The evidence as to rodent ulcer seems to justify the conclusion that the best advice which can be given to a patient with rodent ulcer of the skin is to resort at once to treatment by radium. It has been found that if the lesion has been treated for prolonged periods by the x-rays, zinc ionization, and carbonic acid snow the healed tissue frequently breaks down after radium and repair is slow and imperfect. A small rodent ulcer limited to the skin and not previously treated may be cured by a single exposure, probably because it is safe to use a full-strength applicator unshielded. With a large ulcer it is necessary to proceed more cautiously, as an unshielded application to the whole area will produce severe systemic disturbance. Different parts of the surface are therefore treated at intervals of three or four weeks. If the disease has attacked bone or cartilage, still more caution is requisite to avoid the risk of acute painful and prolonged inflammation. Rodent ulcer of a mucous

membrane is refractory to treatment by radium, though small lesions of the palpebral mucous membrane often respond well to a strong unscreened application. The statistics are encouraging. Omitting one case in which the application was prophylactic only and not treated so recently that the result cannot be stated, there remain 90 cases. Of these, 12 were not improved, 6 abandoned treatment, 31 were apparently cured, and 41 improved. If we assume that treatment was abandoned owing to its want of success, it will be seen that the treatment failed in one-fifth of the cases, succeeded in about one-third, and produced improvement in the remainder. It will be noted that all the patients who applied to the Institute were treated. The cases of sarcoma are relatively few; 26 were treated, of whom 9, or about one-third, were improved, it being said of two of them that they are apparently cured.

Among the other diseases treated the most striking results were obtained in keloid and naevus. In the former disorder they are described in the report as "admirable," and whether judged by the statistics or by the individual cases narrated the epithet seems to involve no exaggeration.

Of the 14 cases of keloid or keloid acne treated, 3 are reported cured and 8 improved, while the treatment was abandoned in the remaining 3. One of the chief practical difficulties in the therapeutic application of radium is so to adjust the strength and duration of the application as to avoid a severe reaction. The cause and nature of the reaction has not yet been fully elucidated. Why it should commonly be delayed for two, three, or even four weeks, is not at all clear, and we are not aware that any explanation has been suggested. In some cases where an eroded surface exists the radium reaction proper is, there can be little doubt, complicated and aggravated by septic infection, and it would seem that in some such cases the severe pain suffered during the reaction is in part, at least, due to this cause.

We are indebted to Professor E. Rutherford, F.R.S., of Manchester, for the information that in his laboratory a number of cases have occurred in which fingers have been burnt by exposure to the alpha rays. This has usually occurred in transference of the emanation or in fixing an alpha ray tube in an apparatus when the fingers were brought into close contact with the tube. As a rule, nothing is noticed at the time, but a week or ten days later the finger becomes very painful, and a slight bluish tinge is observed under the skin. About three weeks after exposure the cuticle peels off, and is replaced by a new layer. The general effect later is that the finger has lost to a great extent its sensitiveness of touch, but there have been no cases of sores which would not heal. These particulars are an interesting addition to the information given in the brief reference to the subject in his *Radio-active Substances and Their Radiation*, a book to which we confidently refer all serious students of the subject.

The treatment at present is in the empirical stage. To get an institution of this novel kind into working order and to evolve and test rules for its administration has been no easy task. Now that it has been accomplished we may look forward to the prosecution of inquiries into the physiological action of radium, for on the perfecting of knowledge on this side the establishment of principles governing the scientific use of the radiations in therapeutics must depend. A question of vital importance is to ascertain whether the rays of radium exert a specific action on cancerous or developing tissue. At present it is not clear which rays produce the effects observed in carcinoma. So far

as can be judged, it is improbable that the alpha rays, under the conditions described, can, as a rule, have reached the tissues. Whether the most penetrating rays—the gamma rays—have any physiological effect is not known with any certainty, but the evidence seems, on the whole, against such an hypothesis. There remain, therefore, the beta rays, which are themselves complex. An analytic study of the physiological effects of the several groups of rays would be a worthy object for the Radium Institute with its unrivalled resources and magnificent opportunities.

A NEW CHAPTER.

THE two matters which seem to be of particular moment among the events of the last week or ten days are, in the first place, the decision of the Representative Meeting last Saturday releasing members of the profession from the obligation to it implied in the undertaking and pledge; and, in the second place, the failure of the determined attempt made in certain quarters to split the Association, or, to use the phrase adopted by some political newspapers, to "smash it."

The decision to release all practitioners from the undertaking and pledge was seen to be inevitable in the circumstances brought about by the success of the tactics of the Insurance Commissioners and some members of the profession itself, with the assistance of the Government press. The further decision to rescind the resolution passed at the Liverpool meeting calling on all practitioners to refrain from applying for or accepting any post in connexion with the Insurance Act until the Government had satisfied the Association that its demands would be met, leaves members free to constitute statutory Local Medical Committees and to accept nomination to Local Insurance Committees, to which their presence will help to give a right direction. After coming to this decision the Representative Meeting unanimously adopted a resolution instructing the Council to take all necessary steps to protect the interests of the profession and asking members of the profession to supply information to the Association after they had had some experience of the working of the present provisional arrangement. The meeting further reiterated its opinion that the Act is unsatisfactory, and instructed the Council to give every assistance in its power to medical practitioners in districts in which opposition to the Act was maintained.

With regard to the campaign against the Association, its political basis in London at least, has been undisguised. It has signally failed, and it is not necessary to play the part of Bunyan's man with the muck-rake; much may be forgiven to politicians in a funk. The Representative Meeting, like many of the individual Divisions of the Association, recorded its emphatic protest against the discreditable methods adopted by the Government whereby a position of urgency was created under which many practitioners, finding themselves threatened with financial ruin, were compelled to give unwilling service under the National Insurance Act. The profession has been hustled into the insurance scheme, but it does not mean to be hustled out of the British Medical Association. Of this there is ample evidence in the opinions expressed by members of the medical profession in all parts of the country; it is further established by the hearty response which so many members of the profession are making to the recent call for a further instalment of their guarantees to the Central Defence Fund.

The profession in most parts of the country is committed to the provisional arrangements which have been entered into for the first three months, and it is of the first importance that steps should be taken at the earliest date to nominate medical members of Local Insurance Committees, and to apply for the statutory recognition of Local Medical Committees.

The importance of the duties assigned to Local Medical Committees will not have escaped the attention of any student of the Act and of the Regulations for medical benefit. Where in any county or county borough or any area for which a district committee has been formed a Local Medical Committee has been formed by members of the medical profession in the area, it must be recognized by the Insurance Commissioners if they are satisfied that it is representative of the duly qualified medical practitioners resident in the county, county borough, or district. Where such a Local Medical Committee has been set up and recognized it must be consulted by the Insurance Committee with regard to the conditions of service upon which it is proposed to afford treatment to insured persons and as to the method of remuneration. Before approving any arrangement with practitioners submitted to them by an Insurance Committee, the Commissioners must consider any representations made to them by the Local Medical Committee. Before fixing, varying, or abolishing an income limit the Insurance Committee must consult the Local Medical Committee, and that Committee may at any time, by notice in writing to the Insurance Committee, dispute the right of an insured person to receive medical benefit on the ground that the income of that person exceeded the income limit. Any question arising between an insured person and a practitioner attending him under the arrangements made by the Insurance Committee, in respect of the treatment rendered by the practitioner or the conduct of the insured person while receiving that treatment, would stand referred to the Medical Service Subcommittee, consisting of six members and a chairman. Of the six members three would be appointed by the Local Medical Committee and three by and from the members of the Insurance Committee who represent insured persons. The chairman would be selected by the six persons, and would be one of those members of the Insurance Committee appointed by the county council or the Commissioners who are neither insured persons nor practitioners. The complaint must be stated in writing and sent to the Clerk of the Insurance Committee. Under the general regulations mentioned above it would be referred direct to the Medical Service Subcommittee; the persons authorized to attend the inquiry would be the complainant and respondent, a representative of the society (if any) to which the insured person belonged, a representative of the Local Medical Committee, and any witness or assistant of either party, but not a barrister or a solicitor. The Medical Service Subcommittee would make a report to the Insurance Committee, stating the facts established and recommending the action to be taken. The findings as to the facts must be accepted by the Insurance Committee as final. With regard to complaints falling into another category—those involving the efficiency of the medical service—made by a practitioner on a panel against any other practitioner on the panel, they would be considered by the Local Medical Committee, which would be empowered to apply to the Commissioners to remove the name of the practitioner from the panel, or to take such other action as they might deem proper. The Insurance Committee would have a similar power of making repre-

sentations to the Commissioners. In either case the Commissioners would be required to refer the matter to an Enquiry Committee composed of two practitioners and one other person who must be a barrister at law or a solicitor in actual practice. The Commissioners also take power to refer any similar representations made by any other body or any person to the same committee if they think it advisable so to do. The Enquiry Committee would appoint one of its members to be chairman, but the chairman would not have a casting vote. The procedure of the Enquiry Committee would be such as it thought fit, subject to the approval of the Commissioners. At the inquiry either party might appear in person, or with the consent of the Enquiry Committee, by counsel or solicitor, or by any member of his family, or by any officer or member of a society to which he belonged, or, in the case of a company, by any officer or director of the company. The Enquiry Committee would be empowered to take written as well as oral evidence, and to require any statement to be verified by a statutory declaration. Upon the determination of the hearing, the Enquiry Committee would draw up a report to the Commissioners stating such relevant facts as had been established by the evidence and the inferences, if any, which in the opinion of the Enquiry Committee might properly be drawn from the facts so found. Should a practitioner raise a question as to whether an operation or other service is comprised in the treatment which he has by agreement undertaken to give, that question would be referred by the practitioner to the Local Medical Committee, and if the Local Medical Committee and the Insurance Committee failed to come to an agreement the matter would be submitted for decision to referees established under the Regulations. A Local Medical Committee would also be empowered to represent to the Commissioners that the inclusion or continuance on the list of persons supplying drugs and appliances (a chemist or other person) would be prejudicial to the service in the county, and the Commissioners must thereupon hold an inquiry. The Insurance Committee must prepare a list of the prices which it is willing to pay for the drugs ordinarily supplied and for appliances, and the Insurance Committee, if it proposes to revise the list of drugs and appliances must consult the Local Medical Committee before submitting its proposals to the Commissioners.

It will be seen, therefore, that the functions of a Local Medical Committee are of no little importance and it can hardly be necessary to insist on the importance of constituting such committees, and obtaining their statutory recognition in every county, county borough, or insurance district in which panels have been formed.

REPAIRING THE PERINEUM.

Is it necessary to repair the torn perineum after confinement? Dr. Frederick Blume¹ says that many practitioners do not regard it as necessary, or rather—and this is not quite the same thing—they do not wish to do it, yet they would not allow a laceration of the skin in any other part of the body to remain ununited. They would put stitches at once in a tear extending out from the angle of the mouth or of the eye into the cheek. Why, then, do they not put sutures into a tear extending from the vulva into the perineum? Dr. Blume recently operated upon:

¹ *American Journal of Obstetrics*, pp. 1028-1036, December, 1912.

patient who had a complete perineal laceration' running back into the rectum, but before the woman came into his hands she had been kept in bed by her physician for three weeks with her legs tied together, "to give Nature a chance" as he termed it. Now, why did he act so foolishly? If she had been riding a bicycle and had fallen on to the bar of the machine and had torn her perineum from the anus into the vagina, her physician would never have thought of tying her legs together "to give Nature a chance"; he would have stitched up her perineum.

Dr. Blume names two or three possible reasons which prevent doctors putting stitches in the perineum in labour cases. He says that obstetrics is so poorly paid that medical men spend as little time as possible over their confinements, and are very glad to leave the repair of the perineum, when it is torn, to Nature, believing—or shall we say hoping?—that she will be able to manage it. This may be one reason. If it be so, then it goes to strengthen the truth of the saying that the lazy obstetrician makes the busy gynaecologist. But there is another reason. Labour no doubt is a physiological process, and it is argued that as it is a natural act, no tear, therefore, is to be expected: but if it occur by any chance, why then it should be left to heal by natural processes. This is an infirm argument. A physiological process may go astray, and a great part of all medical practice is to prevent such going astray or to remedy the error.

Dr. Blume gives other reasons why the torn perineum is sometimes left unsutured; but there is one at least to which he does not refer—it is simply because the medical attendant does not look to see whether it is torn! He does not put a thumb on each side of the perineum and hold the parts aside; he forgets that after soft parts have been widely distended they fall together again naturally; he sees no gaping wound, and concludes that there is no wound at all.

The last reason given by Dr. Blume—and the profession may feel indebted to him for putting it in black and white—is that patients regard the torn perineum as a sign of incompetence on the part of the doctor. They are shocked, and they show that they are shocked, when their physician tells them that he has had to put a stitch or two into the skin. He feels sure they will criticize him severely in discussing his management of the case with other women, and especially with other women who have been attended by doctors who did not confess to perineal tears by announcing the insertion of sutures. More than this, when he meets with a really deep laceration—one which certainly ought to have six or seven sutures in it—he contents himself with putting in one or two stitches, and so risks failure of union altogether rather than confess to what his patient may, and almost certainly will, regard as the result of mismanagement. There are patients, it seems, who "estimate the efficiency of the obstetrician according to the number of sutures which he uses in the repair of the perineum"; the fewer he puts in the higher he is in their regard!

These outspoken remarks and candid criticism of the profession by Dr. Blume call for action. He himself suggests that medical men should begin by educating women in the knowledge of what is involved in childbirth, and he is quite right. A woman ought to know that at her first confinement it is very likely that there will be a tear of the perineum, and that no obstetric skill will be able to prevent it, although proper care will lessen the chances of it occurring and will certainly limit the extent of it.

She ought also to be told that under certain circumstances deeper tears are also unavoidable. Most important of all, she ought to understand that her medical attendant ought to stitch up all such tears, small as well as deep, and that the number of sutures required depends entirely upon the size of the wound, and should be sufficient. It may then come about that the woman with an extensive laceration will praise and not blame the doctor who puts in many stitches.

There are other things, of course, which must be attended to: the best method of managing the passage of the head over the perineum must be taken, the lateral posture in labour should be adopted, and the like; but the chief matter at present is to counteract the prevalent belief that laceration is always avoidable, and so make it possible for the conscientious man, without loss of prestige, to do what is needful and right. In the discussion which followed the reading of Dr. Blume's paper (at the annual meeting of the American Association of Obstetricians at Toledo, Ohio) some speakers maintained that it was better to stitch up such tears twenty-four hours after their occurrence; but that is beside the point, which is that they be recognized and sewed up.

CANVASSING FOR INSURANCE PATIENTS.

It is evident from information which is arriving at the offices of the Association that the new conditions of practice brought about by the National Insurance Act are leading some members of the medical profession into methods of seeking patients which are not only entirely contrary to the traditions of the profession, but which, if persisted in, will inevitably lead to charges before the General Medical Council. There is evidence that some practitioners are issuing circulars informing insured persons that they are on the panel and are open to accept names on their lists; and these circulars, to which probably little exception might be taken if they were sent to actual patients on the books of the practitioners issuing them, are apparently in some instances being distributed broadcast. Not only this, but there are indications that some practitioners have not scrupled to secure the influence of officials of approved societies in order that their persuasive efforts may be brought to bear on those persons who may not have any strong views as to choice of doctor. Already some Divisions have called the attention of the local profession to the need of care in this matter, but it seems that some strong general note of warning is needed if the honoured traditions of the profession in regard to advertising and touting are not to receive a blow from which they will only recover after a series of sharp disciplinary proceedings at the hands of the General Medical Council. The Association will of course lend all its aid in repressing such practices, and looks to the Divisions to watch any tendency of the kind with a jealous eye.

THE RADIUM INSTITUTE IN LONDON.

The first report of the Radium Institute¹ in Riding House Street, Langham Place, London, W., which is published in full this week, seems to show that it has fully justified its existence; and it may be useful to recall the conditions under which patients are admitted for treatment. In the first place, it is to be noted that it is open to all classes of the community, and that paying as well as gratuitous patients are received. According to the rules by which the administration of the Institute is carried out, patients

¹ An illustrated description of the Institute was published in the BRITISH MEDICAL JOURNAL, 1911, vol. II, p. 302, and full particulars of the rules governing the admission of patients, with a tariff of fees charged those able to pay, were there given.

are only treated in association with or through the introduction of their medical adviser. At their first visit they must either be accompanied by him or must bring with them his written statement giving details of the treatment already employed. Necessitous patients are admitted to free treatment if certified by their ordinary medical adviser to be suitable subjects for charity. All other patients are charged according to a scale of fees; the fee for a first consultation at the Radium Institute with the patient's medical adviser or upon a written statement from him is two guineas, and the fees for treatment vary from two guineas to five for each application, being governed by the site of the lesion and the strength of the apparatus used. The duties of the Medical Superintendent towards patients are clearly defined in a letter written by Sir Frederick Treves, the Chairman of the Executive Committee.¹ In this letter it is stated that it rests with the Medical Superintendent to indicate the specific treatment to be employed in each case as well as the details of that treatment, and to see that the treatment by radium recommended is carried out. For that treatment he is responsible, and it rests with him to decline to treat any case in which he considers treatment by radium likely to be of no service to the patient. The diagnosis of the malady rests with the doctor who brings or sends the patient to the Institute. Should a third opinion be considered necessary, the patient's medical adviser is asked to arrange this and to select the consultant, and the ordinary fee for such consultation must be paid by the patient. If the applicant is necessitous, and is therefore being treated as a gratuitous patient, the opinion of a member of the honorary consulting staff can be obtained free, the relation of that staff to the Institute being precisely the same as exists between any other honorary staff and the charitable institution with which the staff is associated. Paying patients at the Institute have no claim whatever upon the services of the consultant staff, and the members of that staff are in no other relation to such patients than are all other consultants or specialists; and the medical superintendent is specially instructed to leave the selection of a consultant to the discretion of the patient's ordinary medical adviser; the supervision of the patient between the attendances at the Institute for the application of radium is in the hands of his ordinary medical adviser. The services of the medical superintendent himself are free to all patients, but his services are entirely confined to the treatment actually given in the Institute and where that treatment involves special manipulation, as, for instance, in the application of radium to the larynx, oesophagus, rectum, bladder, or uterus, he is instructed to ask the medical adviser of the patient for the assistance of a specialist. The Institute has a well-equipped physico-chemical laboratories under the direction of Mr. W. Lester Alton, who has a private work-room, and will carry on researches into the action of radium as part of the work of the Institute. His first report is published as an appendix to the report of the medical superintendent, printed elsewhere in this issue. It is to be gathered that since the laboratory was opened it has been so busily engaged in measurements connected with the purchase of the radium salts required and in the preparation of applicators and of radio-active solutions, that there has been little opportunity for original research. The laboratory determines the activity of the apparatus employed, and, in the case of all emanation applicators, the dosage during the period of application. The work of preparing the applicators began before the Institute was ready to be opened, and by that time twenty-four pieces of apparatus were ready for use, all, with a few exceptions, prepared by or under the supervision of the director. Since then eleven more applicators have been made, and others will be prepared.

CANCER OF THE RECTUM.

It is a trite saying that surgery is our only present hope of curing cancer. By "cure" one means total eradication of the diseased process. If a cancer be wholly removed it does not recur, and the obvious corollary is that a recurrence is evidence not so much of the failure of surgery as of the incompleteness of the particular surgical technique employed in such cases. Whatever be the outcome of experimental research, it is unlikely that surgical treatment will be superseded for many years to come, if, indeed, it will ever be wholly replaced. Time and time again medicinal treatments and more or less wondrous chemical applications are rushed into temporary prominence, cures are vaunted; but in a disease that differs so widely from all other diseases, that is of such widespread distribution throughout the animal kingdom, the causation and mode of onset of which are unknown, and the natural evolution of which is almost invariably a progression towards a fatal issue, the administration of drugs on the chance of effecting a cure is as the act of one who would attempt to extinguish a volcano with a squirt. Many so-called "cures" that one reads of are based upon an imperfect acquaintance with the natural course of the disease. The resources of surgery are always extending, and it would be rash, indeed, to seek to delimit the possible scope of the surgical treatment of cancers. It comes to be a question not of removing tissues wide of the disease in a haphazard manner, such as too often characterized the operative measures of the past, but of removing the definite structures through which the outrunners of the tumour are, or may be, permeating unseen. These danger tracts have, therefore, to be more exactly mapped out and understood, and the surgical endeavours that will recognize them will be the measures of hope. The observation, too, of sites of recurrence after imperfect operations is of considerable practical assistance. The results of particular operative procedures, frequently fortuitous, are not the best means of determining their practical effectiveness. There will always be those who ask for a sign, but when the lapse of years brings the practicable result for them to appraise, the progress of knowledge will by that time have rendered the operation a thing of the past. If, however, surgical measures be built on the surer foundation of pathological facts, progress will be quicker as the means adopted are more rational. Evidently, then, investigations into the surgical pathology of cancer are of immediate practical value to the surgeon. The more extended the operations become, following such lines, the greater the number of cases amenable to treatment. The greater risk must be met by increased dexterity. That is the surgeon's problem; it is beyond the field of the pathologist. As Seneca said of philosophy, it is not the office of pathology to teach men to use their hands. But of late years a younger school of surgeons has arisen, applying to the problem of the treatment of cancer the observations on the surgical pathology of the disease made in the laboratory by themselves or their associates. The operations of Sampson Handley on mammary cancer, of Berkeley and Bonney on uterine cancer, and of Miles on cancer of the rectum, are typical evidences of the work of this school. Under these advanced operations the number of cases amenable to treatment has risen to about 75 per cent., and one might be erring on the safe side to assume that the effectiveness of the operations—that is to say, the proportion surviving a three years' limit of those actually seen—is well over 40 per cent. With the earlier recognition of the signs and symptoms of cancer, we may well hope for greater improvement than has already taken place within the last few years. In Mr. Miles's clinical lecture published in this issue, attention is called to the early symptoms of cancer of the rectum. When the disease affects the anal canal or the upper portion of the rectum noticeable symptoms occur early, but when the ampulla is affected the malignant

¹ BRITISH MEDICAL JOURNAL, 1911, vol. ii, p. 502.

process may proceed for a considerable time before the patient is impelled to seek advice, and the occurrence of intractable constipation followed by a period of diarrhoea and probably due to atony of the bowel wall may prove a symptom of great service in recognizing an early case of cancer in this situation. The whole paper is a brief but readable exposition of the author's views on a subject that has recently, notably at the annual meeting of the Association at Liverpool, excited much discussion.

SIR GEORGE TURNER, M.D.

THE fact with which many of his friends have been for some time acquainted with regard to Sir George Turner, whose name appears in the New Year Honours list, that he is suffering from leprosy, has recently been made public. We shall not now be violating confidence by stating that the letter published in the BRITISH MEDICAL JOURNAL of April 20th last, p. 925, was written by Sir George Turner. In that letter he expressed certain opinions founded upon his experience of leprosy in South Africa. These opinions were that leprosy is not hereditary, that it is contagious, that it is spread wholly and solely by contagion immediately and mediately, that it is communicable from the sick to the healthy, but not nearly so easily as phthisis, and that it is not such a danger to the public health as syphilis. He laid stress upon the difficulty which might in some cases be encountered in diagnosing the disease, and said that if he presented himself for examination and treatment at a hospital, especially if he concealed the fact that he had been associated with lepers, his disease would probably not be correctly diagnosed by the majority of physicians. He strongly urged that leprosy should be made notifiable, and his advice has the more weight because he added, "You may be sure I do not desire that lepers should be subjected to more restrictions or annoyances than are actually necessary, but they should cheerfully submit to any and every precaution likely to prevent others from suffering in the same way as they themselves are suffering." Sir George Turner entered the civil service of Cape Colony as medical officer of health in 1895. He was then nearly 50 years of age, but in the period that followed, until his retirement twelve years later, he rendered very great services to South Africa and to the world at large. An outbreak of rinderpest occurred in Cape Colony in 1896. The late Professor Koch was then studying the disease and had devised a system of inoculation, but had to leave South Africa before his work was complete; for the last three weeks of his stay Dr. Turner was with him. Six months later Dr. Turner had produced a curative and preventive serum, but the immunity produced only lasted for three weeks. He accordingly continued his researches and had for his assistant Wilhelm Kolle, and within six months devised a system of simultaneous inoculation of virus and serum, which produced the most excellent results. The report on his subject was signed by him and Dr. Kolle, and the method is now commonly spoken of as the Kolle-Turner method, whereas it ought certainly to be known as the Turner-Kolle, or the Turner method. The inoculations when made amounted to an experiment on an unusually large scale: how many animals were treated cannot be accurately stated, but in the case of 14,000 the results were ascertained. The epizootic was arrested, and within a year the disease was stamped out. The Government of Cape Colony then closed Dr. Turner's station, but as the prophylactic there produced was urgently required in Rhodesia and Egypt, Mr. Cecil Rhodes defrayed the cost of carrying it on for another four months; then the work finally ceased. Dr. Turner, after his eighteen months of hard work, during which he lived in tents among the cattle, took a holiday in England. On his return to Cape

Colony the then Minister of Agriculture intended to propose a vote of thanks in the Cape Parliament, and to move a grant of money, in recognition of Dr. Turner's great services, which had resulted in the saving of millions of money in South Africa alone; but the Ministry fell, and nothing was done. When the war in South Africa broke out Dr. Turner volunteered at the outset, but it was not until the following year, when the prevalence of typhoid fever in the army had become very severe, that Lord Roberts asked for Dr. Turner's services in dealing with the epidemic in the army and in the concentration camps; subsequently, Lord Roberts bore testimony to the value of Dr. Turner's work. In 1901 rinderpest broke out again, and Lord Kitchener asked for Dr. Turner's help. A station was with some difficulty started at Pretoria, and in twelve months rinderpest had once more been stamped out. On this occasion, also, the prophylactic was supplied to Egypt and Natal. There was at that time at Pretoria a leper asylum containing about 50 Dutch and 40 native patients. Dr. Turner worked there for seven years, the first three purely as a labour of love. He saw the lepers each morning and evening, and gave up the whole of Saturday and Sunday to them. Here he conducted many *post-mortem* examinations, and arrived at the conclusions which have been mentioned in the beginning of this note. Upon reaching the age limit Dr. Turner retired, but continued the study of the bacteriology of leprosy. After several years of laboratory work he had to make the diagnosis of leprosy in himself. He is now living in seclusion in this country, suffering from definite leprosy of the nervous type, which has produced great loss of power in the left arm and some weakness in the right. It is understood that Sir George Turner's name was included in the New Year Honours list on the initiative of the King, who had recently become aware of the facts. His Majesty's ready action in this instance will appeal to every member of every profession, and most of all to the profession of which Sir George Turner is so great an ornament. It has appealed, and will appeal, to all members of the public, and it will be appropriate if the Cape Government to-day carries out the intention of the earlier Ministry. It could, perhaps, best do this by making a substantial increase in Sir George Turner's retiring allowance, so that the disabilities attaching to his unfortunate position may not be aggravated by the pecuniary anxieties which a father crippled in health and with educational responsibilities towards his children must suffer.

PASSPORTS.

A CASE heard recently before Mr. Justice Darling at the Central Criminal Court contains a warning for all medical men. A medical practitioner in London was charged with having put forward false declarations made for the purpose of obtaining passports for two men with foreign names. The passports were issued, and the two men were subsequently taken into custody at Stuttgart on the charge of having procured a girl from England. The counsel who appeared for the Foreign Office said that it was not suggested that the defendant had the smallest knowledge of the real character of the men, and that when the police communicated with him he treated the matter quite frankly and gave full information. Before a passport can be issued to any person there must be a declaration signed by some one of certain specified classes (mayors, magistrates, justices of the peace, ministers of religion, barristers-at-law, physicians, surgeons, solicitors, and notaries) to the effect that to the best of his personal knowledge the applicant is a fit and proper person to receive a passport. The form has recently been changed, and it now bears an endorsement stating that any person who made a statement which proved to be untrue would be liable to prosecution. It appeared that in this case the men were unknown to the medical practitioner

who signed the forms but were recommended to him by a patient in whom he had great confidence. The defendant, through his counsel, expressed great regret for the mistake he had made. The judge, while accepting the defendant's explanation that he was quite unacquainted with the character of the men, imposed a fine of £25 each in respect of two declarations. From this case and from one of a similar order which was reported in this Journal in September, 1911 (page 770), it is clear that medical men are not fully aware that the Foreign Office attaches great importance to the declaration which has to be made by an applicant for a passport which must be supported by some person in a responsible position who is acquainted with the applicant. It is dangerous to give such guarantees unless sufficiently acquainted with the applicant to feel certain that the declaration made is absolutely true. It is, moreover, very desirable to make certain that the applicant is himself about to proceed upon a journey abroad and therefore really requires a passport.

A MAP OF THE INSURANCE ACT.

We have received from the Association of Standardized Knowledge, Limited, of 15-16, Buckingham Street, Adelphi, W.C., a chart of the National Health Insurance Act, prepared on a novel plan. The subject matter of the Act is arranged in vertical columns and the compilers have chosen as headings a series of seven functions into which the operations of the Act naturally fall. Horizontally, the subject matter is further arranged under headings of the different groups of persons coming within the jurisdiction of the Act. By this ingenious system, a map is made, in which the functions of the Act may be termed its longitudes, and the people brought within its operations its latitudes. This device makes it comparatively easy to ascertain the operations of the Act in reference to any particular person or subject; only the essence of the Act is given, but it is to be found rapidly and conveniently. An important feature of the chart is that appended to every statement is the number of the clause of the Act, so that direct reference can be made if desired. The chart has evidently been prepared without political bias, but incidentally it brings out many curious points, for instance, men in the army or navy only receive maternity benefit, so that out of 100,000 men in the regular army who pay insurance tribute, 80,000 have no chance of receiving anything in return, not more than 20 per cent. of the men in the service being married. The Association of Standardized Knowledge appears to be an offshoot of a body called the "Organization Society" which exists to propound and explain the science of organization based on the axiom that society is an extension of the individual, and on three principles—of degree, of a universal duality, and of the line of least resistance—to teach its principles and advocate their application. The president of the society is Mr. Marshall Bruce-Williams, and the other members of the executive committee are Colonel B. R. Ward, R.E., and Colonel F. N. Maude, C.B. Captain R. R. Gibson is the acting honorary secretary, and further information can be obtained from him at 15, Buckingham Street, Adelphi, W.C. The society will arrange for giving lectures illustrated by lantern slides, will institute classes, and is prepared to affiliate literary, scientific, or debating societies which may desire to work along its lines.

A MEDICAL UNION UNDER THE TRADE UNION ACTS.

Medical practitioners in Leicestershire and Rutlandshire are making an experiment which will be watched with much interest. They have formed a Union of Medical Practitioners, drafted rules, and conformed to all conditions entitling the Union to be registered under the Trade Union Acts of 1871 and 1876. The certificate of registration was issued on December 14th, 1912. We are indebted to the chairman, Dr. R. Wallace Henry, of Leicester,

whose brief letter appears elsewhere in this issue, for a copy of the Rules of the Union; but it has not been possible in the time at disposal since its receipt to submit them to more than a cursory examination. It may, however, be noted that any registered medical practitioner who has not, in the opinion of the Central Committee of the Union, been guilty of conduct detrimental to the honour and interests of the profession, or calculated to bring it into disrepute, may become a member of the Union on signing an undertaking to conform to the rules of the Union and to the working rules of the Public Medical Services established and controlled by the Union. There are two classes of members—acting, who are prepared to give medical attendance on contract terms through the Public Medical Service; and honorary, who are not. The Union is authorized to establish branches in the United Kingdom and to institute a system of school clinics for the treatment of necessitous children, and takes power to give legal assistance to its members. The entrance fee and annual subscription are to be fixed at a sum not exceeding one guinea in each case, but the Central Committee has power to make a levy not exceeding £5 on each member. In the constitution provision is made for members unable to attend a meeting to exercise their right to vote. The Union has taken power to indemnify a member in respect of any loss incurred by him on account of action taken by him in accordance with the advice or instructions of the Union. The Union, Dr. Wallace Henry informs us, is no sense intended to be a rival to any other organization.

THE CHINA MEDICAL MISSIONARY ASSOCIATION.

THE China Medical Missionary Association, which held its triennial conference in Peking during the early part of January, is a society which exists for the purpose of uniting all medical missionaries in China working in connexion with the various missionary societies. The *China Medical Journal*, issued quarterly by the association, is perhaps its most important work, and this number deals with important questions of missionary policy, also includes papers on a variety of professional subjects. The association is a purely advisory body, but it has been of great assistance to the missionary societies, particularly with reference to the subject of medical education, and has undertaken the translation and publication in Chinese of many medical works, including such volumes as Gray's *Anatomy*, Halliburton's *Physiology*, Osler's *Medicine*, Ross and Carless's *Surgery*, and Caird and Cathcart's *Surgery Handbook*. Conferences are held annually at various centres, but a general conference takes place only once every three years. It was in connexion with this conference that the President of the Republic (Yuan-Shi-Kai) on January 15th received the members present with great honour, as is reported in a Reuter's telegram. Reply to an address presented by the missionaries, Yuan-Shi-Kai said: "I am delighted to receive the medical missionaries. We are most gratified to you for your charitable services, especially in the interior, where the importance of sanitary principles, once comparatively unknown, is being increasingly recognized throughout the land, owing to your labours. It is also due to you that destitute women and children are being succoured and that the poorest people are receiving the elements of an enlightened education. Many of you assisted during the plague, materially aided in restricting the ravages of the disease which had alarmed the world, while during the revolution many of you faced dangers and difficulties in order to relieve the sufferers. I am glad of this opportunity to offer you my most sincere personal thanks, and I hope that you will continue your labours, thus adding to the glory of your reputation and strengthening the bonds of friendship between your countries and ours, which I hope will strengthen every year."

SECRET COMMISSIONS.

SINCE the passage of the Prevention of Corruption Act, 1906, there would seem to have been a cessation of the corrupt offers to medical practitioners to recommend drugs, appliances, medicated wines, mineral waters, schools and homes for mentally deficient persons, of which examples were brought to our notice in former years, and from an answer given by the Attorney-General in the House of Commons to a question by Sir Samuel Scott it appears that during these six years there have been only eighty applications for the Attorney-General's fiat, twelve of which were refused, leaving only sixty-eight instances in which there was a *prima facie* case. It is therefore to be hoped that these discreditable attempts have been largely checked by the Act in question. A medical correspondent, however, has recently sent us a copy of a type-written letter received by him from the head office of a company concerned in the manufacture and sale of a certain appliance, one paragraph of which reads as follows: "Any member of the medical profession may take advantage of similar discount rates to those granted to our agents, or, if so desired, a commission basis can be arranged for the introduction of our instruments to any patient whom the doctor considers would benefit by its use. The patient so sent to us must bear a letter of introduction, and we handle the case entirely from that moment." There can be little doubt that such a communication is contrary to the spirit of the law, and that any medical practitioner who entered into such an arrangement might render himself liable to the penalties fixed by the Act.

MEMORIAL TO MISS LOUISA TWINING.

A strong desire having been expressed, a sum of money has been privately subscribed in order to perpetuate the name of this well-known worker in a manner which she herself would have approved. Miss Twining has left an example of public spirit, of much work accomplished under difficulties, and of increasing efforts to make known the needs of many who could not speak for themselves. The better conditions of the sick in hospitals, under the Poor Law, and in their own homes, the appointment of women to serve on public bodies, the training and protection of young workhouse girls, the care of aged and lonely women, all engaged her powers, and in the latter cases led to her founding homes, which have proved of great value. Beyond these and many other interests, the sad position of poor people suffering from epilepsy appealed strongly to her sympathies. For many years Miss Twining took charge of a certain number of these women, who, while of superior education, were debarred from earning their living by their cruel affliction; she understood their needs and their difficulties, and her home was their home. Thus their loneliness was lessened, and good treatment, combined with the utmost care and patience, led in some cases to restoration to health. It was felt that Miss Twining would like her name to be remembered by the endowment of a memorial bed in one of the homes for women at the Chalfont colony, Bucks. She thoroughly approved of the methods pursued there by the National Society for Epileptics, and subscribed liberally to the funds of the society during her lifetime. The cost of endowing a bed at the colony is £200, and there is urgent need for such help. This has been paid over to the society, and some of the money will be spent on a first-rate "regulator" clock for one of the dining halls of the colony. A donation will be sent to the Women's Local Government Society, 17, Tot Hill Street, S.W., of which Miss Twining was a Vice-President at the time of her death. As a guardian Miss Twining's name will be long remembered, and she inspired many women to undertake similar work. She herself considered that, if understood rightly, one of the most responsible and the noblest title any human being could possess was "guardian of the poor." J. Wilson (Honorary Secretary and Treasurer),

10, South Hill Park Gardens, Hampstead; Lieutenant-Colonel E. Montefiore, Naval and Military Club, Piccadilly, W. (Joint Treasurer).

LOCAL MEDICAL COMMITTEES.

We are told that there is an idea in some parts of the country that the medical practitioners elected to form a Local Medical Committee must be themselves members of the panel. A glance at the Act, section 62, would have shown that this notion was erroneous. The Act says that the Insurance Commissioners must be "satisfied that such committee is representative of the duly qualified medical practitioners resident in the county, or county borough," or "any area for which a district committee has been formed." Nothing is said about the practitioners elected being on the panel, and we imagine that the omission was deliberate in order that all classes of the profession and all kinds of practice should be represented on the Local Medical Committee. We give above (p. 185) a short account of the important functions which the Act and Regulations assign to a Local Medical Committee.

THE subject selected by Dr. A. J. Jex-Blake for his Goutsonian lectures before the Royal College of Physicians of London, February 25th and 27th and March 4th, is "Death by Lightning and Electric Currents." Dr. F. de Havilland Hall in his Lumleian lectures on March 6th, 11th, and 13th, will deal with intrathoracic aneurysms.

Medical Notes in Parliament.

Health of the Navy.—Mr. Burgoyne asked on January 15th whether the recent official return on the health of the navy might be accepted as a criterion of the established strength of the personnel at any average moment; and, if so, wherein lay the difference between the figures there given and the estimated total for which money was taken in the year in question. Mr. Churchill said that the answer to the first part of the question was in the negative; and he readily admitted that the return referred to was somewhat misleading except for the special purposes of the Naval Medical Service. The figure given under the heading "Average Force," on page 98 of the return—namely, 117,100—represented the average number of men liable to treatment on board, or at the naval establishments, throughout the year. Cadets, Coastguard, and Royal Marines at head quarters were excluded, the latter being shown separately on pages 141, 147, and 166 of the return. The actual number borne on December 15th, 1911, was 133,498 officers and men.

Public Health (Acquisition of Water) Bill.—The Prime Minister informed Mr. Peto, on January 20th, that he feared it would not be possible to give facilities to proceed with this bill this session.

Royal Commission on Sewage Disposal.—Mr. Watt asked the President of the Local Government Board whether he proposed to introduce any legislation in accordance with the recommendations of the Royal Commission on Sewage Disposal so as to enable local authorities to deal satisfactorily with trade effluents which at present prevented purification of rivers; and, if so, would he say when he expected to introduce such legislation? The President of the Local Government Board said that a bill was in preparation, but he was not at present in a position to say when it would be introduced.

THE National Vaccination Officers' Association will hold a public meeting at the Battersea Town Hall on Thursday, February 6th, at 8.15 p.m., to consider the manner in which the President of the Local Government Board is dealing with the question of the loss of income sustained by vaccination officers owing to the number of persons claiming exemption from vaccination under the Vaccination Act and Order, 1907. Mr. John Burns has been invited to attend the meeting.

England and Wales.

(FROM OUR SPECIAL CORRESPONDENTS.)

LIVERPOOL.

THE PANEL.

IN Liverpool the Insurance Act in its various relations is still a burning question. An uneasy feeling prevails that the most has not been made of the strong position which the profession held locally. Down to January 4th Liverpool medical men were practically united in a determination not to place their names on the panels. On that date the Local Provisional Medical Committee quite unexpectedly expressed the opinion that the battle was lost, and that, in view of the situation, men who went on the panel could not be held to blame. An unofficial circular conveying this decision to the profession had the effect of a cry of "Sauve qui peut!" and by January 6th, when the first panel closed, 175 men had joined. This number has been officially declared adequate for the 250,000 insured persons in the area. In practice it is unlikely that they will prove equal to the task, and the irregular distribution of panel doctors among the insured persons will not help matters. Even now there are rumours of a compromise on the lines of the Manchester scheme. Of those who held out until the Special Representative Meeting on January 18th, some will probably join the panels, others will wait the result of the most recent movement in the direction of compromise. The Local Insurance Committee is discouraging "contracting out," and endeavouring to cast the onus of showing cause on the individuals who apply to make their own arrangements.

Surveying the whole course of events, men feel that the Association has suffered from the lack of a certain elasticity in constitution which would have permitted a more rapid adjustment of policy to problems which were changing from day to day. Probably better results would have been obtained by allowing more independent action to an executive elected on such a democratic basis.

DEATH OF DR. O. T. WILLIAMS.

The whole profession mourns the loss of Dr. O. T. Williams, who died last week at the early age of 36. A sketch of his career appears in another page of the JOURNAL. It can only be said here that in Dr. Williams the profession has lost one of the most brilliant of the younger generation of physicians, and in scientific research one of its most original and enthusiastic workers.

SIR RONALD ROSS.

Sir Ronald Ross's departure for London, where he has been appointed Physician for Tropical Diseases at the new King's College Hospital, will entail considerable changes in the School of Tropical Medicine, but for the moment these have not taken definite shape. He has accepted the offices of Professor of Tropical Sanitation in the University of Liverpool and Lecturer on Malaria in the Liverpool School of Tropical Medicine.

MANCHESTER AND DISTRICT.

THE ABERGELE SANATORIUM.

ONLY about nine months have elapsed since the South Manchester Board of Guardians opened the sanatorium for consumption at Plas Uchaf, near Abergele, and they have now agreed to transfer it to the Manchester Corporation. Plas Uchaf is an estate with a large mansion and grounds covering nearly 300 acres. It cost the guardians about £12,000 in addition to some further expenditure in making alterations to fit the mansion as a sanatorium. By the agreement for transfer the corporation undertakes to refund to the guardians all their expenditure on the estate and furnishing and alterations, and to accept all incipient cases of phthisis arising in the township of South Manchester which would in the ordinary course apply to the guardians. The corporation agrees to rent to the guardians the bungalow called Pen-y-Coed, in which there are at present eight children suffering from tuberculosis, so long as the guardians require it, or in the

alternative to receive such children and provide medical treatment for them at Plas Uchaf at a weekly charge to be agreed upon. It is further stipulated that the doctor and matron shall continue to serve the corporation on the present terms and conditions, that the corporation shall take over all running contracts and liabilities of the guardians in respect of the sanatorium, and that the costs of conveyance shall be paid by the corporation. The most important part of the agreement is that the corporation shall receive all the cases of phthisis for which the guardians would otherwise have been called on to provide, without distinction as to whether they are insured persons or not. The number of sanatorium beds previously at the disposal of the corporation for the treatment of insured and uninsured was far too small, and even with the addition of the Abergele sanatorium will be none too great, but the great advantage of the arrangement is that it will allow of a more systematic and co-ordinated control of all tuberculous cases under the single management of the committee of the Manchester Corporation.

THE CARE OF THE FEEBLE-MINDED.

At the annual meeting of the Lancashire and Cheshire Society for the Permanent Care of the Feeble-minded it was stated that there are now 255 boys and girls in the colony, 90 of whom are 16 years of age or upwards. They came from all over England and Wales, and many applications had been received with which at present the society could not deal. Plans for a hospital had been begun, but the money in hand was not sufficient to complete the work. In the day school there were 174 children, and both boys and girls had shown remarkable progress in the handiwork to which they were trained. The laundry girls, for instance, had earned a considerable sum of money, which was of substantial assistance towards their keep. The financial statement showed an increase in both income and expenditure, but it was satisfactory to find that the excess of expenditure over income was £200 less than in the previous year. The Lord Mayor of Manchester expressed the opinion that the strongest representations should be made to the Government to pass a measure which, while allowing the feeble-minded to live their lives as happily as they could, would prevent their going out into the world, marrying, and bringing fresh feeble-minded children into existence. Sir T. T. Shann, President of the society, said that in the report of the chief medical officer of the Board of Education, great praise had been given to the society's homes at Sandlebidge. Several speakers expressed regret that the Mental Deficiency Bill had been dropped to make room for more debatable measures, and Miss Dendy moved a resolution, which was passed, deploring the delay in the passing of the bill, and requesting the Government to pass it next session as amended in committee. The resolution added that without powers of detention, the help given to many individual cases was thrown away, and, without financial help, private charity must always be inadequate to deal with the greater number of feeble-minded persons needing care and attention.

BIRMINGHAM.

NEW CHILDREN'S HOSPITAL, BIRMINGHAM.

HER ROYAL HIGHNESS PRINCESS LOUISE will lay the foundation stone of the new children's hospital in Ladywood Road on April 23rd. The new hospital, together with the statue to be erected in Victoria Square, is the city's memorial to the late King Edward VII. For many years the old hospital in Broad Street has been inadequate to deal with the large numbers of patients urgently needing admission, and the old building is quite unsuitable for the work of a modern hospital; in addition, the lease of the present building has only a few years to run. The cost of the new hospital has been variously estimated at from £50,000 to £60,000. It is expected that the building will be completed by the beginning of 1915, and before that date £13,000 will have to be raised if the hospital is to be opened free from debt.

The new hospital will be a substantial brick and stone structure fronting to Ladywood Road, and the main entrance will be in that road. In the centre of the block

will be the residential accommodation for the staff, with offices and board-room. The out-patients' department will be erected at the extreme end of one wing when more funds are forthcoming, and on the other side provision is made for a large recreation room for the use of the nursing staff. The out-patients, operating, and x-ray rooms now to be put up will be of a temporary character only.

The in-patients' wards will be built at the rear and at an angle with the buildings in Ladywood Road; they will be approached from the main corridor, on either side of which will be rooms for the resident medical staff, matron, nurses, and dispensary. Adequate provision will be made for dealing with infectious disease, one of the most troublesome matters which the management of a children's hospital has to meet. In a special annexe of the administrative block are a group of rooms for the admission of in-patients. There they will be medically examined, and if a patient is found to be affected by infectious disease it will be taken into an isolation ward pending removal. The accommodation of the wards is for 150 children, but as open-air treatment will be an important feature of the work of the hospital, the number of patients may be considerably greater. There will be two main ward units on each of three floors, and in favourable weather patients will be wheeled out into the open air. Each wing consists of a main ward containing fourteen beds, a ward for five beds, in which a high temperature may be maintained, and a smaller room for the reception of children whose surgical dressings require renewing. A lift will give access to the operating theatres on the top floor. All floors will be fire-resisting reinforced concrete, and each ward will have an escape staircase for use in case of fire. The hospital will be heated throughout by a hot-water system. Among the adjuncts are a laundry and pathological department.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

IRISH MEDICAL PROFESSION AND THE FRIENDLY SOCIETIES.

On January 3rd the County Borough of Dublin Local Medical Committee drew up the following provisional arrangement for medical attendance upon members of friendly societies pending the extension of the medical benefit clauses of the National Insurance Act to Ireland, and last week sent a copy of them to all the practitioners in the county borough:

1. Societies approved for State insurance, a capitation grant of 7s. 6d., inclusive of drugs, for a member, his wife and family, to include certificates for State and other purposes.
2. Benefit societies which are not State approved, a capitation fee of 6s., to include drugs and certificates for the payment of sick benefits, but certificates required for State insurance purposes to be paid for at the rate of 2s. 6d. per certificate.
3. Members of female and juvenile branches (children under the age of 16 years) to pay a capitation fee of 3s., to include attendance, drugs, and all certificates.
4. There is no special rate for single men.
5. In the case of medical officership to friendly societies, where the payment is by fixed salary, the remuneration must not be less than, on calculation, would be produced by the above capitation rates.
6. That those doctors who, in compliance with the request of the Local Medical Committee, resigned from their societies in the last quarter of 1912, be not penalized by the societies for having done so, but that each medical officer be reappointed to his respective society (or societies) upon the conditions set out herein.
7. The arrangements for medical treatment must be made through the Local Medical Committee.
8. It was further suggested that in making arrangements under the foregoing terms an endeavour should be made to limit medical benefits to persons with a gross income of less than £160 per annum.

At a meeting of delegates of the medical profession from all parts of Ireland, held on Tuesday, January 14th, at the Royal College of Surgeons, with Dr. Robert Woods in the chair, a prolonged debate took place on the terms of this provisional settlement, and the following resolutions were passed:

1. This meeting of delegates, representing the whole profession in Ireland, repudiates the action of the Dublin Medical Committee in accepting the terms offered for attendance on members of friendly societies:

2. That we accept the same terms as those agreed upon by the British Medical Association until the 31st March, 1913.
3. That dispensary medical officers be requested to refuse certificates to dispensary patients under the Insurance Act, except on terms satisfactory to local medical committees, pending the settlement of the question.
4. The medical delegates of all Ireland assembled in Dublin on January 14th, 1913, on receipt of the report of Conjoint Committee, declines to appoint a medical committee with plenary power to negotiate final terms, as they are satisfied the amount of money available is not adequate to meet the cost of certification; but should the amount be supplemented to the extent of rendering an agreement possible, we empower the Executive Committee to take necessary action towards completing arrangements with the Commissioners.
5. That as the additional grant of £1,650,000 made by the Chancellor of the Exchequer to the British doctors for working the Insurance Act is an Imperial tax to which Ireland will contribute its share, we demand that a proportionate grant be made to Ireland on the basis of its taxable capacity, or in proportion to the number of insured, for the medical administration of the Act in Ireland, and thus afford the Irish parliamentary party an opportunity of redeeming its pledge to the Irish medical profession.

OYSTERS AND SEWAGE AT CORK.

Arising out of the recommendation of the Medical Officer of Health for Cork, that samples of shellfish should be obtained and submitted for bacteriological examination, the Local Government Board applied to the Public Health Committee in Cork for a copy of the report of any such examination. Dr. McCormack, Medical Inspector to the Local Government Board, attended the last meeting of the Public Health Committee, and reported that he had made inquiries into the circumstances connected with the four cases of enteric fever which occurred recently in Cork City, and were attributed to the eating of oysters gathered from the flats below Blackrock Castle, about two miles from the city. The liability to contamination arose from the large volume of crude sewage of the city which emptied itself into the river Lee at that point. The oysters are taken direct to Cork, and sold in the city at the public bars, restaurants, and in the streets. Dr. McCormack once more urged on the public health authority to obtain samples of shellfish and water from suspected layings in Cork Harbour and inlets, and submit them to bacteriological examination. The solicitor to the Corporation of Cork said that the difficulty lay in the fact that Blackrock was not under the jurisdiction of the corporation. The only thing it could do was to let it go to the public that oysters found within the tidal limits of the river Lee were more or less subject to be contaminated with sewage, and consequently were dangerous.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

LIVINGSTONE CENTENARY CELEBRATION IN GLASGOW.

A MEETING of the representative committee in connexion with the Dr. David Livingstone centenary celebration in Glasgow was held on January 15th in the City Chambers. The Lord Provost presided, and among those present were Principal Sir Donald MacAlister, K.C.B., Professor Glaister, M.D., Dr. Macintyre, Mr. A. E. Maylard, and representatives of several public bodies interested in the commemoration. It was unanimously agreed that a fund be inaugurated for the purpose of establishing a permanent memorial of Dr. Livingstone, and there was a full discussion as to the form which this should take. The committee unanimously resolved to submit to the public the following finding:

That a Livingstone Centenary Memorial Fund be established for the promotion (1) of medical missionary work in Central Africa, especially in connexion with the London Missionary Society, the Livingstonia Mission of the United Free Church, and the Blantyre Mission of the Church of Scotland, and towards the establishment of a Livingstone scholarship in Anderson's College Medical School for the training of medical missionaries; and (2) for the promotion of the scientific study of geography in the University of Glasgow by the endowment of a Livingstone lectureship or professorship.

An appeal is now being issued for subscriptions, and subscribers are asked to indicate to which section of the memorial they desire their subscriptions to be allocated.

GLASGOW CITY ANALYST AND PURE FOOD SUPPLY.

In his annual report Mr. F. W. HARRIS, the Glasgow Corporation Chemist and City Analyst, states that the number of samples examined each year had steadily increased since the department was established in February, 1900, and last year 4,832 samples were dealt with. Speaking of the Sale of Food and Drugs Acts, Mr. Harris stated that effectual control of food manipulation is of ever-increasing difficulty both from the analytical and administrative point of view. The avowed object of the manufacturer was to place on the market something which appealed to the public taste, and many processes and systems applied to foodstuffs were of questionable value. The question as to what is a pure article of food must under existing conditions be fought out in the law courts, and results frequently in decisions which were most unsatisfactory from the public health point of view. The present-day method of arriving at a definition of what is a pure article of food was both cumbersome and unsatisfactory, involving totally unnecessary expenditure both of public and private funds. The procedure before a properly constituted board of reference would be simpler and more satisfactory. The usefulness of such a board had been fully recognized in other countries and in the Dominions. Of the food samples examined last year 15.8 per cent. were found adulterated, compared with 11.9 and 13.5 in the two preceding years. In addition, out of 235 samples of milk officially tested 69 were found adulterated.

Special Correspondence.

PARIS.

The Cocaine Habit in Paris.—A Case of Paratyphoid Appendicitis.—Intestinal Obstruction from Cherry-stones.—Tribute to the late Professor Guinard.—Mediastinal Cancer.—Mitral Stenosis and Laryngeal Paralysis.

At a recent meeting of the Society of Mental Medicine a discussion on the cocaine habit in Paris was raised by Drs. Briand and Bessart, who cited examples in which persons addicted to cocaine had presented various hallucinations and delusions due to the habit. Dr. Provost described the various methods of administration employed, but spoke principally of the "snuff" method. Among the evil consequences of this method was, he said, perforation and ulceration of the septum nasi. Cocaine cannot legally be obtained in France without a qualified medical man's certificate; but, in spite of this, a great amount is sold in the Montmartre quarter. The drug can be obtained in some of the cafés, where, after a certain hour of the night, it is sold almost openly; and as many of the clients of these cocaine dens belong to the demi-mondaine class, this accounts for the fact that many of this class take to cocaine drugging.

M. Walther recently reported an interesting case of paratyphoid appendicitis to the Medical Society of Paris. A girl, aged 13, showed all the typical signs of acute appendicitis. At the operation thickening and oedema round the caecum was found, and the appendix was turgid and hard, with a small abscess and a coprolith at the tip. One of the paracæcal glands was enlarged and removed. After operation, the temperature rose to 40° C. each night for four days, and then gradually came down to normal. There was no peritoneal reaction to explain this rise of temperature, the result of Vidal's test was negative for Eberth's bacillus and paratyphoid A bacillus, but markedly positive for paratyphoid bacillus B. It appears probable, therefore, that the case was one of paratyphoid fever, complicated by an attack of appendicitis due to the paratyphoid bacillus B, which was found in the appendix and in the gland removed from the mesentery.

M. Souligoux has reported to the Society of Surgery the case of a patient admitted to hospital suffering from signs of intestinal obstruction. He admitted having eaten a quantity of cherries, and that he had swallowed the stones. Laparotomy was performed, and a tumour 30 by 20 cm. was found in the small intestine. This

tumour consisted of 770 cherry-stones. Entero-anastomosis was performed, and the patient recovered.

At the annual meeting of the Surgical Society of Paris, M. Rochard paid a tribute to the late Professor Guinard, who, as will be remembered, was killed in June, 1912, when leaving the Hôtel Dieu Hospital, after his morning's operations, by a lunatic who had been his patient. M. Rochard said that Professor Guinard had left his home for Paris with the fixed intention of one day becoming surgeon to the Hôtel-Dieu. All through his career Professor Guinard never forgot the "human" side of his profession, and took every opportunity of reminding his students that the charitable side of medicine and surgery must always be remembered. M. Rochard described the great surgeon's last illness, and how, before being operated upon, he gave instructions regarding the incision to be made and the search for the bullets lodged in the abdomen.

The difficulty in diagnosing many mediastinal conditions was illustrated by a case reported at a recent meeting of the Medical Society of the Hospitals by Drs. Bensaudi and Emery. The patient was a man aged 48, in whom diagnosis of cancer of the lung had been made by several physicians, and it was due to a secondary lesion which occurred on the septum nasi that the correct diagnosis was arrived at. On the septum nasi a gumma was visible and Wassermann reaction was markedly positive. After salvarsan was administered and the consolidation of the lung diminished, expectoration decreased and the patient put on weight and lost his cachectic appearance: x-ray examinations confirmed the diminution in the consolidation of the lung, and at present the patient is in good health.

At the same meeting Dr. Claisse reported two cases in which an extremely interesting and uncommon complication of mitral stenosis was observed. In both cases there was aphonia due to paralysis of the left vocal cord; both suffered from mitral stenosis, with marked enlargement of the left auricle, as proved by x-ray examination. In one of the cases *post-mortem* examination showed that the aorta was normal and there was no glandular enlargement, but there was marked hypertrophy of the left auricle and increased amount of fibrous tissue in the mediastinum. In both cases the paralysis appeared to have been due to pressure by the left auricle on the recurrent laryngeal.

Correspondence.

THE FUTURE ORGANIZATION OF THE ASSOCIATION.

SIR,—In the *Times* of January 17th appeared a letter from Dr. Davy, of Exeter, in which was urged the necessity of a postal vote of the members if the corporate opinion of the Association is to be fully ascertained; and in the same issue the editor of the *Times*, in a leading article, suggested that such a vote would afford probably the best solution of the present difficulties. Dr. Davy's argument may perhaps be supplemented by a modern instance. On the day immediately preceding the publication of his letter I moved, in the Marylebone Division, that the Representatives of the Division be instructed to propose in the Representative Meeting that no further action in reference to the pledge and to the Insurance Act should be taken until, by means of a postal vote, the wishes of the members of the Association had been definitely expressed. This proposal was rejected by a considerable majority. The meeting then proceeded to "instruct" the Representatives to press for the full rigour of the pledge, and consequently these six gentlemen were in a position at the Representative Meeting to advance some six to seven hundred votes, although as a matter of fact their immediate authority did not include more than forty members of the Division. I venture to ask whether a safe basis for any policy needing for its success the general support of professional opinion can be found in an arrangement which permits forty voters to appear as though they were really six hundred and fifty.—I am, etc.,

London, W., January 21st.

C. O. HAWTHORNE.

THE UNION OF MEDICAL PRACTITIONERS.

SIR,—As there have been many inquiries as to whether any attempt has been made in Leicestershire to carry out the trade union policy, which I with others advocated at the Liverpool meeting of the British Medical Association last year, may I, through your columns, inform those interested that, in accordance with the unanimous resolution of a large meeting of the practitioners of Leicestershire and Rutland, a committee was appointed to take action thereon.

Articles and rules were drafted in consultation with counsel and submitted to the Registrar, and a certificate of registration under the Trades Union Acts has now been received.

A copy of the rules will be forwarded to any one desirous of obtaining one, on receipt of 1s., by the Secretary, Mr. R. Wood, 6, Market Street, Leicester.—I am, etc.,

R. WALLACE HENRY,

Leicester, Jan. 13th. Chairman, Union of Medical Practitioners.

THE POST-MORTEM EXAMINATION OF
NAPOLEON.

SIR,—In your critical review, entitled "A Riddle of Relics," in which you deal with Professor Keith's most able and interesting lecture on the history of the specimens in the Museum of the Royal College of Surgeons, you were kind enough to quote a passage from my little book, *The Illness and Death of Napoleon*. The quotation is as follows: "From his (Rutledge's) account in the 'Lowe Papers' there can be no doubt that he never lost sight of the corpse until it was soldered down in the coffin." I should like now to state the nature of the evidence concerning the *post mortem* examination of Napoleon, on which such a positive assertion is based. The italics in the following quotations are mine.

The *post-mortem* examination was performed at 2 p.m. on May 6th in the so-called drawing-room of Longwood, an apartment about 15 ft. by 18 ft., and lighted on one side by two windows. It has been contended that this room was badly lighted, and that at the end of the examination the daylight was failing. But in the "Lowe Papers" (vol. 20,133, f. 126) there is a hastily written letter from Sir Thomas Reade, the Deputy Adjutant General in St. Helena, to Sir Hudson, dated, Longwood, May 6th, 1821, *± p.m.*, in which he says:

Nothing was said about the heart until Dr. Shortt ordered the body to be sewn up. . . . I was obliged to consent to its being put in a vessel and left, under the particular care, in the same room with the corpse, of Dr. Rutledge. . . . I shall wait here until dark and go to Alarm House.

It is, therefore, clear that the *post-mortem* examination was concluded before 4 p.m.; and in St. Helena there is little or no twilight, and darkness falls at about 6 o'clock.

It has been suggested that the supply of water necessary for the performance of the *post-mortem* examination was limited; but there must have been a sufficiency, for only a few months before Napoleon had ordered from the individual who has passed into history as the "one-eyed copper" a tub 12 ft. square for his garden, and had established a somewhat elaborate system of waterfalls from one reservoir to the other.

Sir Hudson Lowe did not attend the examination, and he gives his reasons for not being present in a conversation with the Marquis Montchenn. He states that he had never in his life attended a dissection, that he did not know what the effect might be, and that he had, therefore, directed Sir Thomas Reade to represent him. Whether Sir Thomas Reade had any qualms does not transpire; at any rate, he obeyed the order and wrote a long report of what took place at the examination. This report is to be found in vol. 20,133, f. 133 of the "Lowe Papers," and shows how closely he was watching the proceedings, and the care he took to prevent any tampering. He says:

The liver was afterwards examined. The moment the operator took it out, Dr. Shortt instantly observed it was enlarged. All the other medical gentlemen differed with him in this opinion. . . . At this moment the liver was in the hands of the operator, and upon my appearing desirous to see it close, he immediately took his knife and cut it open from one end to the other, observing to me, "It is good, perfectly sound, and nothing extraordinary in it." . . . After this I desired Dr. Shortt would give directions for the body being sewed up,

and I requested it might be done *previous to my leaving the room*. Dr. Shortt desired Professor Antommarchi to do so. . . . The heart was placed in a small silver cup, and given in charge to Assist. Surgeon Rutledge of the 20th Regiment, who was placed in charge of the corpse, and to whom I gave the *most pointed orders* that he was not to allow it out of his sight. . . .

From these two letters it will be seen that, at the *post-mortem* examination, which took less than two hours to perform, the most vigilant supervision was exercised. Seven British doctors and three combatant officers, all hostile to Antommarchi, the operator, were carefully watching his movements. Can it be supposed for a moment that anything he did could have escaped their notice?

Thomas Rutledge, the assistant surgeon to the 20th Regiment, and the junior medical man present, also gives his account. Those who knew Reade will understand the way in which he gave those "pointed orders," and the effect they would have upon a young doctor in the army, with a career depending upon his implicit obedience.

Rutledge has left two reports in the "Lowe Papers," vol. 20,133, f. 150, and f. 159. The first is headed "Memorandum during my visitations at Longwood from May 6th, 1821," and describes in detail how he guarded the body, which had been *sewn up and dressed*, and how he finally saw it placed in the coffin, and securely soldered down. In order to abstract parts from the cadaver, the thief would have to undress the body, to undo the suture, to find the intestines, to remove the pieces, and to sew up and dress the corpse again. Could it be done in less than half an hour, even supposing Rutledge had been absent for that period? But he mentions that after the coffin had been soldered down at 7.30 p.m. on May 7th he felt himself free to accept the invitation of Madame Bertrand to dinner. But he was not alone in his vigil from May 6th to May 7th, for Captain Crockett the orderly officer was with him, and all day on May 7th a constant stream of people paraded before the corpse, marshalled by Crockett.

The second report of Rutledge in the "Lowe Papers" is most important, for it is a critical commentary of the *post-mortem* appearances described in Antommarchi's book. Knowing the thorough untrustworthiness of Antommarchi, and the exposure of the many false statements he has made, it has always been a question as to how much of his account of the *post-mortem* examination can be believed. Now, those who assert that the *post-mortem* examination proved that hepatitis had existed, base their belief on a sentence in Antommarchi's report, in which he says:

The liver was closely united on its convex surface to the diaphragm, the adhesion extended over the whole organ, and was strong, cellular, and of long standing.

But in vol. 20,133, f. 159, of the "Lowe Papers," Rutledge quotes this sentence, and says:

There was no adhesion of the liver to the diaphragm excepting through the medium of a little coagulable lymph which I easily removed with my finger when taking out the liver for examination.

Again, in reply to Antommarchi's statement that:

The concave surface of the left lobe of the liver adhered closely and firmly to the corresponding part of the stomach, and that at every point of contact the lobe was sensibly thickened, swollen, and hardened.

Rutledge states:

The part of the left lobe of the liver which had been in contact with the cancerated part of the stomach was indurated, and there was a superficial thickening which extended to about the one-fourth of an inch round the circumference of the cancer. The remainder of the left lobe was free from disease.

Finally, Rutledge concludes his criticism with a gem of English prose, and says, "These trifling matters add to the number of mistakes which Antommarchi's book are replete with."

Both the official report, and that of Henry, speak of a small adhesion to the diaphragm, and with the direct contradiction of Rutledge it is impossible to believe that Antommarchi has stated the truth in his description of the condition of the liver and its capsule. Dr. Burton, in a letter in the "Lowe Papers" (vol. 20,214), tells us that Antommarchi expressed himself in agreement with the official report when it was read over to him, but on the advice of Count Bertrand, refused to sign it. Rutledge was the junior surgeon present at the autopsy, and it is quite conceivable that to him would be deputed the

unpleasant work of removing the organs from the body preparatory to their examination.

To show how dangerous it was, not only to act, but even to think, in a manner contrary to the official view, the *post scriptum* of a letter from Lowe to Lord Bathurst (vol. 20, 133. f. 170) may be quoted. Dr. Shortt had so far forgotten his official duty, that he had the temerity to say that he thought the liver was enlarged, while Arnott, who had been longer with Lowe, stonily maintained that it was normal. Lowe, therefore, writes:

Dr. Arnott has appeared to me to have conducted himself as a perfectly upright and honest man in not encouraging the desire evinced to ascribe the disease to the liver, and showed his judgement also in having an opinion to the contrary. Dr. Shortt, however, thought the disease proceeded from the liver, without his having even seen the patient alive, but he feels a little ashamed, I believe, of the opinion he has expressed.

But Arnott's reign of favour was short-lived, for when he published his book in 1822, both Lowe and Reade fell foul of him for having the impudence to say that the followers of Napoleon evinced sorrow at his death, and were devotedly attached to him.

A masterly criticism of the "Lowe Papers" can be read in *A Polish Exile with Napoleon*, by G. L. Watson, and all interested in this subject would do well to consult it.—I am, etc.,

London, Jan. 20th.

ARNOLD CHAPLIN.

SIR.—With reference to the lecture of Professor A. Keith published in the BRITISH MEDICAL JOURNAL of January 11th, it may interest your readers to know that there is a case of tooth instruments in the museum of the Royal Army Medical College, Millbank, S.W., accompanied by a card bearing the following inscription: "A case of tooth instruments which belonged to the Emperor Napoleon the First. The case is incomplete, but contains eleven instruments and five key extractor claws. Presented by Inspector-General J. Paynter, to whose father the case was given by Dr. Barry O'Meara, the ex-Emperor's medical attendant at St. Helena."—I am, etc.,

London, S.W., Jan. 22nd.

F. S. IRVINE, Major, R.A.M.C.

THE INTRACELLULAR PARASITES IN SYPHILIS.

SIR.—Since my paper on this subject appeared in the BRITISH MEDICAL JOURNAL on December 14th, 1912, I have received a number of letters concerning it, and some have appeared in the columns of the JOURNAL. The writers either state that they have confirmed some of my observations or that they have already seen, and in some cases have published, one or other phases of the structures I described in human syphilis. As I stated in my paper, many observers have described "bodies" in the lesions of human syphilis, and some have noticed "threads," "flagella," "tails," etc., but they do not seem to know what these bodies are. The latter are usually described as "pseudo-parasites," "perhaps parasites," "possibly parasites," "symbiotic structures," "vacuoles," "in my opinion they may be parasites," etc.

But this is not the point. It is not sufficient to find "bodies" in the lesions of a disease in one species of animal for them to be accepted as the causative agents of that disease. In the case of protozoal parasites some diffidence has always been exhibited before such have been accepted generally as disease-producing parasites because of the difficulty of applying Koch's postulates to the protozoa. More evidence is required than the mere finding of "bodies." It is even doubtful whether Schaudinn's discovery would have been accepted had not Metchnikoff and Roux inoculated syphilis into apes and again found the spirochaetes in the lesions produced. Indeed, it is not sufficient to see different shaped bodies in any one species of animal and to weave them into a life cycle.

The point is this: What are the "bodies" seen outside and within the coils of the blood and lesions in primary and secondary syphilis? Are they parasites, and have they any connexion with the organism known as *Spirochaeta pallida*, which is generally accepted as the causative agent of syphilis?

I have said that the bodies I have found are parasites. This is because they have been found in five different species of animals, and because they are accompanied by similar lesions in four of those species. I have named these parasites Lymphocytozoa, and I am publishing my reasons for the name in the forthcoming volume of the collected papers of these researches. We are a step further than the mere finding of "bodies." We now know the phases of the homologous blood parasite of guinea-pigs, which constitute the cycles of schizogony and sporogony. This has enabled us to name the guinea-pig parasite *Lymphocytozoon cobayae*; the gametes are spirochaetes, and these are formed in a definite manner. A similar parasite, *Lymphocytozoon lumbrici*, has been found in the vesiculae seminalis of earthworms; these also have a spirochaete phase developed in the same definite manner. Another prototype, *Lymphocytozoon pallidum*, has been found in the blood of cases of human syphilis, and these also develop into spirochaetes in the same way as the parasites of guinea-pigs and earthworms. Similar parasites have been found affecting rabbits and hares (*Lymphocytozoon leporis*) and rats (*Lymphocytozoon muris*). All these different species of the Lymphocytozoa resemble each other very closely in all their phases, and each species possesses gametes which are indistinguishable from spirochaetes.

In addition, the animals infected with these parasites—human beings, rabbits, hares, guinea-pigs—show lesions which also resemble each other, and which are the same as those of human syphilis.

Lastly, these parasites have been found in the circulating blood as well as in the lesions of the various animals infected. Two hundred consecutive cases of human syphilis have now been examined, and *Lymphocytozoon pallidum* found in every case. This same observation applies to all the animals showing similar lesions—the species of lymphocytozoon peculiar to the animal has always been seen. Moreover, so far as can be determined at present, these parasites—in human beings, rabbits, guinea-pigs—are amenable to treatment with mercury and arsenical compounds.

Therefore, I think we are now justified in naming these "bodies" parasites, and regarding their presence as diagnostic of disease in the various animals concerned, including human syphilis.

In consequence of several requests it has been arranged with Messrs. Evans, Sons, Lescher, and Webb, of London and Liverpool, to supply at a small cost jellies ready made for the examination of these parasites.—I am, etc.,

The John Howard McFadden Researches, S.W.,
Jan. 20th.

"OXYTOCIC."

SIR.—May I protest against the incorrect spelling of a word which occurs in a headline of the current BRITISH MEDICAL JOURNAL—"Pituitrin as an Oxytocic"? I have only seen the word once before, also misspelt, and it would be well to correct the error before it becomes widespread. If spelt rightly, "oxytocic," it might be a valuable word possessing the Greek characteristic of condensing into one word a whole sentence, "causing to bring forth quickly." The Greek *ὄγος* means sharp, keen, swift, all suitable adjectives to apply to childbirth, not excepting the last, if pituitrin fail us not. The latter half of the word is derived from *τόκος*, birth, and the Greek *κ* in English usually becomes *c* (not *x*), which gives us "oxytocic." Spelt "oxytoxic" the word can only have one meaning, "acting as a swift poison," and in these days of toxins there is much danger of misapprehension arising.

The etymology of the word "toxic" is interesting. It meant originally "of or pertaining to the bow," and hence was applied to the arrows which were tipped with poison, but the word was not used in this connexion by the classic Greek writers.—I am, etc.,

Birmingham, Jan. 19th.

H. EWAN WALLER.

ANTIVIVISECTION IN GLASGOW.

SIR.—I do not propose to bandy words with Dr. Walker over personalities and trivialities which can serve no useful purpose, and which have no bearing upon the subject I dealt with in Glasgow. Nor is it necessary for

me to disprove again statements which he only repeats, apparently under the impression that repetition will make them true. Your correspondent has so sufficiently answered himself that any further rejoinder from my pen is scarcely required. I therefore confine myself to the particular point regarding which he says: he has secured "positive evidence" against me.

He again declares in regard to my lecture that "another part was devoted to the immorality of drinking alcohol and the uselessness and danger of vaccination." I again reply: "This assertion is simply amazing and almost unpardonable: not one word about alcohol drinking or vaccination escaped my lips the whole evening." He produces, as evidence, an anecdote I gave after my lecture was concluded, in reply to an observation from himself in which he sneered at my being almost alone in my opposition to vivisection, and asserted that I had practically the whole of the medical profession against me. The anecdote, as his own quotation shows, had nothing whatever to do with "the immorality of drinking alcohol," but merely went to show that a minority in one generation became converted into a majority in the next. His inability to grasp the point of my argument I can only attribute to the extreme state of nervousness which appeared to possess him at the time.

Similarly in regard to vaccination, not a single word on the subject was mentioned by me in the course of my lecture. I simply stated, in reply to a question subsequently put to me by some one in the audience as to whether I believed vaccination to be a protection against small-pox:

Perhaps my best answer to that will be that I have probably mixed with as much small-pox as any medical man in this city, and yet I have neither been vaccinated nor contracted the disease. My own experience has convinced me that vaccination is no protection against it.

To say, as Dr. Walker does, that I "spoke at length upon both these subjects," is positively false. I never mentioned them. My lecture dealt wholly and solely with the subject of vivisection in its various aspects. Your correspondent, upon the other hand, dealt only in side issues, mostly of an irrelevant nature, as he seeks to do now.

Dr. Walker appears incapable of construing even a written statement correctly. His faculty for turning things upside down is in the following instance highly amusing. He says:

That Dr. Hadwen should consider the recovery of a micro-organism from the body of an individual inoculated with this organism as an astounding feat is more surprising than the feat itself, which any one with any experience in a pathological laboratory must have seen performed hundreds of times as a matter of routine.

Permit me to say I see nothing "astounding" in the "feat," nor could I have believed that my ironical remark at Dr. Walker's expense could possibly have been taken seriously! He must be strangely deficient in sense of humour. Even had I possessed no laboratory or medical experience whatever, I should have had no difficulty in subscribing to the simple and self-evident proposition he has so laboriously advanced.—I am, etc.,

WALTER R. HADWEN, M.D., J.P.,

President British Union for Abolition of Vivisection,

Gloucester, Jan. 20th.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

THE following degrees have been conferred:

M.D.—G. Browne.
M.B., B.C.—E. G. S. Cane, W. T. C. Pearce, F. Roberts.
B.C.—J. W. Joint, G. M. Parker, E. B. Smith.

UNIVERSITY OF LONDON.

THE name of the following successful candidate should be added to the list previously published:

Third M.B., B.S.—Vincent Glendinning, Guy's Hospital.

KING'S COLLEGE.

Special Lectures in Physiology.

A course of four lectures on recent advances in chemical physiology and pathology will be given by Dr. Otto Rosenheim

in the Physiological Laboratory, King's College, on the following Monday afternoons at 4.30 p.m., beginning on February 3rd.

The lectures are free to all medical students in London medical schools, and to all internal students of the University of London, and to medical men on presentation of their cards.

UNIVERSITY OF LIVERPOOL.

Professor Hebblethwaite.

It is with great pleasure we congratulate Professor Hebblethwaite, Registrar of the University, on his return to work at the university after a term's leave of absence owing to illness. Delighted with his recovery, we join in wishing him many more years of health and ability to do the work to which he is so devoted. The work of the University Settlement is progressing well in the newly erected buildings. In the south end of Liverpool the warden and his colleagues are busy with their social work. There is still a debt of £1,000 upon the building, and a sum of £3,000 is necessary and urgently needed for endowment. Those who are interested in the work sincerely hope that the funds will be forthcoming, and that the work will not be crippled for want of them.

Public Lectures.

The following public lectures will be delivered during the Lent term: At 8 p.m. on January 24th Dr. T. R. Bradshaw will lecture on "Some Aspects of the Doctor and his Work." Professor Ernest Glynn, the newly appointed Professor of Pathology in the University, will deliver his public inaugural lecture at 5.30 p.m. on February 21st, and he has chosen as his subject, "The Study of Diseases in Domestic Animals and its Importance to the Community." On March 7th, at 8 p.m., Dr. Kenneth Forbes, Lecturer in Education in the University, will lecture on "Convention and Conventionality in Teaching." All these lectures will be delivered in the Arts Theatre, and admission is free without ticket.

Prize Essay.

Mr. Robert Caspe, a medical student in his second year, has been awarded the first prize in a competition organized by the Home University Library for an essay on the value and use of such a library. Mr. Caspe is to be congratulated upon his success in an open competition of this character.

UNIVERSITY OF GLASGOW.

Final Year Medical Dinner.

A COMPANY of 140 attended the "Final Year Medical Dinner," held in St. Enoch Station Hotel on January 14th. Professor W. K. Hunter presided, and there was a good gathering of the medical professors and lecturers, including Professors Samson Gemmell, Sir Wm. Macewen, Myrdoch, Cameron, Muir, Glaister, Stockman, Munro Kerr, Bower, and others. A capital souvenir programme was prepared, illustrated by topical sketches, one of these, entitled "Childe Harold to the dark tower came," depicting the fortress of "General Practice," with a sinister figure of Mr. Lloyd George crouching behind the left wing of the tower, and flourishing a deadly-looking bludgeon. A photo gallery of "Men of the year" (1908-13) was also given, with a list of their names, and opposite each a more or less descriptive couplet. The list of guests was also provided with classic and other quotations for each. After the loyal toasts Mr. Ian D. Grant proposed "Alma Mater," which was responded to by Professor Samson Gemmell, who took occasion to refer to the affiliations which he said were in the air. The Technical College was to be affiliated; music, too, would soon have affinities; and he thought there was no reason why the Veterinary College should not come in also, and bring the university up to date. Professor Ralph Stockman replied for the guests, and Dr. J. Crawford Renton proposed "The Year," which was acknowledged by Mr. William A. Brechin.

