lobar Pneumonia.

In a series of 20 cases of lobar pneumonia of the acute type we found that the urine when collected was often perfectly clear. In other cases it showed varying degrees of turbidity, and in the centrifuged deposits of the fresh turbid specimens we never failed to find organisms which proved to be either capsulated pneumococci, alone or in combination with the Gram-negative pneumobacilli of Friedländer, or else the *B. influenzae* of Pfeiffer. In the clear urines, in which prolonged search was necessary to show the presence of organisms, incubation of the urine for a few hours in no case failed to give us positive results. In several cases of chronic bronchopneumonia we have also been able to demonstrate in and cultivate from the urine during the pyrexial period capsulated pneumococci, either alone or in combination with Pfeiffer's influenza bacillus. The bacterial deposits from our cases of lobar pneumonia were tested in many instances for virulence by injection into mice. In no case did the deposit from the incubated urine when injected direct into mice produce any harmful effect if incubation was allowed for a few hours only. Yet the same organisms when injected after subcultivation in broth or on agar for one night did not once fail to produce death in a few hours in a much smaller dose. It appears, in fact, as if the urine organisms had become avirulent through sensitization acquired either during their passage through the blood in the case of fresh deposits or in the urine itself after incubation.

We therefore applied ourselves to a study of these as vaccines, using as the medium of growth either the urine itself or healthy human blood. As I showed in 1911, organisms may be profoundly modified in their antigenic behaviour if they are grown on the ordinary laboratory media after recovery from the body. Their value for the preparation of autogenous vaccines when grown on broth or agar, as compared with that of vaccines made from organisms grown on the natural media of the body, is, indeed, gravely impaired. In the past two years I have repeatedly found this use of natural media, especially of whole normal human blood, of the greatest value in vaccine treatment, and before long the use of laboratory media for the latter will probably disappear. It should not be forgotten that serum as a medium of growth for the preparation of vaccines is but a poor imitation of the circulating blood.

Haemic Infections of the Urine in Typhus Fever.

In spite of the attention that has been paid in recent years to the bacteriology of human blood in typhus fever the infective agent is still unknown. In fifteen recent cases of the disease occurring in Ireland we made films from the fresh blood, and obtained cultures from which we were able to identify the large so-called diplococcal and diplobacillary organisms which various observers have regarded, on insufficient grounds, as the causal agents of the disease. We have, indeed, gone farther, and have found that injections of the cultures of these organisms in citrated human blood, in which growth is easily obtained, has in no case produced any observable pathogenic effects in bonnet monkeys. We conclude, therefore, that these large organisms are not themselves responsible for the production of the disease.

The infectivity of human typhus blood when injected into healthy monkeys has been clearly established. But until now it has been quite impossible to say whether the continued fever thus induced is caused by the large organisms referred to or by some other infective agent which may or may not be the cause of typhus fever. And this applies also to the work so far recorded on the transmission of the disease from man to monkey, and from monkey to monkey, by the body louse, though the fact of transmission of the disease from man to man by this agent can hardly now be questioned.

In all of the 30 cases of typhus fever placed at our disposal we carefully examined the urine, by immediate examination of fresh specimens and by cultivation. In the great majority the fresh urine during the period of fever was turbid from the presence of micro-organisms. Both in catheter specimens in the two sexes and in non-catheter specimens the bacteriological findings in films made from the fresh centrifuged urine were strikingly similar, and were, in fact, so constant as to establish a valuable aid to rapid diagnosis. In all of the urines examined before the crisis great numbers of large coccal and bacillary organisms, morphologically similar to those found in the blood, were observed, and their identity was later established in the ordinary way. In each case there were also present in the deposits of the fresh urine minute organisms which occurred singly, or in pairs, or in clusters. When in clusters, as well as when occurring free, they were sometimes coccal in form, sometimes bacillary, and often it was impossible to determine whether they were the one or the other. They were both Gram-positive and Gram-negative in the same clusters, they had no apparent capsules, and they were non-motile. They varied in size from about 0.1 or 0.2 micron to about 0.5 micron in their greatest diameters when in pairs, and when single their greatest diameter was proportionately smaller. They rapidly disappeared from the urine when this was incubated, and after a few hours the larger cocco-bacillary forms only could be found, and these readily multiplied, both in urine and in, or on, the ordinary laboratory media. Injection of these cultures into bonnet monkeys, as we had found to be the case with cultures of the same organisms from the blood, produced no apparent pathological effect.

After filtration of the urine through tested Berkefeld candles we were able in many cases to show, by immediate examination of the filtrate, the small cocco-bacillary forms freed from admixture with the larger non-pathogenic organisms. When, however, the filtrate was incubated, they quickly disappeared, their place being taken by the large coccal and bacillary organisms, which also

proved, on injection into bonnet monkeys, to be non-pathogenic. And in the case of cultures on the ordinary laboratory media which had been inoculated with the fresh filtrated urine the small cocco-bacilli did not survive as such, only the larger non-pathogenic organisms being found.