General Council Register.

The Register of the General Council of the University of Glasgow for the year 1913 contains the names of 8,546 members, an increase of 301 on the previous year. At the annual revision 409 names were added, and those of 103 deceased members removed, including three who died respectively in 1892, 1899, and 1900, regarding whom information had only recently been received. There is still much room for improvement in the matter of intimating deaths and changes of address; no fewer than 187 reports last October were returned through the Dead Letter Office.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have been approved in the subjects indicated:

MATERIA MEDICA AND PHARMACY.—J. C. P. Bayley, J. D. Ferguson, C. T. Gasking.
ANATOMY.—J. B. Fairclough, J. D. Ferguson, L. Kahan, G. Noot, N. W. Rawlings, J. Totton, G. C. Wright.
PHYSIOLOGY.—C. G. Bump, J. D. Ferguson, W. Fox, H. C. C. Hackrey, L. Kahan, G. Noot, N. W. Rawlings, J. Totton, G. C. Wright.

Obituary.

GEORGE ALEXANDER GIBSON, M.D., D.Sc., LL.D.,
F.R.C.P.E., F.R.S.E., ETC.,
EDINBURGH.

We regret to have to report the death of Dr. George A. Gibson, of Edinburgh, which occurred at his residence, 3, Drumshough Gardens, early on Saturday morning, January 18th. He took an active part in the work of the Annual Meeting of the British Medical Association in Liverpool last year, for he not only gave the Address in Medicine on the Relations of the Circulation, but also introduced a discussion on non-valvular cardiac disease. He had himself suffered for several years from cardiac disease, and in August last his health broke down, and though he struggled bravely and hopefully on, the end has come before he had reached 59 years. He had led a constantly strenuous life. After his breakdown in August a cruise to Norway was suggested, but it brought no improvement. Thereafter complete rest was recommended, and for a time it seemed as if he were going to rally, but some three weeks ago these hopes were shattered; there was growing weakness and gradual decline.

George Alexander Gibson was a native of Perthshire, and was born on January 27th, 1854, at Kelliebank, Muckhart, in that county. He was the eldest son of George Gibson, solicitor, Alloa. He was educated at Dollar Academy and at the Universities of Glasgow and Edinburgh. The Bar, for which his father destined him, did not attract him, and he took to scientific studies, with the result that he graduated B.Sc. at the University of Edinburgh in 1874. From 1874 to 1877 he held the Falconer Memorial Fellowship. In 1876 he

had gained the degrees of M.B., C.M.; in 1877 the degree of D.Sc. He became F.R.C.P. Edin. in 1880, and graduated M.D. in 1881. In 1876 he was appointed a resident physician to the Royal Infirmary of Edinburgh. Thereafter he studied at Dublin, London, and Berlin. In July, 1878, he was appointed assistant physician to the General Hospital, Birmingham, but only retained the appointment till the end of the following year, when he settled in Edinburgh. Soon after he became lecturer in the extra-academical school. Then followed his appointment to the staff of the Royal Infirmary, where he remained for twenty-two years; at the time of his death he was senior physician. For ten years he was one of the physicians to the New Town Dispensary, and on its foundation he became physician to the Deaconess Hospital; this position he held for three years, when he was appointed consulting physician. He was principal medical officer to the Life Association of Edinburgh.

For some three years he was tutor in clinical medicine in connexion with the extramural school; for five years

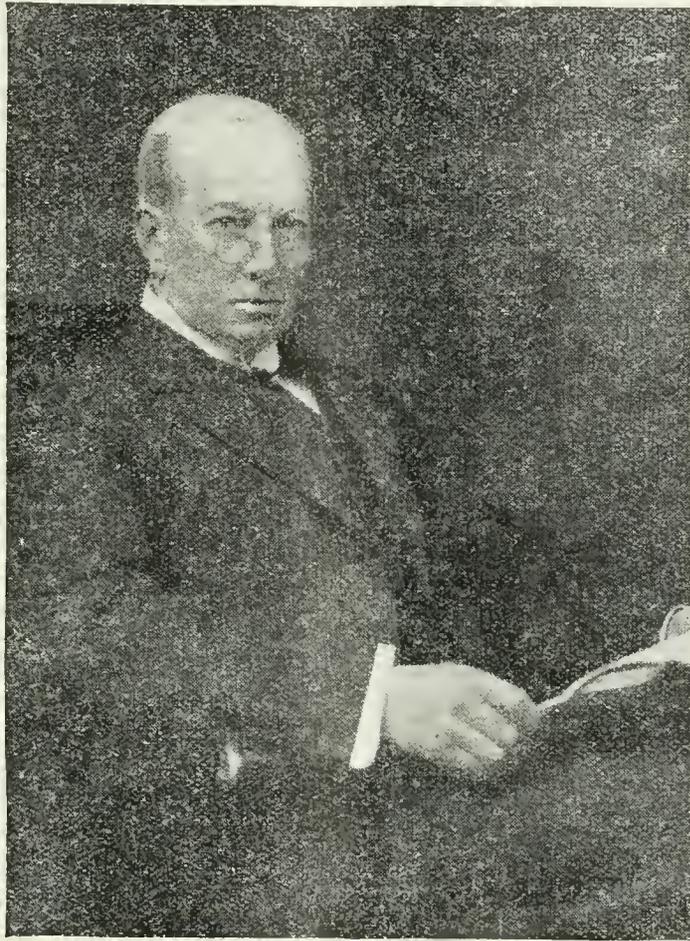

he was a lecturer in materia medica, and later a lecturer on the principles and practice of medicine in the same school. In 1897 he became one of the lecturers on clinical medicine in the Royal Infirmary. During these years he visited the universities and hospitals at home, as well as those of France, Germany, Italy, and America, in order to make himself more fully conversant with the methods prevailing in other medical schools.

He was honorary medical referee for the National Hospital for Consumption at Ventnor, lieutenant-colonel 2nd Scottish General Hospital of the Territorial Force, and a member of the Royal Company of Archers, the King's bodyguard in Scotland. He was at various times examiner in medicine for the Universities of Glasgow, Edinburgh, and Oxford; inspector of examinations for the General Medical Council. He had earlier been a demonstrator of anatomy in the University of Edinburgh.

He wrote many articles in the medical periodical press,

and was himself for some time editor of the *Edinburgh Medical Journal*. He wrote many articles for the last edition of the *Encyclopædia Britannica*, for the *Textbook of Medicine*, and for other works. With Dr. William Russell he was joint author of *Physical Diagnosis*, third edition, 1902. He wrote books on *Cheyne-Stokes Respiration* in 1892, on *Discases of the Heart and Aorta* in 1898, on *Nervous Affections of the Heart*, second edition, 1905, based on his Morison Lecture to the Royal College of Physicians of Edinburgh in 1902-3. This last book was translated into German. Quite recently he published a volume entitled *Memorials of Sir William Gairdner*, to which Sir Clifford Allbutt makes some references below.

At the age of 23 he was elected President of the Royal Medical Society and of the Dialectic Society of the University of Edinburgh. He was at one time Honorary Secretary to the Edinburgh Branch of the British Medical Association

Photograph by]

GEORGE ALEXANDER GIBSON.

[W. Crooke, Edinburgh.

and also of the Medico-Chirurgical Society of Edinburgh. At the meeting of the British Medical Association in 1898 he was vice-president in the Section of Medicine. For ten years he was secretary to the Royal College of Physicians of Edinburgh; subsequently he was on the Council of the College, and had he lived he would this year have been its President. He had been a member of the Council of the Royal Society of Edinburgh, Vice-Chairman of the Governors of the Medical School of the Royal Colleges, a director of the Town and Gown Association, inspector of examinations in Ireland under the General Medical Council, and a special commissioner appointed by the Local Government Board in connexion with the examination and registration of trained nurses. He was an honorary member of the Medico-Chirurgical Society of Norwich, and Correspondent Etranger d'Honneur de la Société de Thérapeutique de Paris. He received honorary degrees from many universities—the M.D. from Dublin, the B.Sc. from Harvard and Liverpool, and LL.D.

from St. Andrews and McGill. He was also an honorary F.R.C.P. of Ireland.

Such is the scaffolding of his life's work. But what of the filling up? He was a man of many interests and boundless energy. He was never at rest. He had always something on hand, and so wore himself out before his time. Apart from his outstanding position in the medical profession, he was a man of culture and of wide reading in general literature. He was not a man of one book. He was interested in everything. He was a most genial companion, of happy disposition, and an excellent friend. He saw the best in everybody. His friends were innumerable, both at home and in America. His teaching was of a high order, and he was a favourite with his students, in whom he took the greatest interest. He was interested in most field sports; latterly curling, fishing and golfing attracted him most. He was a member of the Honourable Company of Golfers, and was frequently seen on their course at Muirfield. He was a member of the University Club.

Dr. Gibson is survived by his widow, a son and a daughter.

The funeral took place from St. George's Church in Charlotte Square on Tuesday afternoon, where there was a very large congregation representing the two Royal Colleges of Physicians and Surgeons, the Territorial Forces, and the general public.

SIR CLIFFORD ALBUTT, Regius Professor of Physic in the University of Cambridge, has written the following appreciation of George Gibson's life and work for the JOURNAL:

The shock and distress of the announcement of the death of George Gibson are such as, for the present, to make us silent rather than vocal in our sorrow. My words must be few. It is not many weeks since Gibson's affectionate and interesting life of Gairdner came into our hands; and for many of us who knew both men well, and who are suffering year by year in the passing of old comrades, there is a still deeper note of sadness in this passing, as it were, of two generations from us. It seems but the other day that Gibson and I were sitting with Gairdner, then nearing death, in his house in George Square—Gibson his skilful and devoted physician, I a visitor to him for the last time. That austere and kindly home, under the shadow of his old University, was a type of both men, of the best of Scottish men. Dear Gairdner, one eye blind, the other armed with a strange conical shield, was on our entrance still undauntedly searching in some treatise of medicine for more light; and it was characteristic of both men that in this crisis of their deep affection they so ruled their hearts as to follow together every trace and winding of the elder man's malady; Gairdner acutely analysing every one of them as dispassionately as if the case were that of a hospital patient. Again the best of Scottish life—earnest and loyal, deep and true.

And with the same strength above passion, not many years later Gibson in his turn had to watch over his own dissolution: again by a heart disease, again in the very sphere of medicine which each had made his own, winning knowledge for us and honour for himself. Three years ago it would have been an unmixed joy to me to find near ourselves, then at Ambleside, Gibson and his family, at Lowwood, had he not been there, as a friend had forewarned us, on account of a breakdown in health. For no man could the prospect of long and healthy life have seemed brighter; but the action of his heart had been much disturbed, and myocardial change more than suspected. Dispassionately watching, as I have said, his own symptoms, he ascribed them to influenza—an opinion which seemed a probable one. It is true he had worked very hard; he had poured into his teaching, his large private practice, and his original researches all his gifts of energy, skill, and insight; and his private practice carried him far and wide over Scotland. But in my experience, both personal and medical, hard work hurts no healthy man, so long as he lives, as Gibson did, a physiological life. He was naturally a man of powerful frame and untiring energy, and in his happy home free from all worries. It seemed probable, then, that influenza, or some other such toxin, must have cut in upon him; and it was with some apprehension that his son and I witnessed his brave if rather wilful determination to reinvigorate his heart, then, as we all hoped, con-

valescent, by climbing, methodically no doubt, the fells behind his hotel. However, the method seemed to be justified. He returned to work, and I presumed his recovery to be complete until we heard that his amendment had not endured. And a letter from Mrs. Gibson was by no means reassuring; so it was with more regret than surprise that a few weeks ago I heard from Dr. James Ritchie that his condition had grown so far worse that there were grave fears for his life.

George Gibson had done much scientific medical work, and much inspiring teaching and research; and much more yet was, we hoped, to have come from his hands. A while ago, in answer to my inquiry, he told me that he had not yet perfected his large recording sphygmometer, on Erlanger's pattern, but was still at work upon it. It is hard to believe that all these labours, these teachings, this devotion to the sick who looked to him for succour, are finished; and we are too prone to murmur at the dispensation under which those whom we can least spare are taken away.

It is not yet time to appreciate Gibson's work in all its bearings; like himself it was strong, orderly, and accurate. In a recess in his library was preserved a remarkably complete series of books on diseases of the heart; he knew them well, and gave to the contents of each its due place in his own writings. Happily much of this survey he had made, and his admirable work on *Diseases of the Heart and Aorta* will keep its place also among the classics. But again, it is not the time yet for such reckonings and comparisons; we his many friends can now feel only that a strong, true, warm-hearted, and learned colleague has been taken from us. To me Gibson was twice a friend, a dear friend in himself, and a memorial of Gairdner, for in him much of Gairdner seemed still to live.

DR. WILLIAM RUSSELL (Edinburgh) writes:

It is unnecessary to enlarge upon the loss that Dr. Gibson is to the Edinburgh School of Medicine and to Scottish medicine. What is wanted from me is a personal estimate and appreciation of a man who has been a friend for forty years. In acceding to the request of the Editor of the BRITISH MEDICAL JOURNAL, I do so in that capacity, and in the hope that my words may in some degree express the feelings of many of his friends.

Gibson began his medical studies in Edinburgh after spending two years at Glasgow University, and at the outset was marked out from most of the men of his year as a student of science as well as of medicine. He had an excellent brain and a retentive memory, which made the details of science easy to him, so that at the end of his second year as a medical student he not only took the B.Sc. degree, but was awarded the Falconer Memorial Scholarship in Geology. This in itself made him a prominent figure amongst us. But this was only one side of him; the other side made his personality distinctive—he had a fine athletic figure, which he carried with grace, while he had the open, frank, friendly, and somewhat rollicking manner of a young man prepared to be on good terms with his fellows, and evidently looking at life in a spirit of the utmost friendliness. Everyone knew Gibson, and his circle of acquaintances was large.

Our friendship was formed at the end of our first summer in medicine, on board a steamer going to the North of Scotland, and the remarkable tenacity of his friendships was strikingly illustrated in our earlier relations, for it was he who kept us from drifting apart in those days. Looking back, as one has often, one has recognized how the faculties of mind, the genial, forceful, and yet easy bearing of those early days naturally developed into the erudite physician and the strong, yet sympathetic, and gracious bearing of the esteemed consultant. His personality was exceptionally attractive, and most people acknowledged it. He had nevertheless ardent dislikes and strong antipathies, and he carried into them the same frank and forceful manner. When he despised men and methods he did so openly, for he was no compromiser between what to him was upright and straight on the one hand and mean and crooked on the other. He always stood, and stood openly, on the side of honour and truth. For the lower forms of self-seeking he had the greatest contempt. The openness and frankness and easy courage of his manner often enabled him to

speak unpalatable truths without arousing a deadly animosity. In all medical affairs he took a keen interest and an active part, and was ever ready to give a helping hand to any good work.

As regards the professional side of Gibson's life, the most outstanding characteristics were his great devotion to the science as well as the practice of his profession and his extraordinary love of work; the latter was almost a form of dissipation with him, in so far, at least, as that he ignored the fact of the strongest of bodies having its physical limitations. The work he published had always a literary distinction and displayed the man of erudition and of critical faculty. There was no mistake about that, however much you might differ from his judgement. He was a great student and a cultured exponent of what to him was the truth in the particular department of medicine he might be dealing with at the moment. His chief interest, although by no means his only interest, was centred in cardiac diseases. The inspiration of this came from Dr. G. W. Balfour, to whom Gibson had been a house-physician in the old Royal Infirmary. It was in this department that he made his earlier reputation, but Gibson never took up the narrow and restricted view of the "specialist." The whole field of medicine attracted him.

As a teacher of students, a man such as I have endeavoured to outline Gibson as being was bound to be popular and to attract many to his clinics, and this he did. The students were fond of him, and his house-physicians and clinical clerks were devoted to him in a special measure. He had the faculty of knowing them by name and remembering them; he was ever ready to help them, and he kept in touch with many of them scattered all over the world. The statement that no one can take Gibson's place in the affection of his friends seems like a platitude, yet it means that no one compared Gibson's personality with any other—it was unique: he was Gibson, and we knew him and we loved him.

Mr. Jas. W. B. Hodson (Edinburgh) writes:

The whole world of medicine is familiar with the work of the late Dr. George A. Gibson as an investigator, an author, and a cultured and skilled physician; while the academic distinctions conferred upon him at home and across the seas were an acknowledgement of his scientific attainments.

In the later Seventies, in the anatomical department of the old university buildings, where a second year's man was dissecting, a tall and somewhat spare demonstrator with a breezy and kindly manner offered to help the student with his difficulties.

From that day a friendship began between the writer and George Gibson which became closer and more intimate after Gibson's return to Edinburgh from Birmingham. For well over thirty years we have been closely associated in public and in private, and in writing a short appreciation of Gibson one would refer to the latter rather than to the former and to his interests in the Edinburgh Medical School.

The debt which the Edinburgh School of Medicine owes to him is one which the present generation of teachers hardly can recognize.

The school founded by the Royal College of Surgeons, which had given the first professors to the newly-established medical faculty of the university, had gradually been dissociated from the Royal Colleges and had resolved itself into a mere collection of separate teachers. It had no position as a whole and no form of government. Gibson was far-sighted enough to see that in such a state it could not maintain its position, and he threw himself with all his wonted energy into a scheme of reform whereby it was made a homogeneous whole and was again brought under the aegis of the Royal Colleges. The result was that when the Carnegie Trust was instituted the School of Medicine of the Royal Colleges was in a position to represent its claims and to secure the benefits which it now enjoys on equal footing with the universities. For many years he was Chairman of the Business and Finance Committee; he was from its institution a member of the governing board of the school, and at the time of his death its chairman.

From the first Gibson was one of the promoters of the foundation of the Royal College of Physicians' Research

Laboratory, and his unflinching support has had much to do with making it the success it has become.

He was one of the founders of the Pathological Club—that most successful of informal societies—and, in its early days, one of its strongest supporters and most regular attendants, and none of those who can recall these early meetings will forget the enthusiastic and genial way in which he threw himself into the discussions, bringing to the subjects touched upon his wide knowledge of science and of medicine and his keen intelligence.

He was the representative of the Royal College of Physicians on the General Medical Council, and when he took his seat last May he was welcomed by his colleagues as one who, by his thorough knowledge of educational affairs, sound judgement, and genial presence, would speedily become a valuable and prominent member of that body.

Gibson had the welfare of the medical student at heart, while his ability and culture as a clinician attracted to his wards the best type of men in every respect. To them he was counsellor and friend as well as the beloved teacher, and his memory will ever be held in affection where Edinburgh men are gathered. There are scattered throughout the empire not a few successful practitioners who can directly attribute their success to the influence, advice, and help of George Gibson. He set them a noble example. The very soul of honour in his dealings with all men, he abhorred meanness, scheming, and self-seeking, and when occasion arose he would denounce such in no measured terms.

Gibson's relations to his patients all through his professional life were characterized by an unselfishness and devotion which made him beloved of all; he never spared himself—it was sufficient that a fellow-creature required his assistance, and he gave his best, even to the humblest. We have heard his entrance into a sick-room described as a "ray of sunshine." Had he considered himself more and husbanded his strength in recent years when the calls upon his time became greater and greater he might have been with us to-day.

He was a many-sided man whose interests were not confined to medicine; widely read in the classics and in general literature, his ready and fluent speeches were embellished by apt quotations. He had travelled much at home and abroad, and readily made widespread and enduring friendships. He loved, however, best of all, the hills and straths of his native land, and was well versed in its traditions and folk-lore. To those of us who had the privilege of enjoying his intimate friendship, the most vivid memories must be of George Gibson in holiday time, when, throwing aside professional cares, he became the jovial boy he remained in heart to the end. His tremendous zest in life, his enjoyment of all the beauties of Nature, his overflowing generosity, his humour, his modesty, and his sincerity made him the prince of good fellows, while his wide general knowledge rendered intercourse with him a constant delight.

There is no one who can fill the blank caused by Gibson's death, while those who have been intimately associated with him in his professional and social life, who had reason to be thankful for his skill and devotion in the time of illness, who have been his companions on moor, on loch, or on golf links, cannot yet realize the extent of their loss.

Professor SAUNDY (Birmingham), writes:

I should like to express my regret at the premature death of my old friend Dr. George Alexander Gibson, and my admiration for his character, ability, and attainments. My first recollection of him is when he joined the Royal Medical Society in the winter of 1874-5, but I did not get to know him well until four years later when he became my colleague as assistant physician at the General Hospital, Birmingham. Although after one year of service Edinburgh reclaimed him, our friendship continued up to his death. I have watched his progress with pleasure, and it was with especial satisfaction that I moved the vote of thanks to him at Liverpool last July, where he delivered the Address in Medicine, which is the highest scientific distinction that the Association has in its power to confer upon a physician. Some who were present may remember that he had difficulty in making himself

heard; this was partly, perhaps, due to the acoustic qualities of the theatre, but mainly because he was feeling exhausted. He told me that he was badly in want of a rest. He had been working very hard at his practice, for success had come to him, and he was in demand as a consultant all over Scotland. From Liverpool he went straight to join a steamer for a holiday in Norway and Sweden, planned so that his journey might be taken everywhere by water. It seemed likely to afford him the physical repose he needed, yet he returned home so ill as to be obliged to go to bed, and, although by the end of November he was able to take walks of some miles, the improvement unhappily did not prove permanent. His loss is great not only to his family and his friends, but to the medical world of Edinburgh and to all who are interested in the scientific progress of medicine. His life has been all too short, and his early death has robbed him of the harvest he had so well earned. His numerous contributions to the science of medicine are well known and will survive him. Had he lived he would undoubtedly have succeeded to such posts of honour as his University and the College of Physicians have it in their power to bestow. He was deservedly popular, for a more frank, joyous, generous, unselfish man never lived. He had an inexhaustible fund of humour, was an excellent after-dinner speaker, a charming companion, and a faithful friend.

Non, Torquate, genius, non te facundia, non te restituet pietas;
Infernis neque enim tenebris Diana pudicum liberat Hippolytum
Nec Lethæa valet Theseus abruptere caro vincula Perithoo.

Dr. JAMES MACKENZIE writes:

It was with the deepest regret that I heard of Dr. Gibson's death. It was known that he had been ailing for some months, but the news of his death has caused a great shock to many of his friends. Until lately he had been so full of buoyant energy, and led such an active and strenuous life, that it is difficult to realize that he has gone.

His whole life has been one of tireless energy. In the early days of his professional career he laid the foundations of his great reputation by long and patient investigations, both clinical and experimental. A good deal of the work of those early days has not been properly appreciated—such, for instance, as his investigations into the nature and causes of the incompetence of the valves of the heart. Although in later years his researches were confined to the clinical field, his interest in and appreciation of experimental work never abated, and few people had such a thorough grasp of the advances which have been made in the various fields of clinical medicine.

In the department of cardiology probably no one had such a familiar acquaintance with the writings of authorities, from the earliest to the most recent times. He could always tell the origin and development of any idea which had a recognized place in the clinical or experimental world. His own writings were always characterized by a wealth of illustration, and this was not confined to those taken from scientific authorities, for he had laid under contribution the whole field of general literature in order to embellish and illustrate his meaning. Thus it was that his contributions to medicine were graced with an attraction that compelled attention for their literary as well as their scientific merits.

The commanding position which he held in the profession was world-wide, not only by reason of his scientific attainments, but also from the remarkable character of the man himself. He was not only a man of wide culture, but he was possessed of a genial humour which ever and anon lighted up the subject of his discourse. Those who were brought into intimate contact with him felt his peculiar charm. Large-hearted and genial, he was a man to rejoice with, and a man whose cheerful disposition invariably brightened his surroundings; he was a man, too, of great kindness and truly sympathetic, as those who in distress have met him well know. His self-sacrificing disposition was almost proverbial, for no one ever appealed to him in vain, and many a one could tell of infinite labour and trouble he has given in order to help a friend in difficulties.

While the world may deplore the loss of a distinguished and eminent physician, those who knew him deplore the loss of a big-hearted and lovable man.

J. E. GARNER, M.D., ABERDEEN,

PRESTON.

WE have the very great regret to record the death of Dr. J. E. Garner, Representative of the Preston Division of the Lancashire and Cheshire Branch. In that capacity he attended the Special Representative Meeting on January 17th and 18th. He returned home on Saturday evening apparently in his usual health, but on Sunday morning suffered an apoplectic seizure, to which he succumbed on the following day.

John Edward Garner was the son of Captain John Garner, R.N., and was born sixty years ago in Aberdeen. He received his education in the university of that city, and graduated M.B., C.M. in 1873, in which year he was appointed junior house-surgeon to the Preston Royal Infirmary. In the following year he became senior house-surgeon, a post he retained until he entered private practice in Preston in 1876. In 1881 he proceeded to the degree of M.D., and in 1886 was appointed honorary medical officer of the Preston Royal Infirmary. For over thirty years he had been medical officer of the first district of the Preston Union. He was an active member of the British Medical Association, in the work of which he took a great interest, and was a member also of the North of England Obstetric and Gynaecological Society.

Dr. Garner was much interested in the various phases of Church work. For over twenty years he was vicar's warden at St. James's Church, and took an active share recently in raising a special fund for beautifying the interior of the church. His interest in sport was shown by his being one of the founders of the Preston Golf Club, of which he was captain from 1895 to 1905; on resigning that office the members presented him with his portrait, which now hangs in the club-house. He was a member and had been president of the Curling Club, and was a member of the Bowling Club. The Preston Board of Guardians, at its meeting on January 21st, adopted a vote of sympathy with the family of Dr. Garner, who was senior medical officer of the union. Dr. Garner leaves a widow, three daughters, and two sons, one of whom, Dr. Colin Garner, has for several years been associated with him in practice.

C. W. MARRIOTT, M.D., ST. ANDREWS, M.R.C.P. LOND.,
F.R.C.S. EDIN.,

READING.

Dr. MARRIOTT, who was Representative of the Oxford and Reading Branch of the British Medical Association in 1905-6, died on January 9th, his 80th birthday, after a short illness. He was born at Leamington on January 9th, 1833, and educated at Bedford. He studied medicine at University College Hospital, and afterwards at Paris. He then began practice in his native town, where he remained until 1891, when he went to Reading. He was appointed a physician to the Royal Berkshire Hospital in that town, and held that post until the end of 1912. Dr. Marriott was a justice of the peace for Berkshire, consulting physician to the Helena Nursing Home, and to the Berkshire Friendly Society, and a medical visitor in lunacy for Berkshire. He was also physician to the Queen Victoria Institute and County Nursing Association. Besides holding these civilian appointments, Dr. Marriott was surgeon to the old Warwickshire Militia, which afterwards became the 4th Battalion of the Royal Warwickshire Regiment, and he retired as surgeon-lieutenant-colonel. He not only had a large private practice, but his total hospital work extended over fifty-four years, as in Leamington he had been for a long period associated with the Warneford Hospital.

Dr. Marriott was extremely popular both in Leamington and in Reading. He was a keen sportsman, and in his younger days an excellent shot. Dr. Lansdown Guilding, at a meeting of the Reading Pathological Society on the evening of Dr. Marriott's decease, referred to the great services which he had rendered to humanity, and to his kindness, his geniality, and his wit. Dr. Marriott was a very good friend, and he had that great virtue that no one ever heard him say an unkind word of any one. Though always active in hospital and private practice, Dr. Marriott wrote but little. He was a Churchman, and a Unionist in politics.

OWEN T. WILLIAMS, M.D., B.Sc.LOND., M.R.C.P.LOND.,
ASSISTANT PHYSICIAN, ROYAL INFIRMARY, LIVERPOOL.

It is with deep regret that we have to record the sudden death of Dr. O. T. Williams, of Liverpool, Honorary Assistant Physician to the Liverpool Royal Infirmary, on January 15th, at the early age of 35 years, of acute pancreatitis. He was a native of Liverpool, and was educated at the Liverpool Institute and the Liverpool University. His career throughout his whole course of study at school and university showed one long unbroken record of brilliant successes. He entered the university as a county scholar from the Liverpool Institute, and during his period of undergraduate study at the university carried off every possible honour and distinction in scholarship available along his course. He graduated as Bachelor of Science, London, in 1900; in 1903 he obtained the degree of Bachelor of Medicine, with honours in medicine, and in the following year he took the M.D. The Membership of the Royal College of Physicians, London, was added to the long list of his achievements in 1907. In the years following his graduation Dr. Williams continued his study of the science of medicine in British and foreign schools of medicine, at the Universities of Liverpool, London, Berlin, and Johns Hopkins, Baltimore. Everywhere throughout his post-graduate career he earned the high esteem of those under whom he studied, and his ripe knowledge he placed freely and wholeheartedly at the service of Liverpool when he was appointed, in 1908, to the honorary staff of the Royal Infirmary.

The special province of medicine which claimed his devotion was the bio-chemistry of the processes of disease especially in relation to the problems of digestion and nutrition. Although his career, so full of brilliant promise, lasted for only a few years, he had already achieved a success which will endure in the annals of science. He was already a master in his science, and co-workers in the acquisition of knowledge of this newest branch of medicine throughout the scientific world will lament the calamity of his death no less keenly than his colleagues in Liverpool. Dr. Williams conducted his researches in the bio-chemical laboratory of the university, and he always had working under his direction a number of the younger graduates of medicine whom he had fired with some of his own enthusiasm for inquiry into the chemical problems of disease. He held the position in the university of lecturer on pharmacology and demonstrator of bio-chemistry, and in these capacities he endeared himself to all the research students by his willing help in every difficult problem. Full as his mind was of new ideas demanding the test of experiment, he always found time and energy to help others, to cheer them on to victory, and rejoice with them in their successes. It is this kindness of heart and nobility of mind that all who knew him remember to-day, and this is the recollection of him that they will always cherish.

As it was in the laboratory, so was it on the other aspect

of his life-work in the hospital. His wonderful ability as a teacher was prized by the students, his knowledge and skill as a physician were admired by his colleagues on the staff, but it was his depth of human sympathy which endeared him to every one around him, so that patients, students, nurses, and colleagues alike felt that he was a friend upon whom they could depend. Dr. Williams possessed one of the rarest gifts in medical science—a capacity for correlating clinical work and scientific observation—and his work in the laboratory always stood in close relationship to his study of cases by the bedside. He was a master mind in both domains, and yet he never lost sight of the human aspect of his work. He took a deep interest in the lives of earlier workers in medical science, and the title of his recent memoir, "Christian Hertes, one who championed the cause of idealism in medicine," might be applied appropriately to his own life-work.

Photograph by OWEN T. WILLIAMS. [Melvington's Ltd., Liverpool.]

Professor BENJAMIN MOORE writes: On behalf of his colleagues in research at the Johnston Bio-chemical Laboratory of the University, may I be allowed in a few words to express our sorrow at the loss of our friend in life, and in the pursuits we have loved together? For ten years we had worked together cheering one another in the vicissitudes of our inquiries, and rejoicing together when discovery came to any of us; and now in the prime and glory of his strength he has gone from his labours, and no more shall we see his pleasant smile, or hear his voice to cheer us in the labours of the day. Yet he has left with us a thing of wondrous beauty, which will abide with us for ever un tarnished by the flight of time. The memory of a noble life, filled with the highest ideals that our profession can give remains with us like the thought of the beauties of an eternal springtime untouched by the breath of winter.

He lived unselfishly for all that was highest in his science and all that was best and loveliest in life. The thoughts and aspirations that he planted in our minds can never die, and he in them will live in us, and from us pass to live in others.

GEORGE GRANVILLE BANTOCK, M.D. EDIN.,
F.R.C.S. EDIN.,

CONSULTING SURGEON TO THE SALARIED FREE HOSPITAL, LONDON. This well-known gynaecologist, so prominent in the Eighties, when abdominal surgery was rapidly developing beyond the boundary of ovariectomy, and when Listerian surgery was at its apogee, died in London on January 15th after a lingering illness. Bantock was born at Dunrobin, Sutherlandshire, on October 10th, 1837, but was of a Suffolk, not a Scottish, family. He studied at Edinburgh University, worked as an unqualified assistant in England for three years, and being appointed surgeon to a whaler went on a cruise to Melville Sound, in Arctic America. He returned to Edinburgh, took the degree of M.D. in 1861 and the diplomas of L.R.C.S. and L.M. Edin. in the same year. He practised at Chester

for several years, but in 1865 went to London and was elected surgeon to the London Surgical Home. At that institution he soon distinguished himself for his manual dexterity, especially in plastic operations on the perineum and vagina. He also undertook ovariectomy with success, so that in 1869 he was elected physician for out-patients at the Samaritan Hospital, and assistant surgeon in 1877. In the middle of the next year Sir Spencer Wells retired, and Bantock and Knowsley Thornton became full surgeons. Bantock did not retire until 1896, six years after the hospital was built as it now stands in the Marylebone Road. Its previous quarters, so closely associated with Sir Spencer Wells's ovariectomies, were in Lower Seymour Street, Portman Square.

Bantock distinguished himself greatly in advancing the surgery of uterine fibromyoma. As the intraperitoneal treatment of the stump was associated with disastrous results thirty years ago, and panhysterectomy was rarely practised, he employed the serro-nend with results good at that time, as the mortality in those days was very high. He was a great advocate of draining Douglas's pouch through the lower end of the abdominal incision, after Koeberlé's method. Foreigners used to visit the hospital in large numbers, and took great interest in his operations. The Italians in particular were impressed by his manner and his methods, and in return he learnt to speak their language with ease. Bantock was also highly popular in America. In 1887 he crossed the Atlantic, operated in American hospitals, and gave an address on abdominal surgery before the Canadian Medical Association. He was elected an honorary fellow of that institution and of the American Gynaecological Society, and was also associated with several similar learned bodies in Europe.

In 1883 there was a schism in the ranks of the Obstetrical Society of London, and he was one of the original members of the British Gynaecological Society, which was founded in December, 1884. He held the office of President in 1887, and his inaugural address, delivered on January 26th in that year, is preserved in the third volume of the *British Gynaecological Journal*. It was a condemnation of Listerism. The true secret and merit of that system, he contended, was the cleanliness which it ensured, but the spray and carbolic solutions were superfluous or even harmful. He had, we must remember, the high authority of Sir William Savory in support of his views. Further research has proved that neither were right in their arguments, although they reasoned right on wrong premises. Antiseptic chemicals, it was found, do damage the tissues which they touch, and thus expose them under unfavourable conditions to infection. Absolute cleanliness was aimed at by Bantock, and he did his very best to ensure it, being one of the cleanest operators in London, but he flourished before it was found that asepsis can only be attained by a special technique, soap, nail-brushes, and filters being insufficient. Bantock outlived the spray and the chemical antiseptics applied to the peritoneum, and in his later days operated occasionally with sterilized water, instruments, and dressings. Most assuredly had aseptic methods as now practised, been at his service in the Eighties he would have had results even better than those he could claim, and did proclaim in his inaugural address.

In 1888 Dr. Bantock took an active part in a discussion at the Obstetrical Society on electrolysis in gynaecological practice. He actively condemned the Apostoli treatment, and declared that he had at the time no confidence in the method, failing to find evidence sufficient to convince him of its utility to anything like the extent claimed for it by its advocates; while he stood on one side with his mind still open to conviction, he was content to allow others to pursue it, provided it were done in a truly scientific spirit and free from the empiricism which at that date characterized it. The President (Sir John Williams) supported Bantock's view, as did many other authorities. It was made clear that Apostoli's results were quite unconvincing. Subsequent experience justified this unfavourable view of the method.

In purely manual dexterity Bantock excelled his distinguished predecessor and his able colleague, and to that fact, there can be no doubt, was due many good results, which would have been replaced by death or had sequelae had the operator been slow, heavy-handed, and careless

about clean water, sponges, and dressings. His plastic operating was admirable, and the short treatise, *Treatment of Ruptured Perineum*, was perhaps the best of his writings, which elsewhere consisted mostly of papers in the transactions of societies and articles in medical journals.

After retiring from the active staff of the Samaritan Hospital, Bantock practised in London for several years, and then moved to Pinner, Middlesex. For the last three or four years, spent in retirement, he lived at King's Norton, near Birmingham. His health rapidly failed last year, and he returned to London in the autumn.

Bantock was a very familiar figure in London twenty years ago. He was of medium height, and wore a long, pointed beard, which gave him a venerable aspect; in short, he was a handsome man of a very "professional" appearance. He was a skilled salmon fisher, having learnt the use of the rod and the fly in his early boyhood, and greatly distinguished himself in this respect in Canada during his tour in 1887.

Dr. Bantock was married, and leaves a family of four children, the eldest of whom, Mr. Granville Bantock, is known as an eminent musician.

On Saturday, January 18th, the funeral service was held at the Crematorium, Golder's Green; the ashes were deposited at Kensal Green in the afternoon.

WILLIAM TAYLOR COLBY, M.D., J.P.,

MALTON, YORKS.

The death took place on December 22nd of Dr. William Taylor Colby, of Malton, a medical man equally well known both in social and professional circles in the North Riding of Yorkshire. One of the oldest members of the medical profession in the North of England, he was among the senior of those surviving students of St. Thomas's who attended its medical school in the days when it was in the borough. Dr. Colby was born in May, 1827, and entered St. Thomas's in his twenty-first year; he became M.R.C.S., L.S.A. in 1851, and took the M.D. degree of the University of St. Andrews at a later date. One of his contemporaries at St. Thomas's was Sir Thomas Boor Crosby, and those on the teaching staff under whom he directly served included Sir John Simon and Mr. Le Gros Clark. In other than medical connexions in Yorkshire, where he was known as a staunch Conservative in politics, he had attained corresponding seniority, for he was one of the oldest justices of the peace for the North Riding, and was among the first twenty-eight volunteers enrolled at Malton. They helped eventually to form the 2nd Volunteer Battalion of the Princess of Wales's Own Yorkshire Regiment. With this corps Dr. Colby remained connected for a very long period, and finally retired with the rank of Surgeon-Lieutenant-Colonel and the long service Volunteer decoration. Dr. Colby was an early member of the British Medical Association. He maintained his interest in gardening and sport. He himself was an excellent shot, and, despite his advanced age, had been out with the guns a month before his death. This took place when he was within four months of completing his eighty-sixth year, and was largely the outcome of anxiety over the illness of his eldest son. He had five children—three sons and two daughters, two of the former being members of the medical profession.

JAMES COULDREY, M.R.C.S. ENG., M.S.A. LOND.,

SCUNTHORPE, LINCOLNSHIRE.

WE regret to record the death of Dr. James Couldrey, which occurred at his residence, Fairholme, Scunthorpe, Lincolnshire, on St. Thomas's Day last, aged 62; he was unmarried. He was the third son of the late Mr. Thomas Couldrey of Abingdon, Berkshire, and was educated at the grammar school of his native town under the late Rev. Dr. Strange. On leaving school he was apprenticed to his cousin, Dr. Thomas Knight of Brill, Buckinghamshire. Subsequently he entered Charing Cross Hospital, London, where he had a brilliant career, gaining medals for materia medica and medicine. He became a Licentiate of the Society of Apothecaries of London in 1873 and later a Member. He took the diploma of M.R.C.S. Eng. in 1875. He was a member of the British Medical Association and of the Royal Society of Medicine. He was the oldest practitioner in Scunthorpe, having practised there thirty-

seven years. He had an extensive practice and held the appointments of Medical Officer and Public Vaccinator for the Scanthorpe district in the Glanford Brigg Union, of Certifying Factory Surgeon, and of Honorary Surgeon to the Frodingham Cottage Hospital. His contributions to the medical press included the record of a case of tetanus following burns (*Lancet*, 1879) and treatment of scarlet fever by sodium salicylate (*Lancet*, 1882). He was one of the first members of the St. Lawrence Lodge of Freemasons when it was formed at Scanthorpe, was a devout churchman, and was honoured by being the first churchwarden of the beautiful parish church built by the late Lord St. Oswald. He was very musical and a composer of several hymn tunes. In private life Dr. Coudrey was a man beloved by all who were brought into contact with him. A man of simple tastes, unassuming modesty, of generous and unselfish nature, his counsel was sought by many, and his hand was ever ready to help without ostentation those who were in need; he annually distributed charity to the widows of the district on St. Thomas's Day. He has left behind the fragrant memory of a good man.

The large funeral and the great number of wreaths bore sorrowful testimony to the general esteem in which he was held; he was borne to his last resting place by the churchwardens and sidesmen, while the flag of the church tower was hoisted at half-mast.

WE regret to announce the death of Dr. J. HERBERT FINEGAN, which took place recently at his residence in Liverpool, at the age of 75 years, after a brief illness. He was born in county Monaghan, Ireland, but was brought to Liverpool at a very early age, and received his scholastic education at the Liverpool Institute. At the age of fourteen he was apprenticed to Dr. Hill of Liverpool. Four years later he attended the Royal Infirmary, and obtained his first distinction, consisting of a two years' scholarship. From that onwards his career was steadily successful, not only in his profession, but as a spirited swimmer, yachtsman, marksman, and all-round sportsman. As a general medical practitioner, for a long time he lived in Rodney Street, but about two years ago removed to Upper Parliament Street. At his death he was the oldest practitioner in Liverpool, and the senior member of the Liverpool Medical Institution. He was for many years connected with the 64th L.R.V. (Liverpool Irish), of which he became Surgeon-Colonel. The following is a list of the distinctions which he gained in his profession and otherwise at various times: Scholarship at the Royal Infirmary and medal for midwifery; certificate of honour in practical chemistry; certificate of honour and medal for surgery at the Liverpool Royal Infirmary. He became a member of the Royal College of Surgeons of England in 1858, received the L.S.A. in 1859, and the M.D.St. Andrews in 1862. He obtained the bronze medal of the National Rifle Association in 1860, and was winner of the challenge cup for marksmanship in the L.R.V., 1871. Dr. Finegan was also honorary surgeon to the Maternity Hospital, and on his retirement became consulting medical officer. He was known throughout his career as a man of genial and kindly disposition, always sympathetic with and ready to relieve distress and poverty. Though latterly his health was far from good, devotion to duty found him attending his patients until within a few days of his death.

DR. JAMES BARCLAY MONTGOMERY, of Penzance, Cornwall, who died on the night of Christmas Day, was born in 1829. He graduated M.D. in Glasgow in 1851, and took the diplomas of M.R.C.S.Eng. and L.R.C.S.Edin. in 1852; he became a Member of the Royal College of Physicians of London in 1859, and a Fellow in 1875. He settled in Penzance, and had a very wide and select practice, extending at one time from Truro to the Land's End. He was in that part the last of a fine type of general practitioner and consultant and physician in one, which is now everywhere dying out. He was honorary physician, with personal attention to out-patients and in-patients, at the West Cornwall Infirmary and Dispensary from 1856 to 1906. When, at his jubilee of office, he retired he was honoured with a presentation of plate and a purse. As a consultant physician his services were sought by medical men all over Cornwall. He was a J.P. for the borough of Penzance, but did not, outside his medical

work, enter much into public life, though probably one of the best informed and most cultured men in the county. He was of a cheerful, witty disposition, with all the kindly courtesy of the physician of his time. The latter years of his life were, however, saddened by the loss of his only son, Dr. Hugh Montgomery, who had lived with him since 1886 and was associated with him in his practice. He nevertheless retained his marvellous memory for people and events and his love and knowledge of music until the end. His wife, with whom he lived happily, survives him.

CAPTAIN JAMES MARTIN BUIST, R.A.M.C., who died January 8th at Davos, Switzerland, aged 36 years, was the youngest son of the late Major-General D. S. Buist. He obtained the degrees of M.B., Ch.B.Edin. in 1899, and entered the service in December of the same year, becoming Captain in December, 1902.

Public Health AND POOR LAW MEDICAL SERVICE

VITAL STATISTICS IN ENGLAND AND WALES (1912). WE are indebted to the Registrar-General for the following statement showing the birth-rates and death-rates and the rate of infantile mortality in England and Wales, and in certain parts of the country during the year 1912.

ENGLAND AND WALES.
Birth-rates and Death-rates in the Year 1912 (Provisional Figures)

| | Annual Rates per 1,000 Living. | | | Deaths under One Year to 1,000 Births. |
|---------------------------------------|--------------------------------|---------|------------|--|
| | Births. | Deaths. | | |
| | | Crude. | Corrected* | |
| England and Wales... | 23.8 | 13.3 | 13.3 | 95 |
| 95 great towns, including London | 24.9 | 13.8 | 14.6 | 101 |
| 146 smaller towns... | 23.8 | 12.4 | 13.0 | 99 |
| England and Wales, less the 241 towns | 22.6 | 12.9 | 12.1 | 87 |
| London | 24.7 | 13.6 | 14.3 | 90 |

* The corrected death-rates are the rates which would have been recorded had the age and sex constitution of the populations of the several areas been identical with that of England and Wales as enumerated in 1901. The corrections applied to the crude rates have been necessarily based upon the constitution of the populations of the areas enumerated in 1901, and are therefore only approximately applicable to the conditions of 1912.

Medical News.

PROFESSOR ARTHUR KEITH, Conservator of the Museum of the Royal College of Surgeons of England, has been elected President of the Royal Anthropological Institute of Great Britain and Ireland.

THE anniversary dinner of the Hunterian Society in London will be held at De Keyser's Hotel, Blackfriars Bridge, on Tuesday, February 4th, when the President, Mr. A. H. Tubby, will take the chair at 7.30 p.m.

THE *Times* states that Mr. Lloyd George has decided to appoint a committee to consider how far medical benefits under the Insurance Act should be extended to Ireland. Mr. H. T. Barrie will represent Irish Unionists on the committee.

On January 21st the Isle of Man House of Keys passed by 17 votes to 5, the third reading of a Vaccination Amendment Bill, which contains clauses making it impossible for a person to be convicted twice in respect of the same unvaccinated child.

THE next Oxford Ophthalmological Congress will assemble on July 16th, and the business will be transacted on the two following days. A discussion on the present position of ophthalmology will be opened by Mr. Robert W. Doyne, Master of the Congress. Members who desire to take part in the discussion or to show cases and specimens are requested to communicate with the Honorary Secretary, Mr. Sydney Stephenson, 33, Welbeck Street, London, W.

Letters, Notes, and Answers.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

S. asks for results of experience of the value of hypnotism in stammering.

G. P. B. would be grateful to learn of a portable typewriter in which jarring of the fingers is reduced to a minimum. One suitable for use in neuritis of the arm, or writer's cramp, is required.

RECURRENT PHLEBITIS.

V. asks for suggestions as to the possible etiology, prophylaxis, and treatment of a case of recurrent phlebitis. The vein usually affected is the left internal saphenous vein. The first attack dates back nearly four years and was due to trauma, but the three or four subsequent attacks have been without ascertainable cause. The patient is a man aged 24, whose urine presents no abnormality, who is not constipated, and who, except for these attacks, is apparently perfectly healthy. There is no history of gout in the family, and his father and grandfather are both alive. Of the half-dozen doctors who have seen him none has been able to throw any light on the case. Most of the attacks have been below the knee.

ANSWERS.

BRAIN EXTRACT.

DR. W. MAULE SMITH (Worcestershire Asylum, Barnsley Hall, Bromsgrove) writes, in reply to Mr. Phiroze A. Dalal's request, contained in the JOURNAL of January 11th: I have to state that the extract is given by the month three times a day. The dose varies from two to four teaspoonfuls. In private practice I would recommend commencing with the former, but the latter is the routine dose given in asylum cases. Messrs. Martindale, New Cavendish Street, London, have placed the preparation on the market.

VARICOSE ULCERS.

DR. W. E. PAIN (London) writes: If "J. H. M." will apply hot boracic fomentations night and morning, bandage the leg with a crêpe bandage, taking internally a tablet of opium at night, which relieves pain without inducing constipation or headache, giving a dose of magnesium sulphate every morning, his ulcer will soon get well. I have been the means of curing a great number by using hot calamine, when there is much irritation, for the hot fomentation and bandaging.

LETTERS, NOTES, ETC.

THE RISK OF ECLAMPSIA RECURRING IN A SUBSEQUENT CONFINEMENT.

"A VILLAGE DOCTOR" writes: Dr. Athelstane Nobbs's most unfortunate experience (BRITISH MEDICAL JOURNAL, January 4th, 1913, p. 19) might, in my limited experience, be considerably mitigated should the general practitioner take up a bolder attitude in dealing with such cases on the recurrence of pregnancy. I happen to be the village doctor he mentions in Case 1, and immediately after attending her I delivered another case single-handed by vaginal Caesarean section, and she got quite well. Just at the same time as Dr. Nobbs's Case 1 became pregnant a second time my own case also became pregnant. I was aware that she had had eclampsia during her two previous pregnancies from her history and my own previous experience of her. I therefore sent her to a maternity hospital and strongly urged the authorities there to induce abortion. My humble suggestion was absolutely ignored, and she was sent home. On my own responsibility, I induced abortion at the third month, and she got absolutely well. The ultimate result, compared with Dr. Nobbs's case, created a deep impression on my mind. I have therefore made it a rule that, should a previously eclamptic patient in her next pregnancy show any sign of renal inefficiency which does not immediately yield to general treatment, the uterus should be emptied at once, and should a patient have shown eclampsia in her two preceding pregnancies gestation should on no account be allowed to proceed in her next beyond the third month.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|--------|
| Eight lines and under | ... | ... | 0 4 0 |
| Each additional line | ... | ... | 0 0 6 |
| A whole column | ... | ... | 2 13 4 |
| A page | ... | ... | 8 0 0 |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 425, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restant* letters addressed either in initials or numbers.

The King has authorized Dr. Llewellyn Powell Phillips, Professor of Medicine at the Medical School, Cairo, to accept and wear the Insignia of the the Third Class of the Imperial Ottoman Order of the Medjidich conferred upon him by the Khedive of Egypt.

THE Lent term of lectures at the Royal Eye Hospital, Southwark, commenced on Tuesday last. The subsequent lectures will be given at 4.30 p.m. on every alternate Tuesday till April 1st. The course fulfils the conditions of Clause 4, Paragraph XXI, Section II of the Regulations of the Examining Board in England. Further particulars can be obtained on application to the Dean at the hospital.

MISS M. E. VERRALL, honorary treasurer of the Lady Chichester Hospital for Women and Children, writes to call attention to an omission from the account of it which was given in the course of an article on Brighton in the JOURNAL of January 4th, p. 34. In this account reference was made to two departments only of the work—the hospital for nerve cases in Brunswick place, and the out-patient department in Ditchling Road. It should have been said that at Ditchling Road there is a third department, a hospital for medical and surgical cases containing twelve beds. This was opened last November, and is quite full. Two houses have been made to communicate, the lower part being used for the out-patient department and the upper for the hospital.

ON the occasion of his retirement from the editorship of the *Bristol Medico-Chirurgical Journal* after twenty-one years of service Dr. Shingleton Smith was entertained at a complimentary dinner at Fort's Restaurant on January 18th, by the members of the Bristol Medico-Chirurgical Society and other local medical men and afterwards presented with a picture, an antique silver salver, and an album with the names of the subscribers. Mr. N. C. Dobson, in making the presentation, thanked Dr. Shingleton Smith for all he had done for the profession during and since the foundation of the society in 1874. Mr. Richardson Cross, who also spoke, said that to no man did the local profession owe so much for his ceaseless energy on behalf of the society and *Journal* and during the early days of University College.

THE Home Secretary has appointed a committee to inquire and report as to the conditions necessary for the adequate and suitable lighting (natural and artificial) of factories and workshops, having regard to the nature of the work carried on, the protection of the eyesight of the persons employed, and the various forms of illumination. The members of the committee are: Dr. R. T. Glazebrook, C.B., F.R.S., Director of the National Physical Laboratory (Chairman); Mr. Leon Gaster; Dr. Francis Gotch, Professor of Physiology in Oxford; Mr. J. Herbert Parsons, Ophthalmic Surgeon to University College Hospital; Mr. W. C. D. Whetham, Fellow of Trinity College, Cambridge, well known as a writer on heredity, and Sir Arthur Whitelegge, K.C.B., M.D., Chief Inspector of Factories. The Secretaries of the Committee are Mr. D. R. Wilson, an inspector of factories, and Mr. C. C. Paterson, of the National Physical Laboratory. All communications should be addressed to Mr. Wilson at the Home Office.

A SERIES of lectures to advanced students and others interested in the subjects discussed will be given at the Lister Institute of Preventive Medicine, Chelsea Gardens, during February and March. The lectures are open to students of the university free, and others can obtain a card of admission on application to the Secretary of the Institute. The first lecture, to be given on Tuesday, February 4th, at 5 p.m., will appropriately deal with the early bacteriological work of Lord Lister, and will be given by the Director of the Institute, Professor C. J. Martin, F.R.S. On February 6th and 11th Dr. G. H. K. Macalister will deal with the various products of the tubercle bacillus used in diagnosis and treatment, and current views upon their mode of action; on February 13th and 18th Dr. J. A. Arkwright will lecture on some recent work on the agglutination of bacteria, with special reference to agglutination with acids; on February 20th and 25th Dr. J. Henderson will speak on recent work on haemolysis and serum-fast bacteria respectively; on February 27th and March 4th Dr. H. Maclean will lecture on lipoids; on March 6th Dr. H. Chick will deal with the subject of the laws governing disinfection by various agencies; and on March 13th and 18th Professor A. Harden, F.R.S., will lecture on the chemical action of bacteria—the chief types of chemical change produced by bacteria and the aid which can be obtained from chemical action in the identification and classification of bacteria and the enzymes concerned. The lectures will be given at 5 p.m. on each day.

An Address

ON

THE EXOTIC FLORA OF THE UTERUS IN RELATION TO FIBROIDS AND CANCER.

DELIVERED BEFORE THE BRADFORD MEDICO-CHIRURGICAL SOCIETY ON THE OCCASION OF ITS JUBILEE,
JANUARY 21ST, 1913,

By SIR JOHN BLAND-SUTTON,
SURGEON TO THE MIDDLESEX HOSPITAL.

In the year 1910, at the Middlesex Hospital, the uterus was removed for fibroids on 65 occasions, and all the women recovered. During the same period the uterus was extirpated for cancer of its neck in 17 women, and of these 4 died. The annual report for that year shows that 13 patients with cancer of the cervix uteri were examined under an anaesthetic and found to be "inoperable." In 5 more women with the same disease the condition of the pelvic organs was examined through an incision in the abdominal wall, and proved to be unsuitable for hysterectomy. Thus, out of 35 women with this terrible disease 17 were selected with extreme care as suitable for hysterectomy, and of these 4 died from the operation or its sequelae.

Although these facts are taken from the reports of one hospital, the results are by no means peculiar to it. An examination of the reports of some other hospitals in London reveals practically the same picture. In the year 1910 abdominal hysterectomy was performed for fibroids in seven hospitals in London on 370 patients with 9 deaths:

| | Cases. | Deaths. |
|------------------------------|--------|---------|
| Middlesex | 65 | 0 |
| Chelsea (for Women) | 113 | 2 |
| Samaritan (for Women) | 53 | 3 |
| New (for Women) | 41 | 1 |
| University | 14 | 0 |
| St. Thomas's | 50 | 3 |
| St. Bartholomew's | 34 | 0 |
| | 370 | 9 |

In that year (1910) abdominal hysterectomy was performed for cancer of the neck of the uterus in the same hospitals as in the preceding table on 81 patients with 13 deaths:

| | Cases. | Deaths. |
|------------------------------|--------|---------|
| Middlesex | 17 | 4 |
| Chelsea (for Women) | 12 | 2 |
| Samaritan (for Women) | 17 | 1 |
| New (for Women) | 12 | 0 |
| University | 9 | 2 |
| St. Thomas's | 11 | 3 |
| St. Bartholomew's | 3 | 1 |
| | 81 | 13 |

The explanation of the difference in the results of removing the uterus for fibroids and for cancer of the neck of the uterus is simple and interesting. It depends mainly on the flora of the uterus.

Bacteriology of the Female Genital Tract.

A large amount of patient labour has been expended in investigating the bacteriology of the female genital tract. The varieties of micro-organisms found there are numerous, but the chief are the gonococcus, streptococcus, staphylococcus, and the tubercle bacillus. Of these the gonococcus attacks mainly the mucous membrane, and is more destructive to function than to life. The streptococcus flourishes in loose connective tissues, and when this tissue is vascular, as in the neighbourhood of the uterus, the micro-organism enters blood vessels and lymphatics. It invades the uterine and periuterine tissues through breaches of continuity in the genital tract caused by childbirth, miscarriage, operations on the uterus, and criminal abortion. The streptococcus is especially destructive to life and often flourishes in company with the staphylococcus, *Bacillus coli communis* and *Bacillus pyocyaneus*.

Until the advent of puberty the uterus is functionless and free from micro-organisms. When the girl becomes pubic and sexual life is established, she runs risks from two sources: infection when the male suffers from urethritis, especially gonorrhoea; and, if she become pregnant, the danger of accidental sepsis at the lying-in. The infection has unfortunate results; some of the patients die. In others the infective agents die, the inflammatory changes in the tissues subside, but the essential organs of reproduction are often so damaged that these infected women become chronic invalids, incapable of conceiving.

The common agents of wound infection are universal in civilized communities; they are present in dust, soiled clothes, dirty surgical instruments, and the like. They exist in suppurating sores on the fingers of doctors, midwives, and nurses, and on the body of the patient. The transmission of pathogenic micro-organisms can only be avoided by scrupulous cleanliness. The leading features of septic infection of the puerperal uterus are well-known. A woman with a submucous fibroid in her uterus, like a pregnant woman is very liable to become septic, but with this difference: Pregnancy terminates at some date within a period of thirty-six weeks, but a fibroid may be retained for thirty-six years, and during the whole of this period the uterus persistently endeavours to extrude it. These extruding efforts dilate the mouth of the uterus and open the door to pathogenic micro-organisms. In fact, a woman with a submucous fibroid is like a parturient woman with a retained piece of placenta and is menaced with the liability of septic infection as long as she retains it. When the uterus succeeds in extruding a submucous fibroid into the vagina and the condition is recognized, the surgeon promptly removes the tumour and no harm follows; but when the extruded fibroid is allowed to remain, it becomes oedematous because its circulation is interfered with, or the surface of the tumour may be abraded, or ulcerated. Breaches of continuity of its surface allow micro-organisms, present in the vagina, to colonize the tumour and convert its tissues into a stinking, decomposing slough. The infection extends to the endometrium and a condition identical with puerperal fever is established. An extruded uterine polypus the size of a golf ball infected with streptococci sometimes destroys life quicker than a virulent cancer.

A woman with cancer of the neck of the uterus is in much the same condition as one with an extruded and septic fibroid, for the cancerous tissues soon become invaded with pathogenic flora; of these the streptococcus is the most deadly. The micro-organisms which flourish in cancerous tissue make this disease so destructive to life; the streptococci in uterine cancer are very virulent, especially for the peritoneum.

The Relics of Bacterial Invasion.

The tolerance of the tissues in regard to micro-organisms varies enormously. For example, the gonococcus thrives and multiplies for a time and then dies out, but leaves its mark in the pelvis in the form of occluded Fallopian tubes, pyosalpinx, and adhesion of the uterus to the bowels, the omentum, bladder, and adjacent peritoneum. A woman with subserous fibroids is as liable to contract gonorrhoea as one free from such tumours, but when the infecting exudate leaks into the pelvis, in addition to its damaging effect in cementing the ovaries and tubes to each other, and scaling up the tubal ostia, it glues the surface of a subserous fibroid to any adjacent viscus. In my early operations on acute chronically infected tubes and ovaries I was often astonished that patients recovered after a large pus sac had burst in the course of removal and drenched the pelvic organs with pus. This led me to have a careful bacteriological investigation made as a routine measure of all tubes removed for inflammatory troubles. They were, as a rule, sterile. Occasionally in a pyosalpinx, which had burst through the rectum and then refilled, the reaccumulated pus would contain the colon bacillus or the streptococcus. It was in the course of this investigation I obtained conclusive evidence that gonorrhoeal exudate leaking into the pelvic cavity sets up peritonitis; in the acute stage the gonococcus can be obtained in pure culture from the peritoneal exudate. This is no longer disputed.

Uterine Infections form Two Groups: Puerperal and Non-puerperal.

Clinically uterine infections form two groups—puerperal and non-puerperal. In the former group the streptococcus is the dominant organism and in the latter the gonococcus. Both organisms cause destructive changes in the tubal tissues; after the micro-organisms have died out, there is nothing in the lesions which enables us to decide whether the damage to the tissues was caused by a gonorrhoeal or a mild streptococcal infection. In clinical terms this means it is impossible to decide in a chronic case whether the trouble began as a puerperal or a non-puerperal infection. The tendency for micro-organisms to die out also applies to tuberculous lesions: it requires much patience to demonstrate the presence of the tubercle bacillus in tuberculous disease of the tubes and endometrium. This bactericidal power of the tissues explains the success which attends surgical enterprises on the Fallopian tubes and the uterus when they are damaged as the result of chronic infection.

Sixteen years ago I satisfied myself that in tubal lesions—such as pyosalpinx, tubo-ovarian abscess, and hydrosalpinx—it was rare in the chronic stages to find micro-organisms in the diseased tissues. This was a stumbling-block in determining the factor which caused the initial lesions. It interested me to find that Dr. N. F. Lock, in an excellent investigation carried out at St. Thomas's Hospital (1911), has come to the same conclusion.

I have again felt it necessary to inquire into the micro-organisms of the uterus in order to seek an explanation for the extraordinary frequency with which pulmonary embolism occurs after hysterectomy for fibroids and for cancer, whilst it is unknown to me after operations performed for lesions due to the gonococcus.

The Spectre of Convalescence after Hysterectomy.

Among the many advances in surgical art which have taken place since the foundation of this society in 1863 the establishment of pelvic surgery holds a foremost place. At that date the word "hysterectomy" was uncoined. The principles concerned in the transport, destiny, and effects of emboli had just been made plain: pyaemia was endemic in every hospital and antiseptics unknown, and the surgical treatment of uterine fibroids was attended by such a heavy mortality that the removal of the uterus ranked as one of the most dangerous operations in surgery. To-day a subtotal hysterectomy for fibroids is one of the safest and most beneficent operations in the whole range of surgery; but I regret to add that there is one danger connected with this operation which invests it with peculiar anxiety—namely, fatal pulmonary embolism. Indeed, every surgeon who has had much experience of hysterectomy fears this sequel, for it occurs so suddenly and so unexpectedly in patients who are apparently making a satisfactory recovery that this tragic occurrence may be spoken of as the spectre of convalescence.

It is difficult to determine the actual frequency of pulmonary embolism as a sequel of hysterectomy, for surgeons are very reluctant to publish their experience; but there is sufficient evidence available to give some notion of its relative frequency and the variations met with in the practice of different surgeons. Baldy states that among 366 operations for fibroids in the Gynecean Hospital, Philadelphia, there were 13 sudden deaths attributed to embolism. In the Middlesex Hospital from 1896–1906, both years inclusive, there were 212 abdominal hysterectomies for fibroids, and of these patients 3 died from pulmonary embolism. At the New Hospital for Women, London, during 1901–1910 hysterectomy was performed for fibroids on 189 patients, and of these 2 died from embolism.

In the practice of individual surgeons the frequency of fatal pulmonary embolism varies widely. Lyle, among 8 subtotal hysterectomies for fibroids, lost 1 patient; H. R. Spencer lost 2 patients from this cause out of 85 total hysterectomies, and Olshausen lost 5 patients among 366 who had hysterectomy performed for fibroids. Among 1,500 abdominal operations for fibroids I lost 3 patients from pulmonary embolism. A broad study of statistics indicates that in the practice of some surgeons fatal pulmonary embolism occurs in at least 1 per cent. of the patients who have abdominal operations performed for

fibroids. This tragic mode of death is more frequent after total than subtotal hysterectomy; it is a recognized sequel of hysteropexy, and the risks of its occurrence after abdominal hysterectomy for cancer is higher than for any other pelvic operation. These figures refer to fatal pulmonary embolism. It is not uncommon for women recovering from hysterectomy to be seized with sudden pain in the chest severe enough to fill them with alarm. Such attacks are usually followed by fever and the ejection of bloodstained sputum. The symptoms gradually subside. These attacks are often due to the lodgement of small emboli in branches of the pulmonary artery.

Thrombosis from the use of Buried Sutures.

At the Hunterian Society, London, in 1909, I attributed the frequency of pulmonary embolism after hysterectomy to infection of the buried sutures used to close the abdominal incision, the channels of infection being the epigastric veins. Being desirous of ascertaining the bacteriologic condition of the cervical canal and the uterine cavity of women with fibroids, I had a series of observations made in cases of subtotal hysterectomy. The investigation was conducted by two independent observers (Mr. Somerville Hastings and Mr. C. H. S. Webb) and their findings tallied uniformly and were confirmed by the clinical course of the patients. In the majority, especially nulliparous spinsters, the cervical canal and uterine cavity were sterile; in married women who have had children, and in whom the mouth of the womb is patulous, staphylococcus, *Bacillus coli*, and Döderlein's bacillus occur. The proportion of cases is small in which micro-organisms are found, but they are more common in a uterus containing a submucous fibroid in a woman who has had children than in that of a nulliparous spinster with a narrow cervical canal.

In regard to the fibroids, I have had very many examined, especially those which have undergone degenerative changes, such as softening and red degeneration. In all cases except one they have been sterile, the exception being a subserous fibroid in a gravid uterus: the tumour was in the condition known as red degeneration, and contained staphylococci. The comparative freedom of the uterus from pathogenic micro-organisms explains the great success of subtotal hysterectomy.

Femoral thrombosis and fatal pulmonary embolism are recognized sequels of hysteropexy. In this operation, if the retaining sutures traverse the endometrium and it be septic, the sutures will become infected and cause trouble. A study of thrombosis occurring under such conditions led me to believe that the factors which produce changes leading to thrombosis of the external iliac or the femoral veins are the buried sutures in the abdominal incision. I made a series of trials in which a number of abdominal incisions were closed with buried silk sutures, also a series of cases in which through-and-through sutures were employed. However carefully the suture material is prepared and inserted with hands covered with sterilized rubber gloves, now and then a buried suture will give trouble. Even when the sutures appear to settle down without disturbance they often cause slight rises of temperature.

For a period of two years I buried no sutures in an abdominal incision, except in one patient. During that period I had no post-operative thrombosis, and only one case of pulmonary embolism, and this happened to the patient in whom I closed the wound with buried sutures. She was a midwife on whom I performed hysterectomy for a big submucous fibroid, and as this woman was very stout and led an active life, it seemed expedient to take every precaution to secure a sound scar. This patient seemed to be making a satisfactory recovery, but on the eighth day her temperature rose to 103 F. On examination some hardness could be felt in the lower portion of the wound. I warned the house-surgeon that there was probably thrombosis of the deep veins, and impending danger of pulmonary embolism. She died suddenly a few hours later, and an embolus was found at the *post-mortem* examination firmly plugging the pulmonary artery.

In 1902, Clark, of Philadelphia, published some observations on post-operative femoral thrombo-phlebitis, especially as a sequel to coeliotomy. He believes that it has its origin as a primary thrombus of the deep epigastric

veins due to injury of the edges of the incision by metal retractors. The thrombosis is slowly propagated along the vessel to the external iliac vein, and by retrogressive thrombosis to the femoral vein. He also published a very convincing case. A woman aged 32 had hysterectomy performed for retroflexion of the uterus. The vermiform appendix was removed at the same operation. Thirteen days later there was well-marked femoral thrombosis. Two months later, the patient's condition being unsatisfactory, the abdomen was reopened; the right ovary and tube, being inflamed, were removed. In the course of the operation the right epigastric veins were found to be varicose and inflamed. They were "like dense cords as large as goose-quills." The epigastric vein was obstructed at its entrance into the iliac vein.

It will be obvious to any one who has studied the flora of the uterus that the surgeon's fingers must become contaminated by handling the tissues of the cervix in the course of a total or subtotal hysterectomy, when the uterus contains pathogenic micro-organisms. It is, of course, true that the uterus, in a large proportion of patients, is sterile, but micro-organisms are present in a sufficient number of cases to account for the frequency of inguinal thrombosis as a sequel of hysterectomy.

The excessive frequency with which inguinal thrombosis follows total abdominal hysterectomy, performed for cancer, is worth bearing in mind, for cancer in the neck of the uterus almost invariably teems with streptococci and staphylococci. Of these cocci, the former are notorious agents in causing thrombi to form in blood vessels. The deep epigastric veins are in intimate relation with the wound area when the abdomen is opened by a median sub-umbilical incision, whether the cut be made in the linea alba or to one side of the middle line in the belly of the rectus muscle. The branches of the vein collect the blood from the subcutaneous as well as from the subserous tissue in the parts adjacent to the linea alba. Some of the branches bleed freely when they happen to be transfixed by a needle in the process of suturing the wound. The deep epigastric artery is accompanied by two veins (venae comites) and they become confluent immediately above the spot where the conjoint vein enters the external iliac vein.

Pulmonary embolism is more frequent after abdominal than after vaginal operations; useful evidence is furnished by Klein, who collected the statistics of the Bettina-stiftung (Vienna), and found 9 fatal cases of pulmonary embolism in 1,720 abdominal sections. During the same period there was no instance of fatal embolism among 1,992 vaginal operations. Wertheim in a recent discussion on this matter admitted that in his practice thrombosis was three times more frequent after abdominal section for myoma than after vaginal myomectomy and hysterectomy for fibroids. It is unnecessary to adduce further figures, because this opinion is accepted by most surgeons who have had a wide experience in this class of surgery, but the evidence furnished by Klein is good circumstantial evidence towards implicating buried sutures as causative agents in the production of the primary thrombosis. Having satisfied myself that the fingers of the surgeon do become contaminated in the course of abdominal hysterectomy when the cervical canal contains micro-organisms, and in this way infect the suture material in the course of the operation, I adopt the following preventive measures:

After amputating the body of the uterus I apply iodine by means of a piece of cotton-wool on a probe to the cervical canal, and also lightly swab the cut surface of the stump with tincture of iodine before tying the vessels and introducing the mattress sutures. In a total hysterectomy I carefully swab the cut edges of the vagina with tincture of iodine before ligaturing the vessels. This trifling modification in procedure has a great influence for good on the post-operative course of the case.

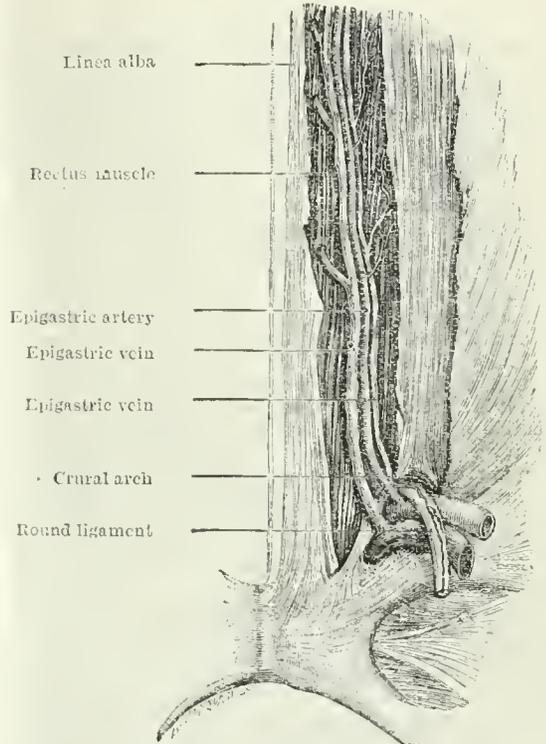

After completing the pelvic part of the operation I wash my gloves with warm soap and water, and rinse them thoroughly with warm water and dip them in a solution of perchloride of mercury (1 in 5,000) before introducing the sutures. In clean cases I insert three or four silk sutures (No. 2) to bring the fascia together, and the wound is closed by a series of through-and-through sutures.

In operating for conditions known to be septic no sutures should be buried in closing the abdominal incision.

Suture Material.

It is the fashion to lay the blame for stitch abscess after hysterectomy upon the suture material, or on the method employed for sterilizing it. I have endeavoured to show that, in spite of every precaution, buried sutures are liable to be infected in the course of this operation when the cervical canal contains micro-organisms. For many years I have employed silk thread as suture material exclusively. The thread, wound on a spool, is boiled for an hour, reboiled immediately before use, and inserted with the hands protected by sterilized rubber gloves.

As evidence that buried sutures used to close the abdominal wall in pelvic operations are liable to become infected by the surgeon's fingers and thus become the cause of suture abscess, I will describe what happens in operations for the removal of the breast. When this organ is amputated for a non-ulcerating cancer, if the cancerous focus be examined with the caution usually displayed in bacteriological investigations it will be found

Posterior view of the rectus abdominis muscle below the level of the umbilicus. The origin of the deep epigastric artery and the termination of the vein is shown. Venous branches are seen coming through the muscle.

free from micro-organisms. Therefore, if the surgeon has taken care that the skin overlying the operation area has been carefully treated with the antiseptic solutions usually employed for this purpose, and his hands, tools, and material used for haemostasis have been rendered germ free, the wound heals speedily and soundly. During the past fifteen years I have used fine silk thread exclusively for ligatures.

During this period I have removed the breast more than 300 times, and each operation requires on an average ten ligatures. This experience concerns 3,000 pieces of silk. Throughout the whole of this period I have had no trouble from these buried ligatures; and throughout the whole of my surgical work, in hospital and private, I have never had a patient die in consequence of amputation of the breast. I mention these facts because they support my contention that buried sutures, used to ensure a firm scar after abdominal hysterectomy, often defeat the purpose for which they are inserted because they become infected by the surgeon's fingers when the cervical canal contains infective organisms.

One of the most conspicuous features connected with pulmonary embolism, apart from its suddenness and the rapidity with which it sometimes causes death, is its unexpectedness. Inguinal thrombosis after abdominal

pelvic operations is by no means uncommon, but it is an extremely rare event for pulmonary embolism to happen in this form of thrombosis. The oedema of the leg associated with this common form of thrombosis is usually attributed to obstruction of the iliac and femoral veins by internal clot, but there is in addition infection of the lymphatics, and this causes a hard painful swelling of the thigh in consequence of interference with the lymphatic circulation. Surgeons know well that during operations in the armpit the axillary vein is occasionally cut. This accident is easily repaired by the application of a ligature to the vein above and below the opening. No oedema of the limb follows. When the axillary lymphatics are blocked by perilymphangitis due to an extension of mammary cancer, a solid oedema of the limb ensues. This is true of the lower limb. The femoral vein is sometimes wounded accidentally by the surgeon in the course of an operation, but it is safely controlled by an encircling ligature placed above and below the hole in the wall of the vein. No oedema follows, nor is the circulation in the limb impaired.

Reservoirs of Clot.

It often happens that a *post-mortem* examination is made on a patient who has died in consequence of a pulmonary embolism, and the source of the embolus cannot be found. In considering embolism of the pulmonary artery in relation to hysterectomy it is necessary to point out that the pelvis contains two potential reservoirs of blood clot—the iliac veins and the ovarian veins. Experience, however, teaches that the external iliac veins are the common source of the fatal clot.

An embolus large enough to fatally plug the pulmonary artery comes, as a rule, from large vessels like the iliac veins, the caval veins, or the right auricle. Virchow pointed out that it is not uncommon for an entire thrombus to slip out of a vein, and an elongated thrombus from a venule may appear to be too thin to obstruct a large vessel, but, when such an elongated thrombus reaches its destiny, it is doubled up by the blood stream and serves as an effective plug. An embolus too small to occlude the pulmonary artery may lodge on the ridge separating the right from the left branch, becoming what is called a riding thrombus; such a clot may act as an autochthonous thrombus, and induce the formation of additional clot such as will fill and fatally occlude the main trunk and both branches of the pulmonary artery, as well as many of its subdivisions in the lungs.

Pulmonary embolism may occur as a sequel to hysterectomy at any time from the hour of the operation onward to the thirtieth day. In the majority of instances it happens about the twelfth day, and many observers have noticed that the detachment and transit of the clot is usually preceded by movement, such as getting out of bed for the first time after the operation, even sitting up in bed, but more particularly in straining during defaecation: sometimes it is deferred until the patient is apparently well, and when about to leave the hospital she may fall dying across the bed, on the floor of the ward, or in the courtyard of the hospital. The periodical literature of surgery and gynaecology contains many instances of these dramatic forms of sudden death due to post-operative pulmonary embolism.

The Bacteriology of the Clot.

The bacteriology of the clot is an interesting matter in relation to thrombosis and embolism. In the opening remarks it was mentioned that the common organisms found in infected uteri are streptococcus, staphylococcus, gonococcus, and the colon bacillus. The common micro-organism found in thrombi and emboli is the streptococcus; it is sometimes mixed with the staphylococcus, the *Bacillus pyocyaneus*, or the colon bacillus, but never the gonococcus. This is a matter of great interest. Extensive pelvic operations are often performed for damage caused to the uterus and the Fallopian tubes by the gonococcus, sometimes in the acute, but more often in the chronic stage of the disease. I have never had a case of pulmonary embolism as a sequel of an operation on the uterus or tubes when the lesion was the consequence of a gonorrhoeal infection. This seems to show that the gonococcus causes great irritation of tissues, and produces masses of adhesions,

but does not coagulate blood. The facility with which the streptococcus causes blood to coagulate in the living vessels is well known, and the extreme frequency with which thrombosis and its sequel, embolism, occur in connexion with cancer of the uterus is explained by the partiality which streptococci manifest for exposed cancerous tissue.

M. B. Schmidt found that when cancer particles enter the blood streams by invading lymphatics and veins they excite thrombosis, and the thrombus contracts upon and may ultimately destroy them. This prophylactic power of the blood prevents colonization of the blood stream, but I hold the opinion strongly that the thrombosis around the cancer particles is incited by the micro-organisms or their toxins which these cancer fragments contain.

It is undeniable that death from pulmonary embolism is especially frequent after abdominal hysterectomy performed for cancer of the uterus; it is far more frequent than after the removal of the uterus for fibroids, and the evidence indicates that the greater frequency of this catastrophe in operations for cancer of the uterus depends on the greater luxuriance of the flora in cancerous tissue, and that the streptococcus, of all the forms of micro-organisms which abound in such uteri, holds the greatest "enmity with blood of man."

In order to improve the results of abdominal hysterectomy performed for fibroids, surgeons must be more careful and more moderate in the use of buried sutures when closing the abdominal incision.

The risks of operations for cancer of the neck of the uterus will be lessened when surgeons, with the aid of bacteriologists, devise means to rid cancerous tissues of noxious organisms before undertaking hysterectomy. The widespread tilling of the pelvic connective tissue inseparable from the operation ironically called radical abdominal hysterectomy favours the sowing, growth, and rapid multiplication of streptococci, with the result that in many instances Death becomes the reaper.

It must be obvious to all thoughtful men that the surgeon in the operating room, as well as in the clinical ward, must look to the bacteriological laboratory for guidance, in the same way that the navigating officer on the bridge directs the ship, under the tutelage of the astronomical observatory, across the trackless ocean.

REMARKS ON ATYPICAL EXOPHTHALMIC GOÏTRE.*

By H. L. McKISACK, M.D., M.R.C.P.LOND.,

PHYSICIAN TO THE ROYAL VICTORIA HOSPITAL, BELFAST.

THE recognition of a well-established case of Graves's disease is one of the easiest tasks of a medical practitioner. The classical signs, with which we are all familiar, leave no room for doubt as to its nature. The chief of these are: Rapidity of heart beat, protrusion of the eyeballs, enlargement of the thyroid gland, tremor, sweating, flushing, sleeplessness, and other evidences of nervous excitement.

Functions of the Thyroid Gland.

It has been established both by clinical and experimental evidence that the thyroid secretion is necessary for the proper development of the bony structures and their maintenance, and also for the due development of mental power, for the growth and maintenance of fatty tissue, skin, hair, and nails. The sexual functions are stimulated by thyroid secretion. In myxoedema, where the secretion is deficient, amenorrhoea is the rule, while excessive menstruation is usual in the contrary condition of exophthalmic goitre. In pregnancy also the symptoms of Graves's disease, if previously present, become accentuated. A notable result of excessive thyroid action is stimulation of the sympathetic system, and it is from this action that many of the classical symptoms arise, and in particular irritability of the vasomotor system. This was well exemplified in cases No. 7 and 15, where a patch of hyperaemia, lasting for a considerable time, resulted from the slightest stimulation of the skin. In a lesser degree it was noticed in

* Delivered at a meeting of the Ulster Branch of the British Medical Association.

several of the other cases. Another effect of excessive thyroid secretion is diarrhoea. The thyroid gland exerts an inhibiting influence on the pancreas; hence diabetes, the result of pancreatic inefficiency, is a not uncommon consequence of exophthalmic goitre. Thyroid secretion increases the activity of nitrogenous metabolism and opposes the accumulation of fat, with the result that emaciation is usual in well-marked exophthalmic goitre, and may also be seen in many of the imperfectly developed cases. The thyroid gland is unique in containing a noteworthy amount of iodine, and it is found that the administration of iodine or its salts increases the activity of the gland, and may in susceptible subjects even produce some of the symptoms of exophthalmic goitre.

Etiology and Symptoms of Exophthalmic Goitre.

It is the difficulty in accounting for the alteration in the quantity or quality of the thyroid secretion that gives rise to the differences of opinion as to the cause of exophthalmic goitre. The simplest way to increase the quantity of the internal secretion in the blood is to administer the extract of the gland by the mouth. By this means the symptoms of excessive thyroid action, or "hyperthyroidism," may readily be produced. Inflammatory or degenerative changes of the thyroid gland may cause it to enlarge, sometimes with excess of function, more frequently the reverse. Emotions, particularly fear, are credited with being a cause of exophthalmic goitre. In this connexion it is noteworthy that the symptoms closely resemble a state of terror. Here the excessive activity of the gland may be produced by direct stimulation. It has been shown by Crile that the more powerful emotions have a definite influence on the functions of the body, either by stimulation or by inhibition of various glands. Brener suggests that the emotion of fear producing vasomotor changes causes the gland to empty itself quickly into the circulation with subsequent compensatory activity, and perhaps hypertrophy. In another group of cases the thyroid is unequal to the task of supplying the amount of internal secretion required by the organism, and in order to overcome this deficiency the gland becomes hypertrophied with, in many cases, hyperthyroidism. It is in this class of case that the administration of thyroid extract by the mouth has been advised, on the assumption that the assistance of the swallowed extract would do away with the necessity for compensatory hypertrophy of the gland. (See case No. 9.)

Cases of exophthalmic goitre in which the majority of the classical signs are absent are apt to be overlooked, and I have no doubt we miss many that should be identified. In hospital practice I have not succeeded in observing more than a few of this class of case, but that, perhaps, is to some extent explained by the fact that such imperfectly developed cases are not usually sufficiently ill to be admitted to the wards of a hospital; no doubt, also, many have escaped my attention. In private practice we are more likely to come across such cases, and my experience only extends to twenty-one instances, to which I wish briefly to direct your attention. I have, of course, excluded the more common fully developed cases of Graves's disease.

The cases are too few to permit any reliable generalizations to be founded on them; but it will be observed that in all the heart-rate was above normal, and in practically all the patient was aware of the rapid beating, either in the form of general throbbing of the arteries or as palpitation of the heart. This is the symptom which should always arouse suspicion, and when combined with tremor and with even a slight protrusion of the eyeballs it may be accepted as an evidence of hyperthyroidism. This last-named sign was, however, absent in 15 of my 21 cases. Careful examination will generally reveal an increase in the size of the thyroid—sometimes only to a very slight degree. In 3 cases it was normal, in 5 it was of moderate size, in 2 considerable enlargement existed, and in 11 there was slight enlargement. Tremor was absent in 9 of the cases. Twelve of the cases were between the ages of puberty and 30, and the remainder were between 30 and 60. All but three were females, and one of the three men, while incomplete in the development of signs when first seen, soon progressed rapidly in an unfavourable course, and became a typical case in a very short time. Two of

the cases, as already mentioned, showed marked vasomotor excitability.

Case 9 was an example of hyperthyroidism in a developing female at the age of puberty. The thyroid gland was slightly enlarged, and headaches, palpitation, flushing, and nervousness were present. These symptoms and the enlargement of the thyroid had only very recently attracted attention, and it seemed probable that the gland had become hypertrophied at puberty in the endeavour to meet the new demands upon its secretion caused by sexual development. Small doses of thyroid extract were therefore administered by the mouth, so as to assist the gland in its work, with the result that the hypertrophy disappeared and the patient got quite well after one or two relapses.

One of the most erratic of the cases is No. 18, in which there is apparently an alternating condition of hypo- and hyperthyroidism. The prevailing symptoms are perhaps those of deficient rather than excessive thyroid secretion. She is inclined to grow stout, is somewhat phlegmatic in manner and character, sleeps well at night and is often drowsy during the day; her hair falls out freely on brushing it, and her thyroid gland is distinctly enlarged—indications of a mild degree of myxoedema. She first came for medical advice on account of a hard, harsh cough, caused probably by the mechanical irritation and pressure of the gland. Her pulse ordinarily is about 70. After a short course of small doses of thyroid extract, the contrary condition of hyperthyroidism appeared, and when the extract was stopped the tachycardia, palpitation, flushing, etc., continued for a considerable time. There still remains a mixture of symptoms indicating an inefficient thyroid, while her functions are very sensitive to the help obtained by the thyroid extract given by the mouth.

Case 19 was of interest owing to the fact that only one eye projected; the other symptoms of exophthalmic goitre were typical. The patient's sister, however, told me that six months previously both eyes were equally projecting in about the same degree as the one eye then was.

The last two cases are inserted in order to draw attention to a large group of cases, many of which are probably examples of hyperthyroidism. These are generally, and

no doubt correctly, described as functional disturbance due to the menopause. It must be remembered that many cases of true exophthalmic goitre begin about this time of life. We know also how intimate is the relation between the sexual functions and the thyroid gland. It therefore seems probable that the ordinary menopause symptoms, which so closely resemble those of hyperthyroidism, are largely the result of temporary hyperthyroidism.

Treatment.

As regards the treatment of these atypical cases, it differs in no material respect from that of the fully developed disease. I do not propose to occupy your time with this aspect of the subject, but I should like to ask the members to give a trial to the x-ray treatment. This procedure seems to offer a fair prospect of reducing the activity of the gland, without having to subject the patient to the risk of an operation for the purpose of removing a portion of the gland or ligaturing some of its vessels.

Finally, I would suggest that the name "exophthalmic goitre" be as far as possible discarded, and that the condition be spoken and thought of as "hyperthyroidism." This term would include all degrees of the abnormal condition, while the more usual description, "exophthalmic goitre," merely suggests two of the chief, but by no means the most constant, symptoms.

THE PORTALS OF ENTRY OF THE TUBERCLE BACILLUS, ESPECIALLY IN CHILDHOOD.

BY

E. EMRYS-ROBERTS, M.D.,

PROFESSOR OF PATHOLOGY AND BACTERIOLOGY, UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE, CARDIFF.

AN enormous amount of work has been undertaken during recent years with regard to the tubercle bacillus, but certain landmarks stand out prominently. These are, first, the differences which distinguish the human from the bovine variety of the tubercle bacillus, and, secondly, the extended use of von Pirquet's reaction.

There exist portals of entry of the tubercle bacillus that have long been recognized. For example, no one denies the transmission into the lungs of tubercle bacilli suspended in air in minute particles of moisture or in dust. Recent experimental evidence has amply demonstrated this very important avenue of infection, and has incidentally shown that the number of bacilli required, all things being equal, to set up pulmonary tuberculosis is relatively small as compared with the number necessary to induce tuberculosis elsewhere—as, for example, into the intestinal tract (1, 2).† No one questions transmission through the intestinal tract, especially in infancy, and here, again, experimental evidence shows that not only may the bacillus induce a lesion in the gut, but may enter the intestinal wall without producing a lesion at the seat of entry (3, 4, 5, 6). No one, again, questions transmission through the naso-pharynx; there is ample evidence, both clinical and experimental. Transmission can occur also through the skin, as was demonstrated in the case of a former colleague of mine, who contracted, presumably in the *post-mortem* room, a tuberculous lesion on his hand (see also 7). Experimentally, transmission through the unbroken skin has been demonstrated (8). Lastly, we reach the antenatal avenue of entry. Omitting for the present this last portal of entry, we may say, with Calmette (9), that "the more frequent channels of invasion are the mucous membranes of the natural cavities of the body, particularly the digestive and pulmonary epithelium, and to these may be added the naso-pharynx." Whether we can go further with him and say, "Of these the digestive path is the one most commonly chosen," is open to question.

Few observations have been so startling, or have had a more profound bearing on the problem of tuberculosis than the extended application of von Pirquet's reaction. Numerous statistics are now available, and Calmette (10), reviewing them, shows that, up to the age of 1 year,

9 per cent. of all children give positive results, up to the age of 2 years 22 per cent., from 2 to 5 years 53 per cent., and from 5 to 15 years 80 per cent. This reaction, which indicates tuberculous infection, has been controlled by statistics obtained from *post-mortem* records, and Binswanger (11) adduces a remarkable agreement between the two sets of figures (see also 12, 13). The reaction is carried out by the use of Koch's old tuberculin. The one forearm is scarified and a few drops of undiluted tuberculin introduced, as in vaccination, the other forearm being inoculated with normal saline in order to act as a control. The development in the course of some days of an inflammatory reaction is acknowledged to indicate the presence of tuberculous sensitiveness—that is, that the person so reacting has circulating in his blood serum certain specific antibodies to the tubercle bacillus—antibodies present owing to an infection, recent or remote, active or quiescent, by the tubercle bacillus. The reaction partakes of the character of anaphylaxis (14), inasmuch as the local inflammation is the result of poisonous products resulting from the disintegration of the introduced tuberculin, which has been acted upon by the two elements in the patient's serum, complement and antibody. There appears to be no specificity regarding the use of human and bovine tuberculin (15), and there does not appear to be any agreement between the intensity of the reaction and the extent of the tuberculous lesion (16, 17),† though the reaction tends to become feeble or absent in severe cases, probably due to the using up of antibodies and complement. It is not my purpose to discuss the subcutaneous (18) injection of tuberculin for diagnostic purposes, or to enter into the evidence so afforded of focal as well as local reaction (19), as full comparative statistics are not yet available.

Does this relative absence of von Pirquet's reaction, then, mean that infants possess a greater insusceptibility to tuberculosis, even when, as above, substantiated by *post-mortem* findings? Two points have to be taken into account in meeting this observation: First, that in children, and especially infants, antibodies are deficient (20), or, at any rate, their non-detection would seem to warrant such a statement; and, secondly, in the *post-mortem* room it is unquestionable that the disease may not be recognized macroscopically as the tubercle is often in the prefollicular stage (21, 22). I would ask especial attention to these explanations of the non-detection of tuberculous infection in infancy, as I shall refer to them later when dealing with the antenatal transmission of the infection.

The full significance of the extended application of von Pirquet's reaction has been held to justify von Behring's (23, 24) pronouncement in 1903:

The seeds of phthisis are laid in infancy through the intestinal mucosa, remaining latent until the powers of resistance happen to become impaired; the disease then becomes active. The tubercle bacilli are usually introduced in cow's milk and absorbed through the intestine.

No doubt von Behring has felt justified in his prophetic utterance by the statistics of von Pirquet (25), Hamburger (26), and a host of other observers (27, 28, 29), which would seem, at first sight, so eminently to substantiate his pronouncement.

But there exists a most important stumbling-block to the full acceptance of von Behring's theory, even though supported by the advocacy of Calmette and his school. It is the placing upon a scientific basis the grounds for distinguishing between two varieties of the tubercle bacillus, the human and the bovine (30, 10). Briefly, they consist, first, in the constant inoculation differences—that is, the rabbit succumbs to a progressive generalized tuberculosis in four to five weeks' time after inoculation with the bovine strain, but exhibits retrogressive lesions with the human strain; and, secondly, in the inconstant, but occasionally useful, cultural differences, as evinced by the comparatively easy and luxuriant growth of the human variety. The allusion in the report of the Royal Commission to peculiar quasi-intermediate forms occurring in lupus and in tuberculosis of the horse (see also 31), while they give us to pause in being too insistent on the distinctions which serve to separate the human from the bovine variety, cannot, I think, in the face of the very many unsuccessful experimental attempts to convert the one variety of bacillus into the other (32, 33, 8), completely

* A paper read before the Cardiff Medical Society.

† The figures in parentheses refer to the bibliography at end of paper.

Morland, *Lancet*, 1912, ii, p. 688, suggests the contrary.

shake our belief in the separate identity of the two varieties.

In the first place, assuming these differences do exist (34), I agree with Cobbett (3) when he says that "von Behring's theory as to the causation of phthisis, so far as it relates to infection by cow's milk, cannot be accepted," on the ground that, with remarkably few exceptions, the bacillus isolated in phthisis belongs to the human variety. Calmette (10), at the International Tuberculosis Congress held last year in Rome, stated that, over the age of 16 years, 98.09 per cent. of all fatal cases of tuberculosis were due to the human tubercle bacillus (see also 35); since, over the age of 16 years, the vast majority of deaths from tuberculosis result from phthisis, it follows that the human variety accounts for practically all the cases of phthisis (36), and not the bovine variety, as von Behring's statement would imply.

In the second place, assuming the "seeds of phthisis" were laid in infancy by the drinking of cow's milk, in the face of these statistics there would have to be postulated a mutation of bovine into human tubercle bacilli, and this, in our present state of knowledge, we cannot accept. Statistics culled from all sources agree in assigning to the bovine variety of the tubercle bacillus varying percentages of cases of tuberculosis under the age of 16. Calmette (10) gives 26.5 per cent. up to the age of 5 years, and from 5 to 16 years a percentage of 25. At the same time it cannot be questioned but that considerable divergences in percentages may be obtained (34). Presumably the source of infection is cow's milk, which, in its turn, is infected chiefly through tuberculosis of the udder, though the bacilli have been shown to be present in the milk of tuberculous cows in the absence of actual affection of the udder itself, either directly or indirectly, by reason of the contamination of the milk by the cow's tubercle-laden faeces (37). Incidentally, this country has a long way to go before it attains to the measure of freedom of its dairy cattle from tuberculosis such as obtains in Denmark. Chiefly through the instrumentality of Professor Bang of Copenhagen, legal statutes enact the separation of herds, by means of the tuberculin test, into two separate divisions, followed by the gradual elimination of reacting animals. The success following these measures has been remarkable, and affords an example of how the problem of infected milk is best attacked.

Surely if the intestinal mucosa is the chief portal of entry, and cow's milk the chief source of the tubercle bacillus, we would reasonably expect to find a very much higher percentage of cases due to bovine infection. As a matter of fact you will note that even under the age of 5 years (see also 36), nearly three-quarters of the cases of tuberculosis are traceable to infection from a human source.

We have travelled far since Koch (38) startled the scientific world by declaring that infection in the human was wholly, or practically so, due to the human variety of the tubercle bacillus, but I think some of us must retrace our steps from having advanced too far in the opposite direction.

The broad facts are these: that whereas bovine infection does occur in infancy and childhood to the extent of 25 per cent., the remaining 75 per cent. of the cases, and practically the whole of the cases after the age of 16 years, are due to the human bacillus.

Ritter and Velding (39) have found that cases of tuberculosis, where the disease was recognized in childhood, or where, owing to infected relations, infection was more than probable, would appear to run a milder course, and be more amenable to sanatorium treatment, than cases where the disease was not recognized in childhood and where the relations were not infected (see also 40). In support of their contention that previous infection renders the disease less virulent they adduce evidence from Turkey to show that, in districts where the disease is almost unknown, tuberculosis, when it does occur, runs a very rapid course. While, as a corollary, they affirm that the ordinary healthy adult, in this and other countries similarly situated as regards the disease, possesses a more or less complete immunity (see also 41).

This opens up several important questions. It suggests that if immunity can be so produced (42) how much better it would be to produce it artificially, as proposed by Calmette (43), than to run the grave risks attending

infection by the usual method. It suggests that persons infected with tubercle bacilli in early life are capable of dealing with fresh infections without difficulty. It suggests that bovine infection in childhood may possess an immunizing effect in later life, and that infection by tubercle bacilli in milk, provided they are not present in too great numbers, may have that desired effect. It suggests that where previous infection can be excluded, the disease runs a course very different from that run where previous infection cannot be excluded. It suggests that military tuberculosis, if not due to an overwhelming infection of tubercle bacilli, is due to infection on virgin soil, and that the more common cavernous tuberculosis is to be regarded as a phenomenon of a certain degree of immunity.

How are we, then, to account for the undoubted high percentage of infection—a percentage which I gave reasons for supposing to be very much higher than is generally conceded—in infants? In other words, what are the portals of entry of the human variety of the tubercle bacillus in infancy?

On the one hand, it cannot be denied that, where one or both parents are phthisical, or where the infant comes into direct contact with persons suffering from phthisis, the chances of infection, both by way of the respiratory system and the alimentary tract, are considerable, and no doubt infection does certainly occur in this manner (44). It is also reasonable to suppose that, where the infective material is abundant, where the dose, in other words, is high, the infant should develop tuberculosis of the miliary type, especially if the predisposing factors are in evidence, and the natural forces of defence weakened (45).

On the other hand, the possibility of the transmission of tubercle bacilli through the placenta must not be altogether disregarded, as would almost appear to be the case at the present time. With the exception of Baumgarten (46), who, it seems, has held the view of antenatal infection for some years, observers in general assign but very little importance to this portal of entry. Schmorl (47) goes even so far as to say that, unless the placenta is definitely diseased, infection by this channel is impossible. One of the strongest arguments used by those opposed to placental transmission is the extreme rarity of congenital tuberculosis (9, 48, 49). It is undoubtedly rare, and, when it does occur, exhibits generalized characters (49). But because congenital tuberculosis is rare, or rather because generalized tuberculosis occurring before or immediately after birth is rare, is, to my mind, no argument against the transmission, in very many instances, of the tubercle bacillus by way of the placental circulation.

In the first place, when we take into consideration the enormous proportion of our population who are definitely tubercularized, well over 90 per cent. (43), and whose systems are constantly being infected with the tubercle bacillus; when we realize that pregnancy, with its stress and debilitating effects, renders the organism less ready to cope with and destroy the infections as they occur (33), we will not be surprised if, in the circulating blood of the mother (50, 51, 13), there may exist tubercle bacilli in far greater numbers than are to be found under normal conditions.

In the second place, when we understand that it has been shown that the normal mucous membrane of the intestine may constitute a portal of entry of the tubercle bacillus and leave no sign by which one can recognize its penetration (see also 52), it is difficult for us to believe that the cells of the chorionic villi, though they be endowed with properties not yet thoroughly understood (53), can prevent the passage of such an extremely resistant body as the tubercle bacillus into the fetal circulation.

Lastly, when we surmise that the bacilli thus introduced into the fetus may, after all, be relatively few in number; that the lesions they produce may be prefollicular and eventually retrogressive; that, as we have before noted, von Pirquet's reaction may yet be absent, it will be very difficult for us to deny the possibility, or even the strong probability, that such manner of infection does occur, that antenatal infection constitutes a portal of entry of the tubercle bacillus.

To sum up, then: the portals of entry of the tubercle bacillus, especially in childhood, include the respiratory system, the alimentary tract, the mucous membrane of the naso-pharynx, the skin, and, lastly, the placenta.

The significance of these many portals is evidenced in the practical tubercularization of the community (48), and is of interest in the detection of the source of infection, both human and bovine.

The questions that yet remain to be solved concern the latency of the infection contracted in childhood. Where do the bacilli live? Do they live in the tuberculous glands and old lesions so frequently found *post mortem*? Do they there remain quiescent for indefinite periods, capable, when the time comes, of setting up disease, as exemplified in the recent attention drawn to pulmonary tuberculosis resulting from extension from tuberculous bronchial glands (51, 55)? If so, how are we to account for the negative results obtained by Cobbett (3) after inoculating animals with the tuberculous tissues? Do the bacilli live in the blood and tissues generally (50, 51, 13), having established a *modus vivendi*, wherein they are tolerated but not allowed to multiply to any extent? This may be so, and thus the vast majority of the people in this country are in reality tubercle carriers, awaiting some impairment of the powers of resistance—to quote von Behring—in order to become obvious sufferers from tuberculosis.

Much might be said regarding the view that the first infection in childhood, by conferring a partial immunity, determines that, in the large st proportion of cases in adult life when tuberculosis does supervene, the disease shall run its most chronic form with cavity formation in the lungs (55, 56), and not the acute military form.

From what has been already brought forward it will be seen that, although the problems that tuberculosis still offers for solution are of far-reaching consequence, still the recognition of the portals of entry and the source of the infection places us in a stronger position than formerly, and enables us to say, in the words of the resolution adopted at last year's International Congress, "Propylaxis of tuberculosis must principally be directed towards the suppression of contamination from man to man, and principally in the family, and, whilst contamination of man by bovine infection is of less frequency, it is, nevertheless, necessary to maintain all measures against infection from this source."

THE VARIETIES OF TUBERCULIN IN THE TREATMENT OF TUBERCULOSIS.

BY NATHAN RAW, M.D., M.R.C.P. LOND.,

PHYSICIAN, HILL ROAD INFIRMARY, LIVERPOOL; RESEARCHER IN TUBERCULOSIS, UNIVERSITY OF LIVERPOOL.

IN the paper which I published in the BRITISH MEDICAL JOURNAL in 1903 I ventured to suggest that a considerable amount of tuberculosis in children was caused by the bovine tubercle bacillus. Since that time a great amount of scientific investigation has been carried out over the whole world, and especially by our own Royal Commission, with the result that we are now certain of the following conclusions:

- That the great mass of tuberculosis occurring in the human subject in the form of pulmonary tuberculosis is caused by the human bacillus (*Typus humanus*), and is conveyed from person to person by infection.
- That a considerable amount of so-called surgical tuberculosis in children and adults is caused by the bovine bacillus (*Typus bovinus*), received into the alimentary canal through milk and food.

Originally of a common species, the bacilli have, owing to long environment in different hosts, assumed marked characteristics, so that we are able, experimentally, to divide them into two types:

- Bacilli of the Typus humanus*, which cause:
 - Pulmonary tuberculosis and pleurisy.
 - Secondary tuberculous enteritis.
 - Tuberculous laryngitis.
 - Fistula in ano and possibly some other lesions.
- Bacilli of the Typus bovinus*, which cause:
 - Primary abdominal tuberculosis.
 - Tuberculous lymph glands.
 - Bones and joints (probably).
 - Genito-urinary tuberculosis.
 - Acute military tuberculosis.
 - Lupus. Meningitis.
 - Pulmonary tuberculosis (a small percentage).

I have for the last ten years separated my wards in hospital into human and bovine wards, and after an observation of over 6,000 cases of tuberculosis, I am impressed with the fact that it is rare to see lesions of the human and bovine type associated in the same patient. In fact they seem to be antagonistic to each other, so that one rarely observes a patient suffering from pulmonary tuberculosis develop any other lesions beyond those mentioned in the human group. It is also rare for cases of gland or bone tuberculosis to develop true pulmonary tuberculosis except in the course of a general systemic infection.

It is necessary to mention this clinical fact to explain my reason for using tuberculin of the opposite strain in the treatment of the disease. There seems to be little doubt that a mild infection by bovine bacilli in the human body, such as neck glands, by way of the alimentary canal, will protect against an infection by human bacilli, and it is most probable that a large number of people are immunized against pulmonary tuberculosis in after-life by having been infected in early childhood by bovine bacilli through milk or food. In all the experimental work throughout the world it has been found to be a rare occurrence to find both types of bacilli in the same body.

Variations in Virulence.

Whether or not a patient is going to be destroyed by tuberculosis seems to me to depend on two important factors: (1) virulence of infection; (2) individual resistance.

The variability in virulence of the tubercle bacillus is

well recognized. In many cases, fortunately, the infection shows little tendency to progress in the body, so that we constantly see in practice patients who have suffered from tuberculosis for twenty or thirty years. In other cases the infection is virulent and rapid, and kills the patient in two or three weeks.

In the former cases the bacilli are of low virulence, in the latter they are highly virulent, giving the body no chance to offer any resistance to the attack.

Treatment by Tuberculin.

It is in the avirulent bacillary infections that tuberculin is of such great service, and I have found it of little or no value in acute virulent infections.

The whole object of treatment by tuberculin is to produce an immunity in the blood against infection by tubercle bacilli; and, what is even more important, to prevent the further spread of the bacillary infection in the tissues. Whether or not it is possible to ever produce a complete lifelong immunity against tubercle is a matter of doubt.

As a result of my experience I have found that the lesions in the body which are caused by the *Typus humanus* are benefited more quickly and certainly if a tuberculin prepared from the opposite strain—namely, bovine tuberculin—is used; and in all cases of pulmonary tuberculosis I now only use bovine tuberculin. It is less toxic, and does not so readily cause reaction, is more easily tolerated, and causes the bacilli to disappear from the sputum more quickly. For the lesions caused by the *Typus bovinus*—namely, lymph glands, tuberculous peritonitis, lupus, tuberculous disease of the bladder, bones, and joints—I invariably use Koch's old tuberculin prepared from human cultures.

The question of dosage is of vital importance, and my routine practice is to administer a course of tuberculin in twelve weekly injections, then resting for a month, and, if necessary, repeating the maximum injection every week. My dosage is as follows of either human or bovine tuberculin:

| | | |
|------------|------------|-----------|
| 0.0001 mg. | 0.0006 mg. | 0.006 mg. |
| 0.0002 " | 0.0008 " | 0.0075 " |
| 0.0004 " | 0.001 " | 0.008 " |
| 0.0005 " | 0.004 " | 0.01 " |

A special watch must be kept on the temperature, pulse, and blood.

It is rare to observe a general reaction if the above dosage is carefully followed.

In a great many cases the tubercle bacilli disappear entirely from the sputum at the end of a course of injections, but, unfortunately, if the tuberculin is not persisted in they in many instances speedily return—so that in some cases of pulmonary tuberculosis the injections should be continued for an indefinite time.

Whilst tubercula *per se* cannot be expected to heal cavities in the lung or replace damaged tissues, yet it undoubtedly has the power of preventing the spread of the tubercle to healthy parts by means of its immunizing effects. Time is thus given for repair of the affected tissues.

In conclusion, I would like to express my opinion, after treating over 600 patients with injections of tuberculin, that it is a remedy of the greatest value, especially in early cases and where the deposit of tubercle is localized, as in one apex or in a lymph gland or single joint; but where the tuberculosis is disseminated and complicated by secondary infections the use of tuberculin cannot be expected to be of much avail. It ought, however, to be tried in every case with the hope of some relief or possible benefit, as we cannot allow the patient to suffer and die without making every effort to arrest the progress of the disease.

Tuberculin is not going to revolutionize the treatment of tuberculosis. It is a valuable aid to the other methods of treatment, hence it must be used with care and discrimination and with a full knowledge of its dosage and therapeutic effects.

I would conclude by saying that the best treatment we can offer to-day to a person infected with tuberculosis is a prolonged open-air life, preferably in a well-conducted sanatorium, excess of nutritious food, gentle exercise followed by plenty of rest, and a course of tuberculin by a careful physician.

ON THE "CONTROLLED" THERAPEUTIC USE OF NEW TUBERCULIN IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

BY

E. E. A. T. RIGG, M.B., B.S.LOND., ETC.,
LATE HOUSE-PHYSICIAN TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.

Introductory Remarks.

THE success claimed for various tuberculins used in various methods in the treatment of pulmonary tuberculosis has been considerably discounted by the fact that many do very well on ordinary hospital or sanatorium treatment or even at home at work, without tuberculin, and this discount is emphasized by the fact that the advocates of the use of tuberculin (or at any rate some of them) say that only such cases of pulmonary tuberculosis as are afebrile and up and about are fit subjects for the treatment.

With these considerations in mind, Dr. Batty Shaw (upon whose patients and at whose instigation these investigations were carried out) suggested that I should carry out observations on the comparison of afebrile cases of pulmonary tuberculosis treated for three months, half with tuberculin and half without, the cases being compared at the beginning and end of this period. The plan of *controlling* the therapeutic use of tuberculin in the way described in this paper is entirely due to Mr. W. Palin Elderton, F.I.A.

Criteria.

The question arose as to what criteria should be used in estimating the improvement or the reverse of the cases after their course of treatment.

1. *General Condition.*—This, as judged by the patient's own feelings and the observations of the medical attendant, was self-evidently too fallacious to place stress upon, as a patient quite often says he or she is better when the temperature has risen or the physical signs show extension of the disease in the chest. This therefore was relegated to a secondary place.

2. *Increase of Weight.*—This also was evidently fallacious, as it might easily coexist with extension of disease and not be present, or to a much less extent, in a case which was in all other respects much improved.

3. *Functional Capability.*—An attempt is made to estimate this partly at the Brompton Hospital by registering the number of miles per diem a patient walks, but this also self-evidently will vary with the natural constitution and habits of the patient.

4. *Occurrence or Non-occurrence of Relapses.*—In a period of three months this could not well be judged of, and the occurrence of temperature, if maintained for more than a day or two, was considered as disqualifying the patient from the conditions of the experiment. No reliance was placed upon the disappearance of tubercle bacilli from the sputum as a sign of improvement, for the extrusion of phlegm is so obviously under the control of the patient, and temporary absence of tubercle bacilli in the sputum of patients suffering from active pulmonary tuberculosis is not infrequent.

5. *Physical Signs.*—The only criterion that remained, therefore, was alteration in the physical signs—that is, whether there was extension or retrogression of them during the three months—and of these the greatest attention was paid to rales as being the most definite indication of the extent of disease which could easily be demonstrated to another observer. Therefore, at admission, the rales were estimated and diagrammatized to the actual intercostal spaces and parts of intercostal spaces (outer and inner ends) in which they were heard. This was done for the front and back of both lungs. These observations were made independently by Dr. Batty Shaw and by myself, and in nearly every case substantial agreement was arrived at. At the end of three months, the cases were again examined by Dr. Batty Shaw (without examination in the interval, and, as far as possible, without his knowing whether the patient had been treated with tuberculin or not). The examination was carried out in the same way, rales being diagrammatized to the space without reference to the first diagram, and then the two diagrams compared. The cases were examined independently by

me, and I made separate diagrams which were afterwards compared with those of Dr. Batty Shaw. Out of 19 cases there was substantial agreement in 17 cases, and minor differences in 2, which were afterwards adjusted. In some cases the extent of rales had increased, in some retrogressed, and in others remained stationary, while in still others there had been increase of rales in one lung and diminution in another. In such cases a balance had to be struck between the two, and the case adjudged as worse, stationary, or better accordingly.

Physical signs were, therefore, taken as the main criterion, and alteration and increase of weight, amount of exercise, and general condition correlated secondarily.

Choice of Cases.

In agreement with one of the safest recognized methods of giving tuberculin, it was adopted as a *sine qua non* that all the cases should be afebrile when up and about all day, and that rise of temperature maintained for more than a day or two should disqualify the patient from being one of the series.

Another point now cropped up, which was that many cases are adjudged suffering from pulmonary tuberculosis on slight and often equivocal signs at one apex, or on no signs at all, and on some hæmoptysis which may very possibly have not been hæmoptysis at all, but have been concealed epistaxis or bleeding from gums, teeth, or posterior naso-pharynx. Therefore, as the second *sine qua non* it was resolved to take only those patients into the scheme who had expectorated sputum in which tubercle bacilli had been found.

The third point was the distribution of the cases between the two methods of treatment, and where a number of cases presented all grades of involvement of the lungs from very slight to extensive (1 apex to 5 lobes), and where some showed fibrosis and some not, it would be almost impossible to apportion the cases fairly between the two treatments so as to be free from any suspicion of bias. To obviate this, the patients were chosen by lot. In this way two series of nine were chosen, but, because of rise of temperature or because they left the hospital, three soon fell out from the names not treated by tuberculin. To replenish these, the next four patients fulfilling the conditions of afebrile tuberculosis drew lots, one to have tuberculin treatment, and three not. The final result was that ten patients were treated with new tuberculin (T.R.) and nine were not, the one out of the latter ten cases being set aside, as she left the hospital before the expiration of three months.

Method of Giving Tuberculin (T.R.).

As before mentioned, tuberculin was only given to afebrile cases.

Dosage.—Treatment was commenced with a very small dose, increased every second day at first, and afterwards at intervals of four days.

General Scheme.—The dose given was as follows in milligrams every second day: 0.00001, 0.00003, 0.00005, 0.00007, 0.0001, 0.00015, 0.0002, 0.0003, 0.0005, 0.0007, 0.001, 0.0015, 0.002, 0.003, 0.005, 0.007, 0.01, 0.015, 0.02, 0.03, 0.05, 0.07, 0.1.

Every Fourth Day.—0.15, 0.2, 0.3, 0.5, 0.7. The last—0.7 mg.—was the maximum dose reached.

The injection, however, was conditioned by the occurrence of reactions. If the temperature rose to 99° F. or above with all but the smallest doses (where the temperature was possibly not due to the injection of tuberculin) the patient was put to bed until it became normal, and no further dose was given for five to ten days (five with small doses and up to ten with the larger), and then the last dose repeated. In the case of the smallest doses, the next dose was given after an interval of four or five days. If the temperature now remained normal, the original increase of dosage was gone on with. If another reaction occurred, the patient was again put to bed till the temperature was normal, and when it had kept normal for from two to seven days, the same or a smaller dose was given. If this produced a reaction a still smaller dose was given after an appropriate interval until one was found which produced no response. This dose was now repeated two or three times before increasing again.

Out of 10 cases, 2 gave no reaction till 0.7 mg. was injected. A third case reacted first with 0.1 mg., whilst the other cases reacted two to seven times with various doses.

A Typical Example.

CASE V.

First dose 0.00001 mg. This produced a reaction temperature 100° F. After eight days' interval 0.00003 mg. was given, and at two days' interval, 0.00005, 0.00007, 0.0001, 0.00015, 0.0002, 0.0003, 0.0005, 0.0007, 0.001, 0.002, 0.003, 0.005, 0.007, 0.01, 0.015, and 0.02 mg. After this last the temperature rose to 99°; five days' interval, and then 0.02, 0.03, 0.05, 0.07, and 0.1 mg. were given at two days' interval, then at four days' interval, 0.15, 0.2, 0.3, 0.3, and 0.3 mg.

At the end of three months all the 19 cases were again examined in the way described and note also made of their weight and amount of exercise taken.

SUMMARY OF RESULTS.

1. Physical Signs:

(a) Tuberculin-treated patients. Out of 10: Improved 1, worse 4, *in statu quo* 5.

(b) Non-tuberculin-treated patients. Out of 9: Improved 4, worse 3, *in statu quo* 2.

2. Increase of Weight:

(a) Tuberculinized patients (10 cases). Gained 10–20 lb. 4, gained less than 10 lb. 4, *in statu quo* 2.

(b) Non-tuberculinized patients (9 cases). Gained over 20 lb. 2, gained 10–20 lb. 3, gained less than 10 lb. 4.

In (a): Average per cent. of increase of weight, 6.3 per cent.

In (b): Average per cent. of increase of weight, 10.3 per cent.

3. Exercise—capacity of walking, maximum amount per diem:

(a) Tuberculin patients (10 cases). Two miles and over, 3; 1–2 miles, 5; less than 1 mile, 2.

(b) Non-tuberculin patients (9 cases). Two miles and over, 6; 1–2 miles, 3; less than 1 mile, 0.

4. *General Condition.*—This is a difficult criterion, but, generally speaking, in (a) only 5 out of 10 were in thoroughly good condition; in (b) 8 out of 9 were in thoroughly good condition.

The net result of these observations is to show that the administration of new tuberculin by one of the more popular approved methods is not followed by greater improvement in the *physical signs*, nor by greater increase in weight, nor by more greatly increased capacity for physical work, nor by a greater improvement in the general condition, as compared with the results of ordinary hospital methods.

The observations on the signs do not support the idea that new tuberculin in any way lessens the activity of the local lesion. It is possible that the less favourable influence on weight, the less capacity for work, and the falling off of the general condition are due to the disabilities imposed on the patient by being treated with tuberculin, as they so often were kept in bed to help restore the temperature to normal.

ORGANIC ACID RATIO OF URINE AFTER TUBERCULIN.

By ARTHUR H. GREGSON, M.B., B.Ch.Vict.,
BLACKBURN.

A GIRL, born in 1892, had suffered from lupus vulgaris of the left cheek from 1895 to 1905. Roentgen rays were tried, but did not benefit. Curetting was successful in 1905, but afterwards the glands of the neck and beneath the jaw on both sides enlarged.

She consulted me, and on December 4th, 1909, received an injection of $\frac{1}{100000}$ mg. T.R. This was repeated weekly in increasing dose until, on February 1st, 1910, $\frac{1}{100}$ mg. T.B.E. was given; after this the temperature rose to 103° F., the patient became delirious, and suffered from severe abdominal pain and tenderness. The temperature was intermittent for months; various methods were tried to reduce it, including administering on May 3rd and 22nd of $\frac{1}{100000}$ mg. T.R. of human origin, as before, but without benefit.

About the middle of July $\frac{1}{5000}$ mg. of bacillary emulsion of bovine origin was administered; the temperature fell to normal and pains decreased.

It seemed as though the failure were associated with the human origin and the success with the bovine origin, and it was determined to repeat the experience.

On August 2nd, 1910, the patient weighed 7 st. 8½ lb., and $\frac{1}{5000}$ mg. T.B.E. was administered. It was increased to $\frac{1}{5000}$ mg. on the 13th and to $\frac{1}{1000}$ mg. on August 23rd and September 1st, after which the temperature became erratic. The question of over-dosage had to be considered, but on September 6th the girl weighed 8 st., a gain at the rate of 1 lb. a week; the idea of the wrong variety of tuberculin was therefore adhered to, and $\frac{1}{3000}$ c.c.m. original bovine tuberculin was administered on September 13th.

The temperature fell suddenly on the eighth day. Increasing doses were given on September 23rd, October 6th, October 19th, and reached $\frac{1}{3000}$ c.c.m. concentrated bovine tuberculin on October 26th.

The patient felt considerably better, and it was determined to attempt an investigation into the acidity of the urine under the action of the different varieties. No constant effect was found upon the total free acidity, and this was then divided into the mineral and organic portions, and the following results obtained for the ratio of organic to total acidity:

Increased Organic Acidity after Human Tuberculin on January 4th.

| Before. | Injection. | After. |
|---------|---------------------------------|--|
| 0.26 | $\frac{1}{3000}$ c.c.m. T. Koch | 1.04 (2 days); 2.2 (5 days); 2.5 (6 days). |

Decreased Organic Acidity after Bovine Variety on January 17th, 26th, and February 6th.

| Before. | Injection. | After. |
|---------|------------------------------|------------------------------|
| 1.7 | $\frac{1}{3000}$ c.c.m. P.T. | 1.6 (3 days); 1.5 (6 days). |
| 2.5 | $\frac{1}{750}$ c.c.m. P.T. | 1.1 (5 days). |
| 1.0 | $\frac{1}{300}$ c.c.m. P.T. | 0.56 (2 days); 0.4 (9 days). |

An injection of $\frac{1}{1500}$ c.c.m. T.K. on December 19th had sent the temperature to 100°, but no rise was noticed after that on January 4th, whilst after the bovine tuberculin on February 26th the temperature rose again to 100°, so this is some evidence that the difference in result is not dependent upon the weaker nature of the bovine variety.

As the effect of only one "human" injection had been tested the following confirmatory observations were made, and the effect upon the lime, magnesium, and phosphorus noted at the same time:

E. II.

| February 12. | | Injection $\frac{1}{3000}$ c.c.m. T.K. | Feb. 15. | Feb. 20. | Feb. 23. |
|-----------------------------------|------------|--|----------|----------|----------|
| | | | Grams. | Grams. | Grams. |
| Lime in 24 hours | 0.122 gram | | 0.288 | 0.378 | 0.254 |
| Lime in 100 c.c.m. | 0.0135 " | | 0.026 | 0.031 | 0.026 |
| Mg in 24 hours | 0.526 " | | 0.277 | 0.708 | 0.431 |
| Mg in 100 c.c.m. | 0.049 " | | 0.025 | 0.059 | 0.044 |
| Ratio of organic to total acid | 1.37 | | 1.65 | 1.44 | 2.1 |
| Ratio of phosphorus to total acid | 0.2 | | 1.2 | 0.7 | 0.5 |
| Ratio of phosphorus to lime... | 1.75 | | 2.9 | 2.35 | 2.35 |

A. R.

| | | Inject $\frac{1}{300}$ c.c.m. T. K. | Oct. 27. | Nov. 1. |
|-----------------------------------|------------|-------------------------------------|----------|---------|
| | | | Grams. | Grams. |
| Lime in 24 hours | 0.688 gram | | 0.790 | 0.292 |
| Lime in 100 c.c.m. | 0.055 " | | 0.046 | 0.03 |
| Mg in 24 hours... | 0.979 " | | 0.884 | — |
| Mg in 100 c.c.m. | 0.034 " | | 0.026 | — |
| Ratio of organic to total acid | 0.03 | | 1.59 | 1.15 |
| Ratio of phosphorus to total acid | 0.02 | | 0.3 | 0.26 |
| Ratio of phosphorus to lime | 1.1 | | 0.8 | 1.5 |

These and four other experiments therefore confirm the increase of the organic acid ratio after administering human tuberculin, and show that it is not due to the lime and magnesium being reduced.

The methods used were as follows:

Total Acid. Neutralization with decinormal NaOH after adding 1 per cent. neutral potassium oxalate, using phenolphthalein as indicator.

Ammonia.—After neutralization of 20 c.c.m. as above, add 8 c.c.m. freshly neutralized 40 per cent. formalin and continue the addition of decinormal NaOH.

Ethereal SO₄.—Difference between precipitation of urino by barium nitrate with and without previous oxidation by conc. HNO₃.

Mineral Acidity.—Add 5 c.c.m. decinormal NaOH, ignite, oxidize, boil with excess of acid, neutralize, and estimate alkali lost. Deduct the ammonia and ethereal SO₄.

Organic Acidity = Total acidity — mineral acidity.

I have been unable to trace any similar experiment. If the prevailing opinion be correct, that there is no fundamental difference between the various tuberculins, we may as well settle the relative activities and cease to encumber ourselves with so many specimens. If incorrect, we ought to find their differences and discover the indications for each.

A YEAR'S EXPERIENCE OF DIORADIN IN SURGICAL TUBERCULOSIS.

By ATKINSON STONEY, F.R.C.S.I.,

VISITING SURGEON TO THE ROYAL CITY OF DUBLIN HOSPITAL.*

ALMOST a year ago I read a paper before this Section of the Academy, giving the results of treatment by dioradin of 15 cases of tuberculosis. Since then I have been more or less continuously engaged in the further treatment of these and other cases by the same means, and I desire to record the results I have obtained during fifteen months' trial of this remedy in cases of surgical tuberculosis, and the conclusions at which I have arrived as to the value of this method of treatment.

I shall first consider the cases which I reported a year ago; they were 15 in number, but to-night I shall only speak of 14 of these, as one of them was a case of pulmonary tuberculosis, and the number of this class of case has been too small to be worth recording the results at present. These 14 cases were divided into two classes according to whether they were complicated by sepsis or not.

Of the 5 uncomplicated cases each had received one course of injections, and one was apparently cured, and the other 4 were greatly improved, and they showed an average gain in weight of 8.3 lb. Four of these have since received a second course of injections, with the result that there are now 4 apparently cured, and 1 greatly improved, and the average gain in weight is 10.5 lb.

Of the 9 cases in the second class, that is, cases complicated by sepsis, there was 1 apparent cure, 2 greatly improved, 4 improved, and 2 not improved, with an average gain in weight of 2 lb. Four of these cases were given a second course of injections, and a fifth was given both a second and a third course, with the result that there were 3 more apparent cures and 1 greatly improved. The fifth, which was a case of tuberculous and septic hip which had been excised, improved further after a second course of injections, but about a month later developed acute nephritis and died. The average gain in weight of these 5 patients was 5.4 lb. As regards the other 4 of this group who did not receive a second course of injections, 1 was a case of multiple foci which left the hospital cured after the first course (No. v previous paper). The second, a septic hip in which there was always much doubt as to the presence of tuberculous disease, left hospital unimproved after the first course of injections (No. viii, previous paper). The third was a case of tuberculous cystitis with almost certainly a similar affection of both kidneys as well; he also left hospital unimproved after the one course of injections and died shortly afterwards (No. xii previous paper). And the fourth was a case

* Read before the Surgical Section of the Royal Academy of Medicine in Ireland, November 29th, 1912.

of lupus which left hospital improved after the first treatment; she reported since that the improvement continued, but she did not return for a second course (No. XIV previous paper). I shall now give a brief account of the treatment of a further series of 14 cases.

CASE XV.

T. E., male, aged 35, admitted January 20th, 1912, with tuberculous disease of left knee, started one and a half years before, had got rapidly worse in previous month. Bier's passive congestion was tried for a month after admission with no sign of improvement; left knee 2 to 3 centimetres larger than right, bulging spot with fluctuation on outside of joint, marked tenderness, increased local temperature; pain on movement, traction, or percussion of heel. Knee flexed to angle of 140°, movement of about 20° only. Put in plaster and given course of injections. Discharged April 11th, 1912. Pain relieved, and patient had put on flesh; unfortunately he had not been weighed before the injections were commenced. Readmitted July 25th; when the plaster was removed an abscess was found on point of bursting on outside of knee. This was opened and scraped on August 3rd; no direct entry into the joint could be found; a second course of injections was given from August 2nd to September 25th. The abscess closed rapidly, but a second formed lower down and was opened and scraped. September 14th; again no direct opening into the joint could be found; a third course of injections were given from October 9th to November 26th, when he was discharged with knee in plaster, both wounds soundly healed, the leg straight and painless, and the knee practically the same size as the other. His weight increased by 30½ lb. during his second stay in hospital.

CASE XVI.

B. G., female, aged 9, admitted September 14th, 1911, complaining of limp on right side. Patient fell on right hip some months before. A month later there was some pain in the hip, which continued on and off till admission. On examination there was apparent lengthening, slight flexion and abduction, pain on percussion of heel, the movement at the joint was greatly limited, and there was loss of tone of the gluteal muscles on the affected side. A course of injections was given between December 18th and February 14th. The patient was kept in bed with extension most of that time. She was put in plaster and allowed up on crutches on January 27th, and discharged soon afterwards. Her weight was the same as on admission. A second course of injections was started early in March, given every second day, as the patient attended as out-patient. She received twenty injections, then ceased to attend, but reported shortly afterwards that she was going about without crutches. She has not been heard of since.

CASE XVII.

A. G., female, aged 32, admitted April 18th, 1912. For the last eight years she had a swelling of the right wrist. She was operated on four years ago and again two months before admission. The swelling was most marked in front and on the ulnar side of the wrist. There was a scar 5 in. in length on the ulnar side with a sinus over the ulnar styloid. She also had a swelling of the base of the first phalanx of the right index finger. No extension of the wrist was possible; flexion was possible only to about half a right angle, and she was only able to partially close the fingers. There were several large glands in right axilla and one small one above the right clavicle. A skiagram showed general blurring of the carpal bones and fusion of the semilunar and os magnum. A first course of injections was given from April 19th to June 7th. The swelling of the wrist became less and the sinus healed. There was less pain on attempted movement, and the weight increased 8½ lb. She was sent to the country with her wrist in plaster. She was readmitted on July 9th, 1912. There was no pain in the wrist, the swelling was further reduced, and the sinus was still healed; the movement was more extensive; loss of weight of 3 lb. had occurred. A second course of injections was given from July 11th to August 28th. She was sent back to the country on September 3rd in plaster; the glands in the axilla were greatly reduced in size and the patient had added over 3 lb. in weight, making a total increase of 8½ lb. since the commencement of treatment.

CASE XVIII.

K. C., woman aged 31, admitted July 8th, 1912. There was a history of pain in the back for about a year, and there was an enormous abscess in the left iliac fossa. An x-ray photograph showed extensive destruction of the third and tenth lumbar vertebrae. There was no visible deformity. On July 21st an incision was made above Poupart's ligament, and over a pint of tuberculous pus was evacuated; the cavity was douched out and partially filled with 2 per cent. formalin in glycerine, and the incision closed. Injections of dioradin were given from July 22nd to September 7th. A week after operation there was an escape of some dark-coloured serum from the wound, the lower end of which remained open, necessitating dressing twice a week. The sinus so formed was scraped on September 11th, when some tuberculous infection of the divided abdominal muscles was found. The wound was cleansed with carbolic acid and iodine, and rapidly healed, and the patient left hospital on September 23rd, 1912. Her weight had increased by 4 lb. 9 oz.

CASE XIX.

F. W., male, aged 36, admitted April 26th, 1912. He had pain in his back, said to be rheumatic, a year ago, and noticed a swelling in the right groin three months ago. On admission there was an enormous swelling of the right iliac fossa and the upper part of the thigh; fluctuation was present, both above and below Poupart's ligament. An x-ray examination showed disease of the third lumbar vertebra on the right side. There was no pain in the back or tenderness, but there was rigidity of the lumbar spine. On May 4th the abscess was opened above Poupart's ligament; about 1½ pints of tuberculous pus was evacuated, and the cavity injected with 2 per cent. formalin in glycerine and completely closed. Five days later a large quantity of blood-stained discharge necessitating dressing two or three times a week. Injections of dioradin were commenced on May 3rd and finished on June 20th. The patient was sent home on July 6th with the wound healed. Though he was not weighed, he appeared to have put on flesh.

CASE XX.

S. M., female, aged 24, admitted April 11th, 1912. An angular deformity existed in the mid-dorsal region which had been coming on for about a year, with great pain in the back and also radiating round the lower part of the chest; paraplegia was also well marked. She was kept flat on her back for over four months. The paraplegia increased till all movement of the lower extremities was lost except slight contraction of the great toes. Pain also increased. An x-ray examination showed extensive disease of the fifth to the eighth dorsal vertebrae, with a large mediastinal abscess. On September 14th the right transverse process of the sixth vertebra was removed and the head and neck of the corresponding rib; the abscess was opened, and nearly a pint of pus and caseous material removed. The cavity was filled with 2 per cent. formalin in glycerine and the wound closed in layers. A slight serous discharge from the lower angle of the wound began after ten days, and has not quite ceased yet. Forty injections of dioradin were given between September 16th and November 5th. The condition of the patient has much improved; she has very little pain now and some movement of the legs has returned. It is hoped that she may be put in plaster shortly and get up and about with the aid of crutches. She has not been able to be weighed, but she has evidently put on flesh.

CASE XXI.

H. S., male, aged 18 months. Admitted November 6th, 1911. He was in hospital in the previous June with tuberculous dacrylitis of the left middle finger, which was amputated; the wound healed slowly. On admission the patient had a discharging sinus of the right ankle, the finger stump was discharging, there were enlarged glands in the right submaxillary region, also in both groins, and there was a sinus on the right arm. He was given a course of forty injections of ½ c.c.m. of dioradin between December 6th and February 12th. The os calcis was scraped out on November 14th. The submaxillary glands were removed on January 9th; his weight increased 2½ lb. The finger stump healed, also the submaxillary incision; but the os calcis still discharged and necessitated further operations on February 20th and March 12th. He left hospital some time later with his condition not much improved.

CASE XXII.

E. Q., aged 7½, a delicate looking boy, was admitted on November 29th, 1911. Swelling and pain of the right knee began four months before. The joint was 1 in. larger than the left; an x-ray examination showed early erosion of the end of the femur. There was marked tenderness, and pain at night. There was no fluctuation. Forty injections were given between December 4th and February 8th. He developed diphtheria while in hospital, and was discharged with his knee in plaster on February 22nd. The gain in weight was 3½ lb. He was seen in the dispensary, and was going on well. Towards the end of May he developed signs of tuberculous meningitis, and died in ten days.

CASE XXIII.

J. A., male, aged 16. Admitted October 21st, 1911. He had pleurisy of the left side, but no signs of phthisis. While in hospital a lump was discovered in the left epididymis; it increased in size, and was tender. He was given eighteen injections of dioradin; he increased 3½ lb. in weight, but the nodule increased in size. He was operated on on December 9th. The testicle was removed; there was a large caseous mass in the epididymis, semi-liquid in the centre, which was beginning to burst through the coverings. The wound healed, and the patient was discharged December 23rd.

CASE XXIV.

M. L., female, aged 4. Admitted June 6th, 1912. She showed all the signs of early tuberculous disease of her left hip. Extension was applied, and she was given a course of forty injections of 1 c.c.m. of dioradin. She was put in plaster and discharged on July 27th. She was in the dispensary recently; the hip was still in plaster, and she was walking well without crutches and with no pain. The record of her weight was lost, but it had increased.

CASE XXV.

R. W., female, aged 19. Attended as out-patient from February 23rd to April 8th, 1912. She had enlarged glands in her neck, there were two scars on the right side, and one on the left where the glands had broken down, and discharged on

three occasions, the last time about six months before. She was given twenty-six injections of dioradin on alternate days. The glands disappeared, her general health greatly improved, and she increased 3 lb. in weight.

CASE XXVI.

J. D., male, aged 18 months. Admitted December 20th, 1911. The left eye had been eviscerated at the Royal Victoria Eye and Ear Hospital for anterior staphylocoma the result of tuberculous ulcer. There was a copious discharge from both ears, extensive ulceration under right eye, discharging ulcers on backs of both hands; the right foot was also discharging, and there was a large cold abscess on the left ankle. The temperature varied from 97° to 101°. The weight was 1 st. 1½ lb. Forty injections of ½ c.cm. of dioradin were given between December 22nd and February 16th. By this time his weight had increased by 1 lb., his temperature was normal, and he was taking his food better; the discharge from the ears and ulcers was about the same. On March 1st a large piece of dead bone was removed from under the right eye, after which this wound healed; otherwise the patient did not improve further, and was discharged some time later.

CASE XXVII.

N. B., female, aged 16. Admitted June 19th, 1912. There was tuberculous disease of the right ankle, present for nearly a year; the joint was greatly swollen, and there was great pain on any movement, but the skin was unbroken. Forty injections were given between June 20th and August 14th, and the foot was put in plaster. The plaster was removed on September 10th, the swelling was greatly reduced, there was almost no pain on movement, and she had increased 2 lb. in weight. The plaster was reapplied, and the patient was sent to the country on October 7th, 1912.

CASE XXVIII.

K. L., female, aged 13. Admitted June 10th, 1912. She had tuberculous disease of the right ankle, which was enormously swollen, with several sinuses, both knees were contracted, and there were numerous superficial tuberculous lesions over both thighs, also enlarged glands in her neck. Forty injections were given between June 20th and August 6th. She increased 3 lb. in weight. She developed phlyctenular conjunctivitis and an ulcer, which healed. There was no definite improvement, and she left hospital on September 28th, 1912.

Dividing these 28 cases into two classes according to the presence or absence of sepsis, there were 15 in which there was no sepsis and 13 in which sepsis was a complication. In the first class there were 7 apparent cures (46.6 per cent.), 4 cases of great improvement, which will probably result later in cures (26.6 per cent.), 2 cases showing some improvement (13.3 per cent.), and 1 case which progressed steadily in spite of the injections and had to be operated upon. Finally, there was 1 case which first improved rapidly and gave hopes that it would go on to a cure, but afterwards developed tuberculous meningitis and died. In the second class of 13 cases there were 4 apparent cures, 2 were greatly improved and will probably become cured, 1 was somewhat improved, 5 showed no improvement, and 1 which improved for a time died later of acute nephritis.

Cases uncomplicated by Sepsis.

| Case No. | Disease. | Apparent Cure. | Great Im-provement (Probable Cure). | Some Im-provement. | No Im-provement. | No. of In-jections. |
|----------|-------------------------------------|----------------|-------------------------------------|--------------------|------------------|---------------------|
| I. | Pott's caries (early) | + | | | | 80 |
| IV. | Tuberculous knee | | + | | | 80 |
| VI. | Tuberculous ankle | + | | | | 80 |
| IX. | Tuberculous hip (large abscess) | + | | | | 80 |
| X. | Tuberculous hip (early) | + | | | | 40 |
| XV. | Tuberculous knee | | + | | | 120 |
| XVI. | Tuberculous hip (early) | + | | | | 60 |
| XXVIII. | Pott's caries (large iliac abscess) | | + | | | 40 |
| XIX. | Pott's caries (large iliac abscess) | | + | | | 40 |
| XX. | Pott's caries (mediastinal abscess) | | | + | | 40 |
| XXII. | Tuberculous knee | | + | | | 40 |
| XXIII. | Tuberculous epididymitis | | | | + | 18 |
| XXIV. | Tuberculous hip (early) | + | | | | 40 |
| XXV. | Tuberculous glands | + | | | | 26 |
| XXVII. | Tuberculous ankle | | | + | | 40 |

* Died later of tuberculous meningitis.

Cases complicated by Sepsis.

| Case No. | Disease. | Apparent Cure. | Great Im-provement (Probable Cure). | Some Im-provement. | No Im-provement. | No. of In-jections. |
|----------|-------------------------------|----------------|-------------------------------------|--------------------|------------------|---------------------|
| II. | Tuberculous cystitis | + | | | | 80 |
| III. | Tuberculous lip (late septic) | + | | | | 120 |
| V. | Multiple foci | + | | | | 40 |
| VII. | Multiple foci | + | | | | 60 |
| VIII. | Hip (septic) | | | | + | 40 |
| XI. | Hip (late after excision) | | | + | | 80 |
| XII. | Cystitis (probable nephritis) | | | | + | 40 |
| XIII. | Ascites and fibroid phthisis | | + | | | 80 |
| XIV. | Lupus | | | + | | 40 |
| XVII. | Wrist | | + | | | 80 |
| XXI. | Multiple foci | | | | + | 40 |
| XXVI. | Eye, ear, and multiple foci | | | | + | 40 |
| XXVIII. | Ankle and multiple foci | | | | + | 40 |

* This case died later of acute nephritis.

In the whole 28 cases there were 11 apparent cures—1 case of Pott's caries without abscess formation, 2 cases of multiple foci, 3 cases of hip disease in an early stage, 1 case of hip disease with a large abscess, 1 case of hip disease in very advanced stage with septic infection, 1 case of advanced disease of ankle, 1 case of cervical glands, and 1 case of cystitis.

In 7 cases there was great improvement, which in some will probably result in cure—1 diseased wrist, 2 cases of Pott's caries with large psoas abscess, 1 case of ascites and fibroid phthisis, and 3 cases of disease of the knee; one of the latter, however, died later from tuberculous meningitis.

In 4 cases there was some improvement—1 case of lupus, 1 case of Pott's caries with mediastinal abscess, 1 ankle, and 1 late case of hip disease after excision and with septic infection, which after considerable improvement died of acute nephritis. In 6 cases there was no definite improvement—1 case of advanced septic hip, where it was doubtful if there was tuberculous disease. 1 case of advanced cystitis with probable involvement of both kidneys, 3 cases of very extensive and advanced multiple foci, and 1 case of acute epididymitis; this latter is really the only marked case of failure, the other 5 were all very bad advanced cases where no treatment could be expected to do much or any good, but this, though an early case, progressed steadily and rapidly while the injections were being given, and at operation the process was found spreading extensively.

As the result of this extended trial of dioradin, I have come to the following conclusions:

1. Dioradin injections are not a certain cure for all cases of tuberculosis; in some cases they will produce a cure more rapidly and more certainly than any other treatment I have had experience of.

2. Early cases of joint disease treated by injections, combined with ordinary methods of rest, good food, etc., will recover more rapidly and more surely than when treated without these injections. The same is probably true of glandular and other surgical affections.

3. In advanced cases with abscess formation, if injections are started before or at the time the abscess is opened, the abscess will usually heal rapidly, the tuberculous process apparently comes to an end, and a cure results in a large proportion of cases.

4. Finally, in those cases complicated by septic infection dioradin injections will generally reduce the temperature to normal, increase the appetite and weight, and lessen the amount of discharge, and in some cases even bring about a final cure, as in Cases III, V, and VII.

After giving over 3,000 injections I can say that I have never seen any harm, either local or constitutional, result from them; it is usually advised that they should be given intramuscularly, but it is just as good to give them subcutaneously: they cause no pain, and have never in my

experience led to abscess formation. Disease of the kidneys is usually mentioned as a contraindication, and Case XI, which died of acute nephritis after two courses of injections, might be thought to point to this; however, the symptoms of nephritis did not start for more than three weeks after the second course was concluded, and there had been septic absorption with a septic temperature off and on for more than twelve months. Also in a case of advanced phthisis, when the urine was loaded with albumen, I gave forty injections on alternate days with no apparent harm to the kidneys. So, if care is exercised and the injections are given every second day instead of daily, even kidney disease need prove no insuperable bar to this method of treatment.

In conclusion, I must acknowledge my indebtedness to Dr. Bernheim of Paris, who has generously provided me with the material used in the treatment of these cases, and also to my colleagues at the Royal City of Dublin Hospital, who have kindly allowed me to try this method on some of their patients, and have seen and examined many of the cases whose history I have brought before you to-night.

GASTRIC HAEMORRHAGE AND OTHER COMPLICATIONS IN A CASE OF CHILDBIRTH.

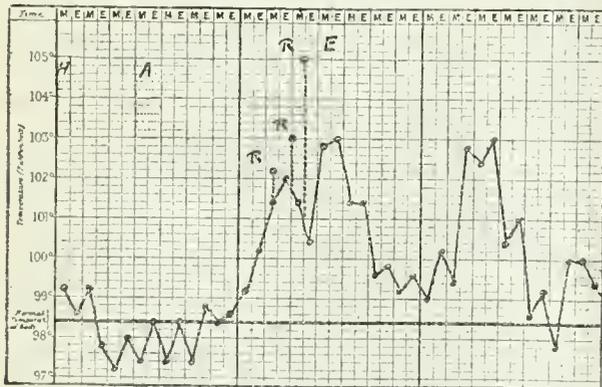

By W. D. STURROCK, M.A., M.D. OXON., OXFORD.

In recording the following case I wish to state facts rather than to draw conclusions, and to seek information rather than attempt to impart it: at the end of the description, however, I have ventured on a few tentative suggestions.

The patient, a primipara aged 43, was delivered on August 9th, 1912. The history of the confinement and of the *post-partum* period is somewhat remarkable.

The *ante-partum* history was uneventful save in one particular—that for three weeks before labour micturition was performed with great difficulty. The urine was examined from time to time during this period, but showed no trace of either pus or albumen; nor were there any other symptoms of pyelitis.

The patient was of excellent physique and constipation, with a roomy pelvis, and there was no reason to fear any special difficulties, though a prolonged labour was likely, in view of the age of the patient, and consequent rigidity of the soft tissues. This was exactly the case so far as the mechanical processes of labour were concerned; there was no bony obstruction, but the cervix dilated with extreme difficulty, and, further, the uterine contractions were for twenty-four hours distinctly weak. Progress was, therefore, extremely slow, and the application of

H, Gastric haemorrhage; A, acetonaemia; R, septic endometritis, *B. coli* and staphylococci; E, rigors.

high forceps was considered, but, since the general condition remained excellent, was rejected for the time being. Shortly after this decision the pains became much more vigorous and progress more rapid; but before long, though the pulse-rate never exceeded 84, the patient became noticeably restless, and very noticeably thirsty. In view of this state of affairs, and since the perineum was obviously offering great resistance, I applied forceps.

Severe Gastric Haemorrhage.

Here we obtained evidence of the first untoward occurrence. Under the anaesthetic (chloroform) the patient vomited a very

large quantity of blood, which I should judge had been lost into the stomach some three or four hours previously. To judge of quantities under such circumstances is obviously extremely difficult, but to all of us present an estimate of two pints appeared very moderate. This haemorrhage, together with the length of the labour, fully explains the restlessness and thirst described above; it is only remarkable that there was no greater effect on the pulse.

Delivery was effected as rapidly as possible; the uterus contracted reasonably well, the placenta was delivered intact, and there was no remarkable bleeding; the uterine haemorrhage, however, together with the gastric, constituted a serious loss of blood and necessarily caused some anxiety. The good condition of the pulse was fortunately reassuring, and it soon became evident that the patient, though seriously weakened, was no longer in imminent danger. The weakness and the bruising and laceration of the soft tissues made the patient particularly liable to septic trouble. I did not, however, give an intra-uterine douche but ordered vaginal douching; I do not, as a rule, douche either uterus or vagina.

The gastric haemorrhage led to further trouble from the fact that it produced intense heartburn, which practically prevented the patient from taking any nourishment. She was encouraged to take frequent small drinks of water; in addition to this the usual fluid nutriment was tried in turn, but for forty-eight hours the only practicable diet was peptonized milk in drachm doses. In consequence of this limitation of diet the patient was still further weakened; as was natural, the secretion of milk was entirely suppressed.

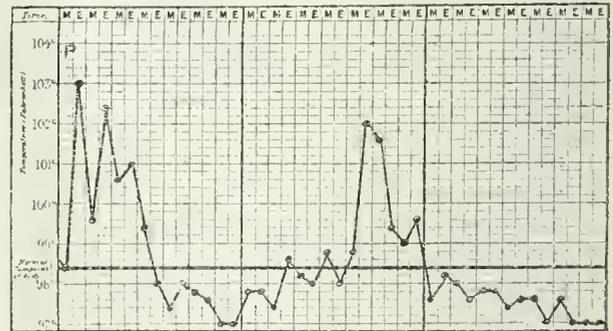

Acetonaemia and Acidemia.

By the fourth day, though nourishment was much better taken, and though the pulse was good and the temperature normal, fresh symptoms supervened; the patient was drowsy, listless, and mentally confused, her memory greatly at fault, and her conversation irrational. She was obviously extremely ill, but I was greatly puzzled to find the cause; true mental disturbance naturally suggested itself, but I did not believe this to be the correct solution.

By the aid of Dr. Eardley Holland, whom I called in in consultation, and to whom my best thanks are due, the cause was eventually found in the presence in the urine of large quantities of acetone and di-acetic acid. To relieve the acidemia rectal injections were given containing sodium bicarbonate and glucose in solution; though they were retained for some time, there was practically no absorption of fluid. I believe recovery was commencing before this treatment was adopted; none the less, it is very possible that, though the bulk of each injection was returned, the crystalloid substances in solution may have been partly absorbed. In any case, however, the patient improved rapidly, the injections were discontinued, and by the seventh day she appeared to be out of danger.

Septic Endometritis (*B. coli* and *Staphylococci*).

On the eighth day the temperature rose to 100.2°; coincident with this rise there was marked tenderness of the breasts, which, in the absence of any sign of uterine trouble, appeared amply sufficient to account for the disturbance. Three rigors, however, supervened, in the last of which the temperature rose to 105 and the pulse to 150; the breasts at the same time became less tender, and it was clear that a further cause must be sought. The lochia had throughout been inoffensive but not suppressed, and there was no uterine tenderness; involution had, however, not been perfect, and the organ was somewhat

P, Pyuria, *B. coli*.

lumpy. Examined under an anaesthetic by Dr. Holland, the cervix was found to be rather patulous, and the endometrium smooth and thickened; there was no visible discharge, but culture tubes inoculated from the uterine cavity developed a few small colonies of *B. coli* and staphylococcus, the former preponderating. Two blood cultures which I prepared the next morning were entirely negative. Vaccines were prepared from the culture colonies and held in readiness, but were never used, and treatment consisted of intrauterine douching twice daily and quinine by the mouth. The uterus contracted well, and the temperature soon fell, but rose again on the sixteenth day to 103.2°; the patient again went through a spell of fever,

this time without any rigors. The uterus throughout this attack appeared quite normal. The temperature again fell, but rose once more on the twenty-second day.

Pyelitis (B. coli).

I had examined the urine regularly every other day, and found nothing amiss save a considerable quantity of urates; the acetone had gradually diminished, and was by now scarcely to be detected. At this stage, however, a turbid deposit appeared, after solution of urates, which under the microscope was found to consist of pus with a few granular casts; a catheter specimen was drawn off into a sterile bottle, and from the pus a pure culture of *B. coli* was obtained.

The patient was given urotropine and bland fluids, and it was hoped that the condition would turn out to be pure pyelitis and not pyelonephritis; this was, fortunately, the case, despite the presence of casts, and though there was a further relapse on the thirty-third day the temperature settled down for good on the thirty-sixth; three weeks later the urine was completely free from pus or albumen. The patient is now in good health and steadily recovering her normal vigour.

The patient was, I believe, in the gravest danger on three separate occasions: First, from the loss of blood occasioned by the combined gastric and uterine hæmorrhages; secondly, from acute acidæmia; and, thirdly, from septic infection with her resistant powers reduced by loss of blood, lack of nourishment, and also, probably, by the acidæmia.

Gastric hæmorrhages during labour, at any rate of a severe type from a healthy stomach, are, I believe, very rare, though they have been recorded, as have also intestinal and intraperitoneal hæmorrhages. In this instance the patient had shown no sign whatever of any previous abnormal condition of the mucous membrane. I believe the stomach was perfectly healthy.

The acidæmia opens up a large field of inquiry; the three questions immediately arise—(1) whether the urine already contained acetone before labour commenced; (2) whether, if so, the protracted labour increased the amount; and (3) whether the condition was partly or wholly one of delayed chloroform poisoning. Not much chloroform was administered; a little was given during the pains when the head was reaching the perineum, but it was discontinued at the patient's request, and the delivery by forceps was quite a short process; certainly there was far less chloroform given than is frequently the case. I am quite unable to give an answer to these questions: I understand, however, that there is a growing belief among some obstetricians that there is considerable danger in the administration of chloroform in the free manner so usual during confinements.

The septic infection also raises an interesting point. I am obviously unable to prove that the germs were not introduced from without; the facts, however, that the soft tissues were much bruised and the perineum lacerated, that the patient was in an ideal condition for the successful lodgement of germs, and that there was no disturbance until the eighth day, make it unlikely that pathogenic germs were introduced by an exploring finger. The question which particularly interests me is that of the possibility of the urine having contained *B. coli* before the confinement and throughout the subsequent illness. The frequency of pyelitis, when micturition is seriously interfered with in the *ante-partum* period, is well known; here was a case of serious interference with micturition, but without any albuminuria, pyuria, or other signs of pyelitis. Under the circumstances the idea of looking for bacilli did not suggest itself to me; but it appears to me conceivable that there may have been bacilli in the urine, even though actual pyuria did not appear until twenty-two days after confinement. Were such bacilli present, a secondary infection of the uterus does not seem a far-fetched idea.

Lastly, it is worth mentioning that throughout the illness we were handicapped by the great depression of the patient. This could obviously be largely accounted for by the nature, both general and specific, of her long illness, but was unquestionably also of a true psychological nature. The child, who, it may be mentioned, was with great difficulty induced to breathe, was born with a hare-lip and cleft palate; his advent had been greatly longed for by the mother, and his deformity was an intense and lasting disappointment. A successful operation by Mr. Berry on the hare-lip had a very noticeable effect on the patient's ultimate recovery.

A CASE OF CARDIAC ASTHMA.

BY

CLAUDE WILSON, M.D.,
TUNBRIDGE WELLS.

A FEW months ago there was some correspondence in these columns as to whether the term "cardiac asthma" was properly applicable to any clinical entity, and, if so, to what. The following case illustrates the condition which this, and no other term, connotes, and to which the appellation should, I believe, be confined:

C. M., aged 71, a retired clergyman, gouty manifestations for many years, albuminuria and casts for several, and dyspnoea on going uphill or stairs for some months. Heart sounds pure, pulse regular, and blood pressure 160 to 180. Sudden angina pectoris a month ago; two or three moderately severe attacks, followed by "gouty conjunctivitis" in both eyes—one after the other similar to many previous attacks. Great prostration and dyspnoea on slight movement in bed. Insomnia. Pulse regular, 80 to 90; blood pressure as above; heart sounds pure. Gradual convalescence, first walking into an adjacent room with help on December 26th—a process which was repeated twice on December 27th, the patient feeling better than at any time since the original seizure. Bromides, chloral, veronal, paraldehyde, hyosine, heroin, and morphine had been used from time to time, none of which affected adversely the heart or the renal secretion. The patient settled for the night at 10 p.m. on December 27th, and as a wakeful night seemed probable heroin gr. $\frac{1}{2}$, which had proved efficacious on two occasions, was injected. Sleep was not obtained: the patient was not comfortable, and at 1 a.m. on December 28th the attack of cardiac asthma developed suddenly. I reached the house at 1.40, to find the patient in a very alarming condition, with the family and two nurses assembled in the room, or just outside, anticipating death. The following notes show the clinical picture presented and the subsequent course of the attack:

1.40 a.m. Patient raised on a pile of pillows. Face and neck congested and cyanosed. Hands and forearms cold, pale, and clammy. Respirations rapid, gasping, oral, 48 per minute. Pulse irregular ("absolutely") and uncountable. Heart, "dehrium cordis," no murmurs. Coarse rales audible all over both sides of the chest anteriorly and laterally; back not examined. Amyl nitrite had failed to relieve.

1.45 a.m. Injection of strychnine and digitaline $\frac{1}{2}$ gr. $\frac{1}{16}$, with morphine gr. $\frac{1}{2}$, into left arm subcutaneously. Oxygen administered from cylinder.

1.55 a.m. Aspect easier, respirations 36.

2.10 a.m. Comfortable. Respirations 23. Pulse about 100, and nearly regular.

2.20 a.m. The patient told his wife to go to bed. He was "all right." Slept and dozed all night, taking nourishment once or twice.

8 a.m. Moving easily in bed, and turning from side to side without assistance. Pulse, 82; regular in time, and nearly so in volume. Heart sounds normal. No rales audible anywhere. Respirations 18.

8 p.m. Has spent a very comfortable day in bed.

It would be easy to comment on this case and to speculate on its cause and true nature, as well as on the share the various remedies had in producing the improvement which so rapidly supervened after their administration; but the sole object of this communication is to give a brief clinical picture of "cardiac asthma" as I understand it.

Subsequent History.

Convalescence was resumed and there was no further attack of angina or dyspnoea till 6.30 p.m. on January 17th, when a second attack of "asthma" developed with abrupt suddenness. The clinical picture at 7 p.m. was the same as described above. The same remedies were used, but their effect was slower and no relief was obtained until another $\frac{1}{2}$ grain of morphine was injected. The distress was relieved by 7.45, but disturbed respiration, irregular fluttering pulse, and coarse rales over the lungs continued. The patient gradually sank and died on the evening of January 18th.

THE twelfth International Congress of Ophthalmology, to be held in 1914 in St. Petersburg, will begin on Monday, August 10th (N.S.), and end on Saturday, August 15th. Members desirous of communicating reports are directed to forward the manuscript and inscription fee not later than February 1st, 1914; papers must be written in one of the official languages—English, French, German, Italian, Spanish, or Russian. The official subjects for discussion, selected at the preceding congress at Naples, are, the etiology of trachoma and the nutrition of the eye. The President will be Professor Arnaldo Angelucci, chosen in homage to the committee of officers of the last congress. The corresponding members for the United Kingdom are Mr. Walter Jessop, London, Sir H. R. Swanzy, Dublin, and Dr. George Mackay, Edinburgh. Further information may be obtained from Mr. Jessop, and from Professor L. G. Bellerminof, Ophthalmic Hospital, 38 Mochowaja, St. Petersburg.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

EMPHYEMA IN AN INFANT.

With reference to Dr. Cummings's memorandum (JOURNAL, January 4th, 1913, p. 20) mentioning a baby four months old suffering from emphyema, may I quote the following case in a much younger infant, with which I met last March?

I was asked to see a baby three weeks old, at whose birth I had attended, the complaint being that the infant had a cough. The temperature was 102°; dyspnoea and a croupy cough were present. On examination of the chest the following condition was found: Right side, normal in front and behind; left side, in front resonant, and a few rales over the upper lobe; behind, at the left base the resonance was much impaired, with distant breath and voice sounds. Next morning marked bronchial breathing was heard over the left upper lobe in front, while behind marked dullness was present from the base up to the spine of the scapula. Breath and voice sounds were diminished over this area. Exploration showed the presence of pus, some of which was aspirated; later a piece of rib was resected. The infant passed through the operation well, but unfortunately died next day.

West Hoathly.

CECIL WORSTER-DROUGHT.

STRANGULATED HERNIA IN YOUNG INFANT.

On August 3rd, 1910, when I was house-surgeon to the Liverpool Infirmary for Children, J. E., aged 1 month, was admitted suffering from right strangulated inguinal hernia. Attempts at reduction by taxis and by raising the pelvis and applying ice having failed, the skin was prepared with lysol and spirit soap, and an attempt at taxis under anaesthesia having also failed, I operated. A loop of dark purple small bowel was released, but could not be returned till the ring was nicked (1 drachm of fluid in sac). The sac was transfixed, tied, and cut away. The ring was closed with two or three catgut sutures, and the skin with horseshair and a silkworm gut relaxation stitch. A dressing of collodion acetone and wool was applied.

Twice during the operation the child stopped breathing and needed artificial respiration. This possibly accounted for faulty haemostasis, which produced a haematocoele by next day, but this cleared up without interference, and the wounds healed by first intention. On August 11th I circumcised the child, as it had a bad phimosis.

Bate, South Australia.

GILBERT BROWN.

RECOVERY AFTER TAKING LARGE DOSES OF CORROSIVE SUBLIMATE.

MR. A. LEONARD FULLER reports in the BRITISH MEDICAL JOURNAL of January 18th, p. 116, a case of recovery after taking 8½ grains of corrosive sublimate. It may be of interest to record that I have had two such cases.

I was called to see Mrs. A. on the day after confinement, and found her collapsed, pulseless, and apparently dying. On inquiry I discovered that a soloid which I had unwisely left to prepare a lotion had been administered to her by a somewhat bibulous attendant. Fortunately immediate vomiting brought up a greater part of the soloid undissolved. Eggs were administered freely, and stimulants and later intestinal sedatives; after a few days of anxiety she was well again.

At Marselles, while acting as ship surgeon, a passenger inadvertently swallowed the whole solution he had made with an 8½ grain soloid, not noticing his mistake owing to a rather too festive evening ashore. He was forced to take eggs to the number of. I think, a dozen, and after abdominal pain for a few days was well. In this case also immediate vomiting, owing to the intensity of the poison, saved the patient.

The above experiences have taught me the danger of entrusting such powerful poisons to persons unless assured of their sanity and sobriety.

CHELTENHAM GENERAL HOSPITAL.

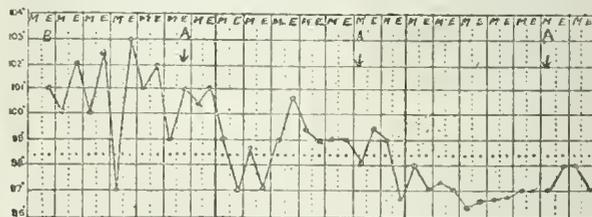

RHEUMATISM AND CHOREA.

(By J. RUPERT COLLINS, M.A., M.D., Honorary Physician.)

THE important paper of Dr. Branson on the Avenues of Rheumatic Infection, published in the BRITISH MEDICAL JOURNAL of November 23rd, 1912, in which he alludes to the relationship between rheumatism and chorea, may render a brief note of the following case of interest.

N. Y., a servant girl, aged 18, was admitted under my care in January, 1911, suffering from severe chorea. She was so violent and difficult to control as to necessitate the use of padding round the sides of the bed, to prevent her hurting herself, and the constant care of a nurse. Arsenic and various kinds of sedatives—including bromides, chlorotone, chloral, and morphine—were tried with little or no benefit. A hot pack at night quieted her to some extent, and this was employed for some weeks. Thyroid extract was tried and was followed by a very marked improvement for four days, when the patient's choreic movements became even more violent than before, and she looked so ill as to raise grave doubts as to her recovery. On January 21st I made a lumbar puncture, and 15 c.cm. of clear cerebro-spinal fluid came away freely. The patient was very quiet following the rachicentesis, and had a good night's sleep. Hitherto she had been much troubled with insomnia. The cerebro-spinal fluid proved sterile and free from cellular exudation. The improvement only lasted a few days. On January 30th I drew off 50 c.cm. of blood from the median basilic vein into a flask containing 60 c.cm. of ordinary nutrient broth and 25 c.cm. into a similar flask containing lactic acid lactose milk broth. When incubated the former flask proved sterile, but the latter yielded a pure culture of a diplococcus. This coccus grew in twos and in short chains of four and six, but no long chains were found. It grew fairly vigorously on agar and was Gram-positive, but not strongly so, a long application of alcohol decolorizing it. A vaccine was prepared of this organism, and on February 6th I inoculated 10 million and on February 7th 50 million of this vaccine. The patient began to improve almost at once after the first injection. On February 9th she was well enough to allow of her bed being pushed on to the balcony, and on February 11th she was able for the first time since her admission to feed herself. On February 14th the sister of the ward showed me that she could now hold a cup without spilling the contents. She continued to improve steadily, and was discharged from the hospital on March 14th. As there was still a tendency to jerkiness when attention was drawn to her, she attended at the hospital for three months as an out-patient, receiving an inoculation once a week for some time after all trace of her unsteadiness had ceased.

Shortly after the above patient was discharged, a girl, M. H., aged 19, was admitted suffering from a second attack of typical rheumatic fever. This patient had a

A = Inoculation with vaccine, 100 million each time.
B = Admission to hospital.

mitral systolic bruit, and her knee and hip joints were swollen and tender. She was given no other treatment than injections of the vaccine prepared from the above case, and her temperature, as figured in the chart, showed

an improvement, which was accompanied by a general improvement of her other symptoms. Her temperature remained down, and she made a good recovery. No doubt it will strike some as being merely a coincidence. Perhaps it was. As the nature of the organism was not investigated by the inoculation of animals I have hitherto abstained from publishing the case, and do so now with diffidence and simply as of some possible interest in relation to Dr. Branson's paper.

Reports of Societies.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

Friday, January 10th, 1913.

MR. R. D. PIERCEY, P.R.C.S.I., President, in the Chair.

Tuberculosis of Lower End of Femur.

MR. W. I. DE C. WHEELER exhibited three cases of tuberculosis of the lower end of the femur in children, illustrating recent pathological and anatomical work on this subject, and spoke on the pathology of tuberculosis in bone. In each of the three cases the disease occurred at the site of election, the metaphysis, and in each case the femur was divided with a Gigli's saw above the diseased area and wrenched from the epiphysis. New bone was rapidly formed, with excellent results. X-ray photographs showed the accurate and complete manner in which the new bone replaced that which was removed. The first case was operated upon in 1909, before any work on the subject had been published. The reason the metaphysis and not the epiphysis or diaphysis was the site of election for tuberculosis in bone was anatomical. The infection was haemogenic, and could be traced in most instances to the milk supply. The nearer the metaphysis was to the joint the more readily the joint became affected, as was seen in the case of the elbow and hip. Mr. Wheeler said that scraping, curettage, and drainage were unscientific methods only to be employed when there was some special reason for not performing the ideal radical operation. Mr. J. BOYD BARRETT asked Mr. Wheeler to illustrate a little of the after-treatment. Mr. W. PEARSON considered that this method of treatment was the only sound practice in dealing with a bony cavity of any large extent. He was of opinion that some extension was necessary while the new bone was forming, otherwise there would be a great amount of shortening of the limb, and he had no doubt that even in the cases shown there would be some shortening. Possibly a less extensive operation, not involving the excision of the whole circumference, might be helpful. He was much interested in the cases, which illustrated how rapidly the bone formed in young subjects. Mr. HAYGTON said that the cases proved the excellence of the operation. His experience was that the vital point in the treatment was the removal of all disease. X-ray photographs should be relied on to ascertain the extent of the disease, and the operation could then be planned precisely. He referred to his experience with osteomyelitis, and said that complete removal of the diseased bone was followed by complete recovery. In a recent case he had removed about 8 in. of the diaphysis of the femur, and when the sequestrum was removed there was a 3-in. gap. Extension was put on, and in three months' time the wound was healed, and in six months' time the patient was walking on a new column of bone. Mr. MAUNSELL said that he thought that a great many of these cases were looked on as tuberculous which were really septic osteomyelitis; but he had no doubt that afterwards they had become tuberculous. He was in agreement with the removal of all diseased tissue, but he had seen cavities which had not been laid thoroughly flat, and they healed up perfectly well. In osteomyelitis cases, either tuberculous or non-tuberculous, he thought that it was not wise to proceed with great haste, and that they should be guided by X-rays. He thought that certain cases would heal up with a much more modified operation than the total removal of the diaphysis. These cases taught the surgeon not to be afraid of removing a large quantity of bone. The PRESIDENT related a case under Dr. Barton, a boy with four-fifths of one tibia in a shocking

condition from chronic disease of the bone. The sequestrum was removed, and the boy made an extraordinary recovery, and a couple of years afterwards had grown to nearly 6ft. in height. Mr. WHEELER, in reply, referred to the after-treatment. He said that this seemed important at first sight, but he found that 7 lb. or 8 lb. of sand-bags were good enough for the pull. He pointed out that the interesting part of the subject was really new, and that it was first pointed out by Lexer, who showed that all the blood vessels anastomosed in this region, and that contusions and sprains easily set up tuberculous abscesses in the joint. With regard to Brodie's abscess, he would like to dissociate himself from everything but tuberculous disease. As to the periosteum being adherent in each of the three cases, he found it easy to separate that membrane. He used bismuth paste and iodoform, and did not attempt to fill up the cavity. The cases were very chronic when he got them, and there was no hurry about them. In the first case he had tried scraping without effect.

Scapular Crepitation.

MR. W. PEARSON showed a child, aged 7, who first came to him about two years ago for creaking in the shoulders. The condition was first noticed after an attack of measles. Symmetrical crepitations were to be found on moving the scapula. X-rays showed nothing to account for this. Massage and fibrolysin injections were tried, but there was no apparent change in the condition. The crackling was quite audible. There might be cartilaginous formation or exostoses, which might be so small as not to be shown by X-rays. There was nothing in the muscles to account for the peculiarity, and there was certainly nothing in the joint. Mr. MAUNSELL suggested hysteria. He had a patient under his care who could make a similar kind of grating with both knees. He knew of another girl who could crack her knees as loud as a carter's whip. The PRESIDENT said that, although unwilling to hazard any observations on a purely surgical question, he had in mind the case of a young girl in which the movement of one knee was attended by a cracking sound that caused her discomfort, but he thought the condition afterwards disappeared. He looked on the case as of rheumatic origin. Mr. WHEELER suggested the possibility of some myositis ossificans affecting some of the muscles. Mr. PEARSON, in replying to the remarks, said he was not inclined to look on the condition as hysterical on account of the child being so young (only 5 years old when first seen). Myositis ossificans ran into his mind, but if this was the cause he thought the movements should be somewhat restricted, and something should be seen by the X-rays.

Aneurysm of Abdominal Aorta Cured by Operation.

MR. R. CHARLES B. MAUNSELL showed a woman, aged 30 years, upon whom he had operated on August 3rd, 1912, for cure of a large aneurysm of the abdominal aorta in the region of the coeliac axis. Before operation the aneurysm had a diameter of over 7 in., pulsated violently, and caused much pain. The operation consisted in abdominal section and the insertion of a Colt's wire wisp, which measured 5 in. and contained 150 in. of wire, having a surface area of 3½ sq. in. On the eighth day after operation she was allowed fish, etc., and on the eighteenth day she was permitted to sit in a chair, but she did not leave hospital until November 5th—three months after operation—as she would have had to work for her living as soon as discharged. Her present condition was excellent; she was free from pain and was able to do ordinary work, including the scrubbing of floors. There was a firm, hard mass, of about 3 or 4 in. diameter, to be felt in the epigastrium, which pulsated with pulsations transmitted from the aorta, but exhibited no distensible pulsation. There was a mitral bruit to be heard over the heart, but the loud bruit over the aneurysm had disappeared. X-ray examinations did not show any distensible pulsation. Mr. C. A. BALL inquired if a Wassermann's reaction had been done, as the case seemed to be of syphilitic origin, and also if any antisyphilitic treatment had been given in addition to the operation. Mr. WHEELER said that he had treated three patients by a similar method, and he thought it was important that every such case should be published, seeing that abdominal

aneurysm was not frequently seen. All had pain like Mr. Maunsell's, which disappeared in a few days after operation. His first case was very similar to Mr. Maunsell's, and it was now done two years, and the man had been working ever since. One ended fatally, but it was complicated by an enterostomy. Mr. MAUNSELL, replying to the remarks, said that a Wassermann's reaction had not been done, but he had no doubt the case was of syphilitic origin. The first case he had met with was in a man who was under treatment for vomiting, and the aneurysm was not discovered until *post mortem*. The second was in a woman who was supposed to need a gastro-enterostomy. The fourth was also a stomach case, and it was accidentally that the aneurysm was found. He had seen seven aneurysm cases, but in only two had he operated.

Child with Webbed Fingers and Toes.

Mr. J. BOYD BARRETT showed a child with webbed fingers and toes. There were six toes on each foot, and the amputation of the outer toe was contemplated. As two of the fingers were adherent, Didot's operation was proposed, lest the deformity should interfere with growth. The PRESIDENT referred to a case of a similar nature, in which the mother of the child exhibited a similar deformity. Mr. MAUNSELL said that recently he kept a patient with extra digits in hospital for a long time, and removed them and separated the fingers. He would advise not doing too many fingers at once; the skin could be brought together perfectly if they were drawn apart and a little of the fat cut out. His method of grafting was to stitch the edges. The hands were now absolutely normal. Mr. J. BOYD BARRETT, in replying, said he was in full agreement with Mr. Maunsell's remarks.

SECTION OF PATHOLOGY.

At a meeting held on Friday, January 3rd, Professor A. H. WHITE, President, in the chair, Dr. W. G. HARVEY showed a car-driver, aged 39, suffering from *Norwegian scabies*, with specimens under the microscope. His general health had always been good. The eruption commenced ten years ago on his hands and fingers, and remained limited to them till recently. About two years ago his hands were *x* rayed, the condition having been probably regarded as a form of hyperkeratosis. He came under the care of Dr. Wallace Beatty, who found that the scalp was covered with abundant dry, greyish scales, forming in places a thick coating resembling psoriasis. The trunk was universally reddened (erythrodermia), the skin somewhat thickened, especially of the back, and the surface was covered more or less abundantly with dry scales, causing roughness in most places, but on certain prominent parts—on the shoulders over the scapulae—the scales formed a thick, dry, hard, adherent coating, and places on the back showed traces of moisture suggestive of an eczematous state. There was an extremely heavy coating of dry adherent scales on the prominences of the hips over the trochanters and on the buttocks, especially the right buttock, on which the patient rested, on account of achondroplasia of the thigh, present on the left side. The extensor aspect of the elbows was covered with thick, heaped-up, dry, adherent scales; the arms showed patchy redness and scaling, but were not universally affected. The hands and fingers presented a remarkable appearance; projecting conical masses of dry, greyish scales were present over and round the nails. There were also smooth scaly masses, readily detached with the blade of a forceps once the edges had been raised all round. This method of removal caused much pain, so that the remainder were left for subsequent removal by softening in hot sulphur lotion. The toes were affected in a similar but slighter degree to the fingers. Mr. WILLIAM PEARSON showed a specimen of *Willous odonoma of rectum* from a female, aged 56, complaining of piles with attacks of diarrhoea and haemorrhage. The patient was a good colour, but stated she had been losing weight. Altogether the abdomen suggested chronic intestinal obstruction in the lower bowel. On rectal examination no haemorrhoids could be found, but the entire mucous membrane, from immediately above the anal canal to the upper limit which could be reached by the finger, felt soft and hypertrophied, with numerous polypoid masses. An exploratory abdominal incision was made through the left rectus muscle, when an enormously

distended atonic colon and caecum were exposed, and it was seen that no growth existed above the rectum. The abdomen was then closed, and the specimen presented was removed by drawing it out of the anus with clip forceps and excising it as in Whitehead's operation for haemorrhoids. It stripped easily off the muscular coats of the bowel. Microscopic section of the growth showed no malignancy. Since the operation the patient had been quite free from symptoms, and control over the bowels was perfect. Dr. R. M. BRONTE showed two cases of *Ruptured thoracic aneurysm*. One had burst into the pericardial sac, the other was a dissecting-room specimen. It showed an aneurysm on both sides of the thorax, the left side dilatation causing extensive compression of the upper lobe of the lung. Both cases were associated with extensive pleurisy. Dr. T. T. O'FARRELL showed a specimen of *Rupture of the right ventricle*. The patient was a middle-aged man who had just fallen 62 ft., and was admitted dead into hospital. Several bones of the extremities were fractured. An examination of the thorax showed fracture of the second and third left costal cartilages, fracture of the sixth rib on the right side, and fracture of the sternum at the junction of first with second part. The pericardium was adherent to the sternum, but not to the heart, and was found full of blood, though not greatly distended; no definite perforation or laceration could be detected. The heart showed some excess of fat, and was contracted. The right ventricle was injured in two places. First, an irregular semi-circular wound $1\frac{1}{4}$ in. long, beginning below the origin of the pulmonary artery, and extending downwards more or less parallel to and with its convexity towards the inter-ventricular groove. Secondly, a punctured wound $\frac{1}{2}$ in. in diameter slightly below the ariculo-ventricular groove, and at the point of junction between the middle third of a line drawn from the margo acutus to the inter-ventricular groove. The injuries to the sternum and costal cartilages did not correspond to the generally accepted surface-marking of the right ventricle. The right ventricle was said to be covered by most of the middle portion of the sternum and the third, fourth, fifth, and part of the sixth left costal cartilages, none of which, with the exception of the sternum, were injured in the present case. The right auricle seemed more exposed to injury. The only explanation would appear to be that in falling the liver, which was enlarged, pressed the heart upwards.

MIDLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.

Tuesday, January 7th, 1913.

Dr. MALINS, President, in the Chair.

THE PRESIDENT announced that the Council had accepted an invitation from the North of England Obstetrical and Gynaecological Society to take part in a joint meeting with the North of England, Glasgow, and Edinburgh Societies, to be held in Manchester upon some date to be fixed in May next.

Endothelioma of the Undescended Testis.

Dr. THOMAS WILSON read notes upon a case of endothelioma of the undescended testis occurring in a male pseudo-hermaphrodite aged 29. The patient, who had been brought up as a woman, sought advice on account of severe lower abdominal pain and of the passage of blood in the urine, said to represent a catamenial period. In the hypogastrium a fairly defined, rounded, tense, and elastic tumour extended from the pubes upwards to 2 in. below the umbilicus. The temperature and pulse were high, and there was troublesome vomiting. The patient had been carrying on the trade of a butcher in partnership with a woman. The voice was quite masculine; the cheeks, chin, and upper lip were covered by sparse coarse hair. $\frac{1}{2}$ in. in length, forming a rudimentary beard and moustache. The hair of the head was fairly plentiful and nearly 3 ft. in length. The patient's figure was markedly feminine, although the breasts were small. The vulva presented an unusual appearance. The labia majora were thin, and between them was a deep cleft, in the anterior part of which was a penis-like organ $2\frac{1}{2}$ in. long, with a well marked glans. A depression, but

no orifice, was present on the lower surface of the glands. An inch further back in the middle line was a urethra-like orifice. A catheter passed into this canal met with obstruction after passing about 1 in. It then turned upwards and forwards and entered the bladder. In the right labium majus was a small, elastic, tender body, which could be pushed upwards into the inguinal canal. The left inguinal canal and labium were empty. The pelvis was filled with a fixed tender swelling the size of a cocoon. The patient stated that at about 20 years of age she began for the first time to lose blood with the urine, and since then had done so fairly regularly for three days every month. Laparotomy was performed, but complete removal of the tumour was impossible. The patient died a fortnight after the operation, having undergone extreme wasting. Microscopically the tumour was considered to be an endothelioma developing in relation with the undescended left testicle. The paper was illustrated by a series of photomicrographs, demonstrated with the epidiascope. Mr. BECKWITH WHITEHOUSE thought that the occurrence of periodical haemorrhages was a point of much interest. He was at a loss to know whence the blood came. Furthermore, if it was a case of true menstruation, the supposed necessary hormone must have been produced by the testicle. The only alternative explanation was that the gland in the right labium was an ovary, the case being thus one of true hermaphroditism. As regards the histology of the tumour, he was not quite prepared to admit that it was undoubtedly an endothelioma. It was an obscure neoplasm in which cells of an embryonic type were present, and to which the term sarcoma could be applied. Beyond this he did not think it was possible to dogmatize. Dr. EDGE agreed with the difficulty raised by Mr. Whitehouse as to the explanation of the alleged catamenia. He suggested that the so-called testicle was in reality an ovary, what appeared to be seminiferous tubules really consisting of mesonephric ducts. The specimen was referred to the consideration of the Pathological Subcommittee.

Chorion-epithelioma.

Dr. EDGE showed a uterus the seat of early chorion-epithelioma, and by means of the epidiascope demonstrated microscopical preparations of the same. Dr. WALTER SWAYNE, quoting his own experience, did not think that chorion epithelioma was so often preceded by vesicular mole as was believed. Chorion-epithelioma occasionally underwent spontaneous cure, as in a patient of his that developed metastases in the lungs, with bloody sputum, six years ago. She had recovered completely and was well to-day. Dr. EDGE agreed with Dr. Swayne's remarks about vesicular mole. If it was as much as 40 per cent. of all cases of chorion-epithelioma, then to him this was an indication to remove the uterus for vesicular mole. His experience was that deposits did not fibrose.

Treatment of Obstructed Labour.

A discussion on the treatment of obstructed labour was opened by Dr. THOMAS WILSON, who said that a satisfactory definition of "obstructed labour" was not possible. It was meant to imply the presence of some factor which interfered with the ordinary sequence of events of normal labour. Obstruction was met with in all degrees, and gave rise at one end of the scale to a little interference with the presentation of the fetus, or mechanism and duration of delivery, and at the other, in the absence of skilled help, to the death of the mother and the child. The most frequent cause for neglected cases of obstruction was failure on the part of the patient or midwife to call in medical advice at a sufficiently early stage. Furthermore, there was also a too prevalent idea that the whole art of midwifery consisted in extracting the fetus, gently if possible, but extracting by any means. The remedy for much of the illness and suffering arising from obstructed labour must be sought in the better teaching of midwifery, which in the future would have to be more practical and clinical than had been possible in the past. By proper care, obstructed labour could generally be foreseen, and its ill-effects obviated. It was well to regard every labour as like to be obstructed, or in some other way complicated, for here most emphatically forewarned was forearmed. Every woman who engaged a medical man or a midwife to attend her first labour should at least have the external pelvic

measurements taken. A history of steadily increasing difficulty in successive labours was not uncommon. The explanation was to be found in Matthews Duncan's observations that the birth weight of the children of a woman gradually increased until her age was 35, after which it again diminished. Another point to note was that contraction at the outlet was more common than was usually understood, and the diameters here should also be measured. Dr. Wilson then drew attention to the importance of "Müller's impression" method in estimating the relation of the size of the fetal head to the pelvic brim. The method had been slightly modified by Munro Kerr and was frequently known by his name. Rules were then formulated to guide treatment, adapted to the various conjugate diameters. Cases in which the true conjugate lay between 2½ in. and 3½ in. were those which furnished most of the difficult problems. Labour should rarely be induced in a first pregnancy. Frequently a living child was born at term through a pelvis that appeared to offer grave difficulties, and it was good practice to regard the first labour as a test one and to watch its course and result very closely. At the onset of labour, if difficulty were expected, the importance of a thorough cleansing of the vulva and detailed examination could not be too strongly emphasized. One vaginal examination made on a patient who had been imperfectly cleansed might be fatal to the success of an operation that later became necessary. Dr. Purkiss referred to the damage frequently produced by the injudicious use of forceps, to which practically every case of badly lacerated cervix was due. In selecting an instrument, care should be taken to obtain one in which the possibility of slipping of the blades was reduced to a minimum. Milne Murray's axis traction forceps was the best instrument. A proper anaesthetist should be present wherever difficult forceps delivery was contemplated. Craniotomy was still quite justifiable when local surroundings absolutely precluded the possibility of performing Caesarean section. Mr. CHRISTOPHER MARTIN concurred in the importance of selecting a method of treatment in accordance with the patient's surroundings; they were not justified in submitting a mother to risk for the sake of a doubtful child. Reliance could not always be placed upon the previous obstetrical history in guiding future treatment. For example, he remembered the subject of a prospective Caesarean section for pelvic contraction who delivered herself with ease. He thought that symphysiotomy and pubiotomy would eventually fall into disuse. The tendency nowadays was to perform more and more Caesarean sections. If this operation were undertaken before labour set in, the risk was very little more than with ordinary labour. Dr. EDGE asked if diet could in any way influence the size of the fetus. He had seen cases of severe cervical laceration not due to the forceps or any other instrument. With regard to "suspect" cases of Caesarean section, he had successfully practised a method of delivering the membranes covering the lower uterine segment into the vagina by pushing them through the cervix. He did this to obviate infection, inasmuch as he thought that the membranes covering the internal os and the lower uterine segment were most likely to be contaminated. Dr. WALTER SWAYNE referred to cases of elderly primiparae in whom the pelvic measurements were practically normal, and yet when labour was in progress it was necessary to deliver by craniotomy. The cause of dystocia was undoubtedly in these cases a rather large child. The difficulty was usually not recognized until labour had been in progress for some time. In such a class of case pubiotomy or symphysiotomy might be valuable, although he was not strongly in favour of either as an operation of election. Dr. SMALLWOOD SAVAGE thought that symphysiotomy and pubiotomy might be of use in producing some enlargement of the pelvis after forceps had failed, and that these operations should be reserved for such cases. He had performed pubiotomy upon two cases, and had been satisfied with the results. Sepsis was undoubtedly a contraindication to the operation, but it was difficult to say which cases were at the time infected. The President observed that the greatest troubles in the treatment of obstructed labour were usually due to want of diagnosis of position. Frequently forceps were applied to undiagnosed occipito-posterior positions, with disastrous results. No speaker had referred to the advantages

of version in preventing obstruction. In some cases of flat pelvis he had found it a very easy and effective operation. With regard to Caesarean section, it would undoubtedly replace craniotomy and become the operation of election and not necessity. Craniotomy performed upon the living child should never be entertained. The President also referred to the importance of the presence of meconium with a head presentation as a sure indication of impending death of the child. Dr. THOMAS WILSON, in his reply, thought that it was sometimes difficult to avoid craniotomy upon a living child. Quite recently he had had to choose between this operation and Caesarean hysterotomy in a case that was obviously infected, and he had preferred the former. He was thus in accord with Mr. Martin's principle, to save the mother primarily, but if possible save both. In Catholic countries, on the other hand, conservative midwifery of the fetus was of greater import. As regards diet, he did not think that it had much influence upon the size of the child, although a diet as free as possible from carbohydrates and fluids had been recommended to produce reduction of weight. He had expected to hear something upon pubiotomy in the course of the discussion, and had not been disappointed. Personally he had performed five pubiotomies, and had had no cause to regret the same from the maternal side. The use of this operation would always be reserved for "borderland" cases, in which the fetus was alive. It should not be employed in first labours, nor yet, again, when infection was present.

ROYAL SOCIETY OF MEDICINE.

PATHOLOGICAL SECTION.

Tuesday, January 21st, 1913.

Professor R. T. HEWLETT, President, in the Chair.

The Transformation of Non-pathogenic into Pathogenic Bacteria.

DR. D. EMBLETON and Dr. F. H. THIBLE made a communication upon this subject. The authors showed that they were able to produce septicaemia in animals with non-pathogenic bacteria. It was found that non-pathogenic bacteria could be divided into two main groups: (1) Those represented by *B. mycoides*, *smegmae*, *phlei*, which would not produce septicaemia unless they were inoculated into animals which had been previously sensitized to them by the injection of the dead homologous bacteria. (2) Those which would not produce septicaemia in the above-mentioned way, and which were not pathogenic even in massive doses, but were rendered pathogenic by injecting the bacteria in a medium which hindered the access and delayed the activity of the antibodies present in the animals. The media which were used for the suspension of the bacteria were hypertonic saline and strong gelatine. These by themselves had no effect on the animal. Thus the authors were able to produce septicaemia with *B. hoffmannii*, *B. cyanogenus*, *Sarcina lutea*, *Proteus zenkeri*, the organism being recovered in all cases from the heart's blood and spleen. Septicaemia was also produced with staphylococci and streptococci not pathogenic to guinea-pigs. They further showed that the bacteria which had been thus rendered pathogenic had now become so virulent that they were capable of producing septicaemia in normal animals without the aid of the above-mentioned processes, and not only in animals of the same species as those used for the original experiments, but also in animals of other species. To quote the case of *B. mycoides*, this organism, as is well known, normally will not grow at 37° C.; the authors educated it to grow at this temperature, and after inoculating an agar slope of this into a guinea-pig which had been sensitized a week previously with dead *mycoides*, were able to produce a septicaemia closely resembling anthrax. The organism isolated from this animal was now capable of producing septicaemia in normal guinea-pigs, rats, and rabbits. The organism had also changed its characters in that it had lost its flagella and had developed a capsule. Similarly a miliary tuberculosis was produced in normal guinea-pigs and rabbits by a like procedure, using *B. phlei* and *B. smegmae*. The authors from their experiments concluded that bacteria do not possess a toxic "endotoxin," but that the toxic

substance is only liberated from the bacterial protoplasm by the action of antibodies in the animal body. They have demonstrated that, in animals dying from any form of bacterial infection or toxæmia, a toxic substance is present in the blood and effusions, which, when inoculated into normal guinea-pigs, produces rapid death. The symptoms and *post-mortem* appearances are identical in every case. The authors considered that the toxic substance was liberated from the bacterial protoplasm by the action of normal and induced specific antibodies, which they considered acted on the bacterial protein similarly to digestive ferments. The toxic substance is an early product of this action, and produces according to its accumulation, the symptoms, fever and death, of bacterial infections. The authors have come to the conclusion that the phagocytic sequence in serous-cavity-infections depends upon: (a) The "innocuousness" of the bacteria: this may be primary or the result of the action of the antibody degrading the toxic to non-toxic substance. (b) The rate of accumulation of toxic substances formed from the bacteria. A migration of polymorphonuclear cells proportioned to the degree of toxicity occurs before the complete sequence ensues, or the animal may die in this stage. They concluded that immunity was cellulo-humoral. The authors considered that: (a) Pathogenicity depends upon (1) the virulence of the bacterium; (2) the antibody activity present in the animal body. Thus they have shown that some bacteria do not become pathogenic until the animal has developed an antibody against that bacterium—for example, *B. mycoides*. On the other hand, other bacteria do not become pathogenic until the antibody activity is greatly diminished. Thus by diminishing the ferment activity by hypertonic salines they were able to produce septicaemia with these organisms—for example, Hoffmann's bacillus, *B. cyanogenus*, *sarcina*, etc. (b) The virulence of a bacterium depends upon the rate of liberation of toxic (aggressive) substance, and the retention of the same in the immediate vicinity of the bacterium. The *Bacillus mycoides* was shown to develop a capsule. And, further, the action of the hypertonic saline used is to bring about the formation of a capsule—that is, a halo of bacterial protoplasm. The authors considered that this capsule protected the bacterium from the further action of the antibody by producing a zone of ferment equilibrium around it, which on the one hand acted aggressively and prevented phagocytosis, and on the other protected the bacterium from destruction by the antibody. The authors were able to produce by their methods septicaemia with the Hoffmann bacillus, which up to now has never been possible, and were able to demonstrate in the blood of these animals the same toxic substance as is present in the blood of all animals dying from septicaemia and toxæmia. They further argued that the so-called exotoxin is only exuded bacterial protoplasm, and like the so-called endotoxin, only becomes toxic after it has been acted upon by the antibodies of the infected animals.

HUNTERIAN SOCIETY.

CLINICAL AND PATHOLOGICAL MEETING.

Wednesday, January 22nd, 1913.

Mr. A. H. TUBBY, M.B., F.R.C.S., President, in the Chair.

Treatment of Fractures.

THE PRESIDENT showed a number of x-ray photographs, showing the results of treatment of fractures. He pointed out that some are best treated by wiring, others by the use of splints. He specially recommended operation in the case of fractures of the olecranon and of the patella, and found that operative treatment was satisfactory in separation of the upper epiphysis of the femur from the shaft, separation of the upper epiphysis of the humerus from the shaft, certain fractures of the leg just above the ankle-joint, and certain fractures of the lower part of the forearm.

Malignant Disease of Tonsil.

Dr. KELSON showed a case of malignant disease in a man aged 45, apparently originating in the lower part of the right tonsil. It pressed the larynx over to the left side, and there was dysphagia. He asked whether, in

view of the inoperable character of the case, any members present had had experience with selenium, Coley's fluid, x rays, or radium.

Specimens.

Mr. F. S. KIDN showed: (1) A curious case of bone disease in a boy, the diagnosis being osteogenesis imperfecta. (2) Skiagrams of kidneys whose pelvis had been filled with collargol. Dr. HALDIN DAVIS showed a case of Paget's disease of the nipple, which had been treated by radium; also microscopical slides of molluscum contagiosum and favus.

BRADFORD MEDICO-CHIRURGICAL SOCIETY.

At the January meeting, Dr. F. W. EURICH in the chair, Dr. WRANGHAM read a paper on *Poisoning*, which was considered chiefly from the point of view of diagnosis. The medico-legal aspect was also discussed. Poisoning might be suicidal, accidental, or homicidal. Clear evidence of suicidal poisoning was, as a rule, not wanting, for generally the poison was known or the symptoms were convincing. If not, or if the patient were found dead, the stomach contents must be investigated. In these cases, although legally the police should be informed, it was not always in the interest of the patient to do so. In most cases of accidental poisoning the fact that the patient had been poisoned was quite clear, as for instance after partaking of poisoned food, when the symptoms appeared suddenly and perhaps more persons were similarly affected. In the cases where medicine had been taken by mistake, the facts were stated readily enough and every assistance given to the medical man. In chronic cases, such as the Manchester epidemic of arsenical poisoning from beer, it was the cumulative evidence of numbers of individuals affected which led to detection. Lead poisoning from water came under the same heading. In acute homicidal cases, and in those where death ensued, the diagnosis was, as a rule, fairly clear. In chronic homicidal cases, as for instance arsenical poisoning, the medical man was often in great difficulty and the question as to the advisability of informing the relatives or the police in such cases was very minutely considered. The paper was discussed by Drs. HONEYBURNE, RABAGLIATI, LANKESTER, ANGUS, HUGHES, LODGE, and EURICH; and Dr. WRANGHAM replied. Dr. HONEYBURNE read a paper on *Toxaemia*. Toxic poisoning in some shape or other was met with in all of the following morbid processes: (1) All the specific infective fevers; (2) diseases of animal parasites; (3) chronic intoxication, such as alcohol, lead, arsenic; (4) food poisons (fish, meat, cheese); (5) diseases of metabolism (gout, diabetes, uraemia). The toxaeemias of the specific infective fevers were taken as an example, more especially that of diphtheria, being the best known of all. After reviewing our knowledge of the diphtheria bacillus and explaining the formation of endotoxins and exotoxins and the action of antitoxins, Dr. Honeyburne pointed out that it was only in the case of the exotoxins that antitoxin was formed, and unfortunately in man the exotoxins only occurred in diphtheria and tetanus. He then went on to discuss anaphylaxis, explaining the cause and showing how it could be avoided. He next described the bactericidal substance in the blood which caused the destruction of the invading bacilli and which was made up of two separate ingredients—the amboceptor and the alexin or complement. A short account was then given of the agglutinating substance and of opsonins. The paper was discussed by Drs. EURICH, ANGUS, LODGE, LANKESTER, WRANGHAM, and HUGHES; and Dr. HONEYBURNE replied.

NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.

At a meeting held on January 17th, Dr. ARNOLD W. W. LEE, President, in the chair, Dr. H. R. CLARKE (Manchester) showed a case of *Uterine endothelioma* arising from the mucous membrane near the entrance of the left Fallopian tube. Dr. WALLACE (Liverpool) showed lantern slides illustrating three cases of *Chorion-epithelioma*, which he described at the last meeting. Dr. STROOKES (Liverpool) read a paper on *Some points in the puerperal mortality*. For the last ten years the average death-rate from puerperal sepsis had been 1 per cent. in Liverpool, and the average for

England and Wales 1.7 per cent. He considered this good result to be due to the high standard set in the examination for midwives originally in Liverpool and now under the regulations of the Central Midwives Board. Dr. M. MONTZ (Manchester) read a paper on *The nature of the so-called ligaments of Mackenrodt*. By means of dissections and drawings he conclusively showed these so-called ligaments to be perivascular tissue surrounding the vessels supplying the uterus, and not separate ligaments.

Reviews.

GYNAECOLOGICAL ANATOMY.

ALTHOUGH pictorial anatomy is not so necessary as it was in days when anatomists and prepared dissections were rare and only to be heard and seen at universities in distant foreign towns, still it has yet its uses. Dr. LIEPMANN has prepared an atlas¹ which is excellent as a collection of anatomical drawings, but will, we must feel, be more resorted to on account of certain matters of deep importance to the gynaecologist. Radical operations, which are really complicated dissections, are largely undertaken for the extirpation of the cancerous uterus and all suspected tissues and structures in its neighbourhood; whilst, on the other hand, the palliative and operative treatment of displacements and prolapse of the pelvic viscera remains quite unsettled. The first question would be solved already were it not for the wholesome dread the operator entertains lest the ureter be wounded or divided, or lest that duct or the bladder itself be stripped of its nutrient vessels, with disastrous results. The surgeon does his duty in making a clean sweep of doubtful surroundings when he extirpates malignant disease of the uterus, but it is now known that the patient, though immune from recurrence, may have her life made miserable by incontinence of urine and ultimately jeopardized by disease advancing up the urinary tract. Liepmann has drawn or caused to be drawn a number of sections of the pelvis and its viscera, hardened by formalin, alcohol, or freezing. The method of preparation in individual or special dissections is explained and will be of service to curators and professional dissectors. The surgeon and gynaecologist will not appreciate the numerous very pretty looking sections across different planes of the pelvis, so familiar in an anatomical atlas, so much as he will value the far more instructive dissections of the pelvic viscera as seen when the subject is placed in the Trendelenburg position. Thus Plates 10 and 11 are just the kind of illustrations which the operator desires and can utilize. They show him what he wants to see and can see when he exposes the pelvic cavity through an incision dividing the abdominal walls, and they explain certain puzzling appearances produced when the surgeon draws the uterus upwards and downwards, or backwards or forwards, or sideways. The full bladder fallen backward in Plate 11 is well worth the surgeon's inspection, and in the preceding plate attention is turned by lettering to the *ligamentum infundibulocolicum* which Dr. Liepmann distinguishes from the *ligamentum infundibulo-pelvicum* closely related to it. This plate depicts quite graphically an appearance familiar to all who have got through a complicated ovariectomy. Amongst what we may term "the pure sections," Plate 9, made at the level of the cervical canal, is one of the most instructive. The position of the ureters—the bugbear of the operator—is well indicated, as is the *spatium praevesciale mediale*. Some other sections help to teach what the surgeon cannot precisely determine even in the course of a necessarily complicated operation.

The question of displacements is quite different from the surgico-anatomical problems to which we have alluded. When we turn to prolapses all is still obscure. Tandler and Halban, Paramore and other living authorities are not always in agreement. Hence the starting point, which is the musculature, fascia and ligamentous flooring of the pelvis, deserves very close scrutiny, for we cannot understand how the uterus loses, or frees itself

¹Atlas der Operations-anatomie und Operations-pathologie der weiblichen Sexualorgane mit besonderer Berücksichtigung des Ersterverlaufes und des Suspensoren- und Stützapparates des Uterus. Von Dr. W. Liepmann. Berlin: A. Hirschwald, 1912. (Pp. 48; Tafeln 35, Mk. 24.)

from, its supports until we thoroughly recognize what these supports may be, and as yet the problem is not thoroughly understood. Liepmann's plates will aid the anatomist in his researches if—much virtue in an "if," as Touchstone says—he takes care to verify the author's conclusions by making, or directing to be made, fresh dissections. The section (Plate 2) of the pelvis of a woman, aged 28, who died during menstruation is interesting; the uterine mucosa is even thicker than might be expected. There are also some good representations of pathological changes.

CUNNINGHAM'S ANATOMY.

IN the fifth edition of Professor CUNNINGHAM'S well-known *Manual of Practical Anatomy*²—the first edition which has appeared since his death—Professor ARTHUR ROBINSON, his successor in the Chair of Anatomy in Edinburgh, has introduced certain new features, one of which must have far-reaching effects. The anatomists of Great Britain and Ireland have not, up to the present, given their whole-hearted support to what is known as the Basle anatomical nomenclature, a form of international terminology adopted in Basle in 1895 by a committee of anatomists. The idea of the commission originated in and was carried out by members of the *Anatomische Gesellschaft* in Germany, and can be regarded as international only in so far as that society and its affiliations can be so regarded. The reasons for this aloofness are, amongst others: (1) Many of the names recommended are cumbersome; for example, the conjoined tendon masquerades as the *Fale aponeurotica inguinalis*, the external annular ligament as *retinaculum musculorum peroneorum, superius* and *inferius*, whilst the white line in the pelvis is the *arcus tendineus musculi levatoris ani*. (2) Some terms seem to us most unsuitable; for example, musculo-spiral nerve and groove become the *radial* nerve and groove respectively, whilst the circumflex nerve becomes the *nervus axillaris*. (3) Although the modifications suggested by the new terminology may be followed with advantage in many cases, its consistent use seems, in the words of Professor Pierson, "less in accord with the directness of English scientific literature than the enthusiastic advocates of such adoption have demonstrated." Undoubtedly there is much good in it, and if we could only take this and leave out or modify the recommendations, which even the most ardent supporter of the scheme would admit are not wholly satisfactory, it might receive a warmer welcome here. Be that as it may, Professor Robinson has boldly taken the step, and has adopted the nomenclature throughout. It should be stated, however, "that the labours of the commission were conducted not to ensure the adoption of a Latin terminology in every country, but rather a uniform system of nomenclature, and the abolition of many different terms." In England we may translate these names as seems best to us. Experience has already shown that students who commenced their work at the beginning of the present session, and have used this edition as the guide to their work in the dissecting-room, have found little trouble with the new terms; but for the teachers it is otherwise. And when these same students go across to the wards of the hospital after passing in anatomy and physiology, and use terms with which the physicians and surgeons for the most part have little or no acquaintance, there must necessarily be a period of transition which will be difficult and trying for all concerned. However, with patience and a recognition of the central factor that a system like this can never be forced on either teachers or students, a gradual acceptance of its best and most helpful terms may confidently be anticipated. With regard to the additions and improvements which Professor Robinson has made in the text, we notice that in vol. i the plans of dissection of the axilla, abdomen, and pelvis have either been entirely altered or greatly modified. In vol. ii the alterations are not less numerous and important. They include changes in the method of dissecting the face, tympanum, the posterior triangle, and the deeper parts of the neck. We have already, in a previous notice, commented on the great

advantages arising from the alterations in the pelvic dissections. The parts are shown in such a way as the necessities of present-day operative procedure demand, and the same may be said of the dissection of the axilla and the special parts, such as the middle ear. In each case we have nothing but praise for the way in which the various stages of the dissection are described. They are admirably clear and constitute, with some new illustrations, a really valuable addition to the work. Leaving out the question of nomenclature, we take this opportunity of again congratulating Professor Robinson on the various alterations he has made, and there is every indication that the book will continue to hold the unique position which it has attained.

Although so many books have been written on the bones of the body, another has recently been added to the list by Professor A. FRANCIS DIXON of Dublin. In his *Manual of Human Osteology*³ Professor Dixon has given an excellent account of the bones, written from an essentially practical standpoint, and illustrated by a fine series of figures, many of them in colour. It is obvious that in preparing both the letterpress and illustrations the greatest care and attention to detail have been displayed, and the volume can be confidently recommended to those who require a handy textbook as a companion to Cunningham's *Practical Anatomy*, issued by the same publishers. The student will find that the description of each independent bone is not too long, and yet is quite sufficient for all ordinary purposes. Special chapters at the end of the book are devoted to the teeth, composition, shape and structure of bones, the development and the epiphyses of bones—a convenient arrangement for reference. With regard to the vexed question of terminology, the author has taken the plunge along with Professor Robinson, and throughout the text has given the names arranged by the Basle Committee. These are printed in black type, whilst the old names appear in italics or in the type used for the text. As this decision is in agreement with that come to by other writers on anatomy whose books have been recently issued from the Oxford University Press, it follows that a considerable number of those who have commenced their medical studies at the beginning of the present winter session must now become familiar with the old and the new terms in anatomical literature—another burden to the already overworked medical student. The many merits of the book will, however, soon be realized by students and practitioners, and we can recommend it to those who are reading for the ordinary qualifying examinations, and also to others who are preparing for the higher examinations, as containing an accurate account of the human skeleton.

CHEMISTRY.

WHILE new textbooks on one branch or another of chemistry appear with great frequency, the number of those which present much new matter or deal with the subject from a new point of view is by no means large. Among the latter a conspicuous place is due to MOLINARI'S *Treatise on General and Industrial Inorganic Chemistry*,⁴ an English translation of which, by Dr. E. FEILMANN, has just appeared. The work is divided into three parts, headed "General," "Non-metals," and "Metals." The first of these deals in a very thorough manner with the fundamental laws; in this section modern conceptions, such as the principles of thermo-dynamics, the ionic theory, the phase rule, and the known facts as to colloidal solutions, radio activity, and the disintegration of atoms, are given their proper place in the systematic study of the subject; it also includes a historical sketch of chemistry up to the beginning of the modern development of the science, ranging from the ancient Chinese to the work of Lavoisier. In the second and third parts the distinctive feature is the prominence given to industrial processes and statistics of production. Laboratory methods of producing each substance are first given, somewhat briefly and

² *Manual of Practical Anatomy*. By A. F. Dixon, Professor of Anatomy, Trinity College, Dublin. London: H. Frowde, and Hodder and Stoughton. 1912. (Cr. 8vo, pp. 328, 178 figures, some coloured, 10s. 6d. net.)

³ *Treatise on General and Industrial Inorganic Chemistry*. By Dr. Ettore Molinari. Third revised and amplified Italian edition, translated by Dr. Ernest Feilmann, B.Sc., Ph.D., F.I.C. London: J. and A. Churchill. 1912. (Roy. 8vo, pp. 729; 230 illustrations and 3 plates, 21s. net.)

⁴ *Manual of Practical Anatomy*. By the late D. J. Cunningham. Fifth edition. Edited by Arthur Robinson, Professor of Anatomy, University of Edinburgh. Two vols. Edinburgh and London: Henry Frowde, and Hodder and Stoughton. 1912. (Cr. 8vo, vol. i, pp. 701, figs. 255; vol. ii, pp. 646, figs. 256. 10s. 6d. per vol. net.)

as a rule without illustrations of ordinary apparatus; its actual uses are mentioned somewhat fully, then the methods by which it is produced industrially, in many cases with illustrations of the plant employed; finally, figures showing the amounts produced in different countries or by different processes are briefly presented. The book is intended principally not for those who are previously quite ignorant of the subject, but for those who have such a general knowledge of chemistry as is now commonly given at a technical institute; for the student who is intending to devote himself to industrial applications of chemistry the information here presented gives the subject a reality and concrete interest which are not imparted by the ordinary textbook, while for the more general student of the subject also its interest is greatly increased. In the numerous cases where rival methods of production dispute the field, it is possible from the descriptions and statistics given to form a fair estimate of their relative importance and advantages. Since the author is an Italian professor of industrial chemistry, prominence is naturally given to the Italian point of view, but the value of the work to students of other nationalities is not appreciably lessened thereby, while many interesting facts as to national progress come under notice. The book occupies an intermediate position between a textbook of inorganic chemistry and an advanced work on chemical technology, and the information given in this third edition is evidently thoroughly up to date. The translation appears to be very well done (though misprints are unfortunately rather numerous), and the book is to be strongly recommended.

Chemical Theory and Calculations,⁵ by Messrs. F. J. WILSON and I. M. HEILBRON, is an elementary textbook for chemical students devoted to a portion of the subject which is not always adequately treated in larger works. The atomic theory and methods of determining atomic weights, valency, the theoretical portion of quantitative analysis, and the elements of thermo-chemistry are among the subjects to which chapters are devoted; numerous examples are given of the calculations necessary to be made in connexion with these and with the laws of diffusion of gases, and of the effect on volume of changes of temperature and pressure, etc. The book will be useful, but a student working without assistance might occasionally be puzzled by apparent discrepancies, as, for example, the statement on p. 8 that specific gravities are determined at 20° C. by means of the pycnometer, and on p. 11 that a temperature of 15° C. is taken when the Westphal balance is employed.

The third volume of THORPE'S *Dictionary of Applied Chemistry*,⁶ like its predecessors, is characterized by the wide range and comprehensive nature of the information which it contains. The section of the alphabet included in this part is from Gr to Oils. Amongst the matters of interest in medicine which are comprised in this volume are some twenty vegetable drugs dealt with individually, besides many included in the articles on gums, gun-resins, and essential and fixed oils; many medicinal chemicals are discussed under their appropriate headings; while the dietetic articles include the important substances, milk, meat extracts, and lecithin, with many others of more restricted interest. It is impossible to turn over the pages without lighting on articles full of value, while for those who require the fullest detailed information on any of the subjects treated the copious references to original papers will be very convenient. The list of contributors to the present volume includes between thirty and forty names, nearly all well known in one department or more of chemical work.

When a textbook has reached its tenth edition it may fairly be supposed to fill its place in a satisfactory manner; the tenth edition of SIMON'S *Manual of Chemistry*⁷ shows

⁵ *Chemical Theory and Calculations*. An elementary textbook by Forsyth James Wilson, D.Sc. Edin., Ph.D. Leipzig, and Isidor M. Heilbron, Ph.D. Leipzig, F.I.C., A.R.T.C. London: Constable and Co., Limited, 1912. (Crown 8vo, pp. 158; figs. 9. 2s. 6d. net.)

⁶ *A Dictionary of Applied Chemistry*. By Sir Edward Thorpe, C.B., LL.D., F.R.S. Revised and enlarged edition, in five volumes. Vol. III, Gr to Oils. London: Longmans, Green and Co., 1912. (Medium 8vo, pp. 797. £2 5s. net per vol.)

⁷ *Manual of Chemistry*. By W. Simon, Ph.D., M.D., and Daniel Base, Ph.D. Tenth edition, thoroughly revised. London: Baillière, Tindall, and Cox, 1912. (Roy. 8vo, pp. 774; 82 illustrations and 9 coloured plates. 15s. net.)

revision and additions which will ensure that it in no way falls behind its predecessors. Among the matters newly introduced or more fully dealt with than formerly are reversible reactions, osmotic pressure, dissociation, etc.; among new compounds touched on are atoxyl and salvarsan. The distinctive features of the book remain the same, including the use of coloured plates to show the exact colours obtained in many tests, both in the inorganic and organic branches.

MR. J. W. MELLOR'S *Modern Inorganic Chemistry*⁸ is, as its title indicates, an account of that section of chemistry distinguished as inorganic, in which recent work and modern theories are included. The earlier part of the book is chiefly devoted to general laws and theories, and in this part each chapter and often each section is introduced with a quotation from some more or less famous chemist or philosopher; these quotations will perhaps tend sometimes rather to distract than to assist the student, and they are occasionally liable to be misapplied, as, for example, that on p. 56, commencing "some boldness and licence in guessing." The author indicates at the outset that he considers it more important to impart an appreciation of method than a mere knowledge of facts; this point of view is fairly obvious throughout the book, which concludes with an "epilogue" and a quotation from Sherlock Holmes! The work might perhaps have been improved had the author exercised greater restraint in the use of quotation, but as it is, it is certainly a very good book.

DR. EKELEY'S *Laboratory Manual of Inorganic Chemistry*⁹ is stated to be written and arranged for use in connexion with Holloman's textbook of inorganic chemistry. It is impossible to discover what merit there can be in the arrangement adopted, and not easy even to justify calling it an "arrangement" at all. The book is divided into some three hundred and odd sections, each headed with the name of the substance or subject referred to. The treatment in most cases is meagre; for example, the whole section headed "Fluorine" is called "Experiment 57," but consists merely of two questions: one, "Draw a diagram of Moissan's apparatus"; and the other, "State the physical and chemical properties of fluorine." The section headed "Volumetric Analysis" occupies half a page, and that headed "Thermo-chemistry" a third of a page; these two are sandwiched between "Sodium Thiosulphate" and "Nitrogen."

HARELIP AND CLEFT PALATE.

ONE of the most striking demonstrations before the Surgical Section of the Annual Meeting of the Association at Birmingham in 1911 was Mr. James Berry's account of his results in the operation for cleft palate. Those present were impressed by two features in the cases shown—the admirable reconstruction of the palate and the excellence of the voice production. In the paper read at the meeting Mr. Berry strongly advocated the claims of what is now the old operation, or properly, the Langenbeck operation, and he maintained that the results obtained with other operations, ingenious and indeed audacious as these mostly were, were not comparable with those achieved by the Langenbeck method. In a volume on *Harelip and Cleft Palate*,¹⁰ Mr. BERRY and his colleague Mr. LEGG have very fully set out the whole anatomical and developmental story of these deformities, and have given in elaborate detail the various operative procedures for treatment and their results. On the question of the proper time to operate the advice is that closure of harelip should be done when the child is about a month or 6 weeks old, provided that the infant is other-

⁸ *Modern Inorganic Chemistry*. By J. W. Mellor, D.Sc. London: Longmans, Green and Co., 1912. (Demy 8vo, pp. 891; 316 illustrations. 7s. 6d.)

⁹ *Laboratory Manual of Inorganic Chemistry*. By John B. Ekeley, Ph.D., Sc.D. New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1912. (Cr. 8vo, pp. 156; figs. 46. 4s. 6d. net.)

¹⁰ *Harelip and Cleft Palate, with Special Reference to the Operative Treatment and its Results*. By James Berry, B.S. Lond., F.R.C.S., Senior Surgeon to the Royal Free Hospital, Consulting Surgeon to the Alexandra Hospital for Children with Hip Disease, and T. Percy Legg, M.S. Lond., F.R.C.S., Surgeon to the Royal Free Hospital, Assistant Surgeon to King's College Hospital. London: J. and A. Churchill, 1912. (Med. 8vo, pp. 340; 242 figs. and appendix of cases of operation for cleft palate. 12s. 6d. net.)

wise healthy. Generally speaking, the sooner the operation is done the better, even (in the case of exceptionally robust children) within the first few days of life. In regard to the palate operation, we find in the second appendix, containing notes of Mr. Berry's 154 consecutive cases, that 20 cases were operated on under 2 years, 50 from 2 to 4 years, 30 from 4 to 8 years, 35 from 8 to 12 years; so that here also no fixed age limit for operation is made.

The authors are strongly in favour of performing the harelip operation before the cleft palate operation, for the reason chiefly that a remarkable degree of spontaneous closure of the cleft, especially the alveolar portion of it, follows the harelip operation. The details of operation for both deformities are extraordinarily, but not unnecessarily, full. We agree with the authors that no operations in the whole range of surgery will better repay attention to minute detail. Gentleness of handling of the tissues is of prime importance; roughness in sponging or in cutting will materially interfere with the nutrition of flaps. The authors accordingly recommend that in cleft palate operations the paring of the edges should be left till after the separation of the muco-periosteal flaps. The most difficult clefts to close satisfactorily are the incomplete wide median clefts which stop short of the incisor teeth, the alveolar arch being normal. These clefts are often very wide and have a broad, rounded, anterior extremity, which is difficult to deal with.

This is an altogether admirable monograph. It is commendable for its clearness, for its ample details, and for its wealth of illustration. It should appeal at once to any surgeon within whose sphere of work these cases come, and mostly to the young surgeon who may be tempted to think that the new ingenious operations are the best, for the work is at once a defence of the Langenbeck or Smith operation and an exposition of what that operation can accomplish.

NOTES ON BOOKS.

AMONGST all those who dabble in eugenics and pin their faith to the doctrine of heredity, none has adopted the most advanced theories more readily than the novelists who find the creed of the eugenicists a convenient peg on which to hang a story. This belief in the transmission of hereditary qualities from parent to child, irrespective of training and environment, is the *leit-motif* of Mr. RICHARD WASHBURN CHILD'S recent novel, *The Blue Wall*,¹ in which the daughter of a drunken libertine, brought up from infancy in the most favourable surroundings, suddenly develops an irresistible craving for strong drink. Her gallant struggle for self-mastery and the extraordinary effect that her mental sufferings have upon all who approach her form the subject of a curious story, the enjoyment of which is only spoilt by the confession of the narrative. The circumstances leading up to and attending poor Julianna's despairing efforts to overcome her "vice of blood" are minutely described by four or five different persons, and the result is a bewildering medley of incident in which the main plot is occasionally lost sight of or forgotten. To make confusion worse confounded, the reader in the end is left in a state of doubt as to the heroine's real parentage, and consequently as to whether her predisposition to vice is inherited from the degenerate Cranch or is merely the result of suggestion. But his curiosity is piqued and stimulated by the skilfully accumulated "rain on ruin, rout on rout." The book is gaily bound and contains several illustrations by Mr. E. Coles Phillips and Mr. Harold J. Cue.

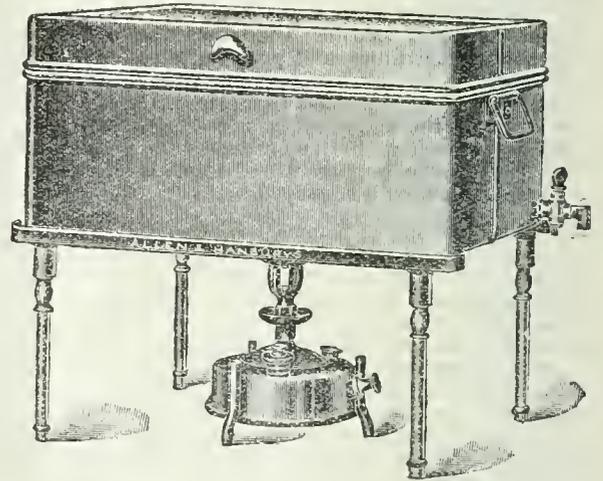

Dr. G. FRANK LYDSTON is well known on the other side of the Atlantic as the author of several books in which he has advocated the sterilization of the unfit as the only effectual means of checking the present alarming increase of crime and degeneracy, and breeding a race of sane and healthy men and women. His latest work, a play in four acts, called *The Blood of the Fathers*,² has been written with the intention of arousing the lay public to a fuller sense of the danger in which it stands, and might serve as a modern illustration of the old text which has warned countless generations of unbleeding mankind, that the sins

of the fathers will be visited upon their children. The plot of the play is very simple. It is merely the unhappy love story of a rising young doctor who, against his better judgement, risks a marriage with the beautiful daughter of a notorious criminal, and lives to repent it. The style and phraseology are intensely American, and the comic relief afforded by Allyn's Japanese valet and his wife's cockney maid-servant appears at times (at least to English ears) to be a little forced and crude: but no thoughtful reader can fail to be struck by the justice of the author's opinions, and the outspoken courage with which he expresses them. In his preface Dr. Lydston tells us that he has adopted his present method of propaganda because "dramatic form is most effective in driving home a social lesson." Those of his readers who share his apprehensions concerning the future welfare of their fellow men, and with him desire to secure for the generations yet unborn the health and sanity which ought to be the birthright of every human being, can only hope that the good seed may not fall on barren soil, and that the solemn warning conveyed by the play may not have been uttered in vain.

MEDICAL AND SURGICAL APPLIANCES.

1 Sterilizer.

MR. C. A. STIDSTON (Wolverhampton) writes: The following are the details of a sterilizer which I have designed for operations in private houses. With the exception of caps, gowns, and dry towels, which are taken already dry-sterilized in drums, everything connected with an operation can be sterilized in the operating room independently of any source of heat in the house. The sterilizer is of copper, and is 14½ in. long, 12 in. wide, and 7 in. deep. Inside it are packed: (1) a collapsible stand; (2) a nest of two circular copper bowls, 7½ in. by 3½ in.; (3) instrument cage, 11½ in. by 3½ in. by 3½ in.; (4) a needle box; (5) a glove box; (6) a number of towels; (7) swabs, sponges, ligatures, drainage tubes; (8) ligature tray, 10½ in. by 11½ in. by 1 in.; (9) a picnic "Primus" lamp in tin 6 in. by 4 in. by 8 in., inside which are tins of paraffin and methylated spirits, spares, and all fittings; (10) instruments and dressings. In the back lower corner of one side is a

hole into which screws (1) a block stop, or (2) a tap. By means of the tap the water or lotion (I use weak lysol) contained in the sterilizer can be run off into instrument and ligature trays, into bowls for hands and gloves, etc., into a douche can, etc. The sterilizer may be boiled on a gas range or coal fire, but with the "Primus" lamp (especially added to dispense with the uncertainty of reliable heat being found at the house) 16 pints of water can be brought to the boil in 30 minutes. The sterilizer will hold midwifery forceps and the largest instruments, and is large enough to contain accessories. By a skewer joint the cover is removed, inverted, and acts as an instrument tray. Messrs. Allen and Hanburys are the makers.

At the annual meeting of the National Dental Hospital for London it was stated that considerable improvements had been effected, but that the funds in hand were not sufficient to complete the equipment. The proposed arrangements for amalgamation with a general hospital had been suspended at the request of the Board of Education until the issue of the report of the Royal Commission on University Education in London.

² *The Blood of the Fathers*. A Play in Four Acts. By G. Frank Lydston. Chicago: Riverton Press, 1912. (Post 8vo, pp. 241. Price, £2.2s. cloth; s 2.2s. edition de luxe.) (Sold by subscription only.)

MEDICAL SERVICE IN THE HIGHLANDS AND ISLANDS OF SCOTLAND.

(Continued from page 129.)

In an appendix to the report of the Committee on the Medical Service in the Highlands and Islands, Dr. Leslie Mackenzie, Medical Member of the Local Government Board for Scotland, deals with a scheme for the administrative consolidation of medical service.

This appendix is analysed below. It contains many valuable suggestions as to the appointment of a central authority for the administration of medical services in the Highlands and Islands.

INTRODUCTION.

The Committee's remit contains the words: "To advise as to the best method of securing a satisfactory medical service therein, regard being had to the duties and responsibilities of the public authorities operating in such district." Dr. Mackenzie points out that if such a grant is to result in the establishing of a "satisfactory medical service," it is essential that the existing medical services shall be consolidated and a large number of statutes affecting the health of the country as a whole readjusted. As the Committee is concerned only with the Highlands and Islands, the present seems a favourable occasion for the framing of a scheme to show how far, through the instrumentality of a grant, it is possible to bring about an administrative consolidation of existing services. Such an administrative consolidation would result in increasing the efficiency and developing the resources of the present services, in demonstrating what additional service is necessary, and in preparing the way for any legislation afterwards found to be expedient.

There are several factors in the problem: The smallness of the unit area of administration of parish medical service, the economic deficiencies of particular districts, the geographical difficulties of transit, the conflicting interests of local administrative authorities, the insufficiency of general and special hospital service, the inadequacy and imperfect organization of general and special nursing services, the economic difficulties of private medical practice, the comparative absence of specialized medical practice. To show how some of these difficulties and defects may be overcome it is necessary to enter with some detail into the statutory constitutions and obligations of the existing medical services, to indicate some statutory resources that are still undeveloped, and to show how the public services, once properly correlated, may become the basis for a more adequate system of private medical practice. A primary point to consider is the relation of the public medical services to private medical service; for it may here be said at once that, over large areas of the Highlands and Islands, private medical practice on the ordinary lines is a demonstrated failure. Large numbers of sick people go untreated; yet the doctors cannot make a living.

THE MEDICAL SERVICES.

The medical services here to be discussed may be classified as follows:

1. Poor Law Medical Service.
2. Old Age Pension Medical Service.
3. Local Lunacy Medical Service.
4. Vaccination Medical Service.
5. Public Medical Service.
6. School Medical Service.
7. Maternity Medical Service.
8. National Health Insurance Medical Service.
9. Factory Medical Service.
10. Post Office Medical Service.
11. Nursing Service.
12. Private Medical Practice, including the club system, fee-paying practice, etc.

Poor Law Medical Service.

At present the following medical services, though not all under the Poor Law Acts, and therefore not all affecting the registered poor as such, are, nevertheless, carried out by the Poor Law authority, namely, the parish council:

- A. Medical attendance on the registered poor in poorhouses or outdoor.
- B. Medical attendance on old age pensioners.
- C. Medical attendance on pauper lunatics.
- D. Vaccination of defaulters.
- E. Attendance, nursing or other, on paupers in poorhouses and also on outdoor paupers and pauper lunatics.

D

The salary of the parish medical officer must be approved by the Local Government Board, who determine what proportion of the salary shall rank for the medical relief grant. This grant amounts to £20,000 for the whole of Scotland. A first charge on it is made for trained sick nursing in poorhouses; the remainder is distributed as a subvention in aid of the medical officer's salary. This subvention at present amounts to about 4s. 3d. per £. No part of the grant is available for the nursing of outdoor paupers, or for lay attendance on paupers or pauper lunatics. The fact that trained sick nursing in poorhouses is a first charge on the grant affects unfavourably the Highlands and Islands districts; for in those districts the vast majority of the registered poor are on the outdoor roll; only a small minority are in the poorhouses. It follows that, although the proportion of poor is large, the proportion of the medical relief grant is small. In the memorandum prepared by Mr. Maxwell, Secretary to the Local Government Board, full details are given as to the inequitable incidence and operation of this grant.

In order to obtain medical officers to discharge these functions, the parish councils have been obliged to offer salaries sufficient to induce men to reside in localities not otherwise likely to attract a private medical practitioner. Consequently, the salaries, compared with the salaries given elsewhere in Scotland, are, in the Highlands and Islands, very frequently out of proportion to the number of paupers and pauper lunatics that have to be medically attended. The incidental result is that the poor rate, supplemented by the medical relief grant, bears to a considerable extent the burden of a "free" medical service; for it is a common understanding that the medical practitioner appointed as parish medical officer shall attend non-paupers at reduced fees. Frequently, indeed, the parish medical officer attends poor but non-pauper residents without any prospect of obtaining a fee. In the Highlands and Islands that is an extremely common practice.

Old Age Pension Medical Service.

As indicated above, the parish medical officer attends on old age pensioners. This is because the majority of old age pensioners in the Highlands and Islands districts cannot afford the expense of a private medical attendant, and they are not disqualified by receipt of medical relief, even when administered under the Poor Law.

The medical attendance on old age pensioners does not amount to a separate service, but it illustrates very pointedly the power of the Poor Law to administer medical relief without involving the recipient in any disqualification either as to his pension or as to certain rights of voting. What applies to old age pensioners applies equally to all others in need of medical relief alone. But it must be said that the medical attendance on old age pensioners does not constitute a serious item at present in the work of the parish medical officers. In some cases the medical officer had never been called to an old age pensioner, although there were many in the parish. Probably the failure to call the doctor is in many cases due to ignorance of the legal right. But, apart from the Poor Law, there is no provision for medical attendance on old age pensioners, and, as they are presumably unable to afford ordinary medical fees, they may in many instances go without medical attendance, even when they require it. The medical officer of the parish is not specially paid for his attendance on old age pensioners, and in one case brought before the notice of the Committee the medical officer himself had to provide any drugs prescribed for such pensioners. This he had to do in every case where application for medical relief had not been made through the inspector of poor in the regular way. This is not a satisfactory state of affairs. The attendance on old age pensioners, who are a special class, ought to be paid separately, and no medical officer should have to pay out of his own pocket for the drugs prescribed.

Local Lunacy Medical Service.

Although the pauper lunatics are attended by the parish medical officer, the Lunacy Medical Service is distinct from the Poor Law Medical Service. The treatment of lunatics, both in poorhouse lunacy wards and in private houses, is supervised by the General Board of Lunacy, who control both parish and other asylums. The local lunacy boards are distinct from the parish councils. It is, there-

fore, important to note that the Lunacy Medical Service is a distinct medical service. In the Highlands and Islands the proportion of lunatics is larger than in many other parts of Scotland, and consequently the cost of the treatment of lunacy is a heavy burden on local rates. It has, on more than one occasion, been suggested that the treatment of lunacy should be entirely met from Imperial funds. If this were done, one serious burden on the Highlands and Islands would be removed. In any claim for an Imperial grant to increase the adequacy of the medical service in the Highlands and Islands, the cost of lunacy may legitimately be emphasized. In several localities it was pointed out to the Committee that lunacy was the most expensive item in the whole medical service. To a certain extent this burden has been relieved in the western islands by the use of the two poorhouses (Stornoway and Lochmaddy) for the accommodation of suitable cases of lunacy. The local lunacy medical service should be paid for on a more adequate scale than at present.

Vaccination Medical Service.

Under the Vaccination Acts the parish council is charged with the duty of vaccinating defaulters, and taking all legal proceedings necessary for the purpose. There is no system of public vaccination as in England. In Scotland vaccination is normally a private medical service rendered by a practitioner to his patient, and paid for by the patient. Only when a child's guardian becomes a defaulter is the child vaccinated at the public expense. In many of the Highland and Island parishes practically all the guardians of infants become defaulters, and thus have their children vaccinated at the expense of the poor rate. There is no grant to assist parishes in the execution of the Vaccination Acts. It may be added that the fee for vaccination acts as a deterrent.

A Vaccination Medical Service is also provided for under the Public Health (Scotland) Act, 1897, which authorizes the local authority for public health to defray the cost of vaccination and revaccination. This power, however, is permissive. In the Highlands and Islands vaccination is entirely carried through by the parish councils, except occasionally, when there is a small-pox outbreak or a small-pox "scare." Vaccination is then offered freely by the public health authorities. It has been suggested that the work of vaccination should be a statutory obligation on the local authority for public health, which is the authority directly interested in the prevention of small-pox. This authority may at any time defray the cost of vaccination and revaccination, but it cannot be placed under obligation to carry out the Vaccination Acts until those Acts are amended.

The operation of the Vaccination (Scotland) Act, 1907, has largely converted compulsory vaccination into voluntary vaccination; and as voluntary vaccination is provided for under the Public Health Act, it is from the public health authority that any future improvement in the Vaccination Medical Service is to be expected.

Public Medical Service.

(a) Hospitals, Convalescent Homes, and Reception Houses.

The Public Health Medical Service is concerned with all conditions affecting the health of the community, and, in particular, with the isolation and treatment of all infectious diseases. For these purposes the public health authorities are under obligation to appoint medical officers of health and sanitary inspectors. They may also be required by the Board, and in practically all cases have been required, to provide hospitals, temporary or permanent or portable, for persons suffering from infectious disease, with the nursing services incidentally necessary. They have also power and may be required to provide reception houses for persons convalescent from infectious diseases; but, although in many cases eminently desirable, these reception houses have nowhere been provided in the Highlands and Islands. Further, they may be required to provide reception houses for persons who may have been exposed to infectious disease. Such houses, however, have nowhere been provided in the Highlands and Islands. Hitherto the hospital accommodation provided has tended to the minimum necessary for the isolation and treatment of a proportion of the persons affected by the most serious infections. (These

obligations are contained in Section 66 of the Public Health (Scotland) Act, 1897.)

In many localities, however, the provision even of hospitals has been found so difficult, on account of the poverty or the geographical conditions of the area, that, even for the major infections, no hospital at all is available. These localities are undoubtedly the exception; but the economic conditions are frequently such that the rates would be grossly overburdened if adequate provision of hospitals, convalescent homes, and reception houses were rigidly enforced. This is an item that may legitimately be pressed in the claim for an additional Imperial grant.

(b) Domiciliary Medical and Nursing Service.

Under the same section (66) the Public Health Authority, with the consent of the Local Government Board, may also, either instead of providing such hospitals or houses, or in addition to such provision, employ nurses to attend persons suffering from infectious disease in their own houses, and may also supply medicines and medical attendance for such sick. In several localities in the Highlands this power has been employed. One or two public health authorities in the Highlands have appointed nurses to attend patients in their homes; but the comprehensive powers of domiciliary treatment conferred by the Act have not been developed to any considerable extent. This, no doubt, is largely due to the expense involved both in the provision and in the housing of trained nurses. All over the Highlands the Committee has been confronted with the difficulty of housing nurses and doctors. In some cases, too, the public health rate has approached or reached its statutory maximum—namely, 1s. per £. In those cases no adequate provision, either of hospitals or of nursing, is possible without Imperial assistance. At the same time, probably the failure to provide nursing may fairly be assigned in part to the inadequate appreciation of the need for nursing. Frequently epidemic diseases—such as measles, whooping-cough, scarlet fever, or diphtheria, typhoid, and even typhus fever—are allowed to run riot until the number of immediately susceptible persons is exhausted. In many localities the nursing provided is quite inadequate for epidemic work; but there is evidence that the need for domiciliary nursing is being better appreciated.

It may here be added that in a great many localities the houses are quite unsuited for the isolation and treatment of any infectious disease (including tuberculosis). It follows that any system of home nursing for infectious diseases must remain more or less abortive. Yet, in the large epidemics that occasionally occur, particularly among children, nursing at home is an essential adjunct of any public medical service.

Hitherto only one or two local authorities have made any fixed arrangements with medical practitioners for attendance on infectious patients at their own homes. This, however, is clearly a competent arrangement under the section, and as the public health authorities are responsible for the management of all infectious diseases, that may legitimately be urged to develop the domiciliary medical treatment of infectious cases where no other arrangement is, for the time being, practicable. In the evidence placed before the Committee several cases were mentioned where the local medical practitioner had to attend, on behalf of the local authority, a large number of infectious cases—such as persons suffering from diphtheria and typhoid fever; but in most localities such attendance was regarded merely as an ordinary part of the duty of the general practitioner to his patients, and was not paid for by the local authority.

The term "infectious disease" in this section includes tuberculosis, whether the disease be compulsorily notifiable or not. The Local Government Board in reports and circulars have indicated their view that the Public Health Act is applicable to tuberculosis as to other forms of infectious disease. In particular they have issued an order requiring the notification of the pulmonary forms of tuberculosis. It is therefore open to the local authority for public health to provide for the domiciliary treatment of tuberculosis, and this has been indicated in a circular recently issued by the Board (P.H., XVII, 1912).

The powers conferred by this section (66) of the Public Health (Scotland) Act, 1897, are, therefore, of the greatest

practical importance in the Highlands and Islands, where hospital accommodation is, for geographical reasons, frequently difficult to establish; where, as in some of the islands, the housing is particularly defective and insanitary; where, too, the population is frequently very much congested. No doubt the occurrence of tuberculosis is largely a problem of housing; but, pending the improvement of housing, there is abundant need for an extension of the domiciliary medical and nursing systems. Illustrations could be taken from almost any part of the Highlands and Islands.

Generally it may be said that in the Highlands and Islands the powers of hospital provision, convalescent home provision, and provision for patients that have been exposed to infection, have not been developed to anything like their full extent, nor has adequate attention been concentrated on the possibilities of medical attendance and nursing at home. Probably, if additional assistance from Imperial grants were available, medical and nursing service for infectious disease, including tuberculosis, could be made immensely more adequate. A nursing service developed under these powers would also cover a large part of the cases emerging from the medical inspection of school children, who, as is well known, suffer in considerable numbers from diseases such as ringworm, impetigo, and other infectious diseases, not to speak of infectious eye diseases, septic catarrh of the ear, and septic conditions of the throat. The amount of money available from the public health rate and the Imperial funds might thus become a substantial basis for a nursing system that could be readily extended to non-infectious cases. There seems to be no sound reason why a nursing system established by a district committee (that is, the local authority for public health) should not be consolidated with any nursing system established under a parish council. If the various moneys available were funded, there is no reason why the nursing work of a whole district should not be so arranged as to suit the purposes of every parish within the district. Such a system would be at once more economical and more efficient than the scattered and sporadic efforts at present made to deal with individual cases.

(c) Control of Non-infectious Endemic or Epidemic Diseases.

By Section 78 of the Public Health (Scotland) Act, 1897,

The Board may from time to time make, alter, and revoke such regulations as to the said Board may seem fit, with a view to the treatment of persons affected with any epidemic, endemic, or infectious disease, and preventing the spread of such disease . . . and may declare by what authority or authorities such regulations shall be enforced and executed.

It is under this section that the recent order for the compulsory notification of pulmonary tuberculosis was issued. If it be held that the terms "epidemic" and "endemic" are to be read as alternatives to the term "infectious disease" it will at once be clear that the powers of this section may cover a number of serious and widespread diseases, infectious and non-infectious. Among the diseases that might be dealt with in such an order are hydatid disease, which is common in Shetland; croupous pneumonia, which is common everywhere; and the malignant diseases (including cancer), which at present cannot receive in the Highlands and Islands the same medical attention they receive even in small towns. It need hardly be said, however, that any serious extension of the present obligations of the public health authorities along those lines could not be contemplated without additional assistance from Imperial funds.

(d) Cleansing and Disinfection of Houses and Clothing.

Under the Public Health Act also there are abundant powers for the cleansing and disinfection of houses, for the cleansing and disinfection of clothes, for the transport of patients to and from hospital. In the direction and execution of such work an adequate service of nursing might be developed with the greatest social profit. Over and over again the Committee has had impressed upon it the value of trained nurses in educating the inhabitants in the maintenance of cleanliness, both of house and of person. Amongst the many incidental benefits from a public nursing system this is undoubtedly one of

the greatest. Such educative direction subserves in no small degree the primary purposes of the Public Health Act.

(e) Ambulance Service.

Further, if it be legitimate to take the larger view of the terms "epidemic" and "endemic" disease, the development of the public health ambulance system might readily dovetail into any ambulance system that was found to be necessary for the removal of cases of general sickness. This would bring the transit of patients either to large distant hospitals or small local hospitals into relation with the public health service of the area. At present patients are removed to hospitals in carts or other conveyances, without any consideration for the nature of the illness or the danger to the patient. The damage to patients must from time to time be considerable. At any rate it is eminently desirable that some regular system of ambulance should be established, and one ambulance could serve for a very large area. The ambulance associations in the thickly-populated centres of Scotland do an enormous amount of good work in this connexion, and if there were proper organization of nursing and medical service, those associations might find for their ambulances a fairly continuous use in the Highlands and Islands. It does seem unsatisfactory that every public health authority should have to provide for the removal to hospital of cases of infectious fever, while a case of pneumonia, or acute rheumatism, or Bright's disease, or heart disease, should have to rely on any chance vehicle that the individual himself may find available in the locality. For insured persons and dependants, cost of removal to or from sanatoriums or other institutions may be defrayed out of the sums available for sanatorium treatment.

This, however, is offered only as one of many possible illustrations of the uses that might be made of the powers of the public health service to provide the mechanism to assist the organization of general treatment and the management of hospitals of every variety.

(f) Pathological Service, including Bacteriological Examinations, etc.

As a pathological service is an essential part of any adequate medical service, it is important to consider how far such a special service can be provided. Already all local authorities for public health have the power to provide for the bacteriological examinations of cases of infectious disease—tuberculosis in all its forms, diphtheria, enteric fever, etc. These powers include the full pathological investigation of all such diseases. Most of the Scottish local authorities have already made arrangements for the most urgent parts of this work, and some local authorities have special laboratories of their own. Such arrangements might, without any difficulty, include such work as the diagnosis of tuberculous cases by tuberculin, the technical direction of tuberculin treatment or other similar treatment, the preparation of special vaccines, and the like. With very little additional outlay, a full system of pathological assistance and consultation could be instituted. This would be an eminently suitable subject for a subsidy from any additional grants contemplated.

School Medical Service.

This medical service has been organized under the powers of the Education (Scotland) Act, 1908.

The School Medical Service will soon be, where it is not already, supported by a system of school nurses, whose first duty will be the "following up" of the cases discovered at the medical inspection. The nurse will thus come to act as a most important intermediary between the school medical officer, the parent, and the parent's family attendant. In the evidence placed before the Committee it was made abundantly clear that hitherto the number of children brought by the parent to the medical practitioner is very small relatively to the numbers needing treatment and notified to the parent by the school officer. There is here an important gap to be filled if the School Medical Service is to be made efficient. This gap can be filled by the school nurse, who, at the instance of the school medical officer, would "follow up" the case in the home, and, under the direction of the medical practitioner, would carry out the treatment prescribed.

Recently a grant has been given by the Scottish Education Department to such school boards as have asked for it to

enable them to ensure that medical treatment is provided for "necessitous" children. A certain portion of this money might well be spent in securing the assistance of the local medical practitioners for the treatment of such ailments as they might properly undertake to treat or do habitually treat. The school nurse would normally superintend or carry out the treatment prescribed by the medical man in charge. But such a nurse would in many localities have time to do nursing work for the parish or the public health authority, or the Insurance Committee. There is here, therefore, opened another line of possible organization of nursing and medical service.

Where the districts are sparsely populated, and where a concentration of nursing and treatment work is readily accomplished, it would be a waste of money and energy for each *ad hoc* authority to provide its own nurses. The "following up" of school cases might easily be fitted into the treatment of such cases and adapted to the other nursing work of a district.

Maternity Medical Service.

In the course of the Committee's investigations nothing has been more striking than the casual nature of medical service in regard to birth and infancy. The medical practitioners in their returns indicate that they are summoned in a considerable percentage of confinements, but the greater percentage of confinements almost everywhere is left to the charge of trained nurses, partially trained midwives, or totally untrained women. In some localities that are difficult of access, or far from a doctor, births take place either without any assistance whatever or with such assistance as the husband or other person can render on emergency. The evidence shows that only a small number of cases are attended even by trained nurses; the majority are attended by the partially trained midwives or by unskilled persons. In almost no locality, however, is there any definite understanding between trained nurses, midwives, unskilled persons, and local doctor. The doctor, no doubt, is often summoned in difficulties, but that is accidental. There is no obligation of any kind on any midwife, trained or untrained, to summon a doctor; there is no notification of births; there is no registration of midwives; there is, in a word, no systematic relation between doctor and maternity nurses. This is true with very few exceptions.

From no standpoint can this chaos of casual practice be regarded as an adequate medical service. Apart, however, from the obvious want of system or mutual understanding, the damage done by the unskilled management of confinements is known to be considerable. Where practice is so casual precise information is naturally very difficult to obtain, but the Committee has had abundant indications of the injury done to individual mothers by the unsuperintended and undirected practice of partially skilled or unskilled women.

The Midwives Registration Act does not apply to Scotland. Consequently, midwives of any grade of qualification may practise absolutely without supervision by any medical man or by any other external authority. In none of the country districts visited has the Notification of Births Act been applied by the local authority. The result is that the attendant at a birth is not brought into official connexion with the health authority. The Act has been adopted in the town of Inverness.

As a first step towards the remedy of this entirely indefensible condition of practice, two things may be suggested: (1) That the bill recently before Parliament for the registration of Scottish midwives should be passed into law at as early a date as possible; (2) that the local authorities should be requested to apply the Notification of Births Act over their whole area.

The medical and nursing care of infancy from the first year to school age is, as nearly everywhere else in Britain, entirely unprovided for as such. It is left simply to the accident of parental solicitude and the availability of a doctor. There is evidence that among these infants bronchitis and catarrhal pneumonia are common, as is to be expected from the conditions of the housing. The perpetual inhalation of peat smoke, whatever other results it may have, may fairly be set down as a contributing cause of bronchitis and pneumonia in infancy. Indirectly it may thus increase the predisposition to tuberculosis. Further, the proved

inadequacy of the milk supply in various localities is a cause of malnutrition, and there was much other evidence that in some of the poorer localities the infants of 1 to 5 years, no less than those of later age, failed to receive their fair share of nourishment. In order, therefore, to bring birth and infancy into line with the services already enumerated, it is eminently desirable first to establish the notification of births, and thereafter to encourage the appointment of skilled health visitors. Both duties fall to the local authority for public health.

In any claim for an additional Imperial grant the care and management of birth and infancy ought to receive a very prominent place. Under the existing law the whole cost, both of the notification of births and of all health visitors, would fall on the public health rate of the district.

Insurance Medical Service.

Whatever medical service is ultimately organized under the National Health Insurance Act, it is certain that at many points it will come into contact with, or overlap, the existing medical services. To prevent overlapping and waste of energy and money it is essential that the Insurance Medical Service should be adjusted to the others. This can be readily done. Whether the work be carried out by the panel system or by whole-time officers, the same medical man will frequently be in a position to undertake the treatment necessary under the Insurance Act, the Poor Law Acts, Public Health Acts, the Education Acts, and the Factory Acts. It ought to be a simple matter to arrange, through the local body afterwards suggested, that the attendance of insured persons, like the attendance on the poor and the school children, shall be made a functional part of a single medical service on the lines already indicated. There is nothing in the special work likely to be required of a medical man under the Insurance Act that should in any way militate against an administrative consolidation of this and the other medical services. On the contrary, the same family may contain a sick insured person, a sick poor person, a sick old-age pensioner, a sick infectious person, a sick school child, and a sick lunatic—each entitled to medical attendance under a special statute.

In the same way, any nursing service established under the Insurance Act could be worked into a system with other nursing services.

Factory Medical Service.

Under the Factory and Workshop Acts there are two chief medical services: First, the Public Health Service, acting through the medical officer of health, who has certain duties in relation to factories and workshops, workplaces, bakehouses, etc.; secondly, the service of certifying surgeons concerned with the personal certification of the workers. Where there is no certifying surgeon for a factory or workshop, the Poor Law medical officer for the district acts for the time being as the certifying surgeon. This is another instance in which unification might be desirable. Factories are not numerous in the Highlands, but workshops and workplaces are. The work of medical inspection of workshops and workplaces normally falls to the medical officer of health. The work of certifying falls to the medical practitioner. As in so many other public health functions, so here—the service of the local medical practitioner might very well be utilized as part of the public health service.

Post Office Medical Service.

Like the certifying surgeoncies, the Post Office medical officerships are under the patronage of the central department. In the Highlands and Islands the money value of the service does not amount to much, except, perhaps, in some of the towns. Like the factory service, however, the Post Office is mentioned as a type of a medical service under the direct control of a central department, yet carried on by a local practitioner who may have many other official duties.

Nursing Service.

Any voluntary association capable of providing a service of trained nurses might well be assisted by contributions,

both from the local authorities and Imperial funds. To a certain extent this is already done, as parishes contribute to the associations, but there is room for organization and development. Thus, if a county nursing association were established on a voluntary basis it would be systematically subsidized either by annual contributions or by payments for work done. In none of the public medical services enumerated is there anything to prevent organization of such nurses into various grades, according to the predominant requirements of the district.

PRIVATE MEDICAL PRACTICE.

(a) *Relation of Private Practice to Official Services.*

All over Scotland private medical practice is frequently bound up in greater or less degree on one or several official services—for example, the parochial medical service, the public health service. In the Highlands and Islands this is more strikingly the case; for, as the evidence everywhere shows, the great mass of practitioners reckon the income from public service as an important factor in their practice. In some cases the whole income amounts to little more than the subsidy from the official services. In a large proportion of the parishes no medical practitioner can live on the income obtainable from private practice alone. The principle, therefore, of securing to the doctor an official income sufficient to induce him to practise in the locality is already everywhere accepted. In the argument here set forth it is proposed to do two things: first, to relate the local practitioner in an official capacity to as many public services as possible, thereby extending the financial basis for a living practice; second, by a correlation of services to develop and extend the medical activities of the public authorities.

(b) *Club System.*

If the club system were to be made a substantial basis for the better organization of medical services it would have to be compulsory; this would involve legislation. As, however, the purpose of the suggested scheme is to ascertain what can be done without legislation, the club system is considered solely from the standpoint of administrative consolidation of services as distinct from legislative consolidation. It is believed that the club system might in certain localities be developed on a voluntary basis if an Imperial grant in aid of local contributions were made available—that is to say, if an association in any locality raised a certain sum, an equivalent sum might be contributed from the grant.

(c) *System of Official Subsidy with Low Fees.*

It seems reasonable to conclude that in many localities within the area the private practitioner, if he is to perform effectively his multifarious duties to the community, must have a minimum official salary assured to him from public services.

But a satisfactory medical service does not consist of general practitioners alone. No hospital medical service is complete without its staff of nurses, wardmaids, and other administrative servants. No outdoor medical service is complete without a parallel system of nurses and other servants. But to constitute a "satisfactory medical service" there must also be provision for consultation between equals, between juniors and seniors, between general practitioners and specialists. There must be provision for assistants at operations. There must also be special provision for such highly specialized work as no country practitioner does normally or can properly undertake.

THE ADMINISTRATIVE CONSOLIDATION OF EXISTING MEDICAL SERVICES.

(1) *The Local Committee.*

(a) *Area.*—If the activity of the various services is to be effectively correlated, the area of any committee must not be limited to a single parish. Probably the area of the local authority for public health would, on the whole, be the most suitable. This area, as determined by the Local Government Act of 1889, has been found after twenty years' experience to be very suitable for public health purposes. It always contains several parishes, and therefore provides for interparochial adjustment of

the services; but, except in two of the Highland counties, it is never co-extensive with the county council area. It is certainly advisable that no new area should be created for the type of committee proposed. It is, further, eminently desirable that the expense of meetings should be reduced to a minimum. In the Islands the difficulty of holding meetings has been found exceptionally great. Consequently the Islands must form a special area.

(b) *Constitution.*—Of existing authorities, the District Committee—that is, the local authority for public health—would form the most natural nucleus for a composite committee. The various interests, so far as not already represented on it, might be either associated with it in the form of a consultative committee or incorporated in it. As, however, legislation is to be avoided, the services of the members of the District Committee would be entirely voluntary. Another form of committee which it is considered would be possible is one composed of representatives from the District Committee; a representative from the Local Insurance Committee; a representative from a group of parish councils; a representative from any local medical association; the medical officer of health of the county or district; one or more officers from the central bodies mainly concerned—that is, the Local Government Board, Scottish Education Department, or the National Health Insurance Commission, or the Central Lunacy Board—such officer to act as assessor.

(c) *Duties.*—The primary duty of the Committee would be to consider the special needs of the area, the financial position of the various authorities and bodies represented, the accommodation for nurses and doctors, the establishment of nursing homes or small hospitals, etc. It would prepare a scheme of improved medical and nursing service for submission to the central authority with a view to the Imperial grant. The central authority could form leading regulations for the duties and responsibilities of the Committee.

(2) *The Central Body.*

I. *Constitution.*—The central body would naturally be composed of representatives from the statutory central authorities already existing—namely:

(a) *The Local Government Board*, which is the central authority for Poor Law, old age pensions, public health, notification of births, unemployment, housing, and local government business generally; for the distribution of the capital grant to county councils and other authorities for sanatoriums and other institutions under the Insurance Act; for the approval of tuberculosis sanatoriums or other institutions under that Act, and for the approval of the manner of treatment of tuberculosis and other diseases otherwise than in sanatoriums, and for the distribution to local authorities of grants in aid of tuberculosis treatment.

(b) *The National Insurance Commission*, which is the central authority for the administration of the Insurance Act, and medical services under that Act other than such service as is rendered by the public health authorities.

(c) *The Scottish Education Department*, which is the central authority for the medical examination and supervision of school children, and for the administration of the grants made for the treatment of necessitous children.

(d) *The General Board of Lunacy*, which is the central authority for the medical supervision of asylums, lunacy wards in poorhouses, and boarded-out lunatics.

These four central authorities are, each in its own sphere, responsible for the official medical and nursing services already enumerated. Any additional grant made by the Treasury would normally be distributed through those central authorities for the work required of them under the various statutes. As, however, the grant contemplated would be a special grant for removing the inadequacies of medical service, it is desirable that the Treasury should also be represented on the proposed central authority. It is suggested that the Treasury representative should be chairman of the central authority, which might be designated as "The Highlands and Islands Medical Service Committee."

II. *Duties.*—The Committee would be responsible for the allocation of the grant. It would adjust the allocation to the specific requirements of the departments.

concerned. It would adjust, in consultation with the various departments, the conditions to be assigned to grants for the various purposes.

CONCLUSION.

Of the system of administrative consolidation of medical and nursing services suggested by Dr. Leslie Mackenzie, the objective would be to build up a minimum salary for medical practitioners from official sources, local or central; to make each general practitioner needed for the locality the officer of as many of the local services as was found on inquiry to be expedient; to make the minimum salary such as to attract well-trained medical men to the difficult and remote localities; to organize a service of nurses for surgical, medical, and maternity nursing; to secure, by whatever official channel was most appropriate, a service of pathological and clinical specialists; and thus, by adjustment of areas where necessary, by the development of existing statutory powers, and by arrangements for the unification of official duties, to effect a working consolidation of the present services.

THE PARLIAMENTARY COMMITTEE ON PROPRIETARY REMEDIES.

EVIDENCE REGARDING BEECHAM'S PILLS.

ON January 23rd evidence was given by Sir Joseph Beecham, of St. Helens, Lancashire, proprietor of Beecham's pills and Beecham's cough pills.

The witness informed the Committee that the business of Beecham's pills was established over sixty years ago by his father, the pills being then made in his father's shop. They were not advertised, but they had a good sale among the customers of the business. Later on his father began to advertise, and had such success that he gave up the shop and proceeded to manufacture the pills on a large scale. The business had continually increased. The witness objected that *Secret Remedies* did not distinguish between household remedies which had been sold for a number of years in great quantities, and fraudulent preparations. Beecham's pills were made from a valuable secret formula; the analysis published in *Secret Remedies* was inaccurate and omitted some active ingredients. Fifty years ago Beecham's cough pills contained some morphine. When the law was altered rendering it necessary for proprietary medicines containing poisons scheduled under the Poisons Act to be labelled "poison" and their sale to be restricted to druggists, the morphine was omitted from the ingredients. Afterwards a very small percentage of the drug was again used, but a High Court decision made it clear that as the proportion was so small the medicine need not be labelled poison.

The witness said he had refrained from publishing medical or other testimonials regarding Beecham's pills although he had received thousands. He knew of many medical men who had advised patients to take Beecham's pills as a useful aperient, and the success of the medicine had been built up entirely on public approval. The circular issued with each box advised purchasers to consult a medical man as to serious or complicated disorders of the nervous system. Other complaints were also specified as requiring the attendance of a qualified medical man. As far as possible the advertising of Beecham's pills was confined to newspapers which did not insert announcements of an objectionable character. Sometimes he made it a condition that if he advertised questionable advertisements should cease to appear in the paper. Since 1906 the sale of Beecham's pills in the United States had more than doubled. In proportion to population the sales in Australia and New Zealand were larger than anywhere else.

The witness expressed the strongest objection to compulsory publication of the formulae of proprietary medicines; this was not required by the law of either Australia or America. Publication would obviously lead to the making up of widely advertised articles by chemists, the imitation being sold to the public as "according to the formula of" the well known preparation. He understood that one of the results of the increased strictness of the law in Germany in regard to this matter was

the growth of the practice of medicine by unlicensed persons. In this connexion the witness quoted an article in the BRITISH MEDICAL JOURNAL of May 11th, 1912, which stated that unregistered practitioners in Berlin had increased from twenty-eight in 1869 to 1,013 in 1911, a much larger increase having taken place in Prussia.

The Chairman (Sir Henry Norman), after consulting the file of the BRITISH MEDICAL JOURNAL, remarked that the witness had evidently misunderstood the purport of the article in the JOURNAL with regard to the German law. The statement was made that, because of laws passed relaxing the conditions under which men were allowed to practise, there had been a great increase of medical humbugs of all kinds.

Continuing, the witness said he regarded it as an advantage to the public that a good formula should be compounded on a large scale. The public would not reap an equal advantage from the same formula made up by different chemists under widely varying conditions. As regards the present state of the law in relation to the proprietary medicine business, the witness considered vendors of medicinal preparations to be liable to a civil action for any fraudulent statements.

Replying to Dr. Lynch, the witness said he did not know whether his father was the discoverer of the therapeutic value of the drugs used in Beecham's pills; it was a case of the discovery of an excellent combination.

Mr. Lawson: He discovered the money value. (Laughter.)

In further reply to Dr. Lynch, the witness intimated that he did not care to state the annual turnover of the business, but he believed it to be the largest of its kind in the world. Over a million pills were sold every day of the week. The total weight of the pills made in 1912 was 50 tons.

Dr. Lynch: Is your turnover about £360,000 a year?—I do not think that is far out. We spend, roughly, £100,000 a year in advertising.

Mr. Lawson asked the witness whether, having regard to his establishment charges and the cost of advertising, other firms could not manufacture similar pills at a lower price at a reasonable profit. The reply was that it depended on the skill displayed in advertising the goods.

Mr. Lawson: Then you consider the reason for the price charged for your pills is the cost of the advertising necessary to inform the public of what you claim to be their merits?—Yes.

In the course of further examination on the question of cost, the witness mentioned that he took the formula published in *Secret Remedies* as the formula of Beecham's pills to three chemists in different large cities to be compounded, and the prices charged for the same quantity as were contained in the 1s. 1½d. box were 1s., 1s. 9d., and 2s. 6d. respectively.

The Committee adjourned for three weeks.

THE National Association for the Prevention of Infant Mortality and for the Welfare of Infancy has arranged to hold an English-speaking conference on infant mortality at the Caxton Hall, Westminster, on August 4th and 5th, immediately before the International Medical Congress. There will be two sections: the administrative will discuss the responsibility of central and local authorities in the matter of infant and child hygiene, and the administrative control of the milk supply. The medical section will discuss the necessity for special education in infant hygiene, medical milk problems, and antenatal hygiene. The President is Mr. John Burns, M.P., and the Chairman of the Executive Committee is Sir Thomas Barlow, President of the Royal College of Physicians of London. The Vice-Chairmen are Alderman Benjamin Broadbent, Councillor W. F. Anderson, of Glasgow, and Sir Lauder Brunton, M.D., F.R.S. The Executive Committee is composed of representatives of statutory administrative authorities, medical officers of health, members of the medical profession engaged in clinical practice, and representatives of voluntary associations. The Honorary Secretaries are Dr. A. K. Chalmers (Glasgow) and Dr. Eric Pritchard (London), and the Foreign Honorary Secretary is Miss Janet Lane-Clayton. The offices are at 4, Tavistock Square, London, W.C., and further information can be obtained on application to the secretary at that address.

"Swarth Gill," the birthplace of Dr. Haygarth.

NOVA ET VETERA.

A MEDICAL PIONEER: JOHN HAYGARTH OF CHESTER.

By JOHN ELLIOTT, M.D., F.R.C.P.,
Physician to the Chester Infirmary.

In the beautiful valley of the Clough, in the West Riding of Yorkshire, and in the parish of Garsdale, stands an old manor house—"Swarth Gill"—hard by the road leading from Sedbergh to Hawes, and some five miles distant from the former. On the porch in a stone panel are cut the initials "I. H. I." and the date "1712"—initials which are repeated on the hinges of the massively studded oaken door and on various oak panels within the house. On the other side of the road winds the river in its rocky limestone bed, fed by mountain streams, or "gills," one of which, crossed by a quaint rustic bridge, skirts the gabled end of Swarth "gill" to dive beneath the road and join its parent stream.

This was Haygarth's home, and the initials "I. H. I." are those of his parents, John and Isabella Haygarth.

Distant a short mile is Garsdale Hall, a long, low farmhouse abutting on the road, which he also owned and farmed in his later years. On the hillsides, in front of Garsdale Hall and in the neighbourhood of Swarth Gill, are the remains of the forest trees which he planted to beautify his native dale.

In the parish church the beautiful stone and marble pulpit bears the following inscription:

TO THE GLORY OF GOD
AND IN
MEMORY OF
JOHN HAYGARTH, M.D., F.R.S.;
BORN AT GARSDALE, 1740.
DIED AT BATH, 10TH JUNE, 1827.
PRESENTED BY HIS GRANDDAUGHTER, 1898.

These are the only existing memorials of one who was a prominent figure in the medical history of his time.

Educated at the famous Grammar School of Sedbergh, he proceeded to St. John's College, Cambridge, in 1759, and graduated M.B. of that university in 1766. He was one of the three first pupils of John Dawson, the Surgeon of Sedbergh, and self-taught mathematician, who relinquished his profession for the pursuit of his favourite study about the year 1788, and coached no fewer than eleven senior wranglers. Dawson, who is said to have been a kinsman of Haygarth, was born at Raygill, in the parish of Garsdale, and "Dawson's rock" on the hillside

above Raygill is still pointed out as the spot where he pursued his lonely mathematical studies.

It is noteworthy, as showing the possible influence of romantic and beautiful surroundings in the determination of character, that two other contemporary physicians of fame, Dr. John Fothergill and Dr. Anthony Askew, originated from the same neighbourhood which produced Haygarth and Dawson.

We shall hear much of Dawson in Haygarth's works, for he provided the statistical data with which the latter loved to embellish his arguments. After completing his studies at Edinburgh, London, and elsewhere, Haygarth was appointed physician to the Chester Infirmary in 1767, and the way in which he utilized the clinical material at his disposal will be best told in his own words: "Since the commencement of my profession in the year 1767 I have constantly recorded, in the patient's chamber, a full and accurate account of every important symptom, the remedies which were employed, and, when an opportunity offered, the effects which they produced. These clinical cases have always been written in Latin, as being most concise and expeditious, and as best adapted to conceal the complaints, especially female complaints, that are confidentially revealed to a physician."

Among the higher and middle ranks of society I have noted and classed the cases of 10,549 patients, from 1767 to 1801 inclusive. I have also written clinical reports of a large number of diseases among persons in the lower ranks of life, being the cases of all my in and out patients at the Chester Infirmary for thirty-one years.

His friend Dr. John Fothergill was in the habit of spending two months of his leisure time each summer at Lea Hall in Cheshire, and thither the young Chester physician constantly repaired for guidance and advice.

The physicians of Manchester, Liverpool, and Chester met four times in the year at Warrington for the discussion of medical subjects and the interchange of views; frequent reunions took place also at Frodsham, whilst the rules of the Chester Infirmary provided for a consultation of the whole staff every week on doubtful and difficult cases.

Such were his opportunities; it will soon be apparent that he was not slow to make the fullest use of them.

THE PREVENTION OF FEVERS.

In a paper read before the Royal Society in January, 1777, on the population and diseases of Chester in 1774, Haygarth gave the first hint of his plan for preventing the spread of fevers by isolation. Typhus fever and small-pox had both been epidemic in the city during that year. There had been 285 cases of fever with a mortality of 1 in 10. The proportion of deaths by the natural Small Pox to all deaths that year had been 1 to 2 and 7-10ths, and from a general survey of the City it appears that

out of a population of 14,713 inhabitants only 1,060 (that is 1 in 14) had never had the Small Pox.

Speaking of the fever he says:

If a regulation could be universally adopted of immediately removing out of the family such of the poor people as are seized with fevers, it is evident that the most salutary consequences would follow. Reasonable objections might be made to receiving such patients into the general infirmary, even into separate wards, lest the infection should spread through the whole house, which, in a former paper on this subject, was proved to be healthy to an uncommon degree when compared with other hospitals. But might not this and every other objection be obviated by erecting, on the ground which adjoins and belongs to the Infirmary, a building to be divided into spacious, airy, separate apartments, where patients affected with fever and properly recommended might be received on any day of the week?

It will be observed that the proposal, first formulated in 1774, at his original

recommended the erection of infectious wards outside the infirmary building. The reasons which induced him to establish fever wards within the infirmary itself will appear subsequently.

SMALL-POX.

Haygarth was now, however, occupied with another matter. The dreadful mortality from small-pox in Chester in 1774, when it was epidemic, and the fact that the so-called "casual small-pox" was never entirely absent from the city, concentrated his whole attention on the possibility of exterminating the pestilence.

In the year 1777 he began to study by exact observation the laws which govern variolous infection. In this year the distemper again became epidemic. Two circumstances rendered the task of fighting the infection peculiarly difficult: the first was the almost universal belief among medi-

cal men, following the teaching of Sydenham, that the cause of any infectious fever becoming epidemic was some morbid condition of the atmosphere, a widely spread influence which it was useless to combat. The other was the ignorance and superstition of the poorer classes, who, far from endeavouring in any way to avoid infection, were in the habit of deliberately exposing their children to the infection of the small-pox, so that they might have the disease and get it over. The graphic accounts given by Haygarth of the way in which patients afflicted with the small-pox, and in every stage of the eruption, were walking on the Walls, in the Rows, and in the public streets, in close association with those susceptible to the disease, sound almost incredible.

Haygarth's exact observations during the course of this epidemic, and the conclusions he drew from them, led him to propose, at first privately in 1777, and then in March, 1778, publicly, a plan for preventing the spread of infection, and the formation of "The Small-pox Society" in

Chester, at a public meeting at the Pentice on March 16th, 1778, was the practical outcome of his inquiries.

It was not, however, until 1784 that he published his *Inquiry how to Prevent the Small Pox*.

The argument on which he based his rules of prevention is summed up under nine headings. It will be sufficient briefly to summarize the principal points:

1. Small-pox never was known to be produced by any other cause than infection.
2. The incubation period is from six to fourteen days after inoculation, and not much longer in the casual small-pox.
3. Clothes, furniture, food, etc., exposed to the variolous miasms never, or very rarely, become infectious.
4. The air is rendered infectious, but to a little distance, from the variolous poison.
5. Persons liable to the small-pox are infected by

breathing the air impregnated with variolous miasms either:

- (a) Very near the patient in the distemper, from about the time that the eruption has completely appeared till the last scab has dropped off the body; or
- (b) very near the variolous poison in a recent state; or
- (c) that has been shut up ever since it was recent.

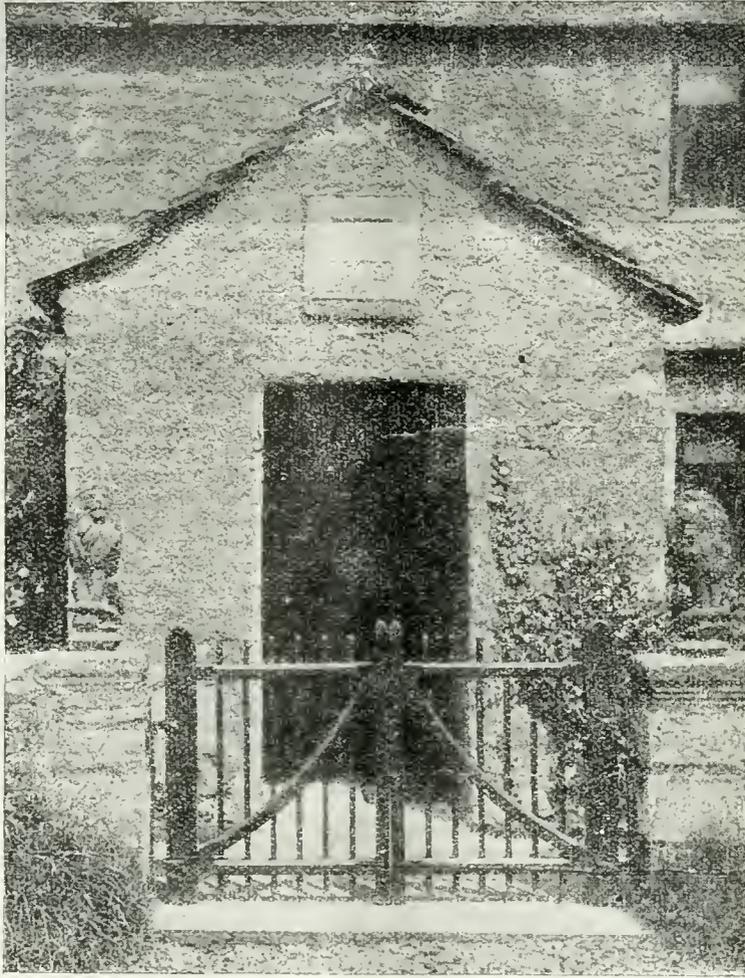

6. Consequently the small-pox may be prevented by keeping persons liable to the distemper from approaching within the infectious distance of the variolous poison till it can be destroyed.

In addition Haygarth laboured to prove that the poison is soluble in the air; a theory which was at once challenged by his medical correspondents, notably by his friend Dr. Percival of Manchester, and by Dr. Waterhouse of New Cambridge in

America. His principal argument in support of this theory was the fact that air impregnated with the poison remained transparent even when illuminated by a ray of sunlight.

It will be seen that the view put forward in the fourth heading—namely, that the air is rendered infectious *only to a short distance*, is at variance with the experience of those in touch with modern small-pox hospitals. Their conclusions, however, are open to fallacy, and, in my opinion, Haygarth produces overwhelming evidence in support of his contention. This also was challenged by Dr. Waterhouse, the physician of New Cambridge, on very strong evidence, but, after careful study of a subsequent epidemic in America, he gave his adherence to Haygarth's conclusion.

Another notable feature of the above argument is the assertion that clothes, furniture, etc., do not become infectious, the author making the important reservation "unless they have adhering to them serum, pus, or scabs

The porch at "Swarth Gill."

from an infectious patient." Here again he encountered opposition from the same source, evidence of infection through a doctor's wig being forthcoming; Haygarth, however, stuck to his guns, and routed his opponents to his own satisfaction.

Based on the results of *The Inquiry* are the *Rules of Prevention*, which must be given in their entirety:

Rules of Prevention.

1. Suffer no person, who has not had the Small-Pox, to come into the infectious house. No visitor, who has any communication with persons liable to the Distemper, should touch or sit down on anything infectious.

2. No patient, after the pocks have appeared, must be suffered to go into the street, or other frequented place.

3. The utmost attention to *cleanliness* is absolutely necessary: *during and after* the Distemper, no person, clothes, food, furniture, dog, cat, money, medicines, or any other thing that is known or suspected to be bedaubed with matter, spittle, or other infectious discharges of the patient, should go out of the house till they be washed: and till they have been sufficiently exposed to the fresh air. No foul linen, or any thing else that can retain the poison, should be folded up and put into drawers, boxes, or to be otherwise shut up from the air, but immediately thrown into water, and kept there till washed. No attendants should touch what is to go into another family, till their hands are washed. When a patient dies of the Small-Pox, particular care should be taken that nothing infectious be taken out of the house so as to do mischief.

4. The patient must not be allowed to approach any person liable to the distemper, till every scab is dropt off, till all the clothes, furniture, food, and all other things touched by the patient during the Distemper, till the floor of the sick chamber, and till his hair, face and hands, have been carefully washed. After everything has been made perfectly clean, the doors, windows, drawers, boxes, and all other places that can retain infectious air should be kept open till it be cleared out of the house.

It will be seen that the measures relied on for disinfection were washing with water and exposure to the air. No doubt this is why Haygarth clung with such tenacity to his theory of the solubility of the poison in air.

THE SMALL-POX SOCIETY.

So much for theory; the results of the inquiry were now to be put to the practical test. At a general meeting of citizens held at the Pentice on March 16th, 1778, a "society for promoting inoculation and preventing the casual Small Pox in Chester" was formed, comprising most of the leading citizens, with Thomas Falconer as chairman.

The proposal to establish the society and the subsequent annual reports were written by Haygarth, and they are models of concise reasoning and persuasive eloquence. He gave statistics to prove that all the inhabitants of the city who were susceptible to the disease were actually infected, except perhaps eight annually; that inoculation

was only fatal to 1 in 100, so that if general inoculation had been practised it would have resulted in the saving of 58 lives annually; that partial inoculation at various times and secretly would perhaps tend to spread the disease, whilst general inoculation at stated and known intervals would be productive of nothing but good. Those who feared that other diseases might be communicated by inoculation he answered by the results of experience and by quoting authorities, for example, Dr. Monro of Edinburgh, who had had a long and extensive experience.

The Small-pox Society was formed, supported by voluntary contributions. Inspectors were appointed (apothecaries or apothecaries' assistants), the medical men of the city gave their services gratuitously, rewards were given to any one who notified an outbreak of the disease, rewards also to parents for nursing their children who had been inoculated, and also to those who were

successful in preventing the spread of the disease. A general inoculation was recommended every two years, and in the intervals the *rules of prevention* were put in operation.

At the end of twelve months' work the report of the society tells us that the spread of the disease had been stopped in thirty-seven places; in thirty-two of these without infecting a second family.

In 1780, 85 children were inoculated; there were no dangerous cases and all recovered. It did not spread the disease, for in the districts where most were inoculated there were fewest cases of the casual small-pox.

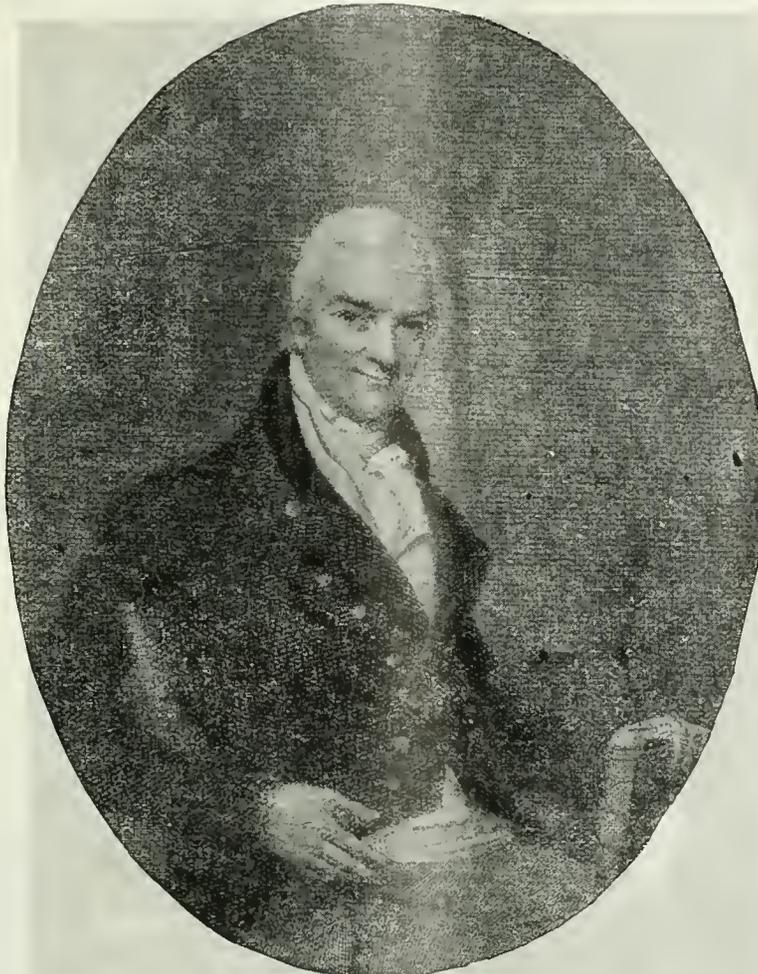

In March, 1781, there was not a single case of casual small-pox in Chester. In this spring 128 poor children were inoculated.

In September, 1782, it was reported that 416 cases had been inoculated since the

beginning of the society, with 2 deaths (1 in 208). These deaths were doubtfully due to the inoculation. There had been great difficulty in preventing the spread of infection from reckless soldiers quartered in Chester on their way from Ireland, but the deaths from casual small-pox in Chester had been diminished by nearly one-half since the society had been in operation. The results were so striking that Leeds and Liverpool followed the lead of Chester, and the Royal College of Physicians of Edinburgh appointed a committee to inquire into the matter.

The Inquiry was translated into French and German, and attracted universal attention and approbation. In 1791 Haygarth received a letter from the Syndick and Council of Health of Geneva, couched in the most complimentary terms, asking his advice and assistance in establishing a similar institution to the Small-pox Society in Geneva; to this he suitably replied.

The initial success of the Small-pox Society was so

John Haygarth.

great that Haygarth suggested privately to Dr. Fothergill a plan to exterminate the disease in 1778. This he afterwards elaborated in his *Sketch of a Plan to Exterminate the Casual Small Pox from Great Britain, and to Introduce General Inoculation*. This was published in 1793, and dedicated to the King. John Dawson, the mathematical genius of Sedbergh, provided the calculations and estimated that such a plan, if successful, would result in an increase of population in Great Britain in ten years' time of 300,000, assuming the population to be 3,000,000, and the annual deaths from small-pox 35,000.

The Plan proceeded on the lines of the Small-pox Society, applied to the whole country and reinforced by legal authority, with rewards and punishments, inspectors and directors, etc.

VACCINATION.

After the epoch-making discovery of Edward Jenner it could have no other than historic interest, and need not detain us. There can be little doubt, however, that if rigidly carried out it would certainly have been successful in stamping out the disease for a time; then, however, would have arisen a difficulty foreseen by Haygarth himself. The public would have grown chary of submitting themselves to inoculation, and a dreadful epidemic might have arisen. He consoled himself with the reflection, however, that on the first signs of the outbreak they would have flocked to the inoculator.

In a later edition of *The Inquiry* Haygarth wrote as follows of Jenner's discovery:

The discovery of Vaccine Inoculation by Dr. Jenner is the most fortunate and beneficial improvement that medical Science ever accomplished. It does not, however, preclude the necessity of investigating the variolous poison, and of considering by what regulations its propagation may be prevented. In order to secure the unthinking multitude from this destructive Pestilence, measures to prevent the Casual Small Pox should everywhere accompany Vaccine Inoculation.

So much for Haygarth's energies and activities in connexion with the prevention of small-pox.

THE MANAGEMENT OF FEBRILE CONTAGION IN GENERAL.

No sooner had the Small-pox Society of Chester been launched on its triumphant career of usefulness than his fertile brain was busy on another matter which was to bring him undying fame.

In 1780 and 1781 he turned his attention to the laws which govern febrile contagion in general. He had ascertained that the pernicious effects of the variolous poison were limited to a short distance from the patient.

I soon also discovered that the Contagion of Fevers was confined to a much narrower sphere. Upon these principles . . . I discerned the safety and wisdom of admitting Fever

patients into separate wards of the Chester Infirmary itself, instead of an adjoining building, as I had proposed in 1774. . . .

In the year 1783, on looking out for proper accommodation, I found the attic story on the north side of the building unoccupied, and merely a lumber-room. It is 96 ft. long, 21 ft. broad, and being net ceiled, it is open to the roof, which is 16 ft. high. This chamber is divided by a partition in the middle, thus forming two wards of 48 ft. in length. Through them is admitted a very free circulation of air, by nine windows, which are placed on all sides of the wards, and by others in the adjoining passages; by a door in the partition between the wards, and by a large aperture in the upper part of the partition. Several of these windows are constantly open during the day, nor are they all closed at night, if the patients be numerous, and the weather moderate. Adjoining to the west end of these wards is a room for the nurse, into which a fever patient is sometimes admitted. At the east end of the wards a wash house is conveniently situated, so that no foul clothes need be brought among the other patients. On the same side and floor there is placed a separate necessity, which prevents of personal intercourse with the rest of the hospital.

At the commencement of this institution, at Chester, apprehensions of the danger of infection were so prevalent that no nurse could be persuaded to attend the Fever wards. In these difficulties a surgical patient was prevailed on to undertake this office in the men's ward. He caught the Fever and died of it. When a proper nurse was procured she (Lowry Thomas) had the care of both wards for eleven years with only occasional assistance. During this period she was infected by the fever several times, and died of it in July, 1794, on the fifth attack, after a week's illness. The nurse who succeeded has twice caught the Fever, and was each time very ill of it, but otherwise has enjoyed good health for four years. A night nurse . . . caught the Fever. And other occasional nurses may probably have suffered infection, but, as far as has come to my knowledge, these four are the only instances of infection communicated in the Fever Wards at Chester during a period of fourteen years and a half—from August, 1783, till March, 1798. Both these nurses (Lowry Thomas and Jane Bird) were susceptible of Fever. They

The memorial pulpit to Dr. Haygarth, Garsdale Church.

both exposed themselves to infection without reserve, even more than was necessary and useful, especially the former. In spite of cautions and exhortations to the contrary, which I have often given her, she used to approach those who were very weak and ill, so close that she must have inspired the infectious breath of a Fever patient with very little dilution of other air, in thousands of instances, without receiving infection. . . . No medical or other visitors were ever suspected to have caught infection in these wards, though they have touched the patients in innumerable instances. Yet the Apothecary (Mr. Manning) was susceptible of infection. He caught a very dangerous putrid Fever by visiting a poor sick family (which I also visited) as out-patients in a close, dirty room. Unreasonable prejudices prevented these poor people when attacked by the Fever from accepting the benefit which the Infirmary offered to their choice of being admitted into the house.

This account of the first institution of fever wards in a hospital is taken from Haygarth's work, *A Letter to Dr. Percival on the Prevention of Infectious Fevers* (1801), which has been justly described as a model scientific

treatise. To the general medical reader it cannot fail to be of the greatest interest, whilst to those resident in Chester and the district it is a fascinating study. In his classical researches on the "latent period" (or incubation period) of fevers, he tabulates by name the cases in the order in which they were attacked; many of these names are familiar Cheshire surnames to-day. As an instance, may be quoted the first series of cases of typhus investigated, which occurred among the family and dependants of Mr. Cheers, a farmer of Barrow, who went a journey to Manchester on April 21st, 1781, where he contracted typhus, which spread through his household, only three out of twenty escaping. The descendant of Mr. Cheers is still farming at Barrow.

The success of the experiment at the Chester Infirmary was immediate. "During the first year," says the annual report, "30 cases of Fever were admitted, many of them in the most imminent danger; yet they all, except one, recovered." Dr. Currie, a colleague of Haygarth, writing in 1802, says:

I constantly attended the Infirmary for sixteen years, and there never was at any one time reason to suspect that contagion had been communicated from the Fever wards to the other patients in the house.

The provision for isolation effectually stopped the spread of an epidemic of typhus, which caused considerable alarm in the city in 1784, and carried off some of the principal inhabitants.

Chester was visited by John Howard, the philanthropist, on his tour of inspection of gaols and hospitals in the

"Garsdale Hall," a farm owned by Dr. Haygarth.

in quality to that sold in the city. Debtors and felons are permitted to beg some hours in the day. That prisoners are not supplied with necessary food is a disgrace to such an opulent city. No proper separation of men and women either here, or in the county gaol. Gaoler's salary £50 in lieu of the tap.

1787, Dec. 21 : Debtors 6. Criminals 1. Convicts 6.
1788, March 2 : Debtors 8. Felons &c. 7. Women Convicts, 2.

City Bridewell.—Chester City Bridewell. A small alteration made by dividing a room or two. No employment; no allowance. Court not secure. Keeper has a spacious garden; his salary only £4. He sells beer.

1787, Dec. 21 : Prisoners 3.
1788, March 2 : Prisoners 2.

CHESTER GENERAL INFIRMARY.

Infirmary.—The wards are spacious and clean, and the beds not crowded. The two fever wards were not in the least offensive; they were fitted up on the upper floor, on account of a contagious fever in Chester in 1784, and very properly were not ceiled, but plastered to the tiles.

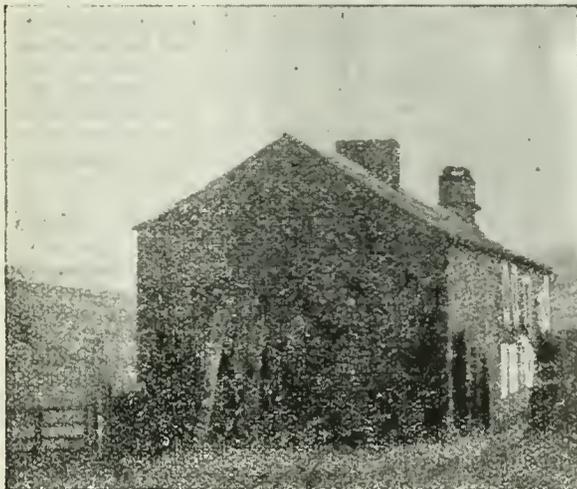

By the attention of the ingenious Dr. Haygarth, and his colleague, most of the patients then recovered. The good rules for these wards I here copy.

Rules for the Fever Wards; to Prevent the Infection of Other Patients in the Chester Infirmary.

Chester Infirmary Rules.—I. Fresh water and coals are to be brought up to the fever wards every morning; and other necessities on ringing a bell.

II. No fever patients, nor their nurses are suffered to go into other parts of the house. No other patient is allowed to visit the fever wards; nor any stranger, unless accompanied by the apothecary or his assistant.

III. Every patient, on admission, is to change his infectious for clean linen; the face and hands are to be washed clean with warm water, and the lower extremities fomented.

"Raygill," the birthplace of John Dawson.

United Kingdom. He was so impressed with the "good rules" for the fever wards that he reproduced them. His observation on both the gaols and infirmary are here quoted verbatim as an instructive object lesson that the extremes of ignorance and enlightenment can exist side by side in the same city:

CHESTER CITY AND COUNTY GAOL.

Chester City Gaol.—No alteration. Prison net secure. The convicts, and prisoner for trial, were severely ironed, by the neck, hands, waist, feet, and chained to the floor; and at night to their beds in the horrid dungeon. Here was the first iron glove I have seen in England, which, though not yet used, shews the severity of the gaoler's disposition. Allowance, a pennyworth of bread to felons, and a pound to debtors; inferior

The old ward in the Chester Infirmary, which was used by Dr. Haygarth for the isolation of fever patients in 1785.

IV. All putrid discharges from the patients are to be taken out of the ward as soon as possible.

V. The floors of the wards are to be washed very clean twice a week, and near the beds every day.

VI. All foul linen is to be immediately thrown into cold water; and carefully washed twice out of clean water, in the adjoining room.

VII. Blankets, and other bed and body clothes are to be exposed to the open fresh air for some hours, before they are used by another patient.

* Such upper rooms in most hospitals and workhouses, having joists laid across, and being ceiled at the square, are generally bad apartments; so also the upper rooms in many houses are by this practice made close, unhealthy places, which, had they been ceiled pretty near the ridge and had the sides coved, would have been more pleasing to the eye and fresher to the inhabitants.

VIII. All the bed clothes of the fever wards are to be marked "FEVER WARD," and all the knives, forks, pots, cups, and other utensils are to be of a peculiar colour, lest they be inadvertently taken among other patients.

IX. All the windows of the fever wards are to be kept constantly open in the day, except the weather be very cold or wet; and some of them should not be shut in the night, if the patients be numerous, and the weather moderate.

X. No relation or other acquaintance can be suffered to take away any linen unwashed, nor other clothes till they have been long exposed to the fresh air.

Writing on the subject of education John Howard remarks:

But no plan that I have seen for the extended instruction of the poor seems more judiciously calculated for the purpose than one lately instituted by the trustees of the Blue Coat Hospital, in the City of Chester, where, to an ancient establishment of an hospital for poor children, a charity for the education of a large number of out-scholars has been annexed, and has been productive of the happiest effects. I will, therefore, here transcribe the following particular account of it.

PLAGUE.

In the second edition of his work in 1791 John Howard prints two letters from Dr. Haygarth on the establishment of lazarettos for the plague; Hilbre Island is here recommended as a suitable site for a lazaretto for the protection of the Port of Liverpool in connexion with the Turkey trade. Of these letters it is sufficient to say that in scientific acumen they are far in advance of their day, and his plans for shortening the absurdly long period of quarantine then in vogue remind one strangely of the regulations now in force in the ports of Great Britain.

THE MANCHESTER HOUSE OF RECOVERY.

As a consequence of the success of the Chester Fever Wards, Manchester, in 1796, opened a "House of Recovery" on similar lines. The beneficial effects of this were at once apparent. The number of fever cases fell from 267 in the preceding year to 25 in the following one. "The bills of mortality for 1796 show a decrease in the burials amounting nearly to 400." "In 1797 the expense of pauper coffins was diminished to one third." As at Chester, the fever patients were conveyed to the House of Recovery "in a sedan chair to be employed solely for this purpose, with a moveable lining, which should be made of linen, and always exposed to the air after it had been used, and frequently washed." "Fever wards were established in 1797 at Liverpool, in imitation of ours at Chester,

but groundless fears soon excluded them from the Infirmary."

GENERAL HOSPITALS.

In 1801 Dr. Haygarth was informed that Gay's Hospital was about to follow the example of Chester, and reserve two wards for fever cases. When I entered St. Bartholomew's Hospital as a student in 1881 there were similar fever wards (the Radcliff wards), which no doubt owed their inception to the same example.

INCUBATION PERIOD OF FEVERS.

Much might be written on the subject of Haygarth's researches on the incubation period of fevers, of which he

was the pioneer; on his hint that possibly the "putrid fevers" might embrace some varieties different from true typhus, based on the variability and long duration of their incubation periods; on his advice as to the prevention of fevers in barracks, in army encampments, and in the navy, tendered to the Government, who afterwards sent down to Chester Castle instructions strictly enforcing his own Rules of Prevention, apparently oblivious of the trifling fact that he himself was the author of them; on his determination of the incubation period of scarlet fever; and his significant instructions that influenza was subject to the same rules of prevention as other infectious fevers.

ISOLATION WARDS IN PUBLIC SCHOOLS.

He was the first to recommend isolation wards in public schools, which he did in the following words:

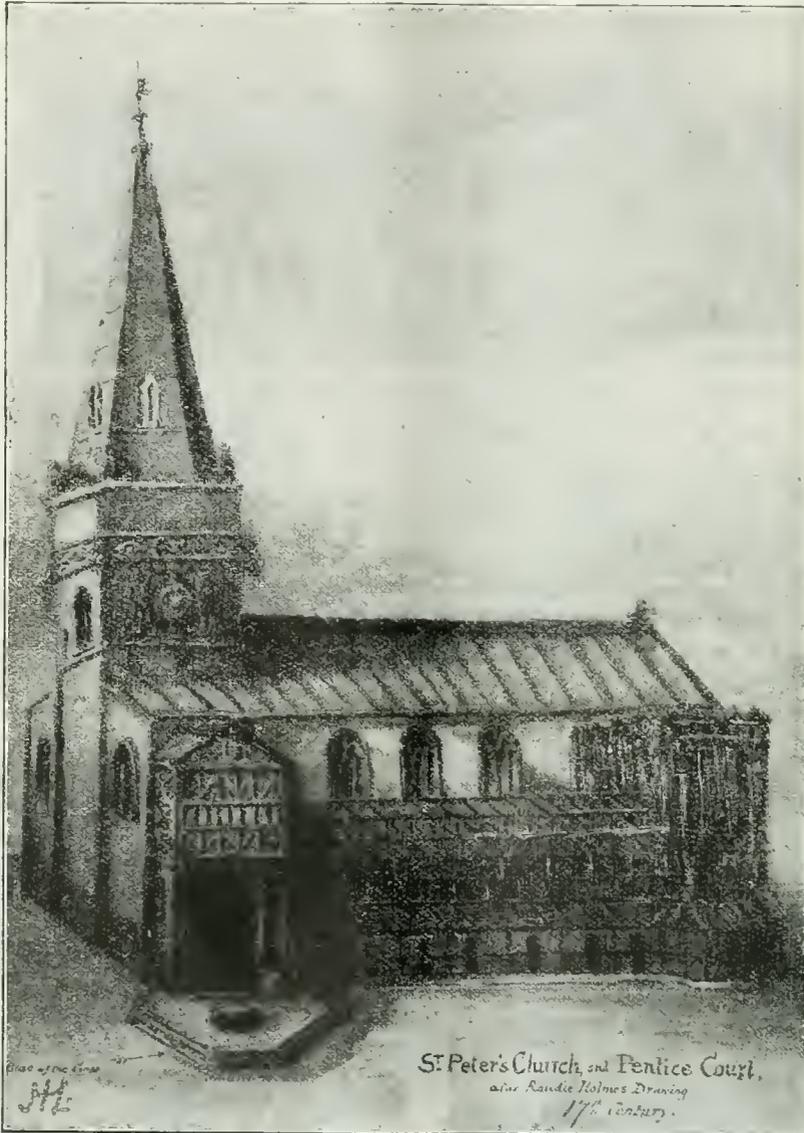

In every boarding school a large airy room ought to be

appropriated to the reception of scholars ill of infectious Distempers. Where the patients are numerous, or where there are several patients in different boarding houses near each other, it would be more commodious, though by no means indispensably necessary, to provide lodgings for them in a separate house.

YELLOW FEVER.

Published along with the *Letter to Dr. Percival* is an *Address to the College of Physicians at Philadelphia on the Prevention of the American Pestilence*, "because I have the fullest confidence that the measures which it recommends, from my own experience at Chester, would effectually suppress the American pestilence" (the yellow fever).

It is noteworthy, in this connexion, that an American contemporary physician (Dr. Caldwell) ascribes the disease

The Ancient Pentice Court at the High Cross, Chester.

to a peculiar constitution of the atmosphere, "as proved by the multitude of grasshoppers, flies, and muskitos."

EPIDEMIC HYSTERIA.

Haygarth was now at the zenith of his fame. He enjoyed the friendship of, and corresponded with, the principal physicians of the day. He was consulted on all obscure and difficult medical questions, for example, an epidemic of convulsions which occurred in Anglesey in September, 1796, and threatened to assume extensive proportions; he at once diagnosed it as hysterical in nature, to be cured by isolation of the sufferers. The affection appeared only among women, and those only who had witnessed the manifestations in others. He quotes a similar epidemic which occurred in Angus some thirty years before, and makes the interesting observation that convulsive affections were excluded from the female wards of the Chester Infirmary.

LIFE IN CHESTER.

He resided during the earlier years of his practice in Watergate Street, but subsequently built for himself and occupied the house in Foregate Street, now in the occupation of Messrs. Churton and Elphick. He had an extensive garden, which, together with the house, he sold on his retirement from Chester to "Madame" Bold. The garden was built upon and occupied the area now known as Bold Square, and named after the lady who acquired the property.

"METALLIC TRACTORS."

In 1798 he removed to Bath, where he practised his profession at No. 17. The Circus, and renewed his friendship with Dr. Wm. Falconer, F.R.S., a former colleague at the Chester Infirmary. About this time Perkins's metallic tractors had acquired a wonderful reputation in the cure of rheumatic affections on account of the animal magnetism which they were reported to exert. It occurred to Haygarth that a lifelike imitation of the tractors, executed in wood, might work similar miracles on the unsuspecting patient, and in conjunction with Dr. Falconer the experiment was tried on some patients of the latter in the Bath General Hospital, with all due solemnity, in the presence of several members of the hospital staff. Five cases were selected for the experiment, being well marked cases of affections of the joints—ankle, knee, hip, and wrist (January 7th, 1799). The result was a complete success, and the patients experienced great relief. Next day the real Perkins's tractors were used, with the same result. These experiments were repeated by Mr. Richard Smith at the Bristol Infirmary; tenpenny nails coloured with sealing wax, bits of tobacco pipe, etc., artfully disguised, were used on various occasions with the most gratifying success. So great a reputation did he acquire that the number of candidates for the tenpenny nail treatment reached quite embarrassing proportions. The reader will find a full account of the matter in Haygarth's work, *Of the Imagination as a Cause and as a Cure of Disorders of the Body*, etc. (1800).

ESSAYS WRITTEN AT BATH.

Having no hospital appointment now, he set to work to analyse the clinical records which he had industriously accumulated; and in 1805 he published (1) *A Clinical History of the Acute Rheumatism*, (2) *A Clinical History of the Nodosity of the Joints*.

The treatise on rheumatic fever was written to show the efficacy of the Peruvian bark in the treatment of that disease, of which 170 cases are analysed and tabulated. On one of Haygarth's early visits to Dr. John Fothergill at Lea Hall, the latter had advised the use of this drug in preference to blood-letting, purging, and the other methods of treatment then in vogue. It appears that there was a prejudice against using the bark in cases of high fever. Haygarth made an extended trial of the drug, and proved its efficacy. His method of procedure was to "cleanse the stomach and bowels with antimonials," and then administer the bark in increasing doses. The treatise, with its careful clinical records, well merits extended study. As usual, it attracted much notice in the medical world, and led to voluminous correspondence with leading physicians. Haygarth's conclusions will meet with the approbation of the physician of the present day, who is in the habit of using quinine in cases which prove refrac-

tory to the salicylates. Haygarth contended that it prevented the chronic rheumatism, which is so painful a sequela of the acute disease.

"Nodosity of the joints" was a name which he proposed to substitute for "rheumatic gout." His treatise on this affection is remarkable for a clear conception of the difference between the various forms of rheumatism and gout. He had read a paper on this affection in 1779 at one of the medical meetings at Warrington.

In 1810 he published his *Synopsis Pharmacopœiæ Londinensis*.

FREE SCHOOLS.

He had always been interested in the state of the free schools in the north of England, and this formed the subject matter of his *Letter to Bishop Porteus*, 1812. It is said that he exerted himself strongly to influence members of Parliament in this question.

SAVINGS BANKS.

In the year 1813 the city of Bath adopted his plan of self-supporting savings banks, concerning which he published his *Explanation of the Principles and Proceedings of the Provident Institution at Bath for Savings* (1816).

THE CLIMATE OF CHESTER.

Dr. Haygarth's account of the climate of Chester, although the subject of one of his earliest publications (*Phil. Trans.*, vol. lxxviii, for the year 1778), has been reserved for later notice. There seems to be nowadays a widespread belief that in some unexplained way the climate is unfavourable, and a surprising amount of sympathy is constantly being showered upon the inhabitants of that devoted city on account of their supposed disadvantages of climate—sympathy which, however, is entirely thrown away upon them, for they are very far from participating in this literary emotion. It would be easy to show from published records that in respect of rainfall, mean temperature, absence of fog and east wind, etc., Chester has a favourable record, but this information is accessible to all. Moreover, it is a well-known fact that children and old people thrive in Chester, and that the latter live to a great age in that city, whilst the climate is a mild and equable one in the winter. What does Haygarth say?

After an exhaustive study of the death-rate in all the principal towns both in Great Britain and on the Continent in his day, and also in rural districts, he concludes:

That the centre is the most healthy part of the city; that a less proportion die annually here than in most country villages; and, as far as observations have hitherto been made, that it is probably as healthy a spot as any on earth are surprising facts; of these facts are clearly evinced by the united evidence of six separate districts taken on a medium of ten years.

Again, having shown that the death-rate in women is comparatively low in Chester, he says:

It will not be improper to observe that the women, especially in the higher and middle ranks of society, are remarkably beautiful. These facts clearly prove that the manners and situation of Chester are peculiarly favourable to the female constitution.

Again:

The average of deaths within the Walls is 1 in 58. This is much superior to what is recorded in the country, and no other large Town approaches it in longevity nearer than in the proportion of 28 to 40.

During his later years Dr. Haygarth paid frequent visits to his native dale, where he owned several farms, and for the inhabitants of which he entertained the warmest affection. His long and useful life, spent in honour, came to a close on Sunday, June 10th, 1827, at Lambridge House, near Bath, at the ripe age of 87.

The name of Haygarth is venerated in Chester, the city of his adoption, the cradle of his fame. The ancient Pentice Court has gone, removed in 1803 as an obstruction to the all too narrow thoroughfares. The fever wards in the Chester Infirmary, still persisting, will be renovated under the reconstruction scheme now in progress. It has been proposed, and the suggestion has met with approval, that the landing comprising these two wards shall be called the Haygarth Block, and the wards named after the two heroic nurses (Lowry Thomas and Jane Bird), who gave their lives for the relief of suffering humanity.

There can be no doubt that the services of one who did

so much for the city will never be forgotten in Chester, but the writer of this essay is of opinion that they have not received adequate recognition from medical writers of to-day. It would be difficult for one, around whose judgement has been cast the glamour of local interest, and perhaps, also to some extent, the bias of hero worship, to form a strictly impartial estimate of them. He will therefore content himself with simply recording the facts as above, and leave them to the judgement of his professional brethren, and venture to recommend to their perusal the works of Dr. Haygarth, and especially his *Letter to Dr. Percival on the Infectious Fevers*.

MEDICAL BENEFIT UNDER THE GERMAN SICKNESS LEGISLATION.¹

THE long-promised Report on the Medical Benefit under the German Sickness Insurance Legislation has been issued. It is based on inquiries made for the Government in the course of a number of visits to towns in various parts of Germany, where typical methods of organizing the insurance medical service are in operation.

In the Prefatory Note it is shown that the German Sickness Insurance system is organized on a local basis by trades, occupations or undertakings, that the rates of contribution are not uniform, and that additional benefits beyond the minimum required by law are freely given. Great variety thus results: thus at one extreme we get the "parochial" organizations, composed mainly of poorly-paid workers, receiving the minimum benefits, while at the other extreme are the factory or works organizations, in which the higher grades of labour are represented, and which give various additional medical benefits. Between these two extremes are so many varieties that it is impossible satisfactorily to compare the German Insurance Medical Service with anything that exists under the more uniform British system.

As regards the cost of medical treatment, the Report points out that in the German official returns cost is calculated by reference to the number of persons insured, though treatment is in many cases extended to dependants. In other words, the cost per head of persons entitled to treatment is not given. In order to ascertain as far as possible what this cost amounts to, it will be seen below that two groups of societies are taken: (1) Those which give medical treatment to members only and (2) those which also give treatment to dependants of members. In each of these groups, again, a great variety is found, depending largely on the social status of the members and the amount of their contributions. It is also noted that the German law may include services which are not included in the British Insurance Act, such as treatment by specialists and dental treatment, and many societies incur considerable expenditure on providing baths, milk, medico-mechanical, and other forms of treatment.

As regards the cost of drugs, it is almost impossible to make a comparison with the English system. The cost of drugs is enhanced by the fact that the chemists' trade is a monopoly, the number of pharmacists licensed to dispense being strictly limited in every district, so that there are always large numbers of fully qualified chemists who can only go as assistants to the licensed pharmacists. Dispensing by doctors is stated to be almost unknown in Germany. It is also to be noted that in many societies drugs are supplied to dependants. In Leipzig, for instance, where the costs of drugs is put down at 3s. 6½d., as a matter of fact 1s. 4½d. or 39 per cent. is incurred on behalf of dependants of the insured. The cost of various expensive appliances, dental treatment, milk, baths, etc., is also included. On the other hand, medical attendance is only given in most cases for twenty-six weeks, whereas in Great Britain it is to be given during the whole period of disablement: it has not been found possible to estimate the additional cost which this will entail.

In 1910 the aggregate number of persons coming under the Sickness Insurance was 13,955,000, and the clubs or "funds" (Kassen) numbered about 23,000. Ordinary wage-earners are compulsorily insured, irrespective of the amount of their earnings, but certain other classes,

including works officials, foremen, technical officials, and persons in a similar position only come under the law if their remuneration does not exceed £100 a year. This was increased to £125 by the law of 1911, which, however, will not come into full operation till the beginning of 1914. Eight types of insurance "funds" are recognized by the law, the societies being organized by separate trades or undertakings, except that in the larger towns there are "federations" for groups of trades, mutual aid associations, and organizations formed by the parochial authorities for persons not entitled to join the trade societies. The result is that the various organizations present a wide variety of social conditions, some composed of workpeople with relatively high wages and others representing the lower grades of labour. All the funds are autonomous, subject to some supervision by the commune or the State. Each is limited to the district for which it was formed, and is governed by an executive council elected by the insured and the employers in the proportion in which they bear the cost of the contributions—namely, two-thirds insured and one-third employers. The law of 1911 so extends compulsory insurance to fresh classes of wage earners that it is estimated that when it is in full operation it will include 19,000,000 persons.

SCOPE OF MEDICAL BENEFIT.

The law does not define what is to be understood by medical treatment, and the widest latitude is allowed to the funds. The doctors claim, and the funds tacitly agree, that medical treatment may comprise everything necessary for restoration to health, irrespective of the cost; the doctor in attendance has alone the right to decide what this treatment shall be. All operations necessary to restore the patient to health are included, but not operations to remove defects or blemishes which do not affect working capacity. At the same time, the surgical work of the insurance doctors is not great owing to the large extent to which the public hospitals are used. Contracting out, that is, a cash payment instead of medical treatment, is allowed only in the case of members who have ceased to be employed, and have become voluntary contributors and reside outside the district served by their fund. The minimum benefits which all funds must provide are (a) medical treatment for twenty-six weeks, (b) medicines, spectacles, trusses, and similar appliances during such sickness, or (c) hospital treatment in lieu of (a) and (b). The "parochial" funds are not permitted to exceed these minimum benefits, but many of the higher grade societies provide, for an extra contribution, some or all the following additional benefits:

1. Treatment with medicine and appliances may be prolonged for not over fifty-two weeks.
2. A wider range of appliances.
3. Treatment during convalescence for not more than a year.
4. Attendance by midwife and doctor in ailments of pregnancy.
5. Free medical treatment with or without medicines and appliances for families and dependants.

Extensive use is made of specialists, with whom the societies often have special agreements. Thus, of the 341 doctors engaged by one of the large Berlin funds, 159 are general practitioners and 155 specialists for eye, ear, nerve, skin, throat and lung, stomach and urogenital diseases, surgery, and diseases of women; homoeopathic practitioners also are employed. In Berlin the general practitioners confine themselves as far as possible to consultations, and refer patients to surgeons on the list for even small operations. Treatment often comprises x-ray applications, electrical treatment, baths, and all kinds of medico-mechanical treatment. Dental treatment is generally included, and some funds contribute towards the cost of artificial teeth, or even have fully equipped dental clinics of their own. The insurance doctors are, as a rule, allowed a free hand in prescribing, but some funds prohibit drugs whose therapeutic value is not sufficiently proved, and certain expensive drugs. The prescriptions may be made up by any qualified pharmacists, except where the fund has a special agreement with particular pharmacists. The prices are as scheduled in an official scale, as provided by the law, with a payment for dispensing and vessels, but subject in general to from 10 to 20 per cent. discount. The appliances that must be supplied are spectacles, trusses, and "similar"

¹ Parliamentary Paper Cd. 6281. Price 1½d. Eyre and Spottiswoode.

appliances, and "it has been held that the test of 'similarity' may be a test either of purpose or of expense." Some of the larger funds provide more expensive appliances, such as artificial limbs, appliances for splay foot, corsets, and other supports up to a maximum cost per member of £2 10s. in Berlin or £3 15s. in Leipzig.

Hospital treatment is very largely given, and forms an important part of the cost of medical benefit. The provision of hospitals is in Germany a duty of the local government authorities, and the public hospitals are used for the great majority of patients so treated. But a certain proportion are also sent to institutions managed by ecclesiastical bodies, or to State, university, or private clinics. "Maintenance fees," which vary from 2s. to 3s. a day, are paid in respect of patients in hospitals. In the public hospitals there is no extra charge for operations, but in private clinics extra payment is required not only for operations, but for the more expensive dressings and appliances. In addition to the sanatoriums and convalescent homes provided under the German Invalidity Insurance, many of the sickness insurance societies have sanatoriums and homes of their own paid for out of the receipts for sickness insurance.

Families and Dependants.

Insurance of families and dependants of the insured is an optional benefit and is paid for in various ways—for example:

- (a) The members pay for it separately and the accounts are kept separate.
- (b) The married members simply pay a higher contribution, but no separate accounts are kept.
- (c) Family benefits are given to the married members, though there is a uniform contribution for married and single alike, and no separate accounts are kept.

In some cases only treatment is given, but without medicines or appliances for dependants. In most cases the doctors receive an inclusive fee for members and families. No record, official or otherwise, exists as to the extent to which family insurance is provided, and the fact that the cost is often defrayed out of the common fund explains why in the annual Government returns no attempt is made to assign to members and dependants their respective shares of the amount under the composite heading "medical treatment." In Leipzig, Stuttgart, and Dresden family insurance is common, but it is rare in Berlin. Moreover, there is wide divergence in the meaning attached to the word "dependants." In some cases it only means wife or husband and children below 14 years of age, but in others it includes relatives in charge of the household, parents, or parents-in-law, and often any relatives by blood or marriage wholly or mainly dependent on the insured member. Thus the capitation fee paid to a doctor who has to attend both member and dependants for that fee is no criterion of the actual payment per person on his list.

Methods of Remuneration.

The sickness funds have a free hand as to the method of remunerating their doctors, though in the absence of a formal agreement payment is by attendance according to the minimum fees of an official scale, and where the doctors are well organized, as in Leipzig, they have insisted on this scale being adopted, making perhaps some modifications in its details; they cannot, however, increase the minimum fees therein specified, but in very few towns is any uniform system adopted. The methods of remuneration may be grouped as follows:

1. *Payment by Attendance.*—Here as a rule a capitation payment per insured person is put into a pool, out of which the doctors are paid for each attendance actually given. The fees are the minimum of the official scale, though in some cases there is a reduction in the case of often recurring services or a general agreed reduction varying between 5 and 20 per cent. on all official minimum fees alike. Under this system the pool is generally limited in advance, but in some cases it is unlimited, and here it is almost invariably found that the total cost is higher; for example, in Munich, in funds where the pool is limited, the cost is about 6s. a member, which covers all services; where the pool is fixed except for extra fees for special services the total is from 5s. 9d. to 7s. 6d., and where there is payment per attendance on the official minimum scale without a fixed pool the cost is from 8s. to 10s. In one large factory fund when the pool was limited in

advance the cost was 9s. 4d. per member, which included treatment of dependants, but when the pool was unlimited the cost was 15s. 10d.

2. *Capitation Payment.*—Here there is a fixed yearly fee per head for all persons on the doctors' lists, choice of doctor being allowed yearly, but different capitation fees are paid to general practitioners and specialists. In a large number of cases general practitioners get 4s. a year, while specialists have from 6s. to 10s. for the treatment during twenty-six weeks, if necessary, of each case referred to them by a general practitioner, the lower fee being paid to eye specialists and the higher fees to specialists for ear, nose, throat, skin, and sexual diseases; surgeon-dentists receive 5s. a case. In some cases, in addition to the 4s. capitation fee to general practitioners, there are extra fees—15s. for confinements, 4s. night visits, 2s. night consultations, and fees for assistance to other doctors.

3. *Capitation Payment into a Pooled Fund, with or without Extra Fees for Special Services.*—This is probably the most common method adopted, the fees for special services being first deducted and the balance being then divided among the doctors according to services rendered. In some cases, however, the pool is all divided among the doctors, and certain specified services are paid for outside the pool. Thus, in the Munich Federation, there is a pooled capitation fee of 4s. 3d., which is divided among the doctors according to services rendered, but extra payments are also made for certain services. In the Essen Federation the capitation sum pooled is 3s. 6d., but there is an arrangement by which the doctors are guaranteed 90 per cent. of the value of their individual services charged for on the basis of 1s. for a consultation and 1s. 6d. for a visit. In Düsseldorf there is a capitation pool from which payment by attendance is made, and the amount of the capitation is based every year on the average value of the services performed during the three preceding years, charged on an agreed scale of fees. In this way the capitation sum paid to the pool has ranged from 6s. to 6s. 6d. per member.

4. *Payment per Case of Sickness Attended.*—This is an uncommon method, but the Frankfort Federation pays its doctors for members resident in rural districts 5s. a case of sickness, subject to the condition that for this fee a patient must be attended for twenty-six weeks, if necessary, and that three cases of sickness at the most may be charged for any one member in one year.

5. *Fixed Salaries with Private Practice Allowed.*—This is also an exceptional method, though it is adopted by two of the largest federations. The Dresden Federation divides its area into 160 districts of unequal extent, and a doctor is assigned to each. The salaries range from £30 to £250, and the only extra payments are 3s. for night visits, and mileage in the rural districts. The total cost of medical attendance, including attendance on dependants, was only 6s. 4½d. a year per member, but the cost of hospital and other institutional treatment, partially given to dependants, was 5s. 3½d., while for medicines and appliances, supplied only to members, it was 4s. 5d. A variation on this method is a minimum retaining salary with an addition dependent on the amount of service actually rendered.

6. *Whole-time Service.*—This has been tried at times, but only experimentally, the longest experiment being for seven years at Reuscheid, where six doctors were appointed to attend 10,000 members and their families at salaries of £300 to £350, except an eye and ear specialist, who received £350, rising to £400. Each doctor had an assigned district, but in case of excessive work could refer patients to a colleague. The cost of medical attendance ranged from 5s. 9d. to 7s. 3d. per member, though dependants also had to be attended.

7. *Medical Benefit Associations.*—In Berlin, Munich, and Cologne groups of societies have established associations for providing medical attendance, the association administering all the statutory medical benefits on behalf of the affiliated societies. The Berlin association has 191,000 members and divides the city and suburbs into districts, appointing one doctor at least to each district at a fixed salary; there are now 160 general practitioners and forty specialists engaged. Members may consult any doctor on the list, but for visits must call in one who is near at hand. The affiliated societies pay 3s. 9d. a member to the association, and the doctors' salaries average £150, but

they are free to attend other members of unaffiliated societies. At Munich a similar association pays the doctors according to services rendered from a fixed pool, consultations being reckoned at 9d. and visits at 2s., with fees for operations according to scale.

Probably most of the chief sickness funds have tried various methods of remuneration, and the medical arrangements are still in a state of flux. In the new Insurance Law of 1911 the Government deliberately refused to bind the funds to any particular mode of engaging the doctors or to any special rate or basis of remuneration, contending that these matters are better left for free negotiation.

Cost of Medical Benefit.

The wide latitude allowed to the sickness funds in regard to the contributions that may be levied upon workpeople and employers would seem to have encouraged a liberal expenditure on medical benefit, and there has been a steady increase in the percentage levy on wages. Taking all the sickness funds together, in 1888 the yearly expenditure per member for medical treatment, including general practitioners, specialists and extras, and also including treatment of dependants in many cases, was only 2s. 3d., and some of the largest funds were actually able to obtain medical treatment for 1s. a member. From this very low beginning there has been a steady rise until in 1910 the expenditure was 5s. 10l. per member. In the same period medicine and appliances, including cost for dependants, rose from 1s. 10d. to 3s. 8d., while hospital treatment rose from 1s. 6d. in 1892 to 3s. 5½d. in 1910, but it should be noted that the hospital treatment here mentioned does not include the sanatorium and institutional treatment given under the invalidity insurance, which in 1910 amounted to 1s. 4½d. per member. Taking the two extreme grades of societies, in the parochial funds which only supply minimum benefits and for members only, the cost in 1910 was 4s. 2.2d. a head for attendance, 2s. 2.4d. for medicines and appliances, and 3s. 1.8d. for hospital treatment, a total of about 9s. 6½d. a member. In the factory funds, which have higher contributions and supply additional medical benefits, often for dependants as well as for members, the cost was 7s. 10.6d. for attendance, 4s. 9.7d. for medicines and appliances, and 3s. 6d. for hospital treatment, a total of 16s. 2d.; but, as already explained, these figures for the factory funds throw no light on the remuneration of the doctors per person on their lists, as the societies, as a rule, do not know the number of the dependants on their members for whom they are liable. The payments to the doctors were, however, ascertained for twelve large sickness funds with an aggregate membership of 985,000, the expenditure of which does not include attendance on dependants, and also for six funds with 475,000 members, which were funds of the highest type, giving a wide range of additional medical benefits in which attendance on dependants was included. In the first class, where dependants were not included, general practitioners and specialists together received an average of 4s. 10d., while in the second class, where attendance on dependants was included, they received an average of 7s. 8d. a member. There is, however, considerable variation in the cost of attendance as between funds of the same type and those of different localities. For example, in the large funds of Berlin, where members only receive attendance, the payments to general practitioners and specialists ranged from 3s. 8d. to 4s. 7½d., while in the Munich Federation it reaches 5s. 9d.

DRUGS.

The report goes on to deal at length with the German pharmacy system and the monopolies enjoyed by the pharmacists. The data available show that the extension of medical treatment to the dependants greatly swells the drug bill. The case of Leipzig has already been mentioned, where in 1911 drugs and dressings came to 3s. 6½d. per member, but of this amount 1s. 4½d. was incurred on behalf of dependants. In the same way the medicines prescribed by the doctors of the Stuttgart Federation came to 4s. per member, but 1s. 8½d. of this was on account of dependants.

MISCELLANEOUS.

Full details are given of the cost of attendance, drugs, and various appliances and hospital treatment for a

considerable number of individual societies and federations of various classes, and the report concludes with translations of the forms of agreement between the doctors and the funds in Leipzig and Berlin, agreements with pharmacists at Frankfurt-on-Main, and the rules of the doctors' federation of Wurtemberg, relating to economical methods of prescribing.

ROYAL MEDICAL BENEVOLENT FUND.

At the January meeting of the Committee nineteen cases were considered, and grants amounting to £172 voted to eighteen of the applicants. The following is an abstract of the cases relieved:

1. Widow, aged 60, of M.R.C.S. Supported herself for some years after the death of her husband by acting as housekeeper, etc., but is now in failing health. Expects to be elected to a pension from another society in a few months, and is temporarily provided with a home by a relation who can ill afford to help. Asks for a small grant towards the expenses of the home. Voted £5.
2. Widow, aged 38, of M.R.C.S., L.R.C.P. At husband's death about four years ago the small estate was left in trust for the elder child, now aged 9 years, and applicant has been unable to earn a living because compelled to give constant attention to a younger child. Her father, too old for work, and living on his savings, has given them a home, but cannot continue to do so unassisted. Voted £5.
3. Daughter, aged 58, of late M.R.C.S. Maintained herself for several years as a companion, but has recently broken down in health, and is quite unfitted for any permanent employment. Relieved twice, £24. Voted £12.
4. Daughter, aged 61, of late M.R.C.S. Supplements a pension of £21 a year by needlework, etc.; sight failing. Relieved six times, £72. Voted £9.
5. Widow, aged 75, of L.R.C.P. Edin. Supplements an old age pension by letting lodgings; has recently had an acute illness of several weeks' duration. Relieved once, £12. Voted £12.
6. Daughter, aged 42, of late M.R.C.S. Is a complete invalid, and practically dependent on a sister who, having been obliged to nurse her mother, has been unable to earn for some months past. Relieved three times, £30. Voted £12.
7. Daughter, aged 57, of late M.R.C.S. Has been unable to support herself owing to ill health for many years past, and is dependent on two half-sisters who have to earn their living. Relieved eight times, £71. Voted £10.
8. Widow, aged 67, of M.R.C.S. Quite unprovided for at husband's death a few years ago. Endeavours to support herself by receiving paying guests; slight help from friends. Relieved twice, £12. Voted £6.
9. Widow, aged 64, of L.S.A. Earns about 15s. a week by selling sweets, but has to maintain a delicate daughter who is unfitted for regular occupation. Relieved five times, £60. Voted £12.
10. Widow, aged 84, of M.R.C.S. Only income an old age pension and an annuity of £10. Children unable to help. Relieved twice, £12. Voted £6.
11. Widow, aged 55, of L.R.C.S. Edin. Asks for assistance to remove to a seaside place where a lodger she has had for many years is ordered to live, and where applicant will obtain a larger house for a smaller rent, and so be able to let more rooms. Relieved five times, £47. Voted £15.
12. Daughter, aged £75, of late M.R.C.S. Income £20 a year, and earns a few shillings a week by needlework. Health and sight both failing. Relieved fourteen times, £137. Voted £5, and to be recommended to apply for an old age pension.
13. Widow, aged 40, of M.D., R.U.I. Receives £25 a year for the benefit of her child, aged 3½, and is given rooms and light in exchange for services as a caretaker. Relieved twice, £20. Voted £5.
14. Daughter, aged 65, of late M.R.C.S. Only income a small allowance from a society for the relief of the blind. Relieved seven times, £66. Voted £12.
15. Daughter, aged 51, of late F.R.C.S. No income. Had a situation as cook, but was obliged to give it up on account of ill health, and finds it very difficult to get employment for which she is fitted. Relieved seven times, £40. Voted £12.
16. Widow, aged 45, of L.R.C.P. Edin. Unprovided for at husband's death a few years ago, and, being lame and in bad health, is unable to obtain a paid post. At present receives a home at a boarding-house for a few shillings a week in exchange for services. Relieved six times, £34. Voted £10.
17. Daughter, aged 37, of late M.R.C.S. Supplements small earnings by letting rooms, by making marmalade, keeping poultry, etc. Health too delicate to allow regular employment. Relieved eight times, £73. Voted £12.
18. Widow, aged 60, of L.R.C.P., L.R.C.S.I. No income, and unfitted for employment owing to the loss of a hand and general bad health. Children unable to help. Relieved nine times, £80. Voted £12.

Contributions may be sent to the Honorary Treasurer, Dr. Samuel West, 15, Wimpole Street, W.

LITERARY NOTES.

We have received from Messrs. Williams and Norgate a copy of the first number of the *British Review*, with which is incorporated the *Oxford and Cambridge Review*; it is to be issued monthly at the price of one shilling net. The editor is Mr. Richard Johnson Walker. The first number includes a good psychological article, "Falstaff: the English Comic Giant," by Mr. W. L. George; a memoir by Leo Tolstoy on true and false science; and a remarkable paper on "Huxley and the Catholic Faith" by Mr. Cecil Chesterton. "The Opium Thrall," by Mr. Litchfield Woods, suggests De Quincey.

The *Arena* for December, 1912, contains a good article on the life and work of a medical student by "A. R. E." It is a very fair sketch of medical education previous to qualification, written in a light style. "Some time ago," we read, "one of the hospital magazines propounded the question 'Who carries the most side, a dresser starting his work in the hospital, or a freshly qualified man.' We have not yet discovered the correct answer." The writer dwells on the greater popularity of surgery than medicine; perhaps it would have been good had he hinted that physician's work is far too much depreciated by the average student. A further feature about medical education not touched upon here, and little noted elsewhere, is the fact that fifty years ago the student began as apprentice to a qualified man, whilst now he commences his medical education in a college or a hospital. As for hospital life, "A. R. E." clearly writes from experience.

Mr. D'Arcy Power¹ has been supplementing the biography of John Banister, the noted surgeon of Elizabethan times, by a careful study of a picture in the Hunterian collection in Glasgow. The picture represents John Banister delivering the "Visceral Lecture," in 1581, in the Barber-Surgeons' Hall in Monkwell Street, London, and so minute is the detail that a great deal can be made out, much more than if the impressionist school of artists had been at work in those days. We may indeed be thankful to Mr. Power for showing how much can be learnt from such a study, and through him to the late Dr. Frank Payne for suggesting to him the investigation of this particular picture. It is an open question whether the solution of many problems in medical biography and history may not lie hidden in old portraits and the like; medical iconography is a little worked and, it may be, a rich mine. Mr. Power, at any rate, has done some profitable digging in it. It is an interesting fact that Banister practised both as a physician and as a surgeon at a time when the surgeons were still servants to the physicians. Perhaps this may account for a curious passage in the commendatory preface written by Banister's friend, William Goodrus, for the former's book, *An Antidotarie Chyrurgicall*, published in 1589. It would seem that Banister had enemies; at any rate, here is what Goodrus writes:

What their malice hath been able to achieve against you hethertoo, you have good experience; it is not to be hoped of them that time to come will bring more prosperous windes for their saying, although they threaten, feare them not: A wise man said, Those that prondlie threaten others, doe eyther suppose themselves to be Gods, or els thinke that those things which they threaten others with, cannot fall upon themselves. . . . The Quale is said to bee most delighted to feede on venomous seedes: and so is the evill tonged man in casting forth venomous speeches, thus envie alwaies traceth vertue, and treadeth upon her heeles. . . . Plinie saith, the Camelacon hath vrie great lunges, but nothing els within her bodie, so (saith hee) there be some that beside their bosting and swelling ostentation have nothing to be found in them. . . . but like as the Maidenhaire, though it bee sprinkled or dipped in water, will nevertheless look still as though it were drie, no more shall reproche and infamie (though it be notable attempted) cleave or sticke unto a good man.

So with strange zoological and botanical figures Goodrus encourageth his friend Banister against his enemies. But who were they? Perhaps they were only the almost inevitable crowd of unwilling witnesses to all successful men, perhaps there was a particular reason for their existence. Perhaps Mr. D'Arcy Power can find out for us; again, perhaps, it is not worth his while to try or ours to inquire.

Le Nourrisson (The Nursling) *Revue d'Hygiène et de Pathologie de la Première Enfance* is the name of a new

serial of which the first number appeared this month; it will be issued, we are informed, six times in the year. The editor in chief is Professor Marfan, Physician to the Children's Hospital, Paris, and he is assisted by Drs. Apers, Aviragnet, Bouliche, Hallé, Lesage, Renault, Triboulet, and Weill-Hallé. Each number will contain at least one article written by a member of the editorial committee above named. The first number includes a paper by Marfan on a case of congenital stricture of the pylorus, with considerations on infection of gastric origin, and another by Aviragnet on control of the rearing of the infants of the poor, in which the author dwells on the legislative and administrative aspects of the question. M. Apers contributes an excellent critical review on the temperature of the newborn at term and the newborn premature child. Under the head of *Médecine Pratique* Dr. Triboulet writes on Ziehl's fucisin as an external application in the treatment of pyodermitis, interesting when we remember the obstinate nature of impetigo and allied pustular affections. Lastly, there is a copious report of current writings in the form of abstracts, a valuable feature in a publication of this type, which deserves to prove successful. The annual subscription is Fr. 12; the price of each number is Fr. 2; the publishers are Messrs. J. B. Baillière et fils.

Gratitude has been defined as "a lively sense of favours to come," but the feelings of the convalescent patient towards the doctor who has cured him are usually of a more disinterested character. The sincerity of Louis XIV's gratitude to the physicians who attended him during his frequent illnesses is testified by the gifts he showered upon them; and even the kingly generosity of *le roi Soleil* scarcely surpassed that of Robert II of Scotland, the grandson of Robert Bruce, whose "beloved and faithful Farquhar Leech" was the recipient of numerous and substantial tokens of regard from different members of the Royal family. Even the King's younger son, the savage "Wolf of Badenoch," gave evidence of an unusual amount of kindly feeling in his dealings with his father's favourite physician, whose sister, according to some authorities, was his own "handfasted" wife and the mother of his children. We learn from the *Caitness and Sutherland Records*, Part VII, vol. i, recently published by the Viking Society for Northern Research, that on September 4th, 1379, the lord of Badenoch bestowed on the court physician a large tract of land in Sutherlandshire, the gift being confirmed on the same day at Perth by the King in the following charter:

Robert, by the grace of God King of Scots and all good men of his whole realm, greeting. Knowye that we have approved and ratified and by this our present charter have confirmed that gift and grant which our beloved son, Alexander Stewart, Knight, Lord of Badenoch, made to and conferred upon Farquhar, our physician, of the lands of Melness, and the two parts of the Hope with their pertinents: To be held and possessed by the said Farquhar with all and sundry liberties, commodities and easements and their just pertinents whatsoever belonging to the aforesaid lands with their pertinents or which by any manner of way may justly be held to belong thereto in time coming, as freely and quietly, fully, entirely and honourably in all and by all as is mere fully contained and set forth in the charter granted by our said son to the said physician thereupon, saving our service. In witness whereof to this our present charter of confirmation we have ordained our seal to be appended; witnesses, the venerable fathers in Christ, William, and John our Chancellor, Bishops of the Churches of St. Andrews and Dunkeld; John, Earl of Carrick, our eldest son, Steward of Scotland; Robert, Earl of Fife and Menteith, our beloved son; William, Earl of Douglas and Mar, our Cousin; James of Lindsay, our dearest nephew, and Alexander of Lindsay, our cousin, knights. At Perth, 4th September, in the ninth year of our reign.

Some years later Farquhar's skill in treating the King (who, we are told by Froissart, suffered from chronic inflammation of the eyes) was rewarded by another grant of land, confirmed in a charter dated December 31st, 1386:

Robert, by the grace of God King of Scots, to all good men of his whole realm, cleric and laic, greeting. Knowye that we have given and granted and by this our present Charter have confirmed, to our beloved and faithful Farquhar Leech, for his service rendered and to be rendered to us, the islands of Jura, Calva, Sanda, also Ellangowan, Ellanwillighe, Eileau Roan, Ellanbaga, Ellanwoera, Ellangelye, Ellanyofo, and all our islands between Rhu Stoer in Assynt and Rhu Armadale, within the Sheriffdom of Inverness: To be held and possessed by the said Farquhar and his heirs of us and our heirs in fee and heritage by all their right meiths and marches,

¹ *Proc. Roy. Soc. Med.*, vi, Sect. of Hist. of Med., pp. 18-35, 1912.

with all and sundry liberties, commodities, easements, and just pertinents whatsoever belonging to the said islands or which may belong thereto in time coming, freely, quietly, fully, entirely and honourably, well and in peace: Rendering to us and our heirs the services of old, used and customary, therefrom. In witness whereof to this our present Charter we have obtained our seal to be appended; witnesses, the very reverent father in Christ, Walter, by the grace of God Cardinal of the apostolic see; the venerable father in Christ, John, Bishop of Dunkeld, our Chancellor; John, Earl of Carrick, our eldest son, Steward of Scotland; Robert, Earl of Fife and Menteith, and James, Earl of Douglas, our beloved sons; and Archibald of Douglas and Thomas of Erskine, our cousins, Knights. At Edinburgh, 31st December, in the sixteenth year of our reign.

Little beyond these few details is known of Farquhar the Healer, or Ferchard, as he is sometimes called. He is said to have been a member of the powerful clan Mackay, and possibly a son of its chieftain, Iye of Strathnaver. This, of course, is more or less conjecture; but it seems tolerably certain that Farquhar found both fame and fortune at the Scottish court. The gifts of his royal patients enabled him to found a landed family of Mackays; and his estates in the north were held by his descendants until the early part of the seventeenth century, when the last of his property passed into the hands of another branch of the same clan.

THE MILK AND DAIRIES BILL.

PROFESSOR SHERIDAN DELÉPINE, Director of the Public Health Laboratory, Manchester, has sent us the following notes on the Milk and Dairies Bill introduced into the House of Commons by the President of the Local Government Board on December 10th, 1912.¹

The notes deal only with three points about which the writer is specially competent to speak, namely:

1. The danger of failure due to the inadequacy of means of efficient inspection in a large number of districts (Clause 2).
2. The absence of any statement as to the duty of farmers or other persons to notify cases of disease which, though not certainly due to tuberculosis, might on investigation by competent persons be proved to be due to that disease. These doubtful cases are very common, and doubt is often used as an excuse for neglect.
3. The absence of reference to the means of obtaining reliable information regarding samples of milk collected by Medical Officers of Health or Veterinary Inspectors.

Past experience has shown that whenever adequate measures have been successfully applied to the control of a milk supply, bacteriological examinations by competent bacteriologists working in suitably equipped laboratories have been essential to success. Co-ordination in the work of the medical officer of health, bacteriologist, and veterinary inspector has not been less essential. Neither the medical officer of health nor the veterinary inspector is (generally speaking) competent to do the bacteriological work, nor, if competent, could he give the time necessary to that work without neglecting his primary duties.

The following suggestions are made in order to meet these omissions. They are put in the form of addenda or corrigenda for the sake of clearness, but without any desire to indicate what the wording should be. Nor has any attempt been made to indicate all the passages which the suggested alterations would affect.

1. INADEQUACY OF MEANS OF EFFICIENT INSPECTION IN MANY DISTRICTS.

Clause 2 (p. 2, line 35).—"And in other cases to the Council of the district in which the dairy is situated." . . . Add something to that effect . . . provided that the said Council can command the services of a medical officer of health devoting the whole of his time to the duties of his office and of a veterinary surgeon or inspector recognized for the purpose of this Act or Section by the Board of Agriculture and the Local Government Board, and devoting the whole of his time to the duties of his office.

Failing which the said Council shall make such arrangements as those indicated in Clause 10 . . . with the county or county borough or other local authority commanding the services of full-time medical officer of health and veterinary inspector recognized by the Board for the purpose of this Act.

2. NECESSITY OF NOTIFICATION OF DOUBTFUL CASES.

Clause 12 (p. 6).—Somewhere in that clause, or immediately after that clause, or elsewhere, the following provisions should be made:

If a person (owner, farmer, veterinary attendant) does not notify to (the proper authority) the presence of any cow affected with some enlargement or induration of the udder or general wasting, the cause of which is not known to him to be certainly other than tuberculosis, he shall be liable to a fine of. . .

3. RECOGNITION OF PERSONS COMPETENT TO CONDUCT BACTERIOLOGICAL EXAMINATIONS.

The following additions or their equivalents are suggested: Memorandum 2.—"The inspection of dairies," . . . Add: and the examination of cow's milk.

Clause 3 (3) (p. 3, line 13).—"And separate samples thereof furnished." Add: When a bacteriological examination of such samples is needed, the samples shall be examined by a bacteriologist (or Public Health Bacteriologist) and in a laboratory (recognized for the purpose by the Local Government Board). (See definition of bacteriologist, Clause 24).

Clause 3 (p. 3, line 22).—"If on any inspection of a dairy." Add: or on receipt of a bacteriological report on the milk of a dairy. (I have some doubt as to the need of that addition.—S. D.)

Clause 3 (p. 3, line 30).—"Any report furnished to him by" . . . Add: the bacteriologist.

Clause 12 (p. 7, line 12).—"To take for examination." Add: by a bacteriologist recognized for the purpose (or the Official or Public Health Bacteriologist).

Clause 14 (p. 7, line 36).—"For the purpose of this Act." Add: a bacteriologist recognized by the L. G. B.

Clause 15 (p. 8, after line 14).—"The bacteriological examination of samples of milk.

Clause 24 (p. 13, after line 36).—"Add: The expression "Bacteriologist recognized for the purpose of this Act" (or Official Bacteriologist or Public Health Bact.) means.

A duly qualified practitioner, provided with adequate laboratory accommodation and recognized by the Local Government Board as competent to carry out the investigation of milk and other products by microscopical, cultivation, inoculation, and other experimental methods such as are used in investigations bearing upon causation and prevention of disease.

Mr. Asquith has stated in the House of Commons that the Government did not propose to proceed with the measure this session, and added that though he could make no promise for next session, the claims of the bill would certainly be considered.

SANATORIUM TREATMENT OF INSURED PERSONS IN GERMANY.

A VOLLMINGUS report has recently been issued on the results of the treatment of insured persons in the Hanseatic towns (Hamburg, Lübeck, and Bremen) in the year 1911.¹ It appears that in that year 6,262 applications for treatment were received, and 420 cases remained over from the previous year; 1,741 patients were admitted to treatment on account of pulmonary tuberculosis, which, with those remaining over from the previous year, gave a total of 2,037 cases under observation. The statistics of individual sanatoriums are elaborately analysed. As an example we reproduce the report on the tuberculous patients of the Oderberg-Gebhardsheim Sanatorium, which is as follows:

Pulmonary Condition.

1. The slight physical signs present on admission were still present, but of lesser degree, in 253 = 29 per cent.
2. The slight physical signs present on admission were unchanged in 323 = 38 per cent.
3. The marked physical signs present on admission were diminished in 84 = 10 per cent.
4. The marked physical signs present on admission were little, if at all, changed in 188 = 22 per cent.
5. The physical signs present on admission were aggravated in 10 = 1 per cent.

General Condition.

1. Marked improvement in 493 = 57 per cent.
2. Some improvement in 282 = 33 per cent.
3. Little or no improvement in 65 = 8 per cent.
4. Worse in 18 = 2 per cent.

Earning Capacity.

1. For the time practically complete, but may not be maintained, in 642 = 75 per cent.
2. Improvement to an extent to take the patient out of the legally defined class of "Erwerbsunfähige" in 155 = 18 per cent.
3. Unable to work, in the sense of the invalidity law, in 61 = 7 per cent.

The report contains a very large number of tables dealing with almost every aspect of the subject.

MEDICAL SERVICE IN THE HIGHLANDS AND ISLANDS OF SCOTLAND.

THE summary of the report of the Committee on the Medical Service of the Highlands and Islands, which appeared in recent issues,¹ will, we believe, have interested many readers for different reasons. Many, probably, will have had difficulty in believing that the conditions of medical practice, as detailed by medical witnesses and others, in the evidence given before the Committee, could exist at the present day. But that such conditions exist is made painfully manifest throughout the report. To those familiar with the Highlands and Islands, the revelations of the Committee will not have come as any surprise, and, although the disadvantages and difficulties of medical practice have been known to the different parties concerned, and described in our columns over and over again, nothing has hitherto been attempted by the Government, or other controlling body, to remedy what may to many seem an almost incredible condition of affairs. The Poor Law Commission in its report brought to light the want of proper medical attendance on non-paupers, as well as paupers, in the Highlands and Islands. Once more it has been fully demonstrated that the social and economic conditions at present existing in these areas cannot be paralleled on a similar scale in any other part of Great Britain. Insanitary dwellings, poverty-stricken households, persistent superstition, the economic bankruptcy of whole districts, families wanting the barest necessities of life, and people, both old and young, dying from want of medical attendance—these are some of the conditions mentioned in the report. It is well that this reproach to our administrative methods should have been brought to the notice of Parliament and of the country in a form which cannot be gainsaid. Clearly some means must be devised to remedy the existing condition of affairs, and we are glad to see that the member for Orkney and Shetland has already shown a desire to take the matter up, and feel sure that he will not allow himself to be put off with official platitudes.

At a time when the benefits of the National Insurance Act are being loudly proclaimed by its author and those who support him, the report discloses the fact that the Insurance Act cannot be applied to a large part of the Highlands. "Inquiry was made from time to time," says the report, "as to whether the average crofter would be ready to pay contributions in respect of at least twenty-six weeks—that is, an annual average of 3½d. a week. The invariable answer was that in those impoverished districts contribution without compulsion is unreliable, and even if legislative power to compel were forthcoming, the system would still lack the main guarantee of success—namely, an employer responsible for the employed contribution. . . . We

are, therefore, convinced that the industrial conditions of the Highlands and Islands are such as to make the provision of the Insurance Act less operative than in other parts of Scotland, and we foresee considerable trouble in providing medical benefit for fully insured persons far removed from a medical centre, more particularly when it is borne in mind that so large a portion of them are so situated."

What we are more immediately concerned with is the medical aspect of the report. It shows clearly and conclusively the inadequacy of the medical service. Owing to geographical and economic circumstances, regular medical attendance is barely procurable, and those who know the Highlands and Islands will not be surprised to read that probably between 50 and 75 per cent. of illnesses are not attended by any doctor. The figures cannot, of course, be given exactly; but it is a confirmation of this estimate that in many parts of the Highlands the percentage of persons whose deaths are uncertified ranges as high as 80, and that over the whole of the rural insular parts of Ross it was over 47 per cent. In these places, as would naturally be expected, infant mortality is high, and the number of women who die in childbirth is distressing.

Such, then, are the conditions—or at least some of the conditions—which the evidence before the Committee elicited. What, then, is the remedy? One essential factor in any remedial measure is more money, and fundamentally this is really the chief recommendation of the Committee. That a large Government grant must be given is very evident. The administration of this grant may present some administrative difficulty. Two administrative authorities—one central and one local—are recommended. A Government grant would render necessary the creation of a central controlling body, and the recommendations of the Committee show how this could be done. The Committee has had regard to all the medical interests involved, the duties and responsibilities of the public authorities operating in the Highlands and Islands, and the desirability of bringing about, as far as practicable, a consolidation of the various services. It would be necessary, no doubt, that this central authority should act under regulations made by the Treasury.

If the money is forthcoming the Committee has a long programme to suggest for the spending of it; every suggested item of expenditure seems absolutely necessary. First, there is the strongly expressed opinion of the Committee that a minimum income of £300 per annum, with travelling allowance, should be secured to every medical practitioner recognized by the central authority. In the case of several doctors living in a common centre, where it would be in the public interest to arrange that outlying patients should be attended at small fees, it is advised that the doctors should receive an annual subsidy to allow this to be done. Should these two proposals be carried out, the financial position of medical practitioners in the Highlands and Islands would be very materially improved, and there would be more inducement for men to remain in the Islands much longer than is at present the rule. Other recommendations of the Committee would very greatly facilitate the working of a practice in the Highlands. They include the provision of small cottage hospitals, the institution of a general and special nursing service, the provision for every person below a certain income of medical attendance on terms adapted to his economic condition; specialized medical service, such as special local consultations, local assistance at operations, dental treatment, eye treatment, and so on. The

¹ January 11th, pp. 98-99; January 18th, pp. 126-129.

need for special travelling allowance for doctors and nurses is also recognized, as also the provision of an ambulance service available in the district for sick or disabled persons, and the extension of telegraphic and telephonic facilities in widely scattered areas.

It is clear enough that the recommendations of the Committee are most moderate, and that the lot of the doctor in the Highlands and Islands and the efficiency of the medical service will be vastly improved when they have been carried out. We have every reason to believe that the Committee is wholly in sympathy with the profession, and recognizes that the conditions under which medical practice is at present carried on in the Highlands demand urgent and liberal consideration.

We give this week (p. 229) a summary of the very valuable appendix to the Committee's report by Dr. Leslie Mackenzie, medical member of the Local Government Board for Scotland. He indicates a way by which the recommendation of the Committee with regard to the creation of a central authority could be carried out, and his suggestions are the outcome of many years' experience in matters connected with public health work: they will, we doubt not, carry much weight with the Government in the drafting of the scheme which it is now under a distinct obligation to propound without delay.

STIMULATION OF REPAIR.

AN account was given some months ago¹ of the curious and interesting experiments conducted by Dr. Alexis Carrel in the Rockefeller Institute for Medical Research, New York, on the growth of portions of mammalian tissue after complete separation from the body. Connective tissue lived and grew, was cultivated as it were, in plasma, and the heart of a chick went on beating for as long as one hundred days. He has recently published some further information as to the nature and properties of the plasma used.² The research seems to have had its origin in the speculation that it was possible that certain modifications in the internal economy of the tissues might bring about increased multiplication of their cells and so, perhaps, a more rapid healing of aseptic wounds or fractured bones. The results of some preliminary experiments on animals favoured the theory, but showed also that the living organism presented conditions too complex to afford probability of precise conclusions. The method used by Harrison for studying the growth of the central nervous system of frog embryos in a drop of lymph then suggested itself, and in 1911 Carrel and Burrows observed that the growth of chicken tissues was more rapid in a culture medium to which extracts of the Rous chicken sarcoma or of chicken embryo had been added. It was in the course of these researches, or as a consequence of them, that Carrel made the observation to which we referred last July.

His more recent paper deals mainly with an attempt to estimate quantitatively the influence of tissue juices on the growth *in vitro* of connective tissue. A hypotonic plasma was obtained by adding two volumes of distilled water to three volumes of normal plasma. Extracts were made from chick embryos from six to twenty days old, of spleen, kidney, and muscle of the adult chicken, of the Rous sarcoma, of thyroid gland, spleen, and muscle of the

adult dog, and of the spleen of the adult rabbit. The tissues were cut into very small fragments or cut and ground with sand in a mortar, or cut, ground, and frozen and then put for a short time in an incubator at 38° C. They were then placed in tubes and one-third of a volume to four or five volumes of Ringer's solution added. The tubes were kept in cold storage for varying periods and were then centrifugalized. The culture medium was made by adding one volume of the supernatant fluid to two volumes of hypotonic plasma. The tissue cultivated was in most instances a fragment of the ventricular wall of the heart of a chick embryo seven to fifteen days old, but fragments of skin were also used, and fragments of the periosteum of the dog. In estimating the effect of the various tissue extracts used, the area of the ring of new tissue formed around the fragment was calculated in relation to the diameter of the original fragment; as the thickness of the ring could not be exactly ascertained, it was not generally taken into account. In every experiment the fragments of heart, skin, or periosteum grew more rapidly in the plasma containing an extract than did the control fragments in hypotonic plasma without addition. The acceleration of growth was greater when the mixture of tissue and Ringer's solution was allowed to remain in the refrigerator for twenty-four hours or several days before being centrifugalized: in one instance in which embryonic pulp had been thus preserved for twenty days the area of new connective tissue formed in twenty-four hours was thirty times larger in the cultures containing the extract than in the controls. The extracts of tissues cut in small fragments mashed and frozen were generally very active, and embryonic tissue gave the most active extracts, though extracts of adult spleen and the Rous sarcoma fell only a little behind. Extracts of kidney and heart were much less active, while those of connective tissue and of blood corpuscles caused a slight acceleration only. The influence of extracts of thyroid gland and muscle of the dog on the growth of periosteum was very marked, the thyroid extract being the more active. The power of an extract to stimulate a growth was observed only in respect of tissues of another animal of the same species, and seemed therefore to be specific. The activating power of the extracts was diminished by heating to 56° C., and destroyed by heating for ten minutes to 70° C. Experiments with extracts of chick embryo and of the Rous sarcoma diluted with Ringer's solution showed that their power was not diminished by filtering through filter paper—was, indeed, slightly increased if the extract contained much cellular debris. The activating power of extracts was greatly diminished by filtering them through a Berkeleyd filter and entirely removed by a Chamberland filter.

These experiments, as Carrel suggests, though they may have no immediate practical application, may indirectly lead to the discovery of some of the factors determining the growth of tissues, in elucidating the dynamics of the cell, and in throwing light, ultimately, on the mechanism of the cicatrization of wounds.

Dr. Carrel more recently has reported to the Académie de Médecine in Paris³ the success of another experiment which will probably produce a greater impression at first sight than his other observations, though not, as it seems to us, of so great intrinsic scientific significance. He has succeeded in keeping alive and active for as long as

¹ BRITISH MEDICAL JOURNAL, July 20th, 1912, p. 135.
² *Journal of Experimental Medicine*, January, 1913.

³ *Bulletin*, January, 1913.

thirteen hours practically the whole of the abdominal and thoracic viscera of a mammal entirely separated from the head and body. In most of the experiments the animal used was a cat. The animal was anaesthetized with ether, and the skin of the neck, thorax, and abdomen sterilized. All the subsequent proceedings were carried out with aseptic precautions. The oesophagus was ligatured and divided. The trachea was cut across, and an india-rubber tube introduced to permit artificial respiration to be performed by the method of Meltzer and Auer. The abdomen was opened, and the aorta and vena cava tied, and severed near their bifurcation. The small intestine and the ureters were next divided, and then all the posterior branches of the aorta and vena cava were tied and cut. The abdominal viscera were thus completely detached from the abdominal walls, and remained connected with the thoracic organs by a pedicle consisting of the aorta and vena cava. The thorax was opened, and the diaphragm separated from the costal wall; the innominate arteries, the superior vena cava, and the azygos were tied and cut, and the animal died. The vagus, sympathetic and phrenic nerves were next divided, as also the posterior branches of the thoracic aorta. Generally at this stage the cardiac pulsations were feeble, and the arterial pressure very low. The thoracic and abdominal viscera were then removed in one mass and placed in a basin of Ringer's solution at a temperature of 38° C. As a rule the heart was still beating slowly and regularly, but feebly; the blood pressure was low, and the organs appeared very anaemic; in a few minutes, in some cases, the blood pressure rose, and sometimes became almost normal. As a rule, some blood from another cat was infused at this stage, whereupon the blood pressure rose, the heart became regular at 120 to 150 a minute, and the lungs assumed a pink colour. Pulsation in the aorta was strong, and could be seen and felt in the arteries of the stomach, spleen, kidneys, and ovaries, and peristaltic contractions were visible in the stomach and intestines; the viscera, in fact, resumed their normal appearance. This "visceral organism" was then placed in a box full of Ringer's solution, covered with a piece of thin Japanese silk, and protected by a sheet of glass. The tracheal tube was brought through a hole in the side of the box, a tube fixed in the oesophagus, by which water or food could be introduced into the stomach through another, and a tube passed into the cut end of the intestine through a third. The box was then kept in an incubator at 38° C. The viscera continued to live and to present a normal appearance. The heart was beating strongly and normally, the intestines showed peristaltic contractions and emptied itself through the artificial anus, and bile and intestinal mucus were afterwards evacuated. In one experiment, in which the stomach was full of meat when the animal was killed, digestion continued normally for several hours. In some experiments the "visceral organism" died rather suddenly in three or four hours, but in most it continued active for ten, eleven, and even as long as thirteen hours. Death was preceded by irregularity and feebleness of the heart, which finally stopped suddenly. Dr. Carrel believes that the study of the visceral organism under these artificial conditions may help in the solution of many physiological and chemical problems. However this may be, the experiment is of interest, as M. Pozzi, who related Dr. Carrel's observations to the Academy, observed, in showing how independent is an animal's life of relation of its vegetative life.

THE ECONOMIC VALUE OF SANATORIUM TREATMENT.

THE question is often asked whether sanatorium treatment is or is not of any value to the State, and a pessimistic answer is frequently given. Every one has experience of success in individual cases, but the general economic effect upon the community of the temporary rehabilitation of tuberculous persons can only be estimated by the study of statistics ranging over a wide field of inquiry. The results of such study carried out under the auspices of the Bureau of Labour at Washington have recently been published,¹ and will help towards the formulation of a trustworthy answer to the question to which we have referred. Under the title of *Care of Tuberculous Wage Earners in Germany*, a comprehensive analysis of the practical experience gained in Germany since the year 1900 is presented, with comments and comparative statistics. It deserves close attention in this country, where too little has as yet been done to co-ordinate the various agencies for dealing with tuberculosis.

By a law which came into force on January 1st, 1900, power was given to insurance institutions in Germany to cause their tuberculous beneficiaries to undergo a cure, compulsory in the case of unattached persons, but requiring the consent of the individual when possessed of a home or responsible belongings. From small beginnings, a widespread system of sanatoriums has been established during the past eleven years, and at the present time there are no less than ninety-nine such institutions scattered throughout the German Empire. The Grand Duchy of Baden appears to have been active especially in the foundation of tuberculosis dispensaries, by means of which all patients are directed into the most appropriate institutions for their needs. The greater number of these institutions have been built and maintained by the invalidity insurance authorities at a very considerable cost, and, in addition to the ordinary sanatoriums, many private establishments have sprung into being during the same period.

The needs of tuberculous children have also been cared for, and the segregation of advanced cases has been attempted. Dispensaries and polyclinics for the observation, regulation, and study of the disease have in like manner kept pace with public demand, and the whole system is under the supervision of the German Central Committee, which has the necessary means at its disposal, derived from subscriptions, donations, and the Imperial subsidy. The antituberculosis movement in Germany is thus thoroughly organized and sustained by ample funds. It should be noted that the life insurance companies are on a different footing to the invalidity insurance institutions which operate under the law of 1900. They none of them undertake the care or treatment of their tuberculous policy holders. The payment of death claims by such societies is quite distinct from the payment of invalidity or disablement benefit under the law.

Turning now to the results which have been achieved by the vast expenditure of capital that has taken place during the past decade, a very large amount of material is available for analysis. More than 270,000 individuals of both sexes have been treated in public institutions at a cost of approximately 4s. 7d. a day each, but against this very heavy expenditure must be placed the saving effected by the relief to the disablement annuity funds of all the sums otherwise

¹ *Care of Tuberculous Wage Earners in Germany*. Bulletin of the United States Bureau of Labour. Washington: Government Printing Office. 1912.

due to those who have been rehabilitated as wage-earners by the treatment received. So satisfied have the central authorities been with the results, that provincial and communal authorities have followed their lead and have devoted large sums of money to the rehousing of their working-class population, fully recognizing the direct relation between defective dwellings and impaired health. This movement cannot fail to react to the advantage of the German people as a whole, and if the present estimate be borne out in future it is expected that not less than 75 per cent. of the wage-earning sufferers from early tuberculosis will be rendered capable of service for many years at comparatively small cost. Apart from the purely economic question, the restored health of the bread-winner must have far-reaching influence upon the stability of family life.

It is notable that the effort to segregate the advanced cases of tuberculosis has not met with complete success. The dying consumptive, although he be a constant source of danger to those about him, prefers to spend his last hours with his belongings. Comparison with the system in vogue in the United States shows that much has yet to be done before the results shown in Germany can be rivalled; but the elaborate investigation which the Washington Labour Bureau has undertaken is deserving of the closest scrutiny, containing as it does the fullest available statistics and information upon a subject which must appeal to all classes of the community.

-CANCER OF THE KIDNEY.

THE kidney is not uncommonly the seat of malignant tumours of a rather perplexing type, not only from the point of view of diagnosis, but also owing to the problems their histogenesis presents, and the wide variations they exhibit in microscopic characters. Leaving on one side the peculiar sarcomas that arise in infancy, the other malignant tumours were formerly variously labelled as carcinoma, sarcoma, and endothelioma, and the confusion remained long after Grawitz, now nearly thirty years ago, propounded the theory that the great majority of them were derived from aberrant parts of the suprarenal gland. They are now generally classed under the term "hypernephroma," and until recently Grawitz's theory was unquestioned. It is indubitable that small bodies composed of cells bearing an exact histological resemblance to those of the zona fasciculata of the adrenal may be found not only in the neighbourhood of that organ and on the under surface of the liver, but also in the cortex of the kidney, along the course of the ureter, in the broad ligaments, and in the spermatic cord. An interesting paper on such adrenal rests was contributed to the *Birmingham Medical Review* of May, 1910, by Mr. Percival Cole. The frequency with which these "rests" have been found in the cortex of the kidney, combined with the influence of Cohnheim's theory of the origin of malignant tumours from embryonic inclusions, gave colour to the supposition that the renal hypernephromata arose from aberrant portions of suprarenal tissue, and this was almost elevated into a certainty by the observation that these tumours were composed of cells identical with adrenal cells, not only in microscopic appearance and arrangement but also in that they contained doubly refractile particles, fats, glycogen, and metachromatic nucleoli. Such cells have long been supposed to occur only in adrenal parenchyma, and they bear no resemblance to those of renal

epithelium. It is a striking fact, however, that true primary tumours of the adrenal gland itself are very uncommon, and with the possible exception of a tumour in the liver described some years ago by Lorrain Smith and Mair, we cannot recall any case of a tumour arising from adrenal rests in other situations.

These hypernephromata have a very characteristic appearance: some are definitely encapsuled, while others invade the substance of the kidney; they generally all show a peculiarly mottled appearance, at parts yellow, at other parts dark red, owing to haemorrhage, and again dull grey or gelatinous, owing to necrosis. It has been pointed out recently by Stoerk that in cirrhotic kidneys the undoubted renal epithelium may undergo changes and present the appearance of the cells characteristic of hypernephromata. In many other pathological conditions as widely separated as proliferative mastitis, ovarian cysts, and myeloma, groups of cells may occasionally be found with the histological characters of adrenal cells, and doubts are beginning to accumulate whether, after all, the so-called hypernephroma is really derived from an adrenal rest. In this country, Dr. J. Shaw Dunn has been one of the foremost opponents of the theory of Grawitz. He regards the tumours as originating from renal epithelium, and therefore to be classified as carcinomas. He has been able to demonstrate in a minute renal cyst composed of typical Grawitz cells a direct connexion with the tubules. It may be remarked, too, that hypernephromas seem to occur most frequently in the lower pole of the kidney, whereas adrenal rests are more common in the upper part.

The degree of malignancy of these tumours is said to vary considerably, but here, as in other malignant neoplasms, it is merely a question of the extent of dissemination at the time of removal. Secondary nodules occur in the lungs and liver and less frequently in the bones, and, in contrast to other types of carcinoma, the cells are carried by the blood stream and not by the lymphatics. In a lecture given at the Cancer Hospital, Brompton, on January 29th, Mr. R. H. Jocelyn Swan showed specimens of 12 cases of these interesting tumours, 10 of which he had removed by operation. In 7 out of the 10, haematuria was the first symptom that attracted the patient's attention; in 2 haematuria developed later than the pain; and in 1 the presence of a tumour was detected before either pain or haematuria had supervened. This is interesting in view of the remark of Sir John Bland-Sutton in the latest edition of his book on *Tumours Innocent and Malignant*, that "these tumours do not give rise to haematuria because the tumour does not invade the pelvis. This is the most striking fact in their clinical history." Some of Mr. Swan's tumours did invade the pelvis, but in at least one of them, in which case haematuria was the earliest symptom, the tumour seemed to be definitely encapsuled, and did not penetrate far even into the cortex. This tends to show that the occurrence of haematuria is not necessarily related to encroachment on the pelvis. All Mr. Swan's cases were upwards of 40 years of age, and it is difficult to conceive, if the tumours were traceable to adrenal rests, that the potentiality of malignancy should have remained dormant so late in life. Recurrences took place in 4 of the series in from three months to two years in the vicinity of the original tumour or in the lungs or liver. At the same lecture Mr. Leitch demonstrated a renal tumour, which showed at parts the typical structure of a pure malignant adenoma, and at other parts

typical Grawitz structure, with all gradations between the two, this tending further to confirm the origin of these tumours from renal epithelium.

Two very remarkable cases of renal cancer are recorded by Dr. Herbert French in the last number of *Guy's Hospital Reports*. The first occurred in a girl $6\frac{1}{2}$ years of age, and was associated with the development of the pubic hair and genitals from the age of 8 months. She experienced a sudden attack of abdominal pain and vomiting, and died after operation. Numerous secondary deposits were found in both lungs, which were invaded from the pulmonary arterioles. The tumour was a renal hypernephroma. The other case occurred in a man of 45, and was considered to be a carcinoma. The symptoms were indefinite, or rather, the abundance of symptoms was too perplexing for diagnosis, and the clinical report given will supply problems enough to baffle the acutest diagnostician. At the necropsy the growth was found to have made its way along the renal vein, up the vena cava, and into the right auricle as an unbroken thrombus.

THE NEXT FIGHT: CONTRACT MEDICAL ATTENDANCE ON UNINSURED PERSONS.

Now that the rates for medical attendance on persons insured under the National Insurance Act have been, at any rate for the present, fixed, a question of hardly less importance faces the profession and presses for solution. We allude to the rates of payment for contract medical attendance on the uninsured. A case which has just happened in London will serve as an illustration both of the dangers to be feared and of the correct method of dealing with them. The Provident Association of Warehousemen and Clerks, having its offices in Cheapside, London, became an approved society, and, in consequence, found itself obliged to make arrangements for medical attendance on a considerable proportion of its members who, for reasons of age, disability, or income, have not become insured persons, or are not entitled to medical benefit under the Act. It applied to its former medical officers, who had resigned their contracts as requested by the British Medical Association, and asked them to undertake the treatment of this residue at the previously accepted rate of 6s. a member per annum. The Provident Association was obviously surprised when a large number of these practitioners, owing to organized action taken on the initiative of Dr. J. A. Butler and Dr. J. Galt, declined to accept these terms, and have demanded rates of 9s. including medicine, for those of the members who are in receipt of less than £160 per annum, and 10s. 6d. for those earning above that amount. The Provident Association does not see, or does not wish to see, that such a demand is perfectly reasonable, and that practitioners who accept less would, in fact, be stultifying themselves in the eyes of the public. The members for whom the fee of 6s. is offered are, in the nature of the case, either not so fit physically as the insured members of the Provident Association, or they are financially better off, and on either of these grounds it seems obvious that there is a perfectly fair claim for, at the very least, the 9s. assigned under the Government Insurance scheme for medical attendance and medicines provided for the insured. The State Sicknes Insurance Committee of the British Medical Association has sent a circular letter to the medical officers of the Provident Association urging them to adhere to their just demands, and at the same time promising the support of the Association to the fullest possible extent. It is hoped that no practitioner will be so ill-advised as to accept the inadequate terms now offered by the Provident Association. There are

several morals to be derived from this incident, but the chief is that the profession will have to be very careful in its dealings with this subject if it is not to fall into serious inconsistencies and set up precedents which will be extremely awkward in the future. It will have been useless to have fought a long and expensive battle for adequate remuneration under the Insurance Act if the profession is prepared at the first demand to accept inferior rates of payment for the same kind of work to be done on behalf of people at least as well off as the insured, many of them being also old and ailing. The insured, being subsidized by their employers and by the State, are precluded from any claim on the charity of the profession, but it may be necessary in dealing with some classes of the uninsured to make allowances on the ground of poverty; the profession has always done so and will doubtless be willing to continue to do so. But the plea of poverty does not apply in cases like that dealt with above, and even where it does apply it must be made perfectly clear that the lower rates charged for contract medical attendance on the poor uninsured shall not be used as a precedent if, at a later date, it is proposed to include them in the insured classes. It is in order to forestall attempts of this kind that the profession must be on its guard in all arrangements made for contract attendance on uninsured persons. While making due allowance for economic conditions, the profession must see to it that the rates now fixed bear some more reasonable relation to the work expected than has been the case in the past. This can only be accomplished by increasing vigilance on the part of the profession in each locality, and by consultation in each Division before local rates are fixed. There must be no individual arrangements made in the bad old way, without a thought of the influence on others and on the general situation.

ATTENDANCE ON AGED AND INFIRM MEMBERS OF APPROVED SOCIETIES.

ANOTHER aspect of the question discussed in the preceding note calls for mention, since it seems to be the cause of much misunderstanding. Section 15 (2) (c) of the National Insurance Act states that the Regulations shall require the adoption by every Insurance Committee of such a system of administration of medical benefit as will secure the provision of medical attendance to members of friendly societies, which become approved societies, who were either (a) not entitled to medical benefit because they were 65 or upwards at the commencement of the Act, or (b) not insurable because they were permanently disabled at that date; the provision is to be made on the same terms as to remuneration as those arranged with respect to insured persons. Regulation 51 leaves it optional for such persons, or their approved societies on their behalf, to claim their medical attendance under the arrangements which the committees are required by the above-quoted section to provide. Circular A.S. 75 of the Commissioners, headed "Medical Benefit," in referring to the fact that Insurance Committees are required to make the above-mentioned arrangements, says, "This is, however, an option granted to societies, and the Act does not make it obligatory upon a society to avail itself of this provision, nor does it either expressly or by implication require any payments made by a society in respect of this treatment to be on the same scale as in the case of insured persons if the society can obtain treatment at a lower rate." Whatever construction may be forced upon an apparently straightforward clause of the Act, it is beyond doubt to those who know the history of this clause that all attempts on the part of friendly societies—and they have been very common—to secure attendance for these classes of their members at lower rates, are an attempt to get behind an understanding which was come to between representatives of the friendly societies

and representatives of the Association. This understanding was reached at a conference held at the Treasury, with the Chancellor of the Exchequer in the chair, on October 16th, 1911, when a large number of leading representatives of the friendly societies were present, including Messrs. Moffrey, McNicoll, Lister Stead, and Marlow. It was regarded at the time by the friendly society representatives as a distinct concession on the part of the Association, and they not only expressed their gratitude for it, but, so far as they could bind their societies, agreed in return not to reopen the demand that the administration of medical benefits should be handed back to the approved societies. The representatives of the societies had felt that there was a danger that the medical profession, if it undertook the proposed statutory obligation to treat the insured, might decline to attend the aged and infirm members of the societies except at higher rates, and there is no doubt they regarded the embodiment of the understanding in the Act as a distinct gain. This arrangement was reported to the Special Representative Meeting in London in November, 1911, and was there endorsed (Minutes 30 and 31), but it would appear that the heads of the friendly societies have neglected to make the understanding on the subject known to their local branches, for from many quarters we have been informed that attempts are being made to secure attendance on these aged or infirm members at the old rates. The State Sickness Insurance Committee has already reminded all Division Secretaries of the requirements of the Act, and has urged that the local profession should take steps to protect its legitimate interests. It need not be feared that in doing so any hardship will be inflicted on the friendly society members referred to. The Insurance Committees are charged with the duty of seeing that they get their medical attendance at the same rate as the insured get theirs; the societies are bound to provide it for them; the physical condition of the persons concerned precludes any appeal for lower terms except on the ground of poverty; and the reserves which have been set free by the operations of the Act leave the societies quite able to meet the extra charge on a small and diminishing class.

CANVASSING FOR INSURANCE PATIENTS.

If anything could add to the sense of humiliation experienced by many members of the profession owing to the events of the last few weeks it must have been the revelations of the means to which some doctors on the panels have permitted themselves to resort in order to attract insured persons to send the strawberry cards to them for signature, with the intention, no doubt, of using this provisional arrangement as an introduction to a large number of insured persons. We called attention to this matter last week, but information given to the Council of the British Medical Association on Wednesday shows that lapses of this nature have been more common than was known last week. Nothing can excuse such a course of conduct. It may be true that the methods recently pursued by the Insurance Commissioners have not reached the high ethical standard which the country has a right to expect from a body of persons to whom functions of great national importance have been confided by the State; it may be true also that these methods appeared to be countenanced by some members of the profession who had no doubt persuaded themselves that the end, which they regarded as good, justified the means. But all this cannot justify the gross departure from the well-recognized ethical rules by which the members of the profession have learnt to govern their relations with each other, which is involved in resort to canvassing by postcards, leaflets, and personal visits to insured persons. Instances of such procedures were given to the Council, and it was also told of the action taken in certain districts by Divisional or Local Medical Committees to recall men, who may have acted without sufficient consideration, to a sense

of their duty to their brethren and to the traditions of the profession to which they belong. It is satisfactory to know that these representations have as a rule produced the effect that was to be expected, and that the canvassing cards and leaflets have been withdrawn and the personal canvassing stopped. But we understand, also, that a considerable number of complaints have been lodged with the General Medical Council, and there can be no doubt that, if evidence of such canvassing were advanced, the cases would be investigated by that Council as it has investigated charges of canvassing with regard to contract practice or in other connexions in the past.

THE SUPPOSED DANGERS OF THE TUBERCULOSIS SANATORIUM.

THE provision of sanatorium treatment is slowly proceeding, and some of the difficulties attending it are becoming manifest. One of these difficulties arises from the not unnatural aversion of rural communities to the settlement of numbers of tuberculous persons in their midst. The average dweller in country or suburb has acquired a vague conviction that consumption is infectious, and hence that consumptive people are to be avoided if possible. Very few, however, have taken the trouble to inquire into the conditions under which infection may take place. It is therefore all the more necessary to point out by the light of experience and common sense that such pessimistic notions are not consistent with the proved facts of the case. The two main objections to the establishment of a sanatorium in a new locality may be thus stated: Firstly, the practical risk of infection of local inhabitants; and secondly, the social aversion to the constant presence of invalids. The supposed liability to infection is probably the more potent influence of the two, but when tested by the facts of death-rate statistics, the evidence affords no confirmation of the supposition. In many health resorts, such as Ventnor and Bournemouth, where consumptive persons have congregated for many years, there is absolutely no evidence forthcoming to show that their disease has been communicated to those among whom they have lived. Instances are probably known to every one where one member of a family has alone been affected by tuberculous disease, although living in close association with others. Such cases are indeed far more common than instances of the converse. It has needed a good deal of careful research to bring to light the well-authenticated cases of direct infection in the family circle. The risk to immediate associates being so small, it follows that the actual risk to the community, living under other roofs, is really infinitesimal. The means by which bacilli may be conveyed are now so well known and so easily controlled that the danger of infection is reduced to the common minimum. Although the tubercle bacillus has occasionally been detected in other excreta, every one knows that it is by way of the sputum that infection is most likely to be spread. Already the habit of public spitting has been greatly diminished, and consumptive persons have been educated so to dispose of their sputum as to prevent its diffusion. There remains, however, the social objection, and that also is apt to be greatly exaggerated. In most sanatoriums the patients are in the earlier stages, and present hardly any distressing features. The advanced case—the typical hectic consumptive of fiction—should have no place in a sanatorium, and, if such cases are eliminated, it is probable that few inmates of the sanatorium would be recognized as such at sight. It will be seen that objection has recently been taken to the use of a certain school in Surrey as a sanatorium for insured persons. The grounds of objection urged by the local authorities illustrate the objections often raised. Amongst other points, the possible contamination of a local milk supply is even hinted at. It is assumed that cows can be infected with the human

brilliant, but the fact is ignored that no such infection has ever been proved except by inoculation of enormous doses for experimental purposes. So far from the sanatorium being a danger to the dairy the fact ought to be recognized far and wide that a single cow with unrecognized tuberculous disease may yield infective milk which may be distributed daily to a whole community of children, and may set up those insidious changes in the glandular and alimentary systems which, although known by various names, are essentially tuberculous in origin. The presence of a sanatorium in such a district would lead to the discovery of a danger of this kind, and thereby confer a benefit which would far outweigh the small risk which might arise from the carelessness of an insubordinate patient. In most sanatoriums the neglect of precaution on the part of a patient leads to immediate dismissal, and thus even that slight risk is soon removed. The public places of a country town where spitting may proceed unchecked are, indeed, far more dangerous than the vicinity of a sanatorium. In Australia and in many other countries the general public are better informed on these matters than they are in country places in England. Frankly, we are behind-hand in the organization of our antituberculosis campaign, and it is time that prejudice should give place to knowledge and common sense.

MIRABEAU AN ABNORMAL INFANT.

MIRABEAU—the great Mirabeau, Honoré-Gabriel Riquetti, who had so strong an attraction for Carlyle¹ that the latter called him "world-compeller and ruler over men," and made him, so to say, the hero of his *French Revolution* (if that marvellous work can be said to have had a hero)—Mirabeau was almost, if not entirely, a monstrosity at birth. Carlyle, in one of the finest of his Essays,² that in which he reviews the eight volumes of *Mémoires biographiques, littéraires, et politiques de Mirabeau*, gives some hint of the abnormalities of this "heir of all the Riquettis" at his birth. "A magnificent, 'enormous' fellow, as the gossips had to admit, almost with terror; the head especially great; 'two grinders' in it already shot!—rough-hewn truly, yet with bulk, with limbs, vigour bidding fair to do honour to the line." S. G. Tallentyre,³ in his much more recent *Life of Mirabeau*, gives further details of this momentous birth. "Then, in 1749," he writes, "there appeared with a twisted foot, a gigantic head with two teeth already cut, tongue-tied, monstrous and hideous, not merely the greatest of Mirabeaus but one of the greatest of the sons of France. The creature was so extraordinary that the Marquis had to be warned and prepared for his first introduction to him." Carlyle, with his genius for restoring past scenes, says: "The paternal Marquis, to whom they said, 'N'ayez pas peur, Don't be frightened,' gazed joyful, we can fancy, and not fearful, on this product of his; the stiff pedant features relaxing into a veritable smile." He, whom Carlyle calls "the paternal Marquis," was Victor Riquetti, the representative of an old Florentine family which flourished about Dante's time in North Italy and later in Provence. Many notables had sprung from this line: it was a fine eugenic stock; they were "the Well-born of the World," says Carlyle, and yet here was a most abnormal baby, a most dysgenic result. Such babies are born now and again, and are labelled cases of multiple malformations in the newborn, or are more specifically called fetal rickets; but how comes a Riquetti to be rickety? The writer of Victor's life in the *Biographie universelle*⁴ hints that this "Friend of Men" (*L'Ami des hommes*), as he was called, had by his debauchery several times compromised the health of his wife (Marie-

Geneviève de Vassan). Antenatal pathology may well have been at work here, poisoning the blue blood of the Riquettis and de Vassans, and leading to this teratological phenomenon in the family annals. Carlyle must have been very far out when he imagined the Marquis Mirabeau looking down joyfully on this product of his; it may have been sorrowfully or shamefacedly, it could hardly have been joyfully, unless indeed he was able to read far into the future, and see that strange "sprawling oaf" with the destinies of France in his hand, the one man capable, had he lived, of chaining the titanic forces of that world-shaking event, the French Revolution. But he was not to live, but to die at the age of 42. Looking out through the window on that last morning of his full-filled but short life, he hailed the sun: "If that there be not God, he is at least his cousin-german," cried he. He was a prodigy at his birth, and he remained prodigious, gigantic, world-compelling, all the days of the years of his life.

LEPROSY AND GOATS.

THE evidence in favour of regarding goats as a source of leprosy in man has lately been collected by Dr. P. Engelbreth,¹ who holds that leprosy is not transmitted from man to man. The strict isolation of lepers in ancient days and in the Middle Ages, he asserts, did not cause an appreciable reduction of the disease. It spread rapidly, and, though isolation was maintained with equal strictness in England, Central and Southern Europe, the disease disappeared only in the two former areas. Further, it does not increase in such countries as Egypt, where isolation is not enforced, while it appears in places where it has previously been unknown. Out of 512 marriages, of which records were obtained, leprosy subsequently developed in the healthy mate of a leper in 17 cases only. The presumptive evidence of the existence of an intermediate host is therefore strong, and for the following reasons Dr. Engelbreth suspects the goat of acting this part. Leprosy is a disease of mountainous countries where the goat is bred. In ancient times, Egypt, Arabia, Asia Minor and India were centres of leprosy and goat breeding. Both goats and leprosy were imported from Asia Minor into Greece, whence they were simultaneously transmitted to Italy and Spain. In the time of Charlemagne, goats were far more numerous than cattle and sheep; but in the sixteenth and seventeenth centuries, goats were largely ousted by sheep, whose wool rose in value. As goats became scarce, leprosy began to disappear. This coincidence was, he says, most striking in Denmark, where, about the year 1400, flocks of 50 to 200 goats were kept on every farm, and where there were twenty leper hospitals. Owing to their ravages on the woods, goats were expelled in 1473 from Fyen by Christian I. In 1541 a war of extermination was waged against them throughout the country, and fourteen years later, Christian III was able to abolish all the leper hospitals, and Dr. Engelbreth estimates that fourteen years is the average term of a leper's life. Norway, however, has kept both her goats and her lepers, and in 1848 there were over 2,000 lepers and about 500,000 goats. Now, the tale of goats has been halved, and that of the lepers has been reduced to 200. All the countries in which leprosy still exists are also goat-breeding countries; and in America, where leprosy was unknown before Columbus, the distribution of leprosy corresponds with the prevalence of goats. The parts colonized by the Spaniards, the Portuguese, and negroes have both goats and lepers; while the northern states, which were colonized by the English, possess neither. In a paper published by Heriba in 1912, two forms of tuberculous disease in the goat have been described. The one is identical with bovine tuberculosis; the other is totally different, and is characterized by greyish-yellow, firm, but

not caseous, nodules in the internal organs. These nodules closely resemble those found in the internal organs of lepers. Whether the infection is carried from goat to man by the finger-nails of the person who tends the infected goat, or by the milk, Dr. Engelbreth does not pretend to decide; but he thinks that much may depend on the extent of the disease in the goat, and on the opportunities for contact with man. He suggests that lepers may again transmit their disease to goats, and, if this be so, the isolation of the former may yet be of use. But he attaches more importance to a campaign against infected goats by diagnostic injections of tuberculin, which causes a reaction in lepers as well as in the tuberculous. He further suggests that a tuberculin prepared from infected goats should be given to the surviving lepers, whose numbers he computes at 300,000, as he believes that in this way a speedy extinction of leprosy would be brought about.

EARTH-EATING.

THAT mine of curious information, *Notes and Queries*,¹ whose vitality has not been diminished by the loss of the services of its distinguished editor, the late Mr. Joseph Knight, has been publishing lately a series of letters bearing upon the subject of earth-eating, and has elicited some new, and brought forward some old, facts regarding this strange practice. A query as to earth-eating among Swedish tribes started the discussion, and although to it no direct answer has yet been forthcoming, some information has come in regarding geophagy in several other countries—in the Sudan, for instance, and in India, China, the Malay Archipelago, and elsewhere. Curiously enough, the nearest answer to the original query about Sweden has come from Japan, the correspondent pointing out that Bennett and Murray (*Handbook of Cryptogamic Botany*) state that "in some countries, such as China, Japan, Siberia, Lapland, etc., they [the fossilized siliceous shells of diatoms] form, cemented together by salts of lime, the edible earths which are mixed with meal to make a kind of flour." Probably it was the allusion to Lapland in this quotation which had been lingering in the mind of the querist who raised the subject. Several replies touch upon earth-eating in times of scarcity; there is, for example, the statement that the Japanese Ainus used to eat a paste made of a mixture of diatomaceous earth and starch in famine years; and another correspondent tells of a native he met in North India who ate a mixture of clay and black ants, and found it pleasant on account of the formic acid in it. The Indians of Guatemala eat a yellowish edible earth containing sulphur, taking it not simply as a food, but also as a prophylactic against disease. Is this, we wonder, the old superstition of the sulphur ball for rheumatism cropping up in Guatemala? The practice of geophagy seems to be particularly common in the islands of the Malay Archipelago; the earth eaten there consists of bituminous clay, is called *ampo*, and is offered for sale in the markets of Java and other places. It is stated that "women in delicate health eat sometimes *ampo* because it is supposed to benefit their babies yet unborn." The practice just referred to may have some connexion with what has been called the perverted appetite (or pica) of pregnant women, and it is just possible that this desire for earthly materials may represent a real physiological outcry by the tissues of the mother or fetus (or of both) for some mineral constituent lacking in the foeto-maternal economy. The dirt-eating of children has probably another origin, and a fatal case of earth-eating was published in this JOURNAL in 1884 (vol. i, p. 994). If some of the correspondents to *Notes and Queries* can lay their hands on the *Index-Catalogue of the Library of the Surgeon-General's Office of the U. S. Army*,

they will find there under "Appetite, abnormal," a number of references to articles in medical journals bearing on the subject of geophagy as a disease.

APPLIED SCIENCE IN MEDICINE.

AT the first meeting for this year of the Académie de Médecine in Paris, the retiring president, M. Gariel, Professor of Medical Physics in the Faculty of Medicine, inducted his successor, the veteran Professor Chauveau, who gave a short address, which, though slight in texture, yet touched on a subject of far-reaching importance. He said that he and his predecessor both belonged to the category of workers engaged in the discovery and codification of the laws which govern the phenomena of life, and it was, he said, proper that the presidential sceptre should pass next year into the hands of the newly elected Vice-President, M. Perier, Surgeon to the Paris Hospitals, who was one of those charged with the duty of preventing or combating disease by the practical application of the laws made and codified in the laboratory and the study. M. Chauveau pointed out that when an occasion arose to apply the discoveries of pure science to practical medicine, it was important always to recognize the position which medicine should take and the share that it should have in the interpretation of results. As an example he quoted the application of the Roentgen rays in diagnosis and treatment. There had been, he said, a controversy between the faculties of science and medicine in Paris as to which should give instruction in this subject. He had been reproached by some scientists *pur sang* for siding with the faculty of medicine. "How is it," he was asked, "that you are siding with the doctors and opposing science?" His answer may be taken to heart in this country also. "I side with the doctors," he said, "in order that I may be on the side of science; with reference to the constitution, the mechanism and the functions of the tissues of the organism, whether normal or pathological, they alone possess the scientific ideas which are the indispensable guides of the observer who would interpret the organic troubles which examinations with the x rays are capable of revealing." It is, as M. Chauveau went on to say, curious to find this prejudice expressed at the present day. There was a time when practitioners of medicine were almost the only serious students of biology. Medicine did not at first share fully in the growth of the application of the experimental method which took place during the final third of the nineteenth century; pathology remained almost exclusively observational, and even in physiology the experimental method was comparatively little applied. With the rapid application of experiment to the study of physiology, and with the extraordinary impetus given to pathology by the development of bacteriology, the conditions changed. But a new danger arose—the divorce of medicine from the sciences which it had caused to spring into life. It was seen some years ago in the attitude of the professed physiologist, and in the academic manner of teaching the elements of the subject to medical students. It is still to be detected among laboratory workers, but it is being steadily modified through the influence of many of the leaders among the physiologists and biologists, especially, we would venture to think, in this country, where so much physiological and pathological work of the highest kind is being done.

AN UNFORTUNATE OBSTETRIC METAPHOR.

It will be remembered that shortly after King Henry VII came to the throne of England he had no small trouble with the pretenders, Lambert Simnel and Perkin Warbeck, who were doubtless favoured greatly by the Lady Margaret of Flanders, widow of Charles the Bold of Burgundy and sister of the late Edward IV. "The Lady

¹ *Notes and Queries*. Eleventh series, vol. vi, pp. 290, 351, 397, 514, 1912.

Margaret," wrote Lord Bacon,¹ "was called by the king's friends Juno, because she was to him as Juno was to Aeneas, stirring both heaven and hell to do him mischief." In 1492 the Perkin Warbeck conspiracy was beginning to look serious, and, although the Treaty of Etaples closed France against the lad, who was, to quote Bacon again, "a finer counterfeit stone than Lambert Simnel, better done and worn upon greater hands," it did not prevent him being received at the Court of Margaret; that lady, indeed, openly acknowledged him as her nephew, and gave out that he was Richard, Duke of York. Henry was well aware of the danger he was running, and, having discovered the true name and origin of Warbeck, he sent ambassadors to the Archduke Philip's Council in Flanders to try to persuade that body to bring pressure to bear on the Lady Margaret and have the pretender expelled. The ambassadors were Sir Edward Poyning and Dr. William Warham (afterwards Archbishop of Canterbury),² and the latter is said to have made a "remarkably telling speech." The remonstrance, however, was fruitless; and after reading Dr. Warham's remarks, as preserved for us by Lord Bacon, this result is not altogether surprising. Alluding to the countenance given by Margaret of Flanders to the two pretenders, he said: "To speak plainly to your lordships, it is the strangest thing in the world, that the Lady Margaret—excuse us if we name her—whose malice to the king is both causeless and endless, should now when she is old, at the time when other women give over childbearing, bring forth two such monsters; being not the births of nine or ten months, but of many years; and whereas other natural mothers bring forth children weak and not able to help themselves, she bringeth forth tall striplings, able soon after their coming into the world to bid battle to mighty kings." There can be little doubt that this laboured metaphor and coarse witticism produced an effect upon the Archduke's Council not very dissimilar from that which Philip of France's obstetric gibe about corpulence had upon William the Conqueror; at any rate the Council replied that the duchess dowager (Margaret) was absolute in the lands of her dowry, and Perkin Warbeck continued to trouble the throne of England for some years longer.

THE UNIVERSITY OF CALIFORNIA.

THE University of California has its principal seat at Berkeley, on the east coast of San Francisco Bay, about nine miles from the city. Hitherto the teaching in the Medical Faculty has been divided between Berkeley and San Francisco—atomy, pathology, and bacteriology being taught in the former place. Rather more than a year ago the committee on medical instruction recommended that the departments of the medical school at Berkeley and San Francisco should be brought together in the latter city, that the clinical years should be put upon an academic basis, and that a teaching hospital and a laboratory should be provided, so that the medical school could attain the highest standard. Last April the Medical Faculty decided that clinical instruction should be carried out in three main departments: First, gynaecology and obstetrics, which was to be put upon an academic basis at once, with full salaries for a professor and an assistant. Secondly, medicine, including pediatrics, neurology, and dermatology; this department³ cannot as yet be put upon a full academic basis, but a sum of about £600 has been set aside for the payment of assistants for the current year. The third main department will be surgery, including orthopaedics, urology, ophthalmology, rhinology, otology, and laryngology; the money available being insufficient to put the department on a full academic basis, a sum of about £350 has been set aside to pay three assistants. The work of the hospital pathologist was reorganized, and an additional assistant professor of

pathology at a salary of £500 a year appointed. A sum of about £250 was assigned for work in radiography. The proposals to provide a new university hospital have gone so far that plans have been prepared for four units of forty to fifty beds each for surgery, medicine, diseases of women, and diseases of children respectively. About £70,000 has already been given by private individuals to build and equip the departments of medicine and children's diseases. Meanwhile, alterations will be made in the existing hospital to accommodate the clinics, and clinical and pathological laboratories will be equipped.

COLLOIDAL COPPER IN THE TREATMENT OF CANCER.

DRS. LOEB, McCLURG, AND SWEEK contribute to an American journal⁴ a report based on the recent work of Wassermann on the effects of intravenous injections of selenium and eosin on mice. They claim good results from the injection of a colloidal solution of copper in cases of ulcerated cancer in man. They first tested the effect of various copper preparations on mouse carcinoma, and then applied the method to man, using a colloidal solution of copper prepared according to Bredig's method. Each patient received daily an intravenous injection of from 300 to 400 c.c.m. of the solution warmed to about the normal temperature of the blood and introduced slowly into the vein. Usually injections were given every week, and were always followed by a temporary rise of temperature. The tumour became hyperaemic and sensitive in a few hours, and the discharge from any ulcerated part increased, but after about fifteen injections both these symptoms disappeared and distinct retrogression of the tumour became noticeable. This retrogression seemed continuous. Eight cases in which carcinoma had developed in different parts of the body are reported. The authors of the paper urge that their treatment seems effective in causing the retrogression of various kinds of cancer which have till now withstood other modes of treatment. They admit that a definite judgement on the ultimate outcome must be suspended. Like other observers, they point out that mouse cancer is an extremely malignant disease, and if controllable by agents introduced into the blood carriers, as seems to be the case, it may be hoped that carcinoma in man may be yet more effectively controlled by similar means.

AUSTRALASIAN MEDICAL CONGRESS IN NEW ZEALAND.

AT the annual general meeting of the British Medical Association at Liverpool Dr. Barrett of Melbourne, addressing the members present, gave a cordial invitation to them to attend the tenth session of the Australasian Medical Congress which is to be held at Auckland, New Zealand, on February 9th to 14th, 1914. A letter has now been received from Dr. Bernard J. Dudley, of Auckland, honorary secretary, written on behalf of the Executive Committee of the Congress, confirming the invitation. It is expected that many representatives from all parts of Australia will be present, and they would be delighted to welcome colleagues from Great Britain. A large Dominion Exhibition, which will give visitors exceptional opportunities of viewing the resources of New Zealand, will be open in Auckland at that time. After the congress facilities will be afforded to visit some of the famous thermal wonders and scenic beauties of the Dominion. It is expected that special favourable arrangements will be made with the various shipping companies for members who may be able to visit New Zealand on this occasion.

At the instance of the President-elect, the Council, at its meeting on Wednesday, decided to add to the Sections to be held at the Annual Meeting of the British Medical Association at Brighton next July a Section of Balneology and Climatology.

"APPENDICITIS—a Plea for Immediate Operation" is the title of a paper Mr. Edmund Owen will read at the Medical Society of London on Monday evening, February 10th. Among those who have expressed their desire to take part in the discussion which will follow are Mr. W. H. Battle, Sir George Beatson, Mr. C. P. Childe, Mr. Connell (Sheffield), and Mr. Grey Turner (Newcastle-on-Tyne). The secretaries will be pleased to receive the names of others desirous of taking part in the discussion.

The Royal Statistical Society has appointed a committee, with Dr. Reginald Dudfield as chairman, to report on the available statistics of morbidity and mortality in the United Kingdom. It is believed that many valuable collections made by hospitals and institutions may be unknown to the society, and the chairman appeals to the authorities of such institutions to communicate any collected data, published or otherwise. The information may be addressed to him at the Royal Statistical Society, 9, Adelphi Terrace, Strand, London, W.C.

DR. J. W. W. STEPHENS, Walter Myers Lecturer in Tropical Medicine in the School of Tropical Medicine in the University of Liverpool, has been appointed to the Sir Alfred Jones chair of tropical medicine in succession to Sir Ronald Ross. Dr. Stephens, who has been associated in the teaching work of the school for ten years, graduated M.D. of the University of Cambridge in 1898, and at one time held the John Lucas Walker studentship of pathology of that university. In 1897 he was appointed assistant bacteriologist to the Government of India, and was subsequently a member of the Royal Society's Malaria Commission in Africa and India.

Medical Notes in Parliament.

Workmen's Compensation Act Regulations.—Mr. Steel-Maitland asked the Home Secretary, on January 22nd, with regard to the fact that in cases of appeal under Section 8 of the Workmen's Compensation Act, 1906, the present Regulations did not state whether the worker possessed a right to have his medical attendant present at the examination by the medical referee, whether he was notified of the right; and whether such modifications could be made in the Regulations as to establish such a right and to provide for the worker being notified of its existence.—Mr. McKenna said that the Regulations gave both workman and employer the right to make any oral statements, or to submit any written statements, to the referee; and this included a written statement by the workman's or employer's doctor, but they did not give either party the right to have his doctor present at the examination. The question of giving such a right was carefully considered when the Regulations were framed in 1907, and it was decided that it would be undesirable to do so. He was not aware of any sufficient ground for making a change in the Regulations on this point. He added that it was open to the referee, if he thought it desirable, to allow the doctors to be present and to question them, and that was, he believed, sometimes done.

Lead Poisoning.—Mr. Steel-Maitland questioned the Home Secretary, on January 22nd, with reference to a case in which a girl had been certified by four doctors to be suffering from lead poisoning, but the medical referee on appeal pronounced against her claim.—Mr. McKenna said that the case had been brought to his notice in November last, when it was stated that the girl and her mother complained that the referee had made only a perfunctory examination. The medical referee had stated that he had very carefully examined the girl, and his detailed report on the case corroborated that statement. The medical referees were men of high standing in their profession

and very carefully selected, and he did not think that there was any negligence on the part of the referee in the ease referred to in carrying out his duties.

Calf Vaccine Lymph.—In reply to Mr. Sutton, the President of the Local Government Board, on January 22nd, said that all calves which were used for the production of lymph were slaughtered and then examined by the Board's veterinary surgeon, and the lymph from any animals not certified to be healthy was destroyed. The carcasses of the animals were also subject to veterinary inspection by the officers of the Corporation of the City of London, and dealt with in accordance with its strict regulations. Any carcasses which were certified as unfit for human consumption were destroyed.

Scottish Universities.—In reply to Mr. Pirie and Sir Henry Craik, the Financial Secretary to the Treasury said that he hoped to lay the correspondence between the Treasury and the Scottish Universities upon the table during the week. The Treasury had made the stipulation that payment in full of the additional grants would be made only on the institution of inclusive fees in all four Scottish universities, and on the footing that all fees should be uniform. The correspondence would show the present position with regard to the institution of such inclusive fees by the universities.

East Africa Protectorate.—In reply to Mr. Crawshaw-Williams, the Secretary of State for the Colonies stated, on January 15th, that the question of the sanitation, not only of Nairobi but of the East Africa Protectorate generally, had been recently before him, and he was considering, in consultation with the Governor and his expert advisers, the best method of improving the present state of affairs.

Board of Trade Medical Staff.—Mr. Peto asked the President of the Board of Trade, on January 27th, whether the present medical staff of the Board of Trade was so inadequate that its duties were almost wholly confined to the inspection of emigrants travelling on emigrant-carrying ships; and, if so, what action he proposed to take in the matter.—Mr. Buxton said that the medical officers of the Board of Trade were appointed to perform certain specific duties under the Merchant Shipping Acts, including the inspection of emigrants. He had no reason to think that the staff was inadequate to perform those particular duties.

Colour Blindness.—Mr. Cathcart Wason asked the President of the Board of Trade, on January 27th, if he was assured that the classification of colour blindness by the Departmental Committee of the Board of Trade was satisfactory, or if he proposed to take any steps to modify it.—Mr. Buxton replied that, as at present advised, he did not propose to take any steps to modify the method of classification of colour-blind persons adopted by the Departmental Committee, which was only one of several methods used by the appeal examiners. The Committee recognized in its report that the method had had only a short trial, and expressed the opinion that the final decision as to whether, in a given case, colour deficiency was so great as to involve incompetency ought to remain with the appeal examiners.

Highlands and Islands Committee.—The Prime Minister on January 23rd, said he could not say approximately at what time the Government's intention with regard to the report of the Highlands and Islands Committee would be stated; and in reply to a further inquiry by Mr. Cathcart Wason (Orkney and Shetland), on January 27th, Mr. Masterman would not go further than say that he hoped to make a statement shortly. An attempt to extract information by a question addressed to the Prime Minister, on January 28th, as to the supplementary estimates, also failed to elicit any definite reply.

Mental Deficiency Bill.—In reply to Mr. Alan Sykes, the Prime Minister renewed his promise that the Mental Deficiency Bill should be introduced early next session.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE CHAIR OF BACTERIOLOGY IN EDINBURGH.

EDINBURGH University has waited long and patiently for its professor of bacteriology. He is in sight at last—at least his chair is. A White Paper issued on January 21st contained an ordinance of the Court of the University providing for a professorship to be called the "Robert Irvine Chair of Bacteriology"; the professor is to belong to the Faculties of Medicine and Science, and his salary is to be the annual free income of the £25,000 which constitutes the Robert Irvine endowment. The late Mr. Robert Irvine, of Royston, Granton, near Edinburgh, left estate to accumulate till it reached the sum of £25,000 or £30,000, for the purpose of founding this professorship and of furnishing the equipment of a class-room and laboratory. The money is now available. Mr. Irvine was a Fellow of the Chemical Society and of the Royal Society of Edinburgh, and contributed in collaboration with Sir John Murray papers to the latter society on blue muds on the floor of the ocean, and on manganese oxides and manganese nodules in marine deposits; to him also the same society awarded the Neill Prize in 1895 for his papers on the action of organisms in the secretion of carbonate of lime and silica, and on the solution of these substances in organic juices. Local medical opinion has already settled who the first occupant of the Robert Irvine Chair of Bacteriology is to be.

TWO MEDICAL PROBLEMS.

Emeritus Professor Crum Brown presided over the annual meeting of the Edinburgh Medical Missionary Society at the Edinburgh Café on January 23rd. The ordinary business was transacted and the financial statement made, and thereafter Dr. Prentice of Livingstonia and Dr. D. D. Muir of Manchuria, both of them former students of the society, gave addresses. In each address a pressing medico-political problem was alluded to. Dr. Prentice spoke of South Africa as the land of insect-borne diseases, and gave a graphic account, not unmixed with dry humour, of the numerous ticks and their insinuating ways; but he spoke more gravely of *Glossina palpalis* and *morsitans* in their relation to sleeping sickness and the protection of the wild game. He expressed his conviction that the antelope served as reservoirs for trypanosome infection. Dr. Muir gave his experience of the attempts being made in Manchuria to stamp out opium-smoking. Whereas some years ago medical missions had to deal with numbers of cases of suicide due to the drug; when he left China they were scarcely meeting with one. The Chinese police, he said, were in earnest about tracking down the vendors of the opium. The last case of attempted suicide from opium which he had seen before leaving Mukden had been brought into the hospital by two Chinese policemen; and the two representatives of the law managed by clever and persistent cross-questioning to find out from the man (not, perhaps, in the clearest state of mind to defy their inquisition) from whom he had bought the drug. Three years ago it was common in travelling through the land to see many fields with crops of the opium poppy and to witness the women going up and down making incisions and collecting the juice; when he left none of these things were to be seen. Dr. Muir also spoke of the 142 Chinese candidates who appeared for the preliminary examination in medicine at the Mukden Medical College, and of the dismay of the examiners, whose duty it was to read the more than seven hundred examination papers (in Chinese) which resulted therefrom. About fifty students had passed, and were doing well at the college.

MEDICAL SERVICE IN THE HIGHLANDS.

The Committee of Management of the Highlands and Islands Approved Society have sent to Mr. Lloyd George a memorial with reference to medical service in the Highlands. It is pointed out that the memorialists represent a society which was formed as the outcome of appeals made by the Scottish Commissioners to the Supreme Courts of the Presbyterian Churches in Scotland,

asking their assistance in administering the Insurance Act in the poorer and remote parts of the Highlands. After conference among representatives of the churches, drawn from their Highland Committees, it was deemed best to form an approved society. The memorialists, as honorary members, are managing the society until the first annual meeting, and express their satisfaction with the report of the Committee of Inquiry on Medical Service in the Highlands and Islands. They hail the proposals of the report as an earnest of sorely-needed reform, and point out that the large contribution which the Highlander makes to the personnel of the Empire demands medical care not merely for men and women of insurable age, but also for school children and infants. Local resources are admitted to be inadequate. The economic conditions of certain portions of the Highland area call for generous treatment by the Treasury, which treatment should include special consideration of educational questions, and particularly of medical inspection and treatment of school children. The memorialists express the hope that the recommendations of the report will be ungrudgingly endorsed by the Treasury and at once adopted by Parliament.

At a meeting of the Executive Committee of the Queen Victoria's Jubilee Institute for Nurses, held at the central office, Edinburgh, the following resolution was adopted:

That in view of the terms of the report of the Highlands and Islands Medical Service Committee and of the expression of approval of the work done by Queen's nurses in the Highlands and Islands, following on similar expressions in the reports of the Departmental Committee of the Local Government Board for Scotland (1904), and of the Royal Commission on the Poor Laws and Relief of Distress (1909), the Executive Committee of the Scottish Branch of Queen Victoria's Jubilee Institute for Nurses urges that the claims of these nurses may be recognized in the allocation of any Government grant towards the support of medical service in the Highlands; that copies of the above resolution be forwarded to the Chancellor of the Exchequer, the Secretary for Scotland, and to the Chairman of the National Health Insurance Commission for Scotland.

JOINT SANATORIUM FOR FORFARSHIRE.

At a conference held on January 24th in Dundee to discuss the question of co-operating in regard to the provision of one large sanatorium suitable for the needs of the county of Forfar, the Dundee Public Health Committee, the county council, and all the burghs throughout Forfarshire were represented. The convener of the Dundee Health Committee, who presided, said that they believed it would be to the advantage of the county to co-operate with Dundee in a large scheme in which cheaper management was possible. Dundee would be responsible for the building and management of the sanatorium, and the county council would be required to guarantee a certain number of beds. The arrangement would be for sanatorium treatment only, for the advanced cases the outside districts would have to make their own provision. During the discussion which ensued, Dr. Templeman (Dundee) pointed out in reply to a question, that it was impossible to give the cost per patient to be charged by Dundee, as the capital expenditure that might be involved was not yet known. The Lord Provost said that negotiations had been opened with the directors of the Royal Infirmary for the purchase of the Sidlaw Sanatorium at Auchterhouse; it would be the most suitable and probably the least expensive. The feeling of the meeting was that it was expedient to co-operate with Dundee.

THE LATE DR. GEORGE A. GIBSON.

At the weekly meeting of the managers of the Edinburgh Royal Infirmary, on Monday, January 27th, Sir James Affleck moved the adoption of a minute recording their deep regret at the death of Dr. George Alexander Gibson, senior ordinary physician to the Royal Infirmary. The minute recalled the fact that it was through Dr. Gibson's instrumentality that a considerable sum of money was given by an anonymous donor to establish and equip a clinical laboratory within the infirmary in which various modern scientific appliances could be utilized for the more accurate investigation of disease. The minute was approved.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

ROYAL COLLEGE OF SURGEONS.

THE Charter Day dinner of the Royal College of Surgeons in Ireland will take place on Saturday, February 1st, at 8 p.m. A meeting of the College will be held immediately before the dinner for the purpose of conferring the Honorary Fellowship on Surgeon-General Sir Launcelot Gubbins, K.C.B., Director-General Army Medical Service, and Sir Berkeley Moynihan, F.R.C.S. The Lord Lieutenant has accepted the invitation of the President and Fellows to be present at the dinner.

RESEARCH DEFENCE SOCIETY.

At the fourth annual general meeting of the Dublin branch of the Research Defence Society, held in the Theatre of the Royal Dublin Society, Dr. Sims Woodhead, Professor of Pathology in the University of Cambridge, delivered a lecture entitled "Experimental Research and its Bearings on Modern Medicine." At the outset he spoke of the necessity there was for making it perfectly clear that experiments on living animals were carried out only under a full sense of what those who were making the experiments owed to their subjects. Between the time of Galen and Harvey knowledge of the conditions under which the blood circulated through the body had made little or no advance, in spite of the fact that anatomists had begun to make dissections of the human body. The whole history of inflammation, of specific infectious diseases of various types, of the action of drugs, of the healing of tissues, of protective inoculations, of localization of function of the brain and spinal cord, of improved methods of diagnosis, had been modified, in fact, had been dependent upon those basal observations and researches made by Harvey and Bell. The real friend of both animals and man was he who, in his search for means of alleviating pain, was not cowardly enough to run away from the clear duty of using every legitimate means of gaining knowledge.

INFANT MORTALITY IN DUBLIN.

The Dean of St. Patrick's preached recently in the cathedral on infantile mortality in Dublin. He dwelt on two facts. The first was that in Dublin hundreds of infants died every year from preventable causes. The second was that the Dublin Corporation had taken definite action towards saving the lives of the children. He described the work that is being done in Dublin by the committee of voluntary helpers who are trying to save the lives of young children by giving them a chance to survive the dangers of unprotected infancy. The first duty was the education of the poor regarding the rearing of children; no money was given to the mothers by the visitors, but all health visitors had books of dinner tickets, which they distributed in necessitous cases. The importance of breast feeding was urged on the mothers, and free pure milk was supplied to those who were unable to nurse their infants. The dean pointed out that these health visitors, numbering over a hundred, were nearly all working women, shopkeepers, shop assistants, and working girls, who, after their hard day's work, gave their leisure, short though it were, to save children's lives. They had to attend lectures and pass an examination before they were allowed to undertake the work. He concluded by an earnest appeal for funds in order to assist in the continuance of the work.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

LONDON.

STAFFS OF INSTITUTIONS AND MEDICAL BENEFIT.

THE Finance Committee of the Metropolitan Asylums Board on January 25th reported as to the arrangements to be made for medical benefit of the insured members of the staff, comprising some 1,800 persons, of whom 1,750 were women, practically all being entitled to residential emoluments. In the case of the non-resident staff, the Committee said there was no reason why they should not proceed as ordinary insured persons, selecting their

medical attendant from the panel or otherwise conforming with the regulations. The case of the resident insured staff, however, was different. Under the regulations any or all of the medical men on the local panel might be chosen by different individuals of the resident staff of any institution. This could hardly fail to give rise to difficulties, even if the managers were willing to allow outside doctors free access to their institutions. The medical superintendents of the Board's London hospitals were unanimous as to the impracticability of such a position. The Board's medical officers were required to attend sick members of the resident staff, although the staff could not demand treatment as a right. In view of the serious considerations of administration and discipline, and the questions of medical responsibility involved, informal inquiries were made of the Insurance Commissioners who advised that the Board should communicate with the Insurance Committees for the areas concerned with a view to their allowing the resident insured staff collectively, in lieu of receiving medical benefit under arrangements made by the Committees, to take their medical benefit direct from the Board. The Board would guarantee treatment, medicines, etc., practically on the lines voluntarily followed heretofore, some modifications in the matter of records being made, and the Board would be entitled to claim from the Insurance Committees in respect of this service. While individual employees were under no obligation to accept this proposal, the Committee expressed the hope that they would all do so.

LOCAL OBJECTIONS TO A TUBERCULOSIS SANATORIUM.

The arrangements are now almost completed for the reception at the Downs School, Sutton, Surrey, of tuberculous persons entitled to sanatorium benefit. The nature of the agreement entered into by the Metropolitan Asylums Board with the London County Council have already been reported, but objection was raised by a deputation from the Sutton Urban Council to the Metropolitan Asylums Board on January 25th. Dr. G. H. J. Hooper, who was the spokesman of the deputation, said that to the south of the Downs school there was some small property, and immediately opposite an elementary school. On the north side was a large eligible building property. The people interested in the development of this property and those living in the vicinity were horrified at the idea that these poor patients should be treated at the school. Near the building was a farm from which a large number of residents were supplied with milk. He did not regard a building intended for the accommodation of 600 girls as suitable for a sanatorium for 300 patients. The consumptives could not be kept within the four walls of the Downs estate; they must have exercise, and would be found walking over the downs and in the streets of Sutton. That involved a danger to the inhabitants; it might be replied that the patients would be supplied with the necessary utensils, but would they use them? The inhabitants knew they could not object to having institutions built in their midst, but there were questions of risk and also of sentiment involved. He did not think the Downs school, from its exposed situation, was suitable for a sanatorium, and that a more suitable place could be found without injuring a prosperous residential town. Sir Edward White, a member of the Board, pointed out that the Brompton Hospital was in the midst of a purely residential neighbourhood, and that the patients could be seen from the road taking exercise in the grounds. Dr. Hooper replied that patients were only kept at Brompton Hospital until they could be sent to a more suitable place. The Chairman (Mr. W. Dennis) said, in reply, that it would not be fair that the deputation should go away under the impression that the arrangements to which it objected could be completely abandoned, after having received the approval of all the authorities and Government departments concerned. These arrangements would only obtain until March, 1914, though he could not promise that they would not be extended. Neither could he say whether it would be possible to keep the patients within the boundaries of the institution. He could assure the deputation that in arriving at its conclusion the Board had had advice which it thought thoroughly reliable and good. No discussion took place after the deputation had withdrawn. The Board approved the arrangements suggested.

PROPOSED MIDWIFERY SCHOOL IN WORKHOUSE WARDS.

The Wandsworth Board of Guardians, at their meeting on January 23rd, adopted a scheme embodying the establishment of a training school in midwifery for nurses at the lying-in wards at the workhouse. It is proposed, with the sanction of the Local Government Board, that eight senior probationers shall be allowed to enter on a fourth year of training, during six months of which they shall be taught midwifery, the remainder of the time being spent in the ordinary wards. They are to be paid £18 a year. No charge is to be made for the special training, but the probationers are to sign an undertaking to remain for the whole of the fourth year in the guardians' service. Dr. A. E. Dodson, the medical superintendent at St. James's Infirmary, is to undertake the teaching. The guardians, in agreeing to the proposal, decided to ask the Central Midwives Board to recognize the lying-in wards at the workhouse as a training school.

Correspondence.

THE POST-MORTEM EXAMINATION OF NAPOLEON.

SIR,—No one is more inclined to accept everything that Dr. Arnold Chaplin writes concerning the fatal illness of Napoleon as authoritative than myself; and yet his letter in your last issue, where he cites Surgeon Rutledge against our mutual friend, the pathologist Antommarchi, confirms me in my belief that the evidence produced in my Hunterian Lecture is convincing proof of the authenticity of the Napoleonic specimens which are now in the museum of the Royal College of Surgeons. The chief point which my opponents have to meet is: How was it possible for O'Meara to hand to Astley Cooper specimens which tally exactly with morbid appearances incidentally described by Antommarchi in his *post-mortem* report? They are specimens which could be obtained only from a case of chronic infection such as we have good reason for supposing Napoleon to have been the subject. Dr. Chaplin has overlooked that part of my evidence and addressed himself to the strictness of the watch over Napoleon's body. Surgeon Rutledge had a vigil by the corpse and the vessels containing the heart and stomach of over twenty-four hours; during that time Antommarchi stole Napoleon's mask, and, we may suppose, could, from his experience in Florence, have easily invented a manoeuvre to obtain anything else he desired.

I know that Dr. Chaplin agrees with me in regarding Antommarchi's account of the *post-mortem* appearances as by far the most complete and reliable document we now have; without it we should know nothing of Napoleon's disease, except that there was cancer of the stomach. Surgeon Rutledge's statement that he cut the liver out is in contradiction to every other account available to me, and no one knows better than Dr. Chaplin that every attempt to discredit Antommarchi's statements would receive the most ready encouragement from the Lowe party, to whom he owes Rutledge's statement. Antommarchi's account of the condition of the liver must stand; the clinical symptoms of Napoleon's case leave not a shadow of doubt that at one period there was an inflammatory disturbance of the diaphragm and of the liver.

There is also another aspect of Napoleon's case to which Dr. Chaplin has not done justice—the evidence that Napoleon's illness was of the nature of a recurrent fever accompanied by enlargement of the lymphoid tissues, and the fact that the specimens in the museum of the College of Surgeons show an enlargement or hyperplasia of a part of this system.

As I corrected the proofs of the above part of this letter I received a communication from Sir Alexander Russell Simpson which throws a welcome light on the manner in which the watch was kept over Napoleon's remains. Many must have come across the tradition that the rats of Longwood attacked the heart, which was preserved in a separate vessel. My friend, Mr. Mackellar, first told me of this tradition; I have also come across it in newspapers, but have hitherto failed to trace the account to any reliable source. Sir Alexander Simpson has kindly

allowed me to make the following extract from his letter:

When my uncle, Sir James Simpson, came back from a professional visit in Berwickshire, where he had met Dr. Arnott, he was full of what Arnott had been telling him of his time in St. Helena. What specially impressed him was that Dr. Arnott had charge of the heart and other things that had been removed at the autopsy for the following night. Afraid that some of the Napoleonic retainers might come in and carry off the vessel in which they had been put at the time of the dissection, he emptied them into his wash-hand basin, covered them up with water, and lay down to sleep with loaded pistols under his pillow. He slept lightly. Hearing a splashing sound he jumped up, expecting to see Bertrand or some one at the preparations, and found that it was only rats trying to get at the flesh. "Fancy rats trying to make away with Napoleon's heart!" said Sir James, in repeating the story.

This account corroborates Antommarchi's statement that Arnott was the officer on watch. Probably he relieved Rutledge. In my lecture I stated that these two men kept alternate watch; the point I wish to emphasize is that Arnott was predisposed towards Antommarchi.

I should like to take this opportunity of thanking—not only Dr. Chaplin, but the other correspondents who have sent me valuable information—Mr. Cyril H. Hawkins and Major F. S. Irvine. I wonder if any of your readers could help me in tracing those two parts of the mould of Napoleon's bust taken by Dr. Burton, who was a cousin of Graves, the famous physician of Dublin. The missing parts are: (1) The mould giving the impress of the back of the head and neck; (2) the front of the neck. They were, according to Graves, in the possession of Dr. Burton and may still be preserved by some of his descendants who have not realized their value. If they were recovered, an accurate cast of the head of the great Emperor could be obtained.—I am, etc.,

London, W.C., Jan. 27th.

A. KEITH.

RESEARCH DEFENCE SOCIETY.

SIR,—It is said that the fifth year in the life of any society is the critical period of its fortunes. The Research Defence Society was founded on January 27th, 1908. To all who are interested—and who is not?—in medical research, we beg you to let us say that the Society has its hands full of work, and only wants more money to do more work. Much has already been done, by lectures and by distribution of literature, to bring home to people the truth about experiments on animals in this country, and the great value of them, not only to mankind, but also to the animal world. The expenses of our society are heavy, but the good results of our work are extended far and wide. We have lately opened a bureau and exhibition at 171, Piccadilly (opposite Burlington House). We are exhibiting pictures, portraits, charts, anaesthetics and inhalers, germs in pure culture, tsetse flies and mosquitos, and so forth. This little exhibition, every day and all day long, displays to "the man in the street" the facts of the case. We are the only society which is doing work of this kind; but, of course, it cannot be done without money. Our record for the last four years gives us the right to hope for a great increase of our membership, and of our funds, in the coming year.—We are, etc.,

ANTIVIVISECTION IN GLASGOW.

SIR.—Dr. Hadwen repeats his statement, "Not one word about alcohol drinking or vaccination escaped my lips *the whole evening*" (the italics are mine). He then professes to quote what he now says he did say upon these subjects, with the reservation that they were said during the discussion, and not during the lecture. Dr. Charles Bennett, one of the gentlemen whose names I quoted in my last letter, was not present at the discussion, but left before the end of the lecture. He remembers, as do the rest of us, that Dr. Hadwen spoke at length on these subjects. My object in writing was to show that many of Dr. Hadwen's statements to you were incorrect. Besides

my own evidence as to this, I have been able to bring several reputable witnesses with regard to a positive matter of fact; and with regard to two other matters of fact. I sent you a copy of the report in the *Glasgow Herald* in order to verify my statements with regard to them, and to prove the inaccuracy of Dr. Hadwen's. As all the cards I care to play are on the table, I can do no more than leave you and your readers to judge as to who is accurate.—I am, etc.,

Glasgow, Jan. 25th.

CHARLES WALKER.

THE TREATMENT OF CANCER.

SIR.—Under this title you published a review on p. 121 of your issue of January 18th. Kindly allow me space in your pages to note one or two points in the review, and to correct one or two errors. You say that I "first invited a general trial" of the pancreatic enzymes without myself being "very clear as to how it (the method) should be applied." I never "invited" any trial at all. On your invitation I published in the *JOURNAL* (January 20th, 1906) a brief account of some preliminary experiments upon cancerous mice. That sufficed. At once, from all parts of Europe and America, but not from Great Britain, I was overwhelmed by requests from medical men either for preparations of ferments or for addresses where such could be obtained, or for general directions for the use of such preparations in cancer. To these I responded because I wished to help my fellow-men. How could I, or any one else, then, seven years ago, know how such preparations should be used to obtain the best results? Like Lord Lister's method of antiseptic surgery, or tuberculin, or salvarsan, much had to be learnt from actual experience of the method; and, moreover, the manufacturing chemists had to find out how to put up active, strong, and keeping injections of the ferments. In 1879 I often saw Professor Edward Lund and Mr. Sam Bradley perform major operations under Listerian methods as they then were. But if either of those departed surgeons could now witness a major operation, undoubtedly he would recognize little or nothing of the Listerian methods they employed. None the less, you would not venture to suggest that Lord Lister should have waited until his methods were made perfect before giving them to the world. Even his first attempts at antiseptic surgery yielded some instances of success; in the same way the very first preparations of trypsin and amylopsin made "for Dr. Beard," as the makers put it, in 1906 furnished a very few cures. I am hardly responsible for damage done by inert preparations.

The preparations of pancreatic ferments, to which I was obliged to refer medical men in 1906, for instance, had only *one-twentieth part of the potencies* of those I should name to-day, and the latter are put out by the same firm of specialists. Therefore, if Dr. Baetzner, who has just published a paper upon the treatment of surgical tuberculosis by means of trypsin,¹ had had to employ the trypsin of 1906, he would scarcely have got the brilliant results he has recorded. Moreover, any one using such a weak trypsin, or some of the useless, even inert, injections still on sale, would, if endeavouring to test Baetzner's finds, conclude, as so many have done after using weak or inert ferments in cancer, that the method was worthless and the author not what he will turn out to be, a very great surgeon. You refer to an "army officer," now in Burma, who cured 3 out of 4 cases of cancer treated by him. If my account of the treatment be puzzling, in his own words his own procedure is recorded in the book reviewed. But, although the book was published nearly fifteen months ago, and although preparations of pancreatic ferments, which appear to fulfil every scientific requirement, that is, the ones Dr. Baetzner employed, have been on sale in London since April, 1912, at this moment I do not know of a single case of cancer in this or any other country which has had a full course of treatment on the lines laid down by this army officer, with such powerful preparations, and in the doses he employs. Indeed, one might imagine cancer had ceased to be the curse of the human race, but for such facts as that only a day or two ago in the weekly summary of deaths it was stated that last week there were eleven deaths from malignant disease in this city. Probably it would not be too much to assert, that not one

of these cases was treated with pancreatic ferments after my methods.

In examining any scientific find, or supposed find, experimentally, nothing is easier than to get a negative result, especially if inert reagents be employed. But in the chemical experiment the observer must satisfy himself as to the true nature of his reagents, and, as the late Professor D. J. Cunningham once remarked to me, "Negative results never prove anything in science." There are many members of the medical profession still living and treating cases of cancer who had declared that the pancreatic ferments were "useless" or "futile" in cancer, and who had in good faith drawn this conclusion after using preparations which were inert, and without even knowing that they were inert. In fact, in the use of inert ferment preparations, in the lack of knowledge of the inert nature of their reagents, and in the erroneous conclusions drawn from such vitiated experiments these medical men agreed with the official researchers.

Any "disappointment" I may feel is in a recognition that mankind would rather die than believe the truth. I have never once spoken, or written, or even thought of "the greatness of his (my) achievement"; on the contrary, I have described the whole thing as merely a side-issue, which it is. Shortly now, for it is in the printer's hands, you will be given an opportunity of reading an account of a small piece of experimental work of mine. This does not deal directly with cancer, and its title is the very simple one, "On the Occurrence of Dextro-rotatory Albumins in Organic Nature." To use a phrase which in a similar connexion has been employed by a distinguished living investigator, in this small paper "*the unchallengeable proof*" is given, not only that dextro-rotatory albumins similar to those of cancer do occur in organic nature, but that they are widely represented. Incidentally, the paper confirms once more my statement, first made some years ago, that the cancer conclusions were merely a side-issue.

Possibly, as you say, "many workers . . . hold that his (my) views are entirely erroneous." If so, they are very careful to avoid pointing this out in places where a reply from me would also be published. Their silent "arguments" and "evidences" cannot be very convincing, otherwise you would scarcely add, that possibly one day these "erroneous" views may turn out to have contained the germ of the final solution of the cancer problem. Again, the successful case of sarcoma you mention is not by any means the only case of cure, and scientifically it is not at all clear why "erroneous" views should lead to successful results. Even one cure is a new fact, and Pasteur held, rightly, that erroneous theories never produced new facts. Pardon me for insisting that we are not dealing with the question of the number of swallows which makes a summer, but with the problem of what is a *crucial scientific test*. "If a doctrine be challenged," said Pasteur, "it happens seldom that its truth or falsity cannot be decided by some crucial test. Even a single experiment will often suffice either to refute or to consolidate the doctrine." An instance of this kind, where a *single scientific experiment* suffices to establish the truth of my doctrines, is the case of the pancreatic ferments, trypsin and amylopsin, *versus* cancer. Finally, permit me to express complete agreement with the following, written by a modern author: "And," he added, "speaking of gratitude, those who lead the way do not expect gratitude. It is enough for them to have led the way."—I am, etc.,

Edinburgh, Jan. 22nd.

J. BEARD.

BOVINE AND HUMAN TUBERCULOSIS.

SIR.—I do not know whether the omission was the printer's fault or mine, but the part of my letter relating to the geographical distribution of tuberculosis should have been in inverted commas. I got the information from Green's *Encyclopaedia and Dictionary of Medicine and Surgery*. I am sorry to say I have forgotten the name of the writer, but he evidently knew what he was talking about. It is a pity Dr. Fisher did not deal with the portion of my letter referring to the condition of affairs as to tuberculosis in Guernsey, where Dr. Bishop tells us that "only $\frac{1}{2}$ per cent. of the cattle are tuberculous, and consequently that cases of bovine tuberculosis in human beings are extremely rare." On the other hand, may I repeat that in 1909, 10,000 children died in England and Wales from

¹ *Practitioner*, January, 1913, p. 205.

tuberculosis (other than from pulmonary tuberculosis) and that 70 per cent. of our dairy cattle are tuberculous.

These facts alone form a strong argument against the acceptance of the Italian axiom that where there is much tuberculosis in man there is little tuberculosis in animals, and where there is much tuberculosis in animals there is little tuberculosis in man.—I am, etc.,

Beverley, Jan. 20th.

T. READMAN.

TO ESPERANTISTS.

SIR.—At a meeting of the Universal Medical Esperanto Association (Tutmonda Esperantista Rinacista Asocio) held in Cracow last August a committee was appointed to organize an Esperanto section, similar to that which was held during the last International Congress at Budapest, in connexion with the forthcoming International Medical Congress. A considerable number of Russians, Poles, Hungarians, and others stated that they would go to London if hopes could be held out of forming such a section. Will any Esperanto medical men or others willing to help kindly communicate with me?—I am, etc.,

G. JAMESON JOHNSTON, F.R.C.S.I.

13, Lower Fitzwilliam Street, Dublin, Jan. 20th.

CERVICAL RIB.

SIR.—On February 14th the meeting of the Clinical Section of the Royal Society of Medicine will be devoted largely to the subject of cervical rib—particularly the results of operative treatment. We should like very much to have: (1) Cases showing the results of the removal of the rib; (2) cases showing neuro-muscular features; (3) cases with vascular features. Gentlemen wishing to show cases will please communicate with the Secretaries, Chas. H. Fagge, M.S., 3, Devonshire Place, W.; W. Essex Wynter, M.D., 27, Wimpole Street, W.—I am, etc.,

Oxford, Jan. 13th.

WILLIAM OSLER.

The Services.

INDIAN MEDICAL SERVICE.

THE result of the January examination was announced on January 25th. There were 28 candidates, the first 12 being admitted as lieutenants on probation with effect from January 25th.

The names of the successful candidates with the marks obtained by each out of a possible total of 5,100 are given below, together with their degrees and medical schools:

| Name. | Degrees, etc. | Medical School. | Marks. |
|---------------------|---|--|--------|
| R. R. M. Porter ... | M.B., Ch.B.Aber., M.A.Aber. | Aberdeen University, Aberdeen Royal Infirmary, and Aberdeen Eye Institute | 3,707 |
| R. Sweet ... | M.B., Ch.B.Glasg. | Glasgow University | 3,489 |
| E. Calvert ... | M.R.C.S., L.R.C.P., B.A.Cantab. | St Bartholomew's Hospital and Cambridge University College | 3,320 |
| P. J. Walsh ... | M.B., Ch.B., B.A.O.(N.U.I.) | Cork, North Charitable Infirmary, Cork, and Cork District Hospital | 3,308 |
| J. R. D. Webb ... | M.R.C.S., L.R.C.P., | Liverpool University, and University College Hospital | 3,301 |
| F. Phelan ... | L. and L.M., R.C.P. and S.Irel. | University College, Cork | 3,203 |
| A. H. C. Hill ... | M.R.C.S., L.R.C.P. | Middlesex Hospital and Vienna General Hospital | 3,150 |
| N. C. Kapur ... | M.R.C.S., L.R.C.P., B.A.Punjab | Lahore Medical College and University College Hospital | 3,086 |
| J. F. Holmes ... | M.R.C.S., L.R.C.P. | Medical Hospital, Calcutta, and Charing Cross Hospital | 3,062 |
| A. C. Macrae ... | M.B., Ch.B.Aberd. | Aberdeen University | 3,057 |
| H. S. G. Haji ... | L.M. and S. Bombay, M.R.C.S., L.R.C.P. | Grant Medical College, Bombay, London Hospital, and Cambridge University | 3,011 |
| N. K. Bal ... | L.M. and S. Bombay, M.R.C.S., L.R.C.P. | Grant Medical College, Bombay, and Middlesex Hospital | 3,008 |

Obituary.

WILLIAM LIVESAY, M.D. EDIN.,

FORMERLY OF SUDBURY, DERBYSHIRE.

WE regret to have to record the death, in his 68th year, on January 24th, at the Pines, Bembridge, I.W., of Dr. William Livesay, who practised for nearly forty years at Sudbury, Derbyshire.

He was born at Ventnor, and received his medical education at the University of Edinburgh, where he graduated M.B., C.M., in 1871, and took the M.D. degree in 1875. He interrupted his medical studies in 1869 in order to accompany Mr. (now Sir James) Lamont on a voyage of sport and discovery to Spitzbergen and Novaja Zemlja, acting as artist to the expedition. He afterwards edited the account of the voyage (*Yachting in the Arctic Sea*, London: Chatto and Windus, 1876), the book being profusely illustrated by woodcuts from his beautiful drawings in black-and-white and water colour. In those days photography was not the convenient process for travellers that it is now, and even water colour drawing was not easy where, as he has told the writer, his washes often froze on the paper. In 1871-2 he was successively resident surgeon to Mr. (afterwards Professor) Annandale and resident physician to Dr. Haldane, while he also received the distinction of being one of the Presidents of the Royal Medical Society.

As a student he took great interest in botany, obtaining a prize for a herbarium, and on his return from the Arctic he read a paper to the Edinburgh Botanical Society on the plants he had collected on that voyage. His interest in botany had an important influence on his life, for it was at the house of Professor John Hutton Balfour that he became engaged to a daughter of the late Dr. Thomas Shapter, of Exeter. He married and settled at Sudbury in Derbyshire, where he remained for the rest of his professional life. To his friends it was somewhat of a disappointment that he aimed no higher, but he was fond of the country and possessed private means which made earning a large income no special object. He enjoyed his life, and generally managed to get a month in Scotland every autumn, while he frequently travelled in the spring. He was an accomplished etcher, and an associate of the Society of English Etchers; but he published few plates. He designed book plates for his friends, and for many years sent them an etched Christmas card. About three years ago his heart began to fail; this was possibly connected with an attack of acute rheumatism in 1872; on the advice of his friends he retired from practice and went to live in the Isle of Wight, but last autumn his condition grew much worse and left no hope of his recovery. He possessed the gift of making friends and will be missed by a wide circle who appreciated his sterling goodness of heart, his love of fun, his ready wit and his genial sympathy.

He lost his wife many years ago, but two daughters survive who have devoted themselves to the work of the Wantage and East Grinstead Anglican Sisterhoods.

THE OBITUARY NOTICES OF DR. G. A. GIBSON AND OF DR. J. E. GARNER.

SIR JAMES BARR writes to us as follows:

The deaths of these two friends, whose obituary notices appear in your issue of January 25th, has cast a gloom over my household, as well as over many others. I should like to take this public opportunity of adding my meed of praise to the character and work of the deceased, and to add my sympathy, which has already been privately expressed, with the sorrowing relatives. Both men lunched together here at the annual meeting of the British Medical Association, both were in exuberant spirits and without the slightest apprehension of their premature decease. I say premature, though both were in the neighbourhood of 60 years, as neither had finished his life's work. Both had a fund of energy and capacity for work, which might have carried them at full steam ahead for many years. Both were hard-headed, industrious, intellectual Scotsmen, though cast in different moulds. Dr. Garner had the solidity and the tenacity of the Aberdonian, while Dr. Gibson possessed all the fire of the

Celt combined with the resourcefulness and energy of the Lowland Scot.

Such deaths often set me soliloquizing, and make me feel, in the language of the Sun-child in Butler's *Brewton Revisited*, that "in the midst of death we are in life." How long will we remain so? "As for man his days are as the grass, as a flower of the field, so he flourisheth. For the wind passeth over it, and it is gone; and the place thereof shall know it no more." Why should strong, healthy, vigorous, intellectual men drop off about the age of 60 years? In a presidential address at the Liverpool Medical Institution in 1904, I said that to my mind it is a deplorable fact that many of the ablest and most popular members of our profession are cut off in the prime of life and vigour of manhood by disorders of the circulation, which are much more easily prevented than the so-called preventable diseases. Men who are engaged in directing others should teach by example as well as precept. I suppose the fact is that medical men are often too busy treating disease to devote much attention to its prevention, and the last individuals to receive attention are themselves. I am not an advocate of longevity for the mere sake of a long life. It is the fullness of a man's life which should count rather than its length. A man cut off in his prime may be remembered as an intellectual giant, whereas if he had existed till his cerebral arteries had become sclerosed, and he had become slow of thought and speech, or tended towards drivelling dementia, much of his former glory would have waned and the memory of him would quickly pass into oblivion. One of the most regrettable features of the present generation is their ephemeral memory of the great and good. Happy in life and blessed in death is the man who has got those near and dear to him to care for him, and mourn their loss.

I have known George Gibson for at least half my lifetime. There was a mutual affinity—because we were working on similar lines—which made us fast friends long before we met one another, and as years rolled on that friendship became more firmly cemented, so that the wrench which has now separated us I keenly feel.

My dear old friend, Dr. Garner, of Preston, was one of those warm-hearted, genial men whom to know was to love and esteem. He took a keen interest in the welfare of his profession, and was never actuated by any selfish motives. As an active and able surgeon to a county hospital he kept well abreast of modern developments in a well cultivated field. He took a keen interest in the Insurance Act as it affects the medical profession. I last saw him at the Representative Meeting on January 17th. He told me that he had had recently some anginal pains, and he promised to see me in the beginning of the succeeding week, but alas! on the first day of that week he had a fatal apoplectic seizure. He has gone, mourned and regretted by all who knew him.

By the death of ALEXANDER MINTO McDONALD, M.B., C.M., which took place on January 9th at his residence, 108, Gilmore Place, still another break has occurred in the ranks of the British Medical Association in Edinburgh. Though in indifferent health for several months, he continued his work till within a fortnight of his death. He was born in Craik, Fifeshire, but spent the greater part of his life in Edinburgh. Having completed his course and taken his degree in Pharmacy, he went on to the study of medicine at the University, and graduated in 1892. Soon afterwards he began general practice in the city, and some years later joined Dr. Stewart Stirling as assistant in the Skin Dispensary, Lauriston Place. On the death of the latter ten years ago he became senior medical officer of the institution. He was devoted to his work there, and that devotion was testified to by the very large attendance of grateful patients at Warreston Cemetery on the occasion of the funeral on Sunday, January 12th. Dr. McDonald was an elder in St. Cuthbert's United Free Church, and took a keen interest in Church work and in all schemes of social amelioration. For the long period of thirty-seven years he was connected with the Riego Street Mission for Young People, first as monitor and later as superintendent. A man of essential probity of conduct and of sociable and kindly disposition, he leaves a

blank in the wide circle of his friends which will not easily be filled, and a greater blank in the life of his only sister and life-long companion.

DR. W. WAKE CLARK, J.P., M.D. Edin., M.R.C.S., L.S.A., died, at the advanced age of 80, on Saturday, January 11th, at his residence in Wellingborough, after several years of retirement. He came of an old family long associated with that town, and was a direct descendant of Archbishop Wake; after pursuing his medical studies at Edinburgh, and graduating in 1856, he assisted Dr. Mash at Northampton, and succeeded to his father's practice in Wellingborough and several appointments in 1893. He was the first medical officer of health appointed when the Local Board was established, and only resigned at the end of 1912. Dr. Wake Clark joined the Volunteers when the movement began in 1859, and retired at the end of thirty-six years' service, holding the rank of lieutenant-colonel. He was the first officer in the Northamptonshire Volunteers to receive the V.D. distinction. He was an alderman of the Northamptonshire County Council. Dr. Wake Clark's funeral, on January 14th, was numerously attended, the procession being escorted by members of the 4th Battalion of the Northamptonshire Regiment, with the regimental band, the body receiving on its interment the usual military honours.

THE *Journal* of Grahamstown, Cape Colony, announces the death of Mr. GERALD EUSTACE FITZGERALD, L.R.C.P., M.R.C.S. Eng., at the Albany Hospital, on November 22nd. He studied medicine at St. George's Hospital, London, and was a member of the British Medical Association. He was surgeon to the hospital in which he died, and medical superintendent of the Chronic Sick Hospital, Grahamstown. He was deeply loved and respected in the city where he practised his profession, and his funeral was on that account one of the largest and most representative that has ever taken place in Grahamstown. A full choral service was held in the cathedral, and conducted by the Very Rev. Dean Vincent; the deceased was afterwards interred in the Anglican cemetery.

SURGEON JOHN MILFORD BARNETT, who died on January 24th, at the age of 82, was the son of Mr. Richard Barnett, of Belfast and Holywood. He was educated privately at Trinity College, Dublin, and at the University of Edinburgh, where he graduated M.D. in 1852; he became M.R.C.S. Eng. in the same year. He entered the service of the Honourable East India Company, on the nomination of the late Marquis of Dufferin, in 1853. As surgeon to the 26th Bombay Regiment N.I., he served with the Persian Expedition under Outram and Havelock, and was present during the forced march on Boorazjoon, the night attack and the battle of Khoosab, where he was wounded, as well as at the bombardment and capture of Mohumera and forts. He served through the Indian Mutiny. When Staff Surgeon at Asserghur he received the thanks of the Bombay Medical Board for his report on the Simrole Ghant route to the front. He was Staff Surgeon to the Katiawar Field Force against the Wagheers in 1860, and was promoted to Surgeon and Major in 1865. He received the medal and clasp for his Persian service. He retired in 1869 and settled at Holywood, co. Down, where for many years he devoted much of his time to philanthropic and temperance work. He left Ireland some fifteen years ago and settled first in St. Leonards, but afterwards removed to Bexhill, where he died. He leaves a widow, a daughter of the late General Brooke Boyd, and three daughters and four sons, one of whom is a Major in the Royal Army Medical Corps. Dr. Barnett lived a busy and useful life after his retirement from the Indian service, and while resident at Holywood was occupied in the work of numerous missions and associations in Belfast, including the Presbyterian Orphan Society for All Ireland. He was invited to the Indian Mutiny dinner for veterans in London some two years ago, but was unable to be present.

Universities and Colleges.

UNIVERSITY OF LONDON.

LONDON HOSPITAL MEDICAL COLLEGE.

A COURSE of lectures and demonstrations on neurology will be held on Mondays, Wednesdays, and Fridays during February and March, at 4.30 p.m., beginning on Friday, February 7th. Dr. Theodore Thompson will deal with lesions of the peripheral nervous system and spinal cord; Drs. Turnbull and Gordon Holmes with the pathology of the central nervous system; Dr. Gordon Holmes with clinical anatomy and regional diagnosis; and Dr. Henry Head with common diseases of the nervous system. The course is intended for senior students and post-graduates preparing for the diplomas in psychiatry. The fee is three guineas. Further particulars can be obtained from Professor William Wright at the College.

SCOTTISH INTER-UNIVERSITY CONFERENCE.

THE Scottish Inter-University Conference opened at Aberdeen on January 24th. The four universities (Aberdeen, St. Andrews, Glasgow, and Edinburgh) were represented, and Principal George Adam Smith, in welcoming the delegates, referred to the growth of students' representative councils, and said the system worked extremely well. He acknowledged gratefully their co-operation with the authorities of the university, and said that any suggestions they might put before the court would receive very careful consideration.

A motion that the President of the Students' Representative Council should attend meetings of Senate when motions affecting that council were under discussion was adopted. A motion was also adopted recommending that the vacations and terms of the four Scottish universities be concurrent, and that the vacations and terms of the faculties be as nearly as possible concurrent.

The conference was continued on Saturday, the 25th, when the following, among other, resolutions were adopted:

That an inter-university committee, composed of members of the Senatus of the different faculties of the four Scottish universities, be appointed to obtain information with regard to vacancies in the Government and other services, and to publish a list of any such vacancies at the four universities for the benefit of students.

That in view of the fact that students taking biology for the degree of B.Sc. (pure) are unable to complete their first science classes in one year, the period between sitting the last subject of the first science examination and the first subject of the final examination be reduced from one year to six months in such cases.

SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have been approved in the subjects indicated:

SURGERY.—E. M. Brand.

MEDICINE.—G. M. Cordingley, G. E. Cattle, R. B. F. Frazer,

*J. W. Harrison, G. R. Lynch.

FORENSIC MEDICINE.—J. A. A. Boddy, G. M. Cordingley, R. B. F.

Frazer, H. C. C. Hackney.

MIDWIFERY.—G. M. Cordingley, G. E. Cattle, J. A. Prongerast, L.

C. Smith.

* Section I. † Section II.

The diploma of the Society has been granted to E. M. Brand.

Medico-Legal.

WORKMEN'S COMPENSATION.

A CORRESPONDENT asks for advice in the case of a workman who received an injury about a year ago resulting in the extraction of the lens and incapacity since. There is a difference of opinion between the doctor acting for the insurance company and other medical men.

* As to precedents in law it would be advisable to consult a solicitor. The applicant for compensation must submit himself to the examination of the doctor paid for by his employer, and the patient can claim that his own doctor shall be present at the examination. We know of no precedent for a medical man representing the employer or the insurance company demanding that the patient should be treated in an institution under his own care. Our correspondent might consult the following books: *Diseases of the Nervous System Resulting from Accident and Injury*, by P. Bailey (London: S. Appleton, 1906); *Injuries of the Eye of the Employed and the Compensation Act*, by W. M. Beaumont (London: H. K. Lewis, 1907, price 5s.); *Industrial Diseases and Accidents*, by W. J. Greer (Bristol: J. Arrowsmith. London: Simpkin Marshall and Co., 1909, price 7s. 6d.); *The Eye and Nervous System*, by W. E. Posey and W. G. Spiller (London: J. B. Lippincott and Co., 1906, price 25s.); *The Diagnosis of Nervous Disease*, by P. Stewart, third edition (London: Edward Arnold, 1911, price 15s.).

Medical News.

THE King has appointed Dr. James Cran, of Belize, to be an unofficial member of the Legislative Council of British Honduras.

THE annual dinner of the West London Medico-Chirurgical Society will be held in the Warnecliffe Rooms, Hotel Great Central, Marylebone Road, on February 6th, at 8 p.m.

THE annual oration before the Innerian Society of London will be given in the library of St. Bartholomew's Hospital by Dr. Edward W. Goodall, on Wednesday, February 12th, at 9 p.m.; the subject selected is serum sickness.

At a meeting of the Royal Sanitary Institute, at 90, Buckingham Palace Road, S.W., on Tuesday, February 11th, at 7.30, Dr. Samuel Rideal will open a discussion on the eighth report of the Royal Commission on Sewage Disposal on standards and tests for sewage and sewage effluents discharging into rivers and streams.

DR. HERBERT HAWKSWORTH, on the occasion of his retiring from Welshpool, where he has been in practice for thirty-one years, was, on January 16th, presented by his friends and patients with an album address and a wallet containing £260; Mrs. Hawksworth was on the same occasion the recipient of a sapphire and pearl pendant.

THE new Hounslow Hospital, which will provide accommodation for twenty-four patients, was opened by H.R.H. Princess Christian on January 25th. The hospital, which is situated on the Staines Road, was built from the designs of Mr. E. Franke at the cost of £5,000, and replaces the old hospital in Bell Road, founded by Dr. Sydney some forty years ago.

THE usual monthly meeting of the Executive Committee of the Medical Sickness, Annuity, and Life Assurance Society was held at 429, Strand, London, W.C., on January 17th, Dr. F. J. Allan in the chair. The accounts for the year were considered, and it was shown that though heavy sickness claims and bonuses had been paid to members, the funds of the society showed an increase. The bonuses now paid at 65 are for substantial amounts, and it is hoped that after the next valuation they will be continued. Many letters from members are received at the office thanking the committee for the way their claims have been settled, and expressing satisfaction with the system of weekly payments. Prospectuses and all further information of the Secretary, Mr. Bertram Sutton, Medical Sickness and Accident Society, 33, Chancery Lane, W.C.

WE have received from the President, Herr O. von Angerer, a programme of the forty-second congress of the German Surgical Society, which will meet in Berlin from March 26th to March 29th. The official orders, programmes, and admission cards will be issued from 8 a.m. to 8 p.m. on Tuesday, the 25th, and on the following day from 8 a.m. to 10 a.m. The general meeting will be held in the forenoon of Wednesday, March 26th, and in the afternoon of the following Friday. Gentlemen intending to read papers or to make demonstrations are desired to announce their intention not later than February 12th. The Roentgen-ray demonstrations will be held at 8 p.m. on March 26th. The subjects selected for discussion are (1) duodenal ulcer, (2) the surgery of the brain and spinal cord, and (3) the treatment of tuberculosis of the bones and joints. Inquiries are to be addressed to the Secretary, Deutsche Gesellschaft für Chirurgie, Berlin N., Ziegelstrasse 10-11 (Langenbeck-Haus).

THE trustees of the Chadwick Trust have arranged a course of lectures on hygiene and sanitary science during March, April, and June. The first course of three lectures on hygiene of the home will be given by Mr. H. Percy Boulnois, M.Inst.C.E., at the Royal Sanitary Institute, Buckingham Palace Road, on Friday evenings at 8.15 p.m., beginning on February 7th. In April Dr. J. T. C. Nash will give a course of three lectures on the evolution of epidemics, at the London County Hall, Spring Gardens; and in June Dr. F. W. Mott will give a course at the Royal Society of Arts on nature and nurture in mental development. Lectures will also be given under the auspices of the trust in Manchester, Birmingham, Glasgow, and Bristol. The lectures in Manchester will be by Professor Henry Kenwood on the public milk supply; those at Birmingham, by Mr. E. P. Hill, M.Inst.C.E., on water supply. The lectures, which are intended for post-graduate and advanced students; of engineering and medicine, are free. Further particulars can be obtained from the secretary of the trust, Mrs. Aubrey Richardson, 8, Dartmouth Street, Westminster.

Letters, Notes, and Answers.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

ALIQUIS, who has a patient who wishes to try antidipltherial serum for asthma, desires to know the proper dose, how often it is to be repeated, and whether it is given before or during the attacks.

M.R.C.S. asks whether extreme susceptibility to Coley's fluid has been observed in inoperable sarcoma of mamma, with involvement of mediastinal glands; and, if so, what dose is best, and what results, if any, have been obtained.

ANSWERS.

PORTABLE TYPEWRITER.

DR. J. M. CARVELL (London) writes: In reply to "G. P. B.," I would recommend the Bennett typewriter, sold by the Bennett Typewriter Co., 75, Cannon Street, E.C. It is, he says, portable, the measurements when in case being 11 in. by 5½ in. by 2½ in., and there is hardly any jarring of the fingers. The price is £4 ds.

TRANSFER OF PRACTICES.

A. 36.—In the transfer of medical practices the income from appointments is usually reckoned together with that from other practice, and the sum of all the professional emoluments constitutes the gross value. It is not usual to put a higher value on private practice than on appointments, and one year's purchase has been the average value of the latter; but not infrequently the amount estimated in the gross value from appointments is made conditional on the latter being transferred to the purchaser.

FOUL BREATH.

J. O. P. (Paris) writes, in reply to "A": Offensive breath in young people, when no local condition can be detected in the digestive or in the respiratory tract to account for it, should be regarded as due to a disturbance of the sympathetic system with perversion of the glandular secretion brought on by habitual masturbation. Many other signs for which no obvious explanation can be found are probably related to the same cause in the young of both sexes. Such are: Some degree of dilatation of the pupils, constant congestion of the nasal mucosa, frequent attacks of palpitation, abnormal sweating in the palms of the hands, the armpits, and the soles of the feet (sweat often foul-smelling), flushing and morbid blushing, offensive breathing, dry cough, etc. It will be seen that all these signs are referable to the vasomotor system and loss of general nerve tone. They may all be grouped together under the general term "sexual syndrome," and may exist either separately or in combination. For the treatment direct questioning and advice to the patient will certainly prove the most efficient means of cure. *Sublata causa tollitur effectus*. When the patient learns that such symptoms may occur as the result of his own injurious habit he is sure to exercise more self-control and bring about a rapid cure; otherwise all treatment may prove of little avail, or the complaint may recur under some form or other. Bromides and belladonna will be useful; tonics may be necessary, but care is required in their administration lest over-stimulation may contribute to the continuance of the evil practice; physical exercises may be recommended, provided they be sufficiently prolonged so as to induce considerable physical fatigue, especially of the lower limbs; mild, unstimulating diet, total abstinence from alcohol in any form, and generally the avoidance of every thing likely to raise erotic feelings. In fact, the whole treatment may be summarized under the general formula—sexual rest and general sedatives and tonics.

LETTERS, NOTES, ETC.

DR. H. BOSHOEWERS (Haarlem) writes in reply to the first question of "A. M." (p. 148): If "A. M." will inject every two hours into the rectum a little glycerine enema syringeful of 1 or 2 grains of antipyrin dissolved in about 200 c.cm. of water, he will certainly keep away the after-pains (*morsis uterini* of the Italians). I may refer him to the *Therapeutische Nachrichten*, July, 1908, and *Deutsche medizinische Wochenschrift*, October 1st, 1908, where I described the treatment.

TREATMENT OF CHRONIC BRONCHITIS AND EMPHYSEMA.

DR. CHARLES READ (Barnstead) writes: Having derived so much benefit from the continued taking of heroin gr. ½ and menthol gr. ⅓ in the form of lozenges for the last two years, I think it may possibly interest some of my medical brethren if I give a brief account of my personal experience. I am now 75 years of age, and for upwards of thirty years I have suffered from occasional attacks of bronchitis, which have gradually passed into the chronic stage, with a considerable amount of accompanying emphysema. For the last two years

I have regularly taken two lozenges at night, one on going to bed, and another later on if the cough or the breathing is troublesome, and sometimes, though rarely, a third, and their effect on me is most beneficial, soothing, and comforting. The menthol is a very useful addition to the heroin, for besides its own specific effect it diffuses a sense of grateful warmth through the chest. The heroin has, I think, an undoubted effect, not merely in soothing the cough through its action on the nervous system, but also in exercising a beneficial influence on the bronchial mucous membrane itself, modifying and checking its secretion. Altogether I am so much better than I was twelve months ago, the cough being now very slight and the mucous expectoration much lessened and of a simple character, that I cannot help attributing the improvement largely to the regular taking of these lozenges. I am not conscious of any heroin habit having formed, as I can omit taking them without experiencing any sense of desire for them. The lozenges are made for me by Messrs. Meggesant Co., lozenge manufacturers, of Miles Lane, Upper Thames Street, E.C.

STORIES OF HIPPOCRATES.

DR. JOHN HADDON (Denholm, Hawick) writes: The stories about Hippocrates in the JOURNAL, whether authentic or not, tend to prove the wonderful power of observation which he, no doubt, possessed. They remind one of the stories told of the late Dr. Joseph Bell, who stimulated the observant power of his students by the way in which he astonished his patients by the remarks he made, as to what they had been doing, or where they came from. Nevertheless, when Dr. Bell explained how he knew so much about one whom he had never seen or heard of before, there was no great mystery involved. We may never be able to tell how Hippocrates gained the power he possessed—so rare even in our profession, which ought to cultivate the power of observation more than any other—but we may try to explain the story told of his saluting the maiden who had lost her virginity. It could not be by her gait, as was the explanation suggested, but the blush that lent a beauty to the maiden's face when he first met her, and its absence on the second occasion, might quite easily account for the difference between the two salutations.

A ROYAL HOAX.

DR. CLIPPINGDALE (London, W.) writes: In the admirable articles which have appeared in the JOURNAL, preparatory to the meeting of the Association at Brighton this year, I have not seen reference to the hoax played upon the doctors of Brighton by the Prince of Wales in 1785. The Prince, who was in residence at the Pavilion, gave a party. Present at this party was a Mrs. Laurell. As this lady was unaccompanied by her husband she thought it discreet to leave early. She left about nine o'clock. Her early departure annoyed the Prince, who sent word that he would come and sup with her. This proposal not meeting with the whole-hearted sanction of her husband, Mrs. Laurell sent word to the Prince that she was unable to receive his Royal Highness as her husband was ill in bed. The Prince, observing that it was "a pity poor Laurell should die for want of a doctor," sent, about one o'clock in the morning, all the apothecaries, surgeons, and physicians (including his own physician, Sir Lucas Pepys) in Brighton to the residence of the Laurells, to find, of course, that their services were not required. (Lady Stanover's Memoirs of Mrs. Delany.)

TREATMENT OF METRITIS.

AN appliance for facilitating the administration of very hot douches in cases of metritis which has been brought under our notice presents some points of novelty and possible utility. It consists of a narrow metal tube for the introduction of the hot water, surrounded by (1) another metal tube for its escape, and (2) by an indiarubber sac or hollow jacket which, when filled with cold water, is intended to fit the vagina. This jacket ends in a cuff, which remains outside and protects the vulva from contact with the attachments of the metal tubes to those communicating with the douche-can and stop-pail respectively. The idea is that, thanks to this water jacket and its cuff, very hot injections may be applied to the cervix without any chance of the vaginal walls or vulva suffering from contact either with the heated irrigation tube or the returning stream of hot water. The name of the appliance is the Leedro double current syringe, and further information concerning it can be obtained from the Leedro Company, 6, Summerhill Avenue, Newport, Mon.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|-----|
| Eight lines and under | ... | ... | ... |
| Each additional line | ... | ... | ... |
| A whole column | ... | ... | ... |
| A page | ... | ... | ... |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restant* letters addressed either in initials or numbers.

VACCINES AND FEVER.

BY

E. C. HORT.*

(From the Lister Institute: The Constance Trotter Researches.)

Is the great majority of infective diseases accompanied by marked systemic disturbance the most prominent clinical feature is that form of intoxication which is expressed in fever. The relationship of fever to general infection is so constant that whenever continued fever occurs we may be almost certain that an infective process is at work. Continued fever is in fact an index both of the continued activity of micro-organisms pathogenic to the individual infected and of the absence of effective protection against such activity. On the other hand, the absence of fever does not necessarily indicate the absence of infection. On the contrary, it is a familiar experience that in severe infections leading to a fatal issue there may be no fever on account of grave impairment of the reactive functions of the infected body. This impairment may exist prior to infection or may be the expression of extreme intoxication after infection has occurred. This observation can be verified with great ease. We have therefore learnt to recognize that whilst the continuance of fever is an excellent indicator of the continuance of infection and of the absence of effective immunity thereto, it is also an index that the power of reaction—whatever that may prove exactly to mean—is not yet lost. Now the power of reaction to infection in terms of fever is in some unknown way intimately associated with the complex problems presented by immunity. And we have some reason to believe that the mere presence of continued fever is a sure sign that the machinery of immunization has been set in motion and is still running. The solution therefore of the mystery that surrounds the nature and source of the substances that are the immediate cause of the fever of infective disease can hardly fail to throw light on many of those problems in immunity production which are at present totally obscure.

Hence determination of the essential cause of the fever of infective disease—from the pathological standpoint as opposed to that of physiology—is a matter of immediate concern to all students of immunity. And, as I shall show, this particularly applies to those who administer dead bacterial vaccines, whether for purposes of prophylaxis or of treatment, as well as to those who make use of bacterial emulsions in test tube reactions.

In all immunity problems, whether of the test tube or the living body, the keystone on which all inquiry rests has long been recognized to be the antigen, or substance that provokes the manifestation of antibodies. Similarly in the pathological problems presented by fever inquiry must always start from the pyrogen, or substance that provokes the manifestation of fever.

The antigens, then, and pyrogens of infective disease are substances so vital to the production of immunity and of fever that precise knowledge of their true source, as well as of their chemico-physical nature, must always be a necessary preliminary to an intelligible conception of how they act.

It is widely believed, largely in consequence of Pfeiffer's early work, that the main source of supply of both antigen and pyrogen in infective disease is dissolved bacterial protoplasm. In an infected subject the primary source of supply of these substances is therefore, we are taught, one foreign to that subject, whether the agents affecting their liberation be of an autolytic or heterolytic character. Moreover, since antigen and pyrogen are supposed to be genuine derivatives of bacterial protoplasm in solution, the theory lays down that it is only dead organisms that can supply them. The living bacterium as such has, we must infer—if we accept the theory—no antigenic or pyrogenic values. Its potential worth, in terms of the production of antibodies and of fever, only becomes kinetic when bacterial death followed by bacterial solution and absorption has occurred.

So far as antigen is concerned, the theory that it is

The protocols for many of the experiments referred to in this paper have already been published. In most of the experiments detailed in such protocols I was aided by Dr. W. J. Pentold. Full data of the additional experiments referred to in this paper will be published elsewhere, and for these I accept sole responsibility.

derived from dead bacterial protoplasm has in the main been accepted without question for many years. And incidentally it is the bedrock of that form of vaccine-therapy—the use of dead vaccines—which is under trial in this country to-day. So far as fever is concerned, the theory that the pyrogen of infective disease is a derivative of dead bacterial protoplasm in solution has also, as a rule, been accepted without serious question till comparatively recent date.¹

In consequence of the general acceptance of this hypothesis as to the source of antigen and pyrogen in infective disease it might reasonably be supposed that it rests on a sound experimental basis. Whether this supposition be well grounded in the case of antigen is a question that cannot be discussed here. In the case, however, of pyrogen I shall show that the evidence hitherto relied on in favour of the view that it is a genuine derivative of dead bacterial protoplasm can no longer be accepted. On the contrary, I shall cite experimental data which suggest—if they do not conclusively prove—that the fever of infective disease is the direct result of absorption of pyrogen derived from the medium offered by the tissues of the infected host in consequence of the activity of the living organism or its products on such medium. And as a corollary I shall indicate the practical bearing of this displacement of current theory on the administration of dead vaccines for prophylactic or therapeutic purposes, as well as on all such test-tube experiments as involve the use of bacterial emulsions of the same nature.

The experimental basis of the theory that dead bacterial protoplasm is the direct source of the fever of infective disease is the undoubted fact that fever does frequently follow the injection into healthy subjects of dead cultures of certain organisms. At first sight this evidence would seem to be conclusive, especially if fever were found to follow the injection of all known forms of dead pathogenic bacteria and protozoa. It has, however, for some years been recognized that there are exceptions to what is by many still believed to be a general rule. For example, injection of dead cultures of the bacillus of Koelt, *B. anthracis* and *B. diphtheriae* into healthy subjects has from time to time been found not to be followed by fever. In the case of the bacillus of Koch it was believed that the "waxy envelope" prevented bacterial solution and consequent extraction of the pyrogen with which this organism was credited. In the case of *B. anthracis* and *B. diphtheriae*, however, no explanation was forthcoming as to the absence of fever after injection of the killed organism. Nevertheless, these exceptions were looked upon as unimportant, and were to a great extent forgotten. When the practice of administering dead bacterial vaccines became general it was soon found that their injection might give rise to mild forms of intoxication, including fever. Prophylactic injections into healthy subjects of dead vaccines of *B. typhosus* are a case in point. Belief in dead bacteria as the primary source of pyrogen became therefore more firmly rooted than ever, though again no explanation was given—beyond a quantitative one—of the frequent experience that fever did not follow, for example, injections of certain staphylococcal vaccines. The subject, in fact, does not seem to have been investigated.

Early in 1911, therefore, I examined, with the aid of my laboratory colleague, Dr. Penfold, a large number of dead and living bacterial vaccines by injecting them, for the most part intravenously, into healthy rabbits. The organisms examined in respect of their pyrogenetic properties are given in the subjoined list. They are divided into two groups, according to whether they did or did not on intravenous injection produce immediate fever if the organisms were first killed. The character of the list given is, I think, sufficient answer to the very reasonable suggestion that the absence of immediate fever after injection of an emulsion of organisms might be due to difficulty of lysis of the particular organism. In all cases the vaccines injected were made from laboratory cultures. Many different strains of several of the organisms were examined, an important point, as will be seen, in the study of the relative pyrogenetic properties of any bacterial emulsion. Attention is drawn to the fact that the list of the organisms from laboratory cultures which did produce fever is a list also of Gram-negative organisms. On the other hand, the list of organisms injection of which did not

produce fever is a list also of Gram-positive organisms. The parallelism is a striking one, though its interpretation is at present obscure.

| PYROGENETIC VACCINES. | APYROGENETIC VACCINES. |
|--------------------------------------|---|
| <i>B. typhosus.</i> | <i>B. diphtheriae.</i> |
| <i>B. coli.</i> | <i>B. anthracis.</i> |
| <i>B. influenzae.</i> | Koch's bacillus. |
| <i>B. pestis.</i> | <i>B. mallei.</i> |
| <i>B. melitensis.</i> | Streptococcus. |
| <i>M. catarrhalis.</i> | Pneumococcus. |
| <i>V. cholerae.</i> | <i>Staphylococcus aureus</i> (certain strains). |
| Acne bacillus. | (Tuberculin.) |
| <i>S. albus</i> (certain strains). | (Mallein.) |
| <i>S. citreus</i> (certain strains). | |
| <i>S. aureus</i> (certain strains). | |

Clearly, then, the list of organisms that apparently do not contain any pyrogenetic substances is much longer than has previously been realized. And no doubt further examination will reveal yet other laboratory-grown organisms injection of which does not produce fever if they have been first killed. So far I have not examined for the presence or absence of pyrogenetic function such protozoa as can be grown on laboratory media. It should also be noted that repeated injection at suitable intervals into the same animal of a dead vaccine of the apyrogenetic type does not produce fever. This observation seriously affects the question of anaphylactic fever in the sense employed by Continental observers. We have gone more fully into this subject in a paper read at Liverpool in the summer of 1912.²

In the face of the experiments referred to here,³ it must be admitted that if some laboratory-grown organisms appear to contain a protoplasmic pyrogen—because they produce immediate fever when injected dead—it is difficult to understand why so many others do not.

In further experiments, however, published⁴ in the autumn of 1912, we showed that certain strains of organisms which after growth on agar are primarily apyrogenetic when injected dead appear to acquire pyrogenetic properties if subcultivation on fresh agar is carried out. For example, some subcultured strains of *S. aureus* readily exhibit the power of provoking fever if the heated organisms be injected. This is particularly the case if animal passage has taken place before subcultivation, the rabbit being selected as the medium of passage. In other words, subcultivation on laboratory media, especially if preceded by passage, appears to select out a race of organisms trained to extract from the culture medium a pyrogen that the original strain either could not extract or had become incapable of extracting. Control observations showed that the uninoculated media used produced no fever in the case both of agar and of broth. The suggestion therefore arises that when the subcultivated heated organism is injected pyrogen extracted or synthesized from the medium by the action of the living organism is unavoidably injected at the same time. It is possible, therefore, that the pyrogenetic properties of all those organisms injection of which when dead produces fever are in reality due not to the possession of pyrogenetic properties of their own, but to adsorption of something elaborated by the action of the living organism on the medium of growth. As will be seen, it has so far not been possible to detach completely this substance from organisms that have picked it up, possibly owing to its inclusion in interstices in the bacterial wall. Adsorption on the free surface of the bacterial wall appears not to prevent partial detachment of this adventitious pyrogen, since its presence can readily be demonstrated in the washings by the fever that follows their injection. If this theory—that the pyrogenetic effect of dead vaccines is due merely to adsorption of some substance manufactured from the medium of growth—is true, we ought to find that an inoculated medium when it has been deprived of its organisms is still pyrogenetic. And experiment proves this to be the case, provided that the centrifuge is used as the means of separation and not the bacterial filter.

A large number of observations have from time to time been made on the toxicity of bacterial filtrates expressed in fever.⁵ And numerous observers have shown that many filtrates are practically non-toxic and produce no fever. At the same time it was shown that the heated material

held up by the filter was often in these cases found to be strongly pyrogenetic as well as the heated unfiltered cultures. These findings naturally gave additional support to the view that the fever of infectious disease was caused by dead bacterial protoplasm. As, however, we showed⁶ in 1911 the use of the filter is quite inadmissible in determining the presence or absence of pyrogenetic substances in culture media. And for two reasons. In the first place, it is difficult—if not impossible—to avoid contamination of the filtrates with antipyretic salts derived from the filter itself. Calcium salts, for example, were, we showed, traceable in the filtrate even after repeated passage of freshly distilled water. And calcium salts have been shown by many observers to inhibit fever. In the second place, although in view of our observation that pyrogen appears to be a body of small molecule⁷ there is no guarantee that filtration of a colloidal liquid containing bodies of small molecule as well as of larger molecule, such as bacteria, will allow the filter to hold back the large and let through the small. On the contrary, larger bodies must tend to block the filter and prevent to an undetermined extent passage of the smaller.

Furthermore, apart from the question of filtration, if we wish to demonstrate the presence or absence of pyrogen by injection, it is always necessary to be sure that a sufficient volume of pure water is used as the diluent or vehicle of injection. This is necessary because increase of the volume of the diluent increases the amount of fever produced by injection of pyrogen, whilst injection of the same quantity of pyrogen in a smaller volume of diluent may produce no appreciable effect. Again, if normal saline be used as diluent instead of water, injection of one animal may produce high fever, whilst injection of a second animal of the same weight with the same quantity of pyrogen in the same quantity of saline may produce none. Experiments⁸ dealing fully with all these points we have published elsewhere, though at present it is not possible to explain them. All observations, therefore, that deal with the pyrogenetic properties of bacteria, or of emulsions of bacteria, must be regarded as suspect (a) if the filter is used, (b) if saline be employed as the diluent, (c) if the relation of the volume of pure water and of the quantity of pyrogen containing material to body weight be not clearly stated, (d) if the water used for injection be not freshly distilled each day and used at once. The numerous fallacies introduced into the study of fever by absence of knowledge as to the necessity for this last precaution we have fully dealt with in other papers.^{2, 3, 4, 7} Here it will be sufficient to point out that the experimental evidence hitherto relied on in favour of the existence of such distinct entities of fever as water fever, salt fever, salvarsan fever, lactose fever, glucose fever, saccharose fever, protein fever, nuclein fever, tissue fever, fibrin ferment fever, serum fever, blood cell fever, haemolytic fever, transfusion fever, and anaphylactic fever no longer exists, since we have reproduced fever charts typical of all of these by injecting pyrogen-containing water alone, whilst the injection of each of these substances in pure water produced no fever.

Hence the only satisfactory method of determining by injection if an infected culture medium, after separation of the infecting organisms, is or is not toxic in the sense of producing fever is to use an efficient centrifuge and to employ as diluent freshly-distilled water in constant and stated volume. When these precautions are taken, the reputed atoxicity of many organism-free culture media that have been submitted to infection entirely disappears. The results of the large number of experiments we have carried out on this subject may be briefly illustrated.

METHOD OF EXPERIMENT.

An eighteen-hours culture, for example, of a stock strain of *B. typhosus* on broth is examined in the following ways:

A.—Unheated.

1. A measured quantity—sufficiently small not to kill—of the whole broth is injected intravenously in a suitable quantity of water into a healthy rabbit of known weight. Fever rapidly follows, reaching its maximum in two to four hours, and disappearing in six to eight hours. Observations are taken every thirty minutes. Observations taken at much longer intervals than this are useless. The next day and on several successive days observations are again repeatedly taken, but fever does not return within the limits of observation.

2. The centrifuged deposit of an equal quantity of the same culture is repeatedly washed and is then injected in water into a second animal, and observations are taken as before. The results are precisely the same as in the first experiment, allowing for the slight variations in the degree of fever produced as a result of the varying personal equation on the part of the animals injected.

3. The supernatant fluid not injected in Experiment 2 before washing is now injected in water into a third animal. Once more the same essential features are recorded.

B.—Heated (to 100.0 C.).

Precisely the same experiments described under A are now repeated with the heated culture, the heated centrifuged and washed organisms, and with the heated supernatant broth. And again the same results are recorded in every case. Examination of the heated supernatant broth shows that no organisms are present.

The heated and unheated centrifuged deposits from a fresh broth culture of the same strain are then washed with a solution of hydrogen peroxide. This procedure entirely removes their pyrogenic properties, as was shown by injection into several animals. Microscopic examination of stained films of the deposit before and after this treatment reveals no differences. The heated and unheated centrifuged deposits from fresh samples of the culture are repeatedly washed with pure water, and the washings pooled. The washings produce on injection slight fever, the deposits produce high fever which is immediate. The heated and unheated centrifuged deposits from yet other samples of the culture are repeatedly washed with 1.4 per cent. sodium citrate solution in pure water and the washings pooled. These produce more fever than do the water washings. The deposits, however, are still markedly pyrogenic. Finally, the heated and unheated centrifuged deposits from the remainder of the culture are repeatedly washed with pure ether and the washings again pooled. These are then evaporated in a water bath and the residue taken up in citrate solution and injected. The procedure is followed by high fever. The original deposit of organisms, however, is still somewhat pyrogenic, possibly because it is not easy to get rid of all the other soluble pyrogen present. Owing to contamination of the bottom and sides of the test tube with the residue of pyrogen left after evaporation of the last remnants of the ether unavoidably left behind in removal of the supernatant fluid this appears to be the probable explanation. Examined by the microscope the ether washed organisms appear intact but moniliform, and they stain badly.

The points brought out by these experiments with ordinary laboratory strains may be thus epitomized:

B. typhosus grown in broth produces, if the heated or unheated organism be injected, an immediate and fugitive fever characterized by a sharp rise and fall. The animal does not become infected after injection of the living organism, and does not show any late fever after injection of either the living or the dead organism. Precisely the same events take place on injection of the culture-medium after separation of the organisms. The pyrogen therefore is present in the separated broth, and in or on the surface of the bacteria. This pyrogen cannot be completely washed away from the organisms, but it can be better detached by citrate solutions than by pure water, and better still by ether. It is, in short, feebly soluble in water, more soluble in citrate solution, and markedly soluble in ether. It cannot therefore, be a protein. It is apparently oxidized by peroxide since washing with this subject renders it inert, and standing for twelve hours in the semi-dry state has the same effect. We find in addition that it is active after incubation with a strong solution of tryptic ferment. Chloroform appears to some extent to inhibit its activity, but it is difficult to determine if this action is reversible owing to the difficulty of accurate determination of relative degrees of fever in the rabbit.

This pyrogen appears to be a preformed pyrogen when injected and to bear in its effects no relation to any known form of infection-fever occurring naturally in man and animals. After the immediate fever has passed off there appear to be no after-effects and there is no secondary fever, and this is also true after injection of the living or dead organism that has been allowed to stand in minimal quantities of water or saline. The pyrogen is, in addition, remarkably heat stable.

Such are some of the characteristics of a pyrogen that has hitherto been believed to be the purely bacterial product of a laboratory-grown organism that is known not to be pathogenic to the rabbit. Clearly, then, *B. typhosus* is not an organism in which it is possible to study natural pyrogen as it occurs in the body. Examination of other strains of *B. typhosus* on broth produced the same results, as also did examination of this organism on agar.

In order, therefore, to determine whether the pyrogen of infective disease is or is not a true bacterial product it is necessary to select for examination an organism that is pathogenic to the rabbit, and which at the same time has not become contaminated by a preformed pyrogen derived from the medium employed in artificial culture.

Certain strains of *S. aureus* satisfactorily meet these conditions. The absence of contamination in such strains is readily proved by injection. If, for example, the heated or unheated agar or broth culture be injected without separation of the organisms from the agar scrapings or broth no immediate fever is produced. The same negative result is obtained if the washed centrifuged organisms, or the supernatant fluid in the case of broth, or the washings in the case of agar, are injected. If, moreover, repeated observations are taken for several days of all the animals injected, it is found that fever only occurs in those which have received the living organism. In these animals, provided that the dose is not large enough to produce early death, or small enough to prevent infection, fever appears in a day or two, and continues till death or recovery takes place. If the virulence of the organism injected has not been reinforced by recent subcultivation, or by subcultivation plus animal passage, recovery is the rule. The fever generally begins within twenty-four hours of injection, but the latent period—if avirulent strains have been selected—was well marked in all the numerous cases examined. Here, then, is a very different picture to that produced by injection of *B. typhosus*. The fever set up is late in appearing instead of early, occurs always after injection of a suitable number of the living organisms, and never after injection of the dead; it has a slow instead of a rapid rise, and continues for several days instead of from one to eight hours. Further, it is not provoked by injection of the culture media from which the organisms have been separated, in marked contrast to the result obtained by injection of *B. typhosus* cultures deprived of that organism. The fever curve produced is that of a natural infection instead of one that bears no resemblance thereto. And finally, the substance—enzymic or what not in nature—which in the living organism liberates or synthesizes pyrogen is heat labile, whereas the pyrogen derived from laboratory media is remarkably heat stable.

Nevertheless the experiments so far quoted do not reveal the true source of the pyrogen in actual infections. A laboratory product, of course, natural pyrogen cannot be, as appears to be the case in the artificially produced fever set up by injection of cultures of *B. typhosus* and other members of the same group. Since, therefore, the source of natural pyrogen is not dissolved bacterial protoplasm, it can only be the substrate offered to the living organism by the tissues of the host.

The next step in the solution of the problem, therefore, was to discard laboratory media and to employ, as far as possible, the natural media of the animal body. For this purpose red cells from the blood of healthy rabbits were washed free of plasma with pure solution of sodium citrate, and were at once lysed in freshly distilled water. Samples of this blood-cell extract medium were exposed for one hour to air infection, and were then placed in a sterile flask, which was at once hermetically sealed and then incubated for twelve hours at 37.0 C. At the end of this time a copious growth of a staphylococcus was present, and demonstrated by film preparations from the centrifuged deposit. Control blood cell extract medium prepared at the same time and treated in the same way, with the exception of exposure to air, was found to be sterile. Injections of this control extract were followed by marked depression of temperature. Injections were then made of the infected extract into different animals as follows: (a) The heated washed centrifuged organisms; (b) the unheated washed organisms; (c) the unheated supernatant blood cell extract proved by control inoculations of agar to be free from organisms capable of growth. In each case immediate fever resulted of a precisely similar nature to that obtained by injection of *B. typhosus* cultures or of staphylococcal cultures after subcultivation preceded by passage. The animals injected with the heated organisms or with the supernatant liquid on the other hand failed to show any secondary fever. The animals, however, that were injected with the living organism

exhibited in addition to immediate fever the late continued fever of a natural infection with a much shortened latent period.

From these experiments it is clear that a pyrogen clinically indistinguishable from the pyrogen elaborated from agar or broth can be readily obtained if blood-cell extract be used as the medium. It is also clear that the immediate fever produced after injection of the heated organism or the supernatant fluid or the unheated organism was due to injection of preformed pyrogen—elaborated from the blood extract in the test tube—whilst the late fever produced after injection of the living organism was due to a second pyrogen—elaborated from the circulating blood or other tissues. The fact that the organisms were obtained direct from the air excludes the possibility of transference of any contamination from the ordinary laboratory media. These experiments appear to support the view that an organism that is unable to produce immediate fever dead or alive can do so both dead and alive if the living organism is first able to extract and adsorb from the medium on which it grows a pyrogen elaborated from that medium. We have elsewhere shown that organisms derived from the air, and not allowed to grow on the ordinary laboratory media, produce no immediate fever on injection provided that pyrogen-free water or saline is employed as the vehicle of injection. The pyrogen of blood-cell extract is just as heat stable as is the pyrogen derived from agar or from broth.

Owing to individual variation in the degree of fever produced in rabbits even after injection of constant quantities of pyrogen in constant quantities of water relatively to body weight, it has not been found possible accurately to measure the increase of "test tube pyrogen" from day to day in living cultures. The concentration, however, of "test tube" pyrogen is certainly high after twelve hours' growth, and remains high, in broth cultures, for many weeks. Abstraction of pyrogen taking place spontaneously is, of course, impossible, and no great destruction occurs within reasonable limits of observation. On the other hand, in the living body, during a natural infection we should not expect to find the same conditions. The concentration of pyrogen in the circulating blood of a feverish subject, for example, should be relatively low, since abstraction, if not destruction as well, must continually be going on. We should expect, therefore, to find that in order to produce fever in a healthy animal by injecting blood from a feverish animal it would be necessary to inject large quantities of blood. And on experiment this proves to be the case. For example, I injected into a series of healthy animals varying quantities of a 40 per cent. centrifuged citrated blood plasma from an animal exhibiting the continued fever of an acute genuine infection. The mixture of plasma and 1.4 per cent. citrate solution was centrifuged in order to get rid of any organisms that might be present. Injections up to 5.0 c.c.m., equivalent to one four-hundredth of the weight of the animal injected, produced no fever. Injections of 10.0 c.c.m. provoked slight rise of temperature, whilst injection of 15.0 c.c.m. produced slight but definite fever. Control injections of healthy citrated plasma produced no rise of temperature. Clearly, therefore, the amount of pyrogen circulating in the blood in such case is much less than that contained in blood-cell extract in the test tube, which only requires injection of 0.50 c.c.m. of a 25 per cent. extract, from which the organisms have been separated by the centrifuge, to produce high fever. The next step, therefore, was to determine if the injection of heated organisms after recovery from the body of a feverish animal does or does not produce immediate fever. If it were found that injection of such organisms did produce an immediate fever similar to that produced by injection of heated organisms after test tube growth on agar or broth or on blood cell extract, the fact would appear to make demonstration of the true source of pyrogen in infective disease by this method of investigation an almost impossible achievement. If, on the other hand, injection of heated organisms recovered from infected subjects produced no fever whatever the number injected, the theory that dissolved bacterial protoplasm is the primary source of the pyrogen of infective disease would be clearly untenable. Demonstration of this would, in conjunction with the experiments already described, leave no alterna-

tive but acceptance of the view that fever is the expression of the activity of living organisms, or their products, in and on the infected body.

Further experiments were therefore carried out (a) with organisms recovered from the fixed tissues of infected subjects, including pus, (b) with organisms recovered from the blood in subjects of septicaemia.

Recovery of Organisms from Infected Tissues.

Organisms were recovered from infected tissues in the following way:

An unheated laboratory strain of *S. aureus* that produced no immediate fever was injected into a series of healthy rabbits. A late continued fever resulted in all cases. After a week's illness with fever one of the animals was killed, and from the multiple abscesses present in the kidneys large numbers of organisms were heated before injection to 57° C. No fever whatever followed the injection early or late. The experiment was repeated with another animal which was killed at an earlier stage of the infection and the same results were obtained. In another experiment an unheated laboratory strain of a pneumococcus of low virulence was injected into a healthy rabbit. No immediate fever followed injection, but a late fever set in. On the eighth day, the fever still continuing, the animal was killed. An emulsion of splenic pulp, shown by film preparations to contain enormous numbers of organisms, was injected. Again no fever followed injection. In this experiment, as well as in the first series, control cultivations from the kidney and spleen showed that living organisms were present in the material examined, since copious growth was obtained on agar. Injection of the heated and unheated agar organisms produced high immediate fever in every case, and the injections in the case of the living organisms led next day to a fatal issue.

These observations therefore appear to show that organisms recovered from tissues other than the blood, and injected at once, possess no pyrogen, but that when grown on laboratory media they readily elaborate a contaminating pyrogen from such medium, which they subsequently adsorb. They also show that the concentration of body pyrogen cannot be high in the infected organs, since the tissue material injected in some of the cases was considerable in amount. Owing to the difficulty, however, of freeing organisms recovered in this way from tissue debris, their enumeration cannot be satisfactorily carried out. Moreover, it is conceivable that absence of pyrogen in the dead organisms after recovery from the body might be explained by exhaustion of any pyrogen they might have contained whilst in the body during the continuance of fever. The low concentration of pyrogen, however, already demonstrated in the blood plasma during high fever, and the fact that injection of organisms recovered from the body at an earlier stage of an infection shows them also to be pyrogen free, make such a view improbable.

Fresh Human Pus.

Pus was first taken from an abscess believed to be tuberculous in a patient with a temperature of 100° F. In film preparations no organisms could be found. Intravenous injection of small quantities of this pus in water was not followed by fever, early or late, whether heated or unheated. Samples of fresh pus were then taken from several patients with fever, and were examined bacteriologically and by intravenous and subcutaneous injection. Only those specimens were selected for injection which were found to contain large numbers of micro-organisms indicating the presence of recently-formed pus, or of pus from the periphery of abscess sacs. Control cultivations on agar gave in all cases selected copious growth. The organisms injected in different specimens included staphylococci, diplococci, and streptococci. One specimen contained both staphylococci and streptococci. In no case did injection of quantities of heated pus from 0.1 gram in 1 c.c.m. of water to 2.50 grams in 2.50 c.c.m. of water produce fever early or late. On the other hand, injection of sufficient quantities of unheated pus in this series never failed to produce a continued fever with a much shortened latent period.

These experiments are of interest in view of the numerous observations that have been published to show that injection of pus is constantly followed by fever. Such observations can only be explained by injection of pus in pyrogenetic saline, or by injection only of unheated pus. The experiments here quoted, however, lend additional support to the view that fever can only be produced during a natural infection by the living organism. In the case, however, of pus injections it is again impossible to carry out satisfactory enumeration of the organisms injected, and this method was therefore abandoned.

The only convenient method remaining of determining whether organisms recovered from the body during an infection with fever do or do not produce immediate

fever when injected dead is to obtain them direct from the blood stream in cases of septicaemia. If the circulating blood in septicaemia be received into pure sodium citrate solution and the mixture at once centrifuged, the deposit can, after lysis of the red cells in pure water, be readily examined. Any organisms present can then be counted in the ordinary way. In laboratory experiments, however, as is well known, it is a difficult matter to produce a genuine bacteraemia, since the injection of organisms after growth on ordinary laboratory media is followed by their rapid disappearance from the blood stream as estimated by ordinary cultivation methods. And the cultivation of serum-fast strains has certain disadvantages. I have, however, overcome these difficulties by growing, for example, a laboratory strain of pneumococcus on the rabbit blood cell extract above described for forty-eight hours. Injection of the living organism from such extract into a healthy rabbit produces an infection with fever that can be demonstrated for some days. And injection of known numbers of organisms recovered from the blood during this fever can be readily carried out. Injection of 3,000 million dead organisms recovered in this way failed to produce any fever early or late, whilst injection of 10.0 c.c.m. of a 40 per cent citrated solution of plasma from the same animal, after removal of any organisms present by the aid of the centrifuge, produced slight but definite rise of temperature, and injection of the living organisms produced a typical continued fever.

Demonstration of the absence of pyrogen in dead bacterial protoplasm of organisms recovered during natural infections appears therefore in the cases examined to be complete. Whether this will prove also to be true of all organisms recovered from infected subjects, including man, is a question that only further study can decide.

In the meanwhile, in view of the cumulative evidence here presented, it is difficult to resist the conclusion that a rising temperature is not—as we have paradoxically been led to believe—a sign of increase of bactericidal and bacteriolytic function, but is on the contrary an expression of the activity of living organisms. Dead organisms, in short, do not in natural infections give rise to fever.

The next question that arises is the practical bearing of these observations on immunity problems in general and in particular on the administration of dead bacterial vaccines in the diagnosis, prevention and treatment of infective disease.

It will, I think, be clear that the non-bacterial pyrogen derived from laboratory media which is so misleading a factor in the experimental study of fever is also one that we cannot afford to ignore in practical medicine.

There are in connexion with prophylactic and therapeutic vaccines two possibilities to be considered. On the one hand contamination of bacterial vaccines with pyrogenic substances of purely laboratory origin may greatly enhance their prophylactic and therapeutic value. In this connexion the observations made some years ago on the effect of injecting nucleinates are of interest, though they cannot be dealt with here. If comparative experiments with the vaccines at present in use and with detoxicated vaccines prove that the presence of non-bacterial substances is an advantage, steps will have to be taken by subcultivation or in other ways to ensure that all vaccines are toxic. At present some vaccines are toxic in this respect, and some are not. Some of the causes for these differences I have explained. On the other hand, contamination of vaccines with laboratory material may be a distinct disadvantage. If this prove to be the case, vaccines, before they can be justifiably used in man, must first be tested for the absence of medium derivatives by injection of animals with the precautions mentioned, or in some other way. And such vaccines as are found to be toxic must then be rendered atoxic by one or other of the methods given, or by some other method if shown to be more convenient. It will not be forgotten that the injection of contaminated vaccines into healthy subjects for purposes of prophylaxis may be a less serious affair—if disadvantage be proved—than therapeutic injection of subjects already gravely ill. In these the question of dosage will necessarily be a matter of special concern, unless vaccines shown to have been detoxicated, or to be primarily atoxic, are employed.

Of more importance, however, even than the question of the positive good or harm effected by injections of contaminated vaccines is the larger question of to what extent the specific antigenic values of vaccines in general depend on the presence of this contamination. (In passing it may be well to point out that there is some evidence that the toxic substances elaborated from culture media by the action of living organisms on such media are to a certain extent specific to those organisms.²)

In other words this problem presents itself: Have we at present unimpeachable evidence that a pure dead vaccine has any antigenic values in the prophylaxis or treatment of general or local infections? It is worth notice that the vaccines for which the highest protective and therapeutic values are claimed are just those in which the content of laboratory pyrogen is highest. Cases in point are *B. typhosus*, *B. coli*, possibly *B. pestis*, and the acne bacillus. I am not here suggesting that this relation is more than accidental, or that dead vaccines have no specific antigenic values apart from their laboratory contamination. It is obvious, however, that until the point has been fully investigated we are no longer justified in attributing to dead bacterial vaccines antigenic values that may prove to belong—in whole or in part—to substances that are not primarily derived from dead bacterial protoplasm. At present when we employ these vaccines we have no guarantee that any single vaccine provided is a pure vaccine.

In future, therefore, we shall require such guarantee, as well as an assurance that the process of purification has not damaged any genuine antigen the purified vaccine may possess. And in passing it may be well to glance at the question of the so-called autogenous vaccine, which in one important respect is a somewhat misleading name, as I pointed out in 1911. A vaccine made from dead organisms collected from the blood or other tissues of an infected subject and injected without intermediate cultivation on laboratory media is a genuine autogenous vaccine, and its injection in animals appears not to be followed by toxic symptoms, though it remains to be seen if it has any therapeutic effect. A vaccine, however, that is made from organisms collected in the same way, but then cultivated on artificial media and then injected—after death of the organisms has taken place—is not a genuine autogenous vaccine, because, as I have shown, the toxic symptoms that may now arise are due to contamination from the laboratory medium of growth. The organism, in short, has had a new function imposed upon its descendants by such growth, and it is not impossible, therefore, that the increased therapeutic values with which the *soi-disant* autogenous vaccine is credited may prove to be due to this very fact.

It is not stretching the argument too far to point out that it is also necessary in view of the experiments here described to examine afresh the evidence that has hitherto been relied on in favour of the existence of bacterial toxins in general and especially of the so-called endotoxins. The endotoxin of *B. typhosus* is a case in point. In all these cases it will now be necessary before we can postulate the existence of a genuine endotoxin to be sure that the organism selected for purposes of extraction, whatever the method of extraction selected, is first of all deprived of the highly toxic material elaborated from the culture medium. In all experiments so far undertaken with the reputed toxin of *B. typhosus* when cultivated on laboratory media this precaution has for obvious reasons not yet been taken.

Finally comes the question of diagnosis. If, for prophylactic or therapeutic purposes, it is necessary to use pure vaccines, it is equally so in all those test tube reactions in which antigen and antibody are the essential factors. We shall not only have to make certain that only pure vaccines are used for the production of animal immune serums, but we shall also have to ensure that all bacterial emulsions used as diagnostic antigens are equally above reproach. In the case of such organisms as the bacillus of Koch, and of such other members as apparently do not elaborate

² For example, the centrifuged washed organisms of *B. coli* laboratory cultures cannot be deprived of their pyrogenic properties by washing with hydrogen peroxide. This fact appears therefore to indicate that the living *B. coli* elaborates from its culture medium a pyrogen of a different nature to that elaborated by the living *B. typhosus*. Moreover, *B. coli* is able to synthesize a pyrogen from protein-free media which before inoculation with the living organism are apyrogenic.

this contamination from culture media these precautions may prove unnecessary. On the other hand, in the case of all those organisms which we have shown to be characterized by their ability in the living state to elaborate toxic derivatives from the media of artificial growth, these precautions cannot be neglected.

In conclusion, although it is premature to indicate the practical lines of direct immunity research opened up by these experiments, it is impossible to ignore the suggestions they offer as to the meaning of sensitization and the superiority of living vaccines over dead, as well as to the necessity for re-examination of the whole scheme of vaccine-therapy. And in the meanwhile, if they do no more than press home the necessity for fresh investigations into the true source and character of the natural antigens of disease they will faithfully have served their purpose.

NOTE.—Since this paper was placed in type two articles on experimental fever have appeared in a German periodical by Thiele and Embleton which might seem at first sight to affect some of the conclusions reached in this communication.⁹ In the articles referred to, the authors—as so many have done before them—have fallen victims to the very fallacies which Dr. Penfold and I have already exposed in the English journals.¹⁰ One of the fundamental errors, for example, in all study of experimental fever produced by injection is the assumption that water which is innocent of demonstrable infection at the time of injection must also be innocent of pyrogen, and that water collected direct from the condenser of a distilling apparatus in daily use and then filtered is necessarily pure water. In consequence, therefore, of failure to recognize this source of error these workers in many of their experiments unwittingly used impure water, as is clearly shown in their own protocols. This accident is alone sufficient to invalidate all the experiments and deductions based thereon, though there are other fallacies of almost equal importance which I have fully described elsewhere.

APYREXIAL TYPHOID.

BY

NORMAN FLOWER, M.A., M.B., B.Ch., Oxon.,

M.D.,

APYREXIAL typhoid, although known to exist, is of excessively rare occurrence, and may therefore readily pass unrecognized, particularly in the absence of an epidemic of the disease. Cases of this type have been described by Gerhardt and Dreschfeld, and of these brief mention is made by the latter in Allbutt's *System of Medicine*.

In typhoid fever we know that, in patients of over 40 years of age, the temperature curve is lower and less characteristic, but although cardiac, pulmonary, and renal complications are more common, splenic enlargement and rose rash are frequently absent. For these reasons, therefore, the diagnosis may be rendered more difficult. The case recorded below will serve to illustrate these points.

The patient was a woman aged 60, who had resided in the same house for more than thirty years, and during that period had never required medical assistance for more than minor ailments. A careful investigation into her previous history precluded all possibility of any previous attack of typhoid fever.

The present illness commenced in the first few days of September, with the usual feelings of malaise, and with gradually increasing diarrhoea. She took to her bed on September 8th.

When first seen, on September 10th, the patient was in an exhausted condition, with a dry, furred tongue and subnormal temperature. The outstanding feature of the case at the time was the exceedingly profuse diarrhoea, which persisted in spite of all the usual remedies. On September 12th (two days later) the patient began to wander, and sank into a semi-comatose state, in which she remained for the ensuing fourteen days. During this period the intestinal symptoms were unchanged, there was a moderate distension of the abdomen, but no spots or enlarged spleen were present then or later. Widal's reaction on September 16th was positive in every dilution. From the onset of the attack until September 25th (that is, the fourth week of the disease), when complete consciousness returned, the mouth and surface temperatures were invariably subnormal, and the rectal temperature, taken twice daily, never exceeded 99.4°. From September 26th to October 4th the mouth and rectal temperatures each reached their maximum of 99.6° and 100.4° respectively, after which they dropped again.

During the fourth week a further specimen of serum was obtained for the purpose of comparative agglutination reactions to *B. typhosus* and other allied organisms, with the following results:

- B. typhosus* agglutinated up to 1 in 2,000.
B. paratyphosus B agglutinated up to 1 in 200.
B. paratyphosus A agglutinated very slightly.
B. enteritidis (Gaertner) agglutinated not at all.

The patient ultimately made a good recovery, and without serious complications.

An investigation of the water-supply of the (isolated) dwelling revealed a privy in close proximity to the well, which constituted the sole supply of drinking water on the premises. This water, on examination by the county authority, proved to be contaminated with sewage.

In the light of all the bacteriological findings, I think there can be very little doubt that in this case there existed a true typhoid infection.

A SIMPLE AND RAPID METHOD FOR THE ADMINISTRATION OF SUBCUTANEOUS SALINES.

By E. MUSGRAVE WOODMAN, M.S., F.R.C.S.,
 ASSISTANT SURGEON, GENERAL HOSPITAL, BIRMINGHAM.

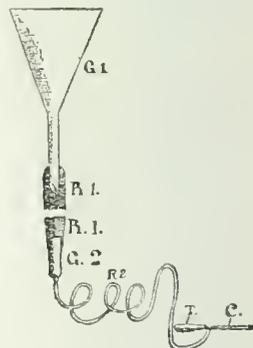

THE administration of saline solution by the method of subcutaneous injection has many points in its favour and should by no means become obsolete. There is no method to equal it when the absorption of a large quantity of fluid is required.

In numerous cases of late years I have made use of an apparatus which, from its convenience and simplicity, has served to replace more cumbersome methods.

The only requisites are (1) a large silver cannula from a Southey's tube apparatus; (2) Southey's rubber tubing; (3) a small piece of glass tubing, narrow at one end to fit this tubing, and larger at the other (for this an ordinary clean fountain-pen filler does very well); (4) a large glass funnel connected to the glass tube by rubber. The various parts are joined together and the whole is sterilized by boiling.

The mode of introduction deserves special notice, for it differs considerably from the usual method. The anterior axillary fold is grasped firmly and drawn outwards. The trocar with its cannula is then passed into the skin in a direction vertical to the chest wall and is pushed steadily through the axillary fold so that its point emerges within the axilla. The trocar is then withdrawn and the cannula is pressed onwards into the axilla until its shoulder rests flush with the skin.

The fluid as it emerges from this cannula spurts in all directions and is poured out into three distinct plains, separated anatomically into watertight compartments by the deep fascial layers. Into the most superficial of these

G1, Glass funnel. R1, Large bore rubber tubing. G2, Glass tube. R2, Southey's rubber tubing. T, Trocar. C, Cannula.

fluid flows into the fatty tissue over the pectoral muscle and around the breast and extends upwards over the clavicle into the neck. Beneath this saline exudes into the pectoral muscles and is limited by the deep fascia on either side. Absorption is here rapid owing to the great vascularity of the part and to the pressure maintained by the fascial limitations. Lastly distension of the axillary space takes place and the normal concavity of the axilla is replaced by a rounded swelling.

Fluid is absorbed very rapidly when introduced in this way and two pints can be run into the tissues in twenty minutes, little trace of swelling being found. After an hour the cannula is left *in situ*, and the administration can be repeated as often as necessary.

This method has one disadvantage, and I think only one. The introduction is rather painful, but hardly more so than when the needle is merely inserted beneath the skin, while the pain resulting from distension is largely obviated. But in the majority of cases the patient is still under the influence of the anaesthetic when the administration is given or is so collapsed as to be insensitive to pain.

This objection is more than compensated for by the ease of introduction and rapidity of absorption of a large quantity of saline by means of a simple appliance which every practitioner has at his command.

ADRENALIN IN THE EMERGENCY TREATMENT OF NON-CORROSIVE POISONING BY THE MOUTH

(CYANIDE, STRYCHNINE, ACONITE, ETC.).

BY

JUDAH LEON JONA, D.Sc., ADEL., M.D., B.S., M.E.D.,

DEPT. MEMORIAL FELLOW, LISTER INSTITUTE; FORMERLY ASSISTANT LECTURER IN PHYSIOLOGY, UNIVERSITY OF MELBOURNE.

WHEN a chemical substance enters the stomach or bowel it must first be absorbed into the circulation before it can exert a general direct action on the body. One of the chief factors determining the rate of absorption of any substance introduced into any part of the gastro-intestinal tract is the vascularity of the part, and particularly of the lining membrane. Now if, after the introduction into the stomach of a poisonous chemical substance whose general toxic action depends partly upon the rate at which it enters the circulation, we are able to limit the rate of absorption of the drug—for example, by diminishing the blood supply to the mucosa of the stomach—time is provided for the preparation and adoption of methods to neutralize any possible action which would normally follow the introduction of the particular substance into the stomach, either by removing it altogether by means of a stomach tube and a stomach wash-out, or by inactivating it by means of a chemical antidote. Particularly valuable would such an agent be which would lower the rate of absorption into the circulation of a substance which, entering the blood in large quantity, would destroy the life of the individual, but which the body is able, by the exercise of special powers, to efficiently neutralize when it gains entry into the economy slowly. To such a category belong the cyanides. Theis⁶ and Buttner¹ have demonstrated that when an animal has been killed by a lethal dose of KCN the amount of cyanide present in the organs diminishes on standing, while Lang⁴ and Grober³ have shown that when HCN is introduced into the diet of an animal the amount of cyanide in the stomach diminishes, while the amount of sulphocyanate in the saliva and urine is increased.

Intraperitoneal injection of adrenalin has been found by Exner² to diminish the rate of absorption of a poison, such as strychnine or potassium cyanide, when introduced into the stomach. This academical piece of work suggested the investigation of the effect of the introduction of adrenalin into the stomach on the absorption of rapidly-acting poisons, such as cyanides, strychnine, and aconite, also introduced into the stomach, and whether such administration of adrenalin had any value in the practical

treatment of cases of accidental poisoning by these rapidly-acting drugs.

CYANIDES.

The hitherto generally recognized antidote in cases of cyanide poisoning has been that advocated by Professor C. J. Martin and Mr. J. A. O'Brien.⁵ Its principle is the formation in the gastro-intestine of Prussian blue, which is a practically innocuous substance, by the administration subsequent to the cyanide poisoning of ferrous sulphate and alkali. They proposed that 30 c.c.m. (1 oz.) of ferrous sulphate solution of 25 per cent. strength, 50 c.c.m. (1 oz.) of KOH (5 per cent. solution), and 2 grams (30 grains) of magnesia, the former two kept in hermetically sealed phials, be mixed and immediately taken. In their experiments on rabbits, using a lethal dose of 0.01 gram, given as 10 c.c.m. of a 0.1 per cent. solution of KCN per kilogram of body weight, they found that death invariably ensued unless the antidote were administered within five minutes. Considering that the antidote consists of three separate ingredients, which must be mixed before use, the preparation of the antidote must occupy time and would probably take about two minutes, even if everything were at hand; so that if about three minutes were lost before discovering that cyanide had been accidentally taken, the patient's chances of recovery would be very small, for we may legitimately assume that the respite or "latent period" would only be a little if any longer in the human being than in the rabbit. Also, the ordinary medical man might not have the antidote ready at hand, and the value of some means of delaying the absorption of the poison from the gastro-intestine is apparent, and this is especially so in the case of poisoning by cyanide, whose action is so rapid.

Intraperitoneal injections of adrenalin having been found to diminish the rate of absorption of strychnine introduced into the stomach,² it was therefore decided to try and see if adrenalin administered by the mouth would have any effect in giving us more time to treat a case of cyanide poisoning. As a preliminary investigation, KCN solution, of strength varying from 1 per cent. to 5 per cent., was painted on various mucous membranes (conjunctiva, buccal mucous membrane, gastric mucosa) for five minutes, and then adrenalin (1 in 10,000) painted on, when blanching occurred in every case.

These experiments showed that adrenalin will still exert its vaso-constrictor action even after the arteriolar wall has been subjected to cyanide.

Further experiments showed that when adrenalin solution was administered (about 4 to 5 c.c.m. 1 in 10,000 solution per kilogram body weight, the rabbit receiving the lethal dose of 0.01 gram KCN per kilogram body weight) either with or subsequently to the administration of the poison the animal's life was prolonged, and if the adrenalin solution were administered within five minutes of the poison, and Martin and O'Brien's antidote given, or the stomach washed out within four or five minutes subsequent to the administration of the adrenalin, the animal's life would be saved. Thus, the administration of adrenalin "on sight" would give a respite of some minutes during which the antidote could easily be prepared and administered or the stomach contents evacuated.

The results of a few of the more crucial experiments are appended. A number of experiments have been discarded because the rabbits did not tolerate the washing out of the stomach to which many were subjected. It may also be stated at the outset, that Martin and O'Brien⁵ found that if a dose of cyanide were going to prove fatal the rabbit always died within thirty minutes, so that we may take it that if we are able to tide a patient over the fatal thirty minute limit by any means at our disposal, then the patient will have a very fair chance of recovery. Of course, if it be borne in mind that the adrenalin only delays the absorption of the poison (principally by its vaso-constrictor action on the vessels of the mucosa), it will be recognized (as Experiment No. 4 shows) that those cases are practically hopeless in which a large dose of the poison has been taken and in which the amount of poison being absorbed through the mucosa even under maximal adrenalin influence exceeds the lethal limit, unless the chemical antidote be immediately given or the stomach immediately evacuated. The time relation here indicated (namely, that the pathological effect depends to a certain degree upon the amount of poison coming into contact with the tissues per unit of time), and the fact that the administration of

⁵ Throughout this investigation adrenalin (P. D. and Co.) and hemisine (B. W. and Co.) were both used with the same effect.

an amount of KCN below a certain limit is accompanied by very little, if any, evident effect on the animal, seem to suggest that we have in the case of the action of chemical substances on all tissues of the body a parallelism to the action of various strengths of stimuli acting on a motor nerve and affecting the muscular response in the presence of a limit or threshold, an optimum and maximal strengths of stimulation. Further research, however, is required to determine this.

Further experiments showed that the administration of doses of adrenalin far in excess of those recommended by the cited experiments left, as far as the eye could detect, no lasting effects on the animals. The general results obtained from rabbits were:

The animal (receiving a lethal dose of 0.01 gram KCN per kilogram body weight) will recover if—

1. Adrenalin (3 c.cm. 1 in 10,000 solution) be administered within five minutes of the poison.
2. Martin and O'Brien's antidote given or the stomach washed out within about four minutes of the administration of the adrenalin.
3. A further small dose of adrenalin be given.

The area of a rabbit's stomach was found to be 95 sq.cm. That of a man is given as about 3,000 sq.cm.¹⁹ Therefore the dose of adrenalin which a man should take on this basis of, say, 3 c.cm. of 1 in 10,000 per 100 sq.cm. stomach area, would be about 90 c.cm., that is, 9 c.cm. (3 dr.) of 1 in 1,000 solution, diluted (that is, 90 c.cm. or 3 oz. of 1 in 10,000 solution) followed afterwards by about 5 c.cm. (1½ dr.) of the 1 in 1,000 solution, diluted (that is, 50 c.cm., or nearly 2 oz. of 1 in 10,000 solution).

Method of Treatment.

The experiments seem to show that in a case of cyanide poisoning the following procedure is advisable:

1. Adrenalin be immediately given.
2. Then Martin's antidote if it be at hand.
3. Then wash the stomach out; and
4. After having washed the stomach out, administer some more adrenalin.

The object of the latter is to "follow up" any cyanide which has escaped the washing out process or Martin and O'Brien's antidote, and so retard its absorption, for Martin and O'Brien found that if death did not ensue within thirty minutes of administering the cyanide, the animal would live. It might also be advisable to give a brisk saline purge soon afterwards. Should Martin's antidote not be at hand, the order of procedure should be 1, 3, 4, as above.

There are two further considerations which must be taken into account before the recommendations made above are to receive acceptance. First, is the adrenalin affected by the HCl of gastric juice or by the pepsin? This question has been answered by Oliver and Schäfer⁷ who showed that gastric digestion (by pepsin—HCl) for twenty-four hours does not seem to lessen the physiological properties of extract of suprarenal gland. Secondly, how long will the adrenalin introduced into the alimentary canal continue to act on the lining membrane? The results obtained by Oliver⁶ furnish the desired information. To quote from his paper: "Suprarenal extract invariably produced the most decisive contraction, and one, moreover, which persisted for thirty to sixty minutes. The constriction was equally pronounced whether the spinal cord remained intact or was destroyed. The velocity of the circulation was likewise lessened, and at the acme of the constriction the onward flow might cease." Oliver's recommendation that these might be verified on the inflamed conjunctiva of a rabbit has been confirmed. It was also found that on administering adrenalin solution to a rabbit with a full stomach, there was a constricting action not only on the vessels of the gastric mucosa but also on the vessels of the mucosa some inches down the small intestine, which lasted for quite fifteen minutes.

STRECHNINE AND ACONITE.

In the case of these poisons, too, a number of experiments were performed, and the efficiency of adrenalin in delaying absorption conclusively proved. With these poisons the administration of adrenalin until the stomach

can be thoroughly emptied is indicated, and in them the stomach *must* be emptied and the poison got rid of, otherwise the poison will be absorbed and exert its action on the body when the action of the adrenalin on the stomach has ceased. This is shown by Experiment No. 14.

Experiments were also tried with other rapidly acting poisons, such as potassium binoxalate (neutral), but the gastric mucosa was found (*post-mortem*) corroded, and free blood was found in the stomach, so that disturbing factors due to erosion and not remediable by adrenalin were present.

From these experiments on rabbits and dogs it is at once seen that in extract of the medulla of suprarenal gland—which is marketed under the names of adrenalin (P. D. and Co.), hemisine (B. W. and Co.), suprarenin, epinephrin, adrenine, reuaglandin, etc.—we have an agent which will convert the stomach or other absorbing viscous on which it is acting into a practically non-absorbing bag in which the poison lies, ready to be absorbed when the action of the adrenalin passes off, but at the same time being absorbed in relatively small amount while the adrenalin is acting; and so a respite is gained during which the poison can be removed by mechanical means or neutralized *in situ* by some chemical antidote.

SUMMARY OF PRINCIPAL EXPERIMENTS.*

Experiments with Cyanide.

Experiment 1.—Rabbit. Conjunctiva: KCN (0.1 per cent.) painted on for five minutes. Adrenalin (1 in 10,000) applied. Blanching. Mucosa of Lips: Same as conjunctiva.

Experiment 2.—Rabbit. Chloralized. Stomach opened. One spot on mucosa painted with 5 per cent. KCN for five minutes (and another control spot with normal saline). Adrenalin (1 in 10,000) then painted on both spots, and blanching produced in both.

Experiment 3.—Two rabbits in full digestion. Chloralized. Stomach tube passed per oesophagus.

Rabbit A, 1,100 grams. 11 c.cm. KCN solution (0.1 per cent.) administered. Three minutes after giving KCN respirations ceased.

Rabbit B, 1,100 grams. 11.5 c.cm. KCN solution (0.1 per cent.) administered. Eight minutes after giving KCN respirations reduced to mere flicker, then respirations improved and became normal, then gradually shallower. Thirty minutes after giving KCN respirations ceased. On opening the stomach the mucosa was seen to be red.

Experiment 4.—Two rabbits in full digestion. Chloralized.

Rabbit A, 1,000 grams. 4 c.cm., 0.5 per cent. KCN solution. Two and a half minutes after giving KCN respirations ceased.

Rabbit B, 1,200 grams. 4 c.cm., 0.5 per cent. KCN solution:

- 2 minutes after giving KCN, 4 c.cm. 1 in 10,000 adrenalin given.
- 2½ minutes after giving KCN, respirations ceased.

Experiment 5.—Rabbit, 1,600 grams in full digestion. 16 c.cm. KCN (0.1 per cent.) solution given:

- 2 minutes after giving KCN, 6 c.cm. adrenalin (1 in 10,000) were given.
- 6 minutes after giving KCN, rabbit had a few convulsions which passed off.
- 10 minutes after giving KCN, commenced washing stomach out, but washing out process was unsuccessful.
- 24 minutes after giving KCN, further convulsions.
- 29 minutes after giving KCN, respirations ceased.

The stomach-tube was found blocked with a piece of stomach content (mucus).

Experiment 6.—Rabbit, 1,600 grams in full digestion. Etherized, 16 c.cm. KCN solution (0.1 per cent.) given:

- 2 minutes after giving KCN, convulsions.
- 4½ minutes after giving KCN, 4 c.cm. adrenalin (1 in 10,000) given.
- 7 minutes after giving KCN, stomach washed out.
- 65 minutes after giving KCN, respirations ceased.

There were signs of hypostatic congestion and oedema of the lungs on *post-mortem* examination.

Experiment 7.—Rabbit, 1,300 grams. Chloralized (lightly), 13 c.cm. KCN solution (0.1 per cent.):

- 2 minutes after giving KCN, convulsions.
- 2½ minutes after giving KCN, 6 c.cm. adrenalin solution (1 in 10,000).
- 6 minutes after giving KCN, stomach washed out.
- 7 minutes after giving KCN, 3 c.cm. adrenalin solution (1 in 1,000).

Recovery.

*Some of these results originally appeared in the *Intercolonial Medical Journal of Australasia*, July 20th, 1909.

Experiment 8.—Rabbit, 700 grams, in full digestion. Chloral-ized lightly.

- 7 c.cm. KCN solution (0.1 per cent.) given.
- 4 minutes after giving KCN, 6 c.cm. adrenalin (1 in 10,000 given).
- 9 minutes after giving KCN, stomach washed out.
- 19 minutes after giving KCN, 3 c.cm. adrenalin (1 in 10,000 given).

Recovery.

Experiment 9.—Rabbit, 950 grams, 9.5 c.cm. KCN solution (0.1 per cent.) given:

- 5 minutes after giving KCN, 6 c.cm. adrenalin (1 in 10,000 given).
- 8½ minutes after giving KCN, Martin's antidote administered.

Convulsions. Recovery.

Experiment 10.—Rabbit, 1,250 grams. 12.5 c.cm. KCN solution (0.1 per cent.):

- 4 minutes after giving KCN, 3 c.cm. hemisine (1 in 10,000).
- 8 minutes after giving KCN, convulsions.
- 12 minutes after giving KCN, Martin and O'Brien's antidote given.
- 25 minutes after giving KCN, respirations ceased.

Experiment 11.—Rabbit, 1,300 grams. 13 c.cm. KCN solution (0.1 per cent.) administered:

- 3½ minutes after giving KCN, 3 c.cm. adrenalin (1 in 10,000) given; convulsions.
- 11 minutes after giving KCN, Martin's antidote + 2 c.cm. adrenalin (1 in 10,000) given; respirations were slowed.
- 15 minutes after giving KCN, respirations were of expiratory type for about one minute.

Conjunctival reflex absent and pupils dilated till about twenty-two minutes after poisoning. Pupils then began to contract somewhat. At this time the breathing was alternately mouth and nasal, and respirations were sixteen per minute. About thirty-seven minutes after poisoning respirations were twenty per minute, and breathing still mouth and nasal alternately. Conjunctival reflex returning fifty-two minutes after poisoning; respirations twenty-four per minute, and nasal in character. Animal apparently asleep, and breathing quietly, when it was left tied up in the laboratory two hours after administering the cyanide. Found dead next morning. There was a strong smell of gas in the laboratory and it is quite possible that the animal died of CO poisoning.

This experiment shows the beneficial effect to be derived from giving the animal a further small dose of adrenalin.

Experiment 12.—Rabbit, 1,300 grams. 23 c.cm. adrenalin (1 in 10,000) given. Twenty-four hours afterwards stomach examined. No pathological condition of mucosa apparent.

Experiment 13.—Rabbit. 35 c.cm. adrenalin solution (1 in 10,000) administered. Twenty-four hours afterwards no abnormal appearances in stomach, intestines, kidneys, liver, heart.

Experiments with Strychnine, Aconite, and Other Poisons.

Experiment 14.—Two rabbits, in full digestion, were taken.

Rabbit A, weight 950 grams. Received 11.5 c.cm. strychn. sulph. solution (that is, 12 c.cm. per kilogram body weight) into its stomach. Death occurred forty-two minutes after.

Rabbit B, weight 1,150 grams. Received 13.8 c.cm. strychn. sulph. solution + 4 c.cm. adrenalin (1 in 10,000) into its stomach. It was still alive four hours twenty minutes after, but was found dead next morning in position of opisthotonus.

Exner² showed that rabbits which received a dose of 0.0052 gram strychnine sulphate on the average exhibited convulsions in ten minutes and death in twenty minutes.

Experiment 15.—Dog, weight about 8½ kg.; starving; was morphined, and received ½ grain (0.025 gram) strychn. sulph., dissolved in 30 c.cm. saline.

- 10 minutes after giving the strychnine, 12 c.cm. adrenalin (1 in 10,000) were given.
- 16 minutes after giving the strychnine, stomach washed out.
- 21 minutes after giving the strychnine, 8 c.cm. adrenalin (1 in 10,000), immediately followed by 1 oz. mag. sulph.

Recovery.

A dog of about the same weight, size, age, and breed received ½ grain strychn. sulph., and died in six hours.

Experiment 16.—Eighteen days after Experiment 15. The same dog used: in full digestion; morphined. Received ½ grain (0.025 gram) strychn. sulph., dissolved in 30 c.cm. water.

- 12 minutes after giving the strychnine, 12 c.cm. adrenalin (1 in 10,000) given.
- 18 minutes after giving the strychnine, commenced washing stomach out.
- 27 minutes after giving the strychnine, 8 c.cm. adrenalin (1 in 10,000), immediately followed by 1 oz. mag. sulph.

Recovery.

Experiment 17.—Two rabbits in full digestion taken.

Rabbit A, weight 1,150 grams. Received 11.5 c.cm. lin. A.B.C. Died fifty-nine minutes after.

Rabbit B, weight 1,250 grams. Received 12.5 c.cm. lin. A.B.C. + 5 c.cm. adrenalin (1 in 10,000). Died two hours four minutes after.

Experiment 18.—Two rabbits in full digestion taken.

Rabbit A, weight 1,350 grams. Received 13.5 c.cm. lin. aconit. (lin. aconit. B.P., diluted ½). Died fifty-seven minutes later.

Rabbit B, weight 1,350 grams. Received 13.5 c.cm. lin. aconit. (lin. aconit. B.P., diluted ½) + 5 c.cm. adrenalin (1 in 10,000). Died six hours twenty-five minutes later.

Experiment 19.—Two rabbits in full digestion.

Rabbit A, weight 1,300 grams. Received 2 grams pot. oxalate in 20 c.cm. water. Died fifty minutes after poison.

Rabbit B, weight 1,400 grams. Received 2 grams pot. oxalate in 20 c.cm. water + 5 c.cm. adrenalin solution (1 in 10,000). Died fifty-eight minutes after poison.

My sincere thanks are due to Professor W. A. Osborne, D.Sc., under whose direction this research was conducted, for the very valuable advice and encouragement he has given me while the work was in progress.

THE LATE VASOMOTOR PARESIS DUE TO ADRENALIN.

By HAROLD WIALE, M.D. CANTAB., F.R.C.S. ENG., ASSISTANT SURGEON, METROPOLITAN EAR, NOSE AND THROAT HOSPITAL.

A GENTLEMAN consulted me on account of multiple exostoses of the external auditory meatus, which so far occluded the lumen that beyond them only the finest Eustachian bougie was passable, and nothing was visible. Presumably the marked tinnitus, which was his chief complaint, was due to an accumulation of sebun and epithelial débris deep to the growths; for this tinnitus remained absent so long as he regularly used drops of hydrogen peroxide.

His unwillingness to persist with this treatment; a moderate degree of obstructive deafness to speech, acoumeter, and tuning-fork; and the danger that an infection of débris between the growths and the membrane might lead to perforation and otitis media, were the indications for surgical interference.

The external meatus was unusually tortuous; the growths, only one of which was pedunculated, were very deep, and at subsequent operation proved to be actually continuous with the annulus tympanicus. The difficulty of access emphasized the necessity for a clear bloodless field in operating. Therefore, before making the post-aural incision, adrenalin chloride was injected along the superior, posterior, and inferior meatal walls as far as the growths—5 drops of a 1 in 2,000 solution in each situation. The whole area became and remained remarkably bloodless, and a branch of the posterior auricular was the only vessel tied during the operation, at the conclusion of which a rubber tube, of such a length that its outer end hitched just under the tragus, was pushed down to the intact drum.

At the first dressing, on the third day, the tube had become slightly unhitched from the tragus, and had slipped out about ¼ in. It could be pushed back, but on the release of pressure again emerged for this small distance, very slowly, as if levered up by an elastic body beneath. Next day the tube projected about ½ in.; it was again replaced, and pressure applied over it by a small pad under the dressings.

On the fifth day, finding it impossible to keep the tube in position, it was removed, and an inspection made. The membrane was completely hidden by the edge of the skin of the posterior meatal wall, where this skin had been cut across just distal to the growths. The skin could not be replaced in position, being pushed forwards from behind, presumably by blood-clot.

On the seventh day, as the flap showed no promise of retracting, I reopened the post-aural wound, and found that from here all along the posterior meatal wall bone and skin were separated by a clot. In amount this clot was sufficient to fill a dessert-spoon, and more than the space would be expected to hold; much of it lay in the deepest part of the meatus, levering the cut skin-edge forwards, so that it lay directly over and parallel to the drum. After the removal of the clot and the passage of a tube as before, healing, with a good lumen and cure of all symptoms, was uneventful.

This case shows that, apart from any of its general physiological disadvantages, adrenalin may cause mechanical trouble by reason of the vasomotor paresis which follows the phase of vaso-constriction.

THE BREAKING OF THE VICIOUS CIRCLE.

BY

JAMESON B. HURRY, M.A., M.D.,

LATE MEDICAL OFFICER, UNIVERSITY COLLEGE, BIRMINGHAM.

DISEASE, when complicated by the presence of a vicious circle, presents problems for solution peculiar to itself. The physician is no longer confronted with a morbid process which Nature is doing her best to rectify, and where treatment mainly consists in furthering and regulating her efforts. When a circle is present Nature is aggravating the disorder. The *vis medicatrix* has become the *vis devastatrix*, and what looms before the sufferer is at best a prolonged disorder, at worst a *descensus Aerni*.

Vicious circles are widespread in their distribution, and play a great part in clinical medicine. Their study promotes a visualization of those pathological sequences that are ever acting reciprocally on each other, and greatly assists the accurate adaptation of remedies to the complex conditions of disease.

Although a large part of the *ars medendi* consists in "breaking the circle," this aspect of therapeutics has, strange to say, almost wholly escaped attention. True, many years ago a great teacher wrote: "Let it be a cardinal principle of treatment to make an effort to interrupt vicious circles."¹ But even to-day our textbooks give but little assistance in the solution of problems presented by reciprocally acting consequences. It may be useful to indicate the principles on which treatment under such circumstances must be based, and to illustrate those principles by a few examples.

LOCUS MINORIS RESISTENTIAE.

One signal advantage presented by the circle is that there are at least two points at which its evil round may be interrupted. In the words of Lauder Branton, "We must see where the circle can best be broken," since, "if we can break the circle at one point, we allow recovery to commence."² Our first step then is to seek the *locum minoris resistentiae*. The discovery may not be easy, inasmuch as it presupposes an accurate diagnosis of the various factors that constitute the circle, and this may involve a painstaking investigation, as emphasized by Clifford Allbutt:

First of all we shall begin by a close searching for any vicious circle of function, and, if found, of cutting any link of it, whatsoever or wheresoever. . . . A floating kidney, a disorder of the uterus, a faulty eye, a "tea" or "tobacco" heart, or other local irregularity, trivial enough perhaps in itself, may close and perpetuate the vicious orbit of function.³

When the factors constituting the circle have been elucidated, our duty is to break it through at the weakest point. If the gyration can be stopped the whirling currents will be restored to their normal direction. "The bound which had turned to hunting its own tail may be put again on the track."

The *modus operandi* will vary with the special circumstances of each case. But some illustrations may be grouped under the following heads:

- I. The breaking of the circle by hygienic measures.
- II. The breaking of the circle by surgical appliances.
- III. The breaking of the circle by drugs.
- IV. The breaking of the circle by operation.

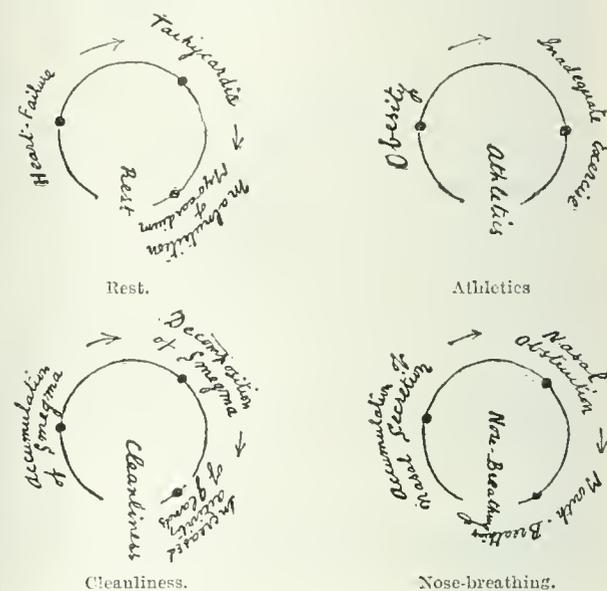

I. The Breaking of the Circle by Hygienic Measures.

Rest.—Physical rest is a powerful means of breaking some circles. An illustration is presented by many cases of cardiac failure, where a dilated and overburdened myocardium is associated with visceral disorder, the two conditions acting and reacting on each other.

(Gibson thus describes the circle:

Sooner or later, according to its form and severity, chronic valvular disease, with compensation, itself disposes to failure by establishing a vicious circle of slow, progressive impairment of the viscera and their great vital functions—the lungs, liver, stomach, bowels, kidneys, indeed the myocardium itself.⁴

In many such cases, if the patient is kept so quiet as "not to take one beat out of the heart more than can possibly be avoided," immense relief is given to the failing myocardium. More blood is sent to the lungs and viscera, and returns as a more nutrient and aerated supply. The cardiac action is strengthened, its tonicity is raised, so that the heart can pump out the stagnating blood and lower the venous pressure. Even moribund persons

THE BREAKING OF THE CIRCLE BY HYGIENIC MEASURES.

recover, and continue practically well for years. Lauder Branton describes the value of such absolute rest:

As in many other things the conditions in cardiac disease form a vicious circle. The disordered circulation disturbs the function of other organs, and these in turn make the circulation worse. . . . In such cases it is evident that the patient is bound to die, and to die a somewhat painful death, unless medical art can afford him some assistance. It is very fortunate, however, that in such cases medical art can do so much. . . . If we break the vicious circle at one point, we allow recovery to commence; and one of the most important agents—I think I ought to say the most important agent—in the physician's power is *absolute rest*.⁵

Exercise.—Under other circumstances the opposite measures, namely, increased exercise, is called for, as in the circle of obesity, which Krehl describes:

As soon as the accumulation of fat begins to deter the patient from taking active exercise a vicious circle is established, and he tends to increase in weight more and more.⁶

If the physician insists on some athletic sport, or at any rate on a more active mode of life, the morbid correlations may be interrupted and health restored.

Cleanliness.—Want of cleanliness may give rise to various circles, as, for example, to scabrous genitalia, where retained and putrefying secretions irritate the prepuce and glans, and thus provoke further secretion and putrefaction. In Corner's words:

The greater the irritation of the glands by decomposing secretion the greater the amount of secretion they produce. In this way a vicious circle is established.⁷

The regular removal of these secretions will rapidly diminish the excessive glandular activity, and thus check the morbid reactions.

Prevention of Infection.—This may be illustrated by the success of preventive measures where thread-worms are present. When a case is left to Nature, the irritation at the anus secures by auto-infection the continuance of the race of parasites producing it, and patients thus keep up their stock of parasites for many years. If, however, precautions are taken so as to prevent reinfection from without as well as auto-inoculation, the worms disappear rapidly and a radical cure may be looked for in four to six weeks, that being the period by which all the ova swallowed on a particular date will have developed into worms and been evacuated in the faeces.⁸

Nose-breathing.—A fifth illustration may be found in restoration of nasal respiration, where mouth-breathing has established a circle. In weakly children nasal secretions are sometimes allowed to accumulate and block the nostrils until the child resorts to mouth-breathing. This in its turn favours the retention of nasal secretions and consequent nasal obstruction. As Ashhurst says:

Obstruction, by preventing or interfering with the expulsive force of the expiratory current, prevents the removal of the usually abnormal amount of secretion, either by blowing the nose or otherwise; its accumulation is in its turn an efficient factor in producing obstruction, and a vicious circle . . . is thus established.⁹

By efficient use of the pocket-handkerchief the nasal passages can be cleared and the circle broken.

II. The Breaking of the Circle by Surgical Appliances.

Elastic Bandage.—Varicose veins are frequently complicated by a circle, since the dilatation leads to increased tension on the vein-walls, and the increased tension aggravates the dilatation. As Romberg writes:

It is often impossible to say how the disorder originates, for the venous dilatation (due to some mechanical obstruction) and the anatomical changes in the vein-walls act reciprocally on one another. Thus a vicious circle, whose pathogenesis is obscure, controls the course of events.¹⁰

The use of an elastic bandage supports the weakened walls of the veins, prevents their further dilatation and breaks the circle.

Catheter. Prostatic retention of urine is often due to reciprocal correlations. For the enlarged venous plexuses

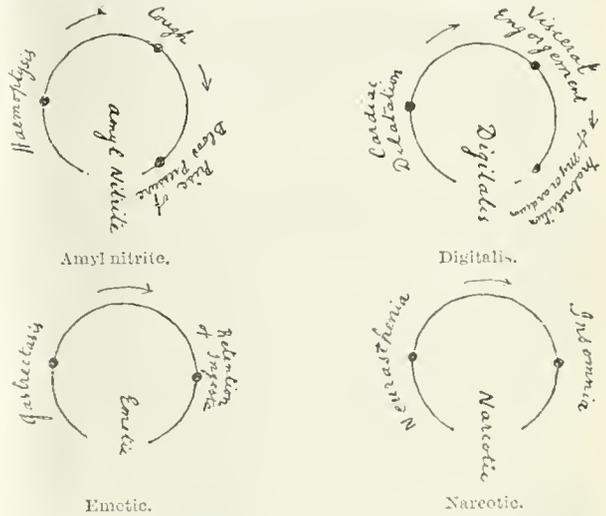

Concave Lens.—A fourth illustration is presented by progressive myopia in which the myopia and the elongation of the eyeball react on one another. As Sattler writes:

If the elongation of the eyeball has once begun, myopia has a tendency to react upon itself by a kind of vicious circle as long as the noxious conditions which caused it are still in action. The posterior wall of the sclerotic, now somewhat attenuated, is more liable to give way, and the more egg-shaped the globe becomes the longer is the region of contact of the muscles with the surface of the eye.¹¹

The prescription of concave lenses removes the near point, relieves the undue pressure on the globe, and checks the progress of the myopia.

III. The Breaking of the Circle by Drugs.

Amyl Nitrite.—Haemoptysis may be complicated by what Hare calls "one of the most highly vicious circles in pathology," the haemorrhage, the cough, mental per-

THE BREAKING OF THE CIRCLE BY DRUGS.

turbation and rise of blood pressure being factors that act and react on one another. One practitioner considers that he can best break the circle by using amyl nitrite¹² to lower the blood pressure. A second prefers to lull the cough by means of morphine. A third pins his faith to the styptic action of ergot. In each case what appeared the *locus minoris resistentiae* is attacked.

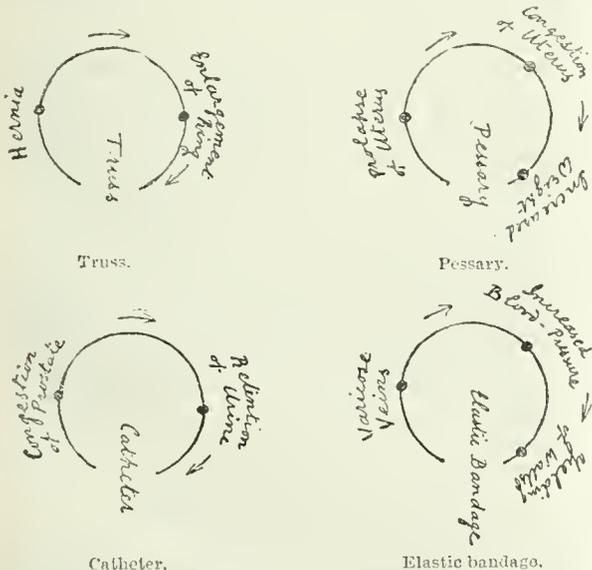

Digitalis.—Many cases of failing heart are complicated by tachycardia. The enfeebled myocardium beats so rapidly that the ventricles can neither fill nor empty themselves as they should. The result is progressive weakening of the myocardium, and a dangerous circle is present, which may be broken by digitalis, as Pavlov describes:

An uncompensated heart beats rapidly, and thereby only aggravates its condition. Its time of rest that is of recovery—of restitution of the organ is shortened. A vicious circle is set up. The weak action of the heart lowers blood pressure, the lowering of this leads (from known physiological causes) to an increase in the number of beats, the quickening leads to weakening of the organ. Without doubt the digitalis aids by breaking through this vicious circle in that it greatly slows the pulse, and thereby gives new power to the heart.¹³

Sedatives.—Conditions of exaggerated reflex excitability are often met with in which prolonged irritation and weakness have led to a state of unrest which perpetuates and intensifies the weakness. Thus the respiratory centre may be exhausted by constant irritation of the air passages giving rise to incessant coughing. Or the gastric centre, taxed by severe stimulation from stomach, kidney or uterus, lapses into a similar condition of irritable weakness. Although useless, the vomiting continues incessantly and may prove fatal.

Rest is urgently indicated for all cases of this kind, and has to be secured in many instances by means of morphine, which breaks the vicious circle of unrest and irritability; and a beginning once made, rest begets rest.¹⁴

Other circles are closely associated with the presence of pain or insomnia. The reciprocal correlations can here be

THE BREAKING OF THE CIRCLE BY A SURGICAL APPLIANCE.

surrounding the prostate in elderly men readily become congested, causing obstruction to the urine which accumulates in the bladder. The pressure of the urine in its turn aggravates the venous engorgement, and so the process is perpetuated. Catheterization by evacuating the bladder relieves the pressure on the venous plexuses and cures the retention.

Pessary.—Uterine congestion and prolapse are other conditions which aid and abet one another, and so give rise to a circle. A well-adjusted pessary prevents the prolapse and thus relieves the congestion, and breaks the circle.

attacked by a suitable sedative, which by the removal of pain will break the circle; as Herman has well described:

The great causes of neurasthenia are conditions which (a) cause continuous pain, and (b) prevent sleep. The two things often form a vicious circle. A small local cause disturbs sleep, and want of sleep makes the nervous system over-sensitive. In proportion as the neurasthenic symptoms have coincided in time with the development of local pain, so surely may we conclude that the removal of the local pain and the procuring of sound sleep will cure the neurasthenia.¹⁰

Emetic.—A troublesome circle may be due to dilatation of the stomach associated with prolonged retention of food. The dilatation increases the stasis, and the stasis the dilatation.

Dilatation may be the cause, accompaniment, or sequel of chronic gastritis; subacidity with fermentation and stagnation forms a vicious circle constituting Cohnheim's so-called vinegar and gas factory, and may likewise be regarded as an important etiological factor.¹⁶

The timely use of an emetic may rapidly and completely relieve the condition. Even a greatly dilated and overloaded stomach may be braced up. The unburdening is followed by contraction and renewed functional activity.

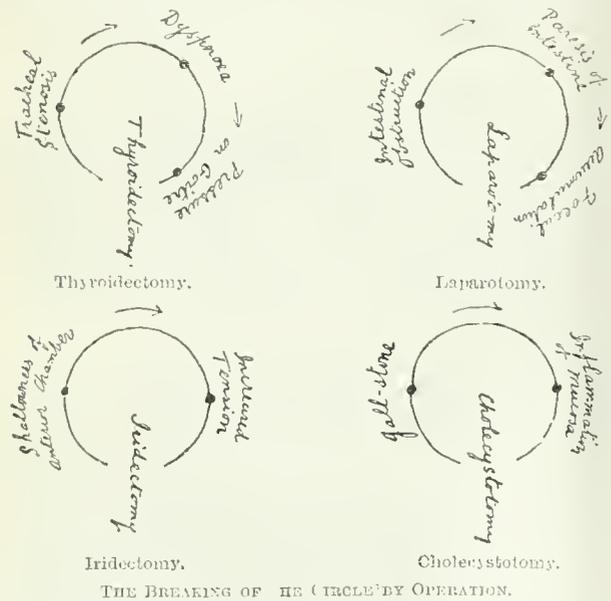

IV. The Breaking of the Circle by Operation.

Surgery achieves some of her greatest triumphs by attacking the *locum minoris resistentiae*, and so breaking the circle.

Cholecystotomy.—Biliary, renal, vesical, and other calculi are all associated with reciprocal correlations established between the mucosa and the irritating calculus. Rolleston thus describes the circle associated with gall stones:

Although gall stones are due to inflammation, of a comparatively mild character, of the gall bladder, their presence predisposes to fresh infection of the gall bladder, and thus to cholecystitis and to a vicious circle.¹⁷

Here the surgeon can remove the calculus that is perpetuating the morbid condition. The pathological sequences

are interrupted, and the mucosa returns to a more or less quiescent condition.

Thyroidectomy.—Another circle frequently broken by operation is associated with tracheal stenosis due to goitre. When an enlarged thyroid compresses the trachea so as to greatly reduce the lumen, any unusual effort may interfere with the adequate supply of oxygen. Nature, in response, calls the supplementary respiratory muscles into action. But unluckily the contraction of these muscles, so beneficial in some respects, presses the hypertrophied thyroid further against the trachea so as to narrow the lumen even more than before. They thus increase instead of relieving the dyspnoea, which often ends in self-strangulation. In Franke's words:

The sufferer gets into the clutches of a vicious circle. The greater the wall of oxygen, the more vigorous and prolonged the muscular contractions; the more vigorous the latter, the greater the compression of the trachea and the less room for the admission of air.¹⁸

Here prompt relief can be given by thyroidectomy, which relieves the stenosis and arrests the dyspnoea.

Iridectomy.—Glaucoma is another grave disorder, which, in the words of Price-Hey Smith, "perpetuates and intensifies itself in a vicious circle." The correlations are thus described by Lawson:

The sudden raising of the intra-ocular pressure increases the congestion, to be followed in its turn by a serous exudation from the venous channels, with a consequent further increase of pressure, and thus a vicious circle is quickly established, with symptoms of ever-increasing violence.¹⁹

The iridectomy lowers the intra-ocular pressure, which would otherwise end in blindness.

Laparotomy.—Intestinal obstruction may be complicated by various circles, which the surgeon breaks by laparotomy. One of them is thus described by Nothnagel:

Paresis and paralysis of the bowel may appear very early in the course of peritonitis, especially in perforative peritonitis, where it is most probably due to reflex inhibition of intestinal peristalsis. Paresis gives rise to meteorism, since gas continues to collect and accumulate in the bowel, as it is not driven onward. . . . As soon, however, as a considerable quantity of gas accumulates in the intestine, the vicious circle is completed, for gaseous distension of the intestine leads to further impairment of its muscular powers and eventually to over-distension and paresis or to definite paralysis.²⁰

These few examples illustrate the principle of breaking the circle by attacking the *locum minoris resistentiae*.

TREATMENT OF SEVERAL FACTORS.

At other times it may be impossible to ascertain the weakest link in the chain. The wisest course is then to attack each of the factors concerned, at any rate in such complex conditions of disease as Amand Routh describes:

We have frequently to deal with a vicious circle, with local and constitutional states so interacting that no real improvement is possible until both the general and local states receive their due share of attention.²¹

Striking examples of this are met with where digestive disorders are associated with disease of other organs, whether as cause or consequence of the visceral condition. Thus Mitchell Bruce writes:

The pathological relations of the gastric disorder or catarrh and the diseases of the other organs are usually complex, a vicious circle being set up between them; and the stomach therefore calls for direct treatment as well as attention to the cause.²²

If the practitioner cultivates the habit of thinking of disease as operating in circles, he will continually meet with illustrations of that interdependence of organs and of the importance of attacking each factor in the morbid process. His study of the art of breaking the circle will render his treatment more philosophical and more successful.

THE IMPORTANCE OF EARLY TREATMENT.

Lastly, since the circle is a self-aggravating process, it should be broken at the earliest moment. As Clifford Allbutt graphically says:

In vicious circles every gyration deepens the groove, an abnormal habit is formed so that arrest of such a local waste of energy and such a distress becomes more and more difficult. . . . The longer the "habit"—the fixtures of organic memory—the harder the impulse needed to "break the circle," for the habit has become independent of the original cause, which, indeed, had often vanished.²³

Worthy to be kept in everlasting remembrance are the words of Ovid:

Principiis obsta; sero medicina paratur,
Cum mala per longas convaluerunt moras.

THE TREATMENT OF MUSCULAR PARESIS BY MEANS OF ECCENTRIC MOVEMENTS.

BY

RODOLPH ABERCROMBIE, M.D. CANTAB., M.R.C.S.,
L.R.C.P.,

MEDICAL DIRECTOR, EDGAR ALLEN INSTITUTE, SHEFFIELD.

THE treatment of conditions of muscular paresis by means of the so-called eccentric movements originated in Sweden; though widely used in Scandinavia and Germany, it is apparently little known in England.

The terms "eccentric" and "concentric" as applied to muscular movements are rather clumsy; but it is necessary to adhere to them, because they are in general use on the Continent. By a "concentric movement" is meant the ordinary movement of a muscle which does work while becoming shorter: on the other hand, a muscle is said to perform an "eccentric movement" when it does work while becoming longer. The significance of the terms arises from the fact that during concentric movements the ends of the muscle approximate more nearly to the muscle's central point; while during eccentric movements they become more widely separated from it.

To take a simple example: if a patient flexes his arm at the elbow-joint by means of his biceps, the biceps performs a concentric movement, for it does work while becoming shorter. If now a manipulator grasps the wrist of the patient's flexed arm, and gradually extends the arm at the elbow-joint while the patient resists the extension, the biceps performs an eccentric movement; for in resisting the extension at the elbow-joint, the biceps does work while becoming gradually longer.

The general rule for the performance of eccentric movements is that the manipulator first puts the muscle into its shortest position, and then gradually elongates it, while the patient resists the elongation.

In England, concentric movements are almost exclusively used in the treatment of paresis, the use of eccentric movements being very little known.

Paresis after Fracture.

The following case, however, shows that the little-used eccentric movements may be of far more value than the more ordinarily used concentric movements.

H. M., aged 11 years, suffering from wrist-drop due to fracture of the lower end of the humerus eight weeks previously. Callus, which had obviously interfered with the musculo-spiral nerve, was to be felt at the seat of fracture. The paralysis had been treated for four weeks, without effect, by means of electrical treatment and massage, and the limb had been splinted with the hand in the hyperextended position.

At the commencement of the treatment by eccentric movements the paralysis of the extensors of the wrist appeared at first sight to be complete. The hand hung limply in the position of extreme flexion; the extensors of the wrist were overstretched, and the power of raising the hand was completely lost. In such a case exercise of the extensors by the ordinary concentric movements was obviously impossible; the boy could not begin to raise his hand, so could not initiate the movement. Eccentric movements were here of high value. These were performed in the following manner: The manipulator first grasped the boy's hand, and raised it into the position of full extension, thus putting the extensors of the wrist into the shortest position; the manipulator then gradually and slowly allowed the hand to sink into the position of flexion, at the same time urging the patient to delay the fall of the hand. The hand did not fall completely "dead," thus showing that the extensors, when put into the shortest position, possessed a trace of contractile power in the way of resisting elongation, although in their overstretched position they had seemed quite powerless.

By repeating the described manœuvre, it was possible to exercise the extensors, with the result that rapid daily improvement took place, so that by the end of ten days the boy could hold his hand in a horizontal position. Thus treatment by eccentric movements for ten days produced a more marked effect than one month's previous treatment by massage, electrical treatment, and splinting in the hyperextended position.

At this stage the extensors were exercised somewhat differently. The boy held his hand in a horizontal position, and the manipulator pressed it down into the position of flexion, while the boy resisted the movement. Complete recovery of the power of the extensors took place more slowly, occupying several weeks, but was ultimately complete.

The above case illustrates the advantages of treatment by eccentric movements. In the first place, they enable

the muscles to be exercised while still too weak to raise the weight of the limb; in the second place, it will frequently be found that a muscle which in the overstretched position appears quite powerless may yet, if put into its shortest position, give evidence of undoubted power in the way of resisting elongation. The concentric movements ordinarily performed bring the muscle into action in its longest or overstretched, and therefore least favourable, position; eccentric movements, on the other hand, bring the muscle into play in its shortest, and therefore favourable, position. Thus, by their means, it is possible to exercise a paretic muscle at the earliest possible moment, when it possesses only the smallest trace of contractile power. Herein lies the value of this treatment, for if a muscle can be got to contract physiologically, however feebly, the restoration of function will be far more rapid than can be brought about by merely passive manipulations.

In the case of wrist-drop just described, the delay in recovery was clearly not due to the continued pressure of the callus on the nerve, but was caused by some change in the muscles themselves, which was a sequel of that pressure, for it was only necessary to exercise the muscles for rapid recovery to take place.

Anterior Poliomyelitis.

In the treatment of the results of anterior poliomyelitis eccentric movements are of great service. It may be of interest, for the sake of contrast, to quote the description of the method usually employed in England, as given by Mr. Tubby:¹

When there is foot-drop, or paralysis of the dorsiflexors, the attendant may gently press his hand against the sole, and encourage the patient to dorsiflex the foot.

It will be noticed that what is described is a concentric movement; it is open to the objection that in a severe case the movement could not be carried out because the paretic extensors would not be strong enough to raise the weight of the foot, and thus the patient could not initiate the movement. In such a severe case the value of eccentric movements would be evident, for by their means the extensors could be exercised long before they were strong enough to raise the weight of the foot. To perform them the manipulator would first bring the foot into a position of extreme dorsiflexion, thus putting the paretic muscles into their shortest position; he would then gradually allow the foot to drop, while the patient attempted to delay the fall of the foot. By this means even the smallest trace of contractile power could be utilized, and the muscles could be exercised at an earlier date—often many months earlier—than would be possible by the method followed in England.

Other affected muscles are dealt with on a similar plan. I frequently see cases of this condition, which had been treated without avail by massage and electricity, improve considerably under eccentric movements. It is worth noting that treatment by eccentric movements takes far less time each day than electrical treatment or massage—a matter of importance when numbers of patients have to be dealt with. All three methods may be well used in conjunction.

Facial Paralysis.

In facial paralysis a similar method is followed. In dealing with the muscles of expression, the manipulator first draws the affected muscle into its shortest position, and the patient attempts to hold it there, and this manœuvre is repeated. If, owing to paresis of the orbicularis, the eye can only be partially closed, the manipulator first draws the upper lid fully down by means of the forefinger; he then removes his forefinger, and the patient endeavours to delay the opening of the eye. Later, when the orbicularis possesses more power, the lid is first closed, and the manipulator then draws it gently upwards with the forefinger, while the patient resists the movement. Even in old-standing cases, this treatment is sometimes successful.

Paresis of the Upper Limb.

In treating the paresis of the deltoid which so often follows injuries to the shoulder, the manipulator first raises the affected arm to the horizontal; he then supports the arm by placing his hand under the patient's wrist; the manipulator then gradually lowers the arm, while the

patient endeavours to delay its fall. By this means the deltoid may be exercised while still too weak to raise the arm from the side.

Paresis of the short muscles of the hand and of the flexors of the fingers provide suitable cases for this form of treatment. As before, the muscles are first put into their shortest position and then elongated, while the patient resists the extension.

Mode of Application.

The question as to how often the movements should be performed is of importance. They should be performed from five to ten times at each sitting, and the sittings may be given once or twice daily. A common mistake is to exercise paretic muscles too frequently. If this is done, the muscles become exhausted and recovery is retarded, not hastened. The manoeuvres must be performed slowly and carefully with a strength proportionate to the muscle's power.

The results obtained will obviously depend largely on the nature and causation of the paresis. In general terms, cases of lower-segment paralysis are better suited to this form of treatment than cases of upper-segment paralysis. In order that the treatment may be of benefit, the affected muscles must not be absolutely paralysed, but must possess some trace of contractile power. But it must be remembered that a muscle, which in its over-stretched position may appear absolutely paralysed, may yet possess latent contractile power which may be obvious in its shortest position. In general terms, it may be said that if a muscle possesses any contractile power at all, that power may be increased by the persevering use of eccentric movements. This holds good even in long-standing cases: in such cases possibly the result is obtained by the hypertrophy of individual muscle fibres.

As mentioned before, treatment by eccentric movements may well be used in conjunction with electrical treatment and massage. Percussions and vibrations may also be used, and in certain cases the limb may be splinted so as to prevent over-stretching of the affected muscles. The writer, however, considers that eccentric movements are the most valuable single measure in the treatment of paresis.

Theoretical Explanations.

I suggest that an explanation of the above phenomena is to be found in the microscopic structure of striped muscle fibre. Schäfer's² views on the histology of muscle are here followed, but are only given in bare outline; the division of the muscle fibre into sarcofibrils and sarcomeres is omitted as not essential to the present question.

A striated muscle consists of fibres each of which is marked by transverse bands of alternate light and dark material. According to Schäfer, the dark bands are made up of longitudinal channels or tubules arranged parallel with the long axis of the muscle fibre. Each such channel or tubule is closed at one end (line of Hensen), but at its other end opens by means of a minute pore towards the light band, which is composed of clear translucent material. In Schäfer's view, when the muscle contracts, the translucent material of the light band flows or is drawn into the channels of the dark band, and becomes hidden from view. By this means each individual channel of the dark band becomes shorter and wider, and by the sum of similar processes shortening and widening of the muscle fibre occurs. The evil effects of over-stretching on a muscle may now be considered in the light of this minute structure.

Mr. Robert Jones³ has recently emphasized the injurious effects of over-stretching. He suggests that it has the effect of causing the nerve cells to become inactive, though not extinct. I put forward the view that the evil effects of over-stretching have nothing to do with the nervous apparatus of the muscle, but have their origin in certain changes produced by the stretching on the muscle itself.

When a muscle fibre is over stretched its sheath (sarcolemma) is brought into a state of tension, causing lateral compression of its contents. By this lateral compression the longitudinal channels which compose the dark bands will be compressed one against the other, and this will have the effect of obstructing the orifices of the minute pores through which the translucent material gains entrance to the channels. This affords a simple

mechanical explanation of the ill effects of over-stretching; for since the ingress of the translucent material into the channels of the dark band is impeded, so also will physiological contraction of the muscle be hindered or prevented, even though the nervous mechanism of the muscle may be intact.

The same considerations explain why a muscle, which appears functionless when over-stretched, can yet exhibit contractile power when put into its shortest position; for in the latter position the sheath of the muscle fibre is relaxed, the channels of the dark band do not press on one another, and therefore their pores will be unobstructed and the ingress of the translucent material easy.

It will also be clear why physiological contraction is so important in the treatment of paresis, for it is the only means of causing ingress and egress of the translucent material to and from the channels, passive manipulations being powerless to effect this. The rapid improvement that sometimes takes place in a paretic muscle as the result of exercise (as in the case of wrist-drop quoted above) may be explained by supposing that through disuse the entrances to the channels may become clogged, and possibly the translucent material altered in consistence. A few physiological contractions may serve to clear the entrance to the channels, and thus bring about rapid improvement in the muscle's power.

CONCLUSIONS.

1. In order to perform eccentric movements, the manipulator first brings the affected muscle into its shortest position and then gradually elongates it, while the patient resists the elongation.

2. Such movements are of more value in the treatment of paresis than the more ordinarily employed muscular movements.

3. The explanation of the effect of such movements is to be found in the microscopic structure of striped muscle.

RAYNAUD'S SYNDROME AND SYPHILIS.

BY

HENRY SEMON, M.D., M.R.C.P.,

SENIOR ASSISTANT, DERMATOLOGICAL DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL.

It would appear that Sir Jonathan Hutchinson was the first to call attention to the relation of syphilis to certain cases of Raynaud's disease,¹ so that the idea of their possible association is by no means new. Since his paper (1889) there have been an ever-increasing number of reports of similar cases, and the occurrence of one in the out-patient department at the Great Northern Hospital, which Dr. Whitfield has kindly allowed me to make use of, and was the subject of an animated discussion at the Dermatological Section of the Royal Society of Medicine,² must be my excuse for once more calling attention to the importance of recognizing not only the syndrome which Raynaud described, but still more to the vital necessity, from the patient's point of view, of tracing to its ultimate cause or causes the etiology of the condition.

Inasmuch as the physician has in a majority of cases only the clinical evidence to go upon, it would be better to look upon Raynaud's disease, not as a disease *sui generis*—a tendency which is undoubtedly still generally prevalent—but rather as an associated clinical picture, a symptom complex, dependent, perhaps, on a variety of factors in which the angiospastic conception of Raynaud plays only a part, and for which some organic and structural change of the vascular system concerned is mainly responsible.

The case referred to is that of a woman aged 56, who has suffered for over seven years from symptoms which Raynaud would have called typical, and which in the present attack have terminated in gangrene of the dry type) of the tips of the thumb, first, fourth, and little fingers of the left hand, and in local syncope as evidenced by cyanosis of the third left finger, and of the digits of the right hand. In none of these situations is more than the pulp of the distal phalanx involved, and the

nails, though scored by transverse dystrophic lines, the evidence doubtless of past attacks, show no tendency to separate at present.

There are no symptoms of Raynaud's syndrome elsewhere, although there is a history of a similar asphyxial affection of the toes, ears, and nose, without gangrene.

As far as can be ascertained there has never been hæmaturia, and at the present time there is nothing abnormal in the urine. The Wassermann reaction is positive.

The present attack began in the early part of September, 1912, when intolerable aching of the arms (a not unusual symptom in acroasphyxia of the upper extremity) first brought her to the hospital. On September 18th she presented herself, with gangrene well advanced, and although she had been taking mercury (byd. & cret.) and iodides since the Wassermann reaction had proved positive, and had entirely lost her pain, the gangrene had supervened notwithstanding.

The points of importance in this case are the following: The woman can recall nothing suggestive of a syphilitic infection. She has had five children, one of whom died in infancy from bronchitis, and another at 9 years from lymphadenoma. There have been no miscarriages, and her husband, though not living with her, is alive and well.

It seems plausible to suggest that a more energetic antiluetic treatment (as, for example, salvarsan injection), commenced on the day the result of the Wassermann reaction became known, might have entirely prevented the onset of gangrene, and it is with the object of urging this procedure in similar cases that I have appended the following cases from the literature:

CASE I.—The symptoms were engrafted on hereditary syphilis in a boy, aged 4, who is reported by Krisowski² in an exceedingly able article (1895), in which he takes an identical view of the position of Raynaud's syndrome, to have been the victim of a symmetrical gangrene involving the tips of the ears. The condition was very quickly brought under control by administration of iodides and energetic inunctions of mercury; but, of greater importance still, it never relapsed thereafter, in spite of intentional exposure of the child to cold weather, which had in previous years always brought about an attack of local syncope, thus proving that an essential factor in the production of the syndrome had been removed.

Krisowski took the view, and in that he was considerably ahead of his contemporaries, that the Raynaud syndrome is the product of at least three factors: (1) A disease which produces an organic structural change in the blood-vessel wall, and of all diseases syphilis is probably the most potent in this respect; (2) some poisonous substance or toxin which is able to produce spasm of the arterioles; and (3) the external influence of cold. Patients with Raynaud's disease are notoriously worse in winter, and the most exposed parts—namely, the ears, nose, and fingers—are those most subject to syncope and gangrene.

In his own case he removed, by his energetic inunctions of mercury, probably the whole of factor (2), and considerably alleviated the first. The third factor then, unsupported by the other two, became impotent, and the child was able to run about out of doors in all weathers.

Whether this attractive hypothesis is indeed the true explanation of certain cases of Raynaud's disease must be left at present undecided; it is sufficient if it forms the basis of therapeutic measures; and whether the first and second factors be syphilis (congenital or acquired) or, as has been claimed at other times, tuberculosis, rheumatism, malaria, and gout, the true underlying etiological causes should always be sought for, and such remedial measures as massage, galvanism, etc., relegated to a position of secondary importance.

CASE II.—Gaucher⁴ recently showed a young man who developed the symptoms of symmetrical acroasphyxia one month after the appearance of a chancre and a fortnight before the eruption of the roseola. The symptoms were typically spasmodic and involved the index, middle, and ring fingers of both hands, which during the crisis became painful and lost their tactile sensibility, whilst at the same time the distal phalanges were objectively observed to change their tint through red and violet to black. Cold water accentuated the syndrome, and stimulating lotions and friction relieved it. The condition completely cleared up in one month from the commencement of biweekly mercurial injections and did not recur.

CASE III.—At the same meeting Brocq⁴ reported a similar case in a congenital syphilitic, aged 50, in whom the condition had gone to gangrene of the toes of both feet after a prodromal history of Raynaud's disease lasting over several years. This case was also cured by iodides and mercurial inunctions.

Both these cases are interesting in that they are definite proofs of the possible association of both congenital and

acquired syphilis (even in its secondary stages) with the complex of symptoms described by Raynaud, and in themselves justify the examination of the blood for the Wassermann reaction in every case the etiology of which is at all doubtful.

In the American literature also the association of syphilis with the syndrome has not escaped observation:

CASE IV.—In 1906 Lustgarten⁵ showed a case of a young man who had had Raynaud's symptoms for two years, culminating in gangrene of the finger-tips. It does not appear that Wassermann's reaction was sought for (the test was published in the same year) in this case, but there was a suspicion of luetic infection in the history, and "leukoplasic patches" in the mouth supported the presumption. Under antiluetic treatment the pains were cured, but, as in my case, the gangrene was not arrested. Salvarsan was not in use at that date.

His demonstration was followed by the relation of three similar cases in his practice by Dr. Klotz. All three had shown the coldness and blueness of fingers with superficial necrosis of the tips, and they had entirely lost their symptoms under mercury. Two of them had remained well for years. In the discussion at this meeting the pathology of the condition was held to be an endarteritis obliterans of many small arteries of an ascending type. Exception has been taken to such a view on the ground of its unlikely manifestation in so symmetrical a fashion, but, if it be remembered that syphilis is undoubtedly a constitutional disease and that evidence is rapidly accumulating that the organism, in one stage at least, is present in the circulating blood, the difficulty in accepting the premise should vanish.

The literature on Raynaud's disease is exceedingly voluminous, and it has been found impossible to do more than select for my purposes just those cases in which the etiology of syphilis was undoubted. But those are not the cases which are commonly met with in practice or in the out-patient departments of hospitals. If Raynaud's syndrome can be caused by florid syphilis—and of that there would seem to be no doubt—it would be very difficult to disprove its inability to produce the same train of symptoms at later and less obvious stages, and therefore I would urge that in every case of the syndrome Wassermann's test should be applied; that the physician should not be satisfied with one negative result, but should institute a second inquiry at some interval of time, with or without a provocative injection previously of salvarsan or mercury. As far as I am aware, salvarsan has not as yet been administered in these cases, but in view of the vascular involvement and the occasional concomitancy of hæmoglobinuria, which is now admittedly in its paroxysmal variety often found associated with a positive Wassermann reaction, the intravenous injection of the drug should prove a valuable adjunct to the treatment of the condition.

IN a paper read at a meeting of the British Medical Association at Capetown last October, Dr. Bayon summed up the present position of leprosy research. He believes that the isolation and artificial cultivation of Hansen's bacillus has at last been successfully achieved, and the definite etiological relationship of the culture to leprosy conclusively established by morphological examination, animal experiments, serological tests, and by the observation that a specific reaction follows upon an injection of a filtered cultural extract. The micro-organism of human leprosy only reaches its bacillary acid-proof stage after injection into animals, but retains these properties in further artificial cultures. Vaccine treatment by killed cultures is not to be recommended in leprosy because the bacilli remain absolutely quiescent in the tissues, and the production of antibodies does not follow. Bayon said that the existence of an insect vector of the disease has not been established, and expressed the belief that investigation on these lines should be preceded by the acquisition of a thorough knowledge of the complete life-cycle of the micro-organism in man and rats, and the similar bacteria found in cattle and horses.

Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

A CASE OF VERONAL POISONING.

The following case may be of sufficient interest to merit publication, as the lethal dose of veronal is a disputed point.

At 11.30 p.m. on January 21st, 1913, I was called to see a case of supposed poisoning. I found the patient, a retired prize-fighter, aged 35 years, in bed, fully dressed except his boots. His wife said he had taken some drug to make him sleep, that he had been sleeping all day, and that they could not wake him. A lodger told me he thought veronal had been taken, and gave me a bottle containing ten tablets, each 0.5 gram. The patient was pallid, the hands cold and clammy, and the pulse 72, very soft and feeble, and difficult to count. The breathing was semi-stertorous. The pupils were not dilated, but did not react to light; this puzzled me until I found out that the patient had been for years an habitual chlorodyne drinker and had been taking it heavily for some weeks. I was told he was "just as you see him" for about twenty-seven hours.

All my efforts to wake him having failed, I gave at once a hypodermic injection of strychnine and digitalin and in a quarter of an hour one of strychnine alone. As the pulse and appearance of the patient were improving steadily, I used a small-sized siphon rubber stomach pump and washed out the stomach. I only passed the tube with considerable difficulty, after having well warmed and oiled it. Using a weak solution of sodium bicarbonate, I got away a lot of flocculent material and mucus. After passing in half a pint of strong black coffee and 2 oz. of brandy and finding it retained, I contented myself with occasional hypodermic injections of strychnine, strychnine and digitalin, and oleum camphorae. The latter, in 20-minim doses every quarter of an hour, I firmly believe in; it keeps the heart going, and an overdose is impossible.

About 1.30 a.m. on January 22nd (after over two hours' treatment) I fed the patient by nasal tube, giving bovril and brandy. In about an hour he opened his eyes, after a "shake and shout," and since then his recovery has been uneventful.

The interest in this case lies in the following facts, which I carefully verified:

1. He had taken chlorodyne for some years, and for one week preceding January 20th took 2 oz. of Collis Browne's preparation daily. Between 5 and 6 p.m. on that date he emptied the bottle, taking 150 drops, all that was left. Fearing he could or would not sleep, he remembered the veronal bottle. This, which had been in his possession about one year, had been given to him by a man who cleaned out the rooms of a poor fellow who died from veronal poisoning. The patient took three tablets every quarter of an hour between 7 p.m. and 8 p.m., and after taking the last lot he felt dizzy, and had just time to drop into bed as he was, dressed.

2. The chlorodyne was taken to relieve pain in his stomach, and also a feeling as if "his stomach was dropping out," which he had felt for years as the result of the heavy blows he had received in that region in the prize-fighting ring.

3. The remaining tablets weighed, on the average, $8\frac{1}{2}$ grains each. Allowing for excipient the amount of veronal present would be 7 $\frac{1}{2}$ grains. The dose on the label was 0.5 gram. This would mean that the patient took 5 grams, or just over 92 $\frac{1}{2}$ grains.

4. The bottle of tablets, which originally held twenty-five, had been opened one year previously and three taken out. Can veronal deteriorate in one year so that 92 grains of the "aged" drug cannot be reckoned as a poisonous dose? I have looked up all the literature I could find without satisfactory result. The poisonous dose appears doubtful, and its stability is not mentioned.

5. The patient's wife states that he had had no food for two days. I questioned her closely as regards this, and she stated "he would take nothing, only dose and sleep, wake and dose." Absence of food in the stomach confirms this.

6. Could the veronal and chlorodyne (150 drops one hour previously) have any counter-effect and thus save the man? The patient has more than once confirmed his statement as to how and when he took the drug. The splendid physique and stamina of the man no doubt stood him in good stead, and the fact that he had been a total abstainer all his life.

MANCHESTER ROYAL INFIRMARY.

A CASE OF GASTRIC HAIR BALL.

(By S. B. RADLEY, M.B., B.S. Lond., M.B., Ch.B. Vict.)

For courteous permission to report the following case I am indebted to Professor William Thorburn, under whose care the patient remained during her stay in hospital:

The patient, a female, aged 21, was admitted on December 21st, 1911, complaining of a "lump" in her abdomen, which she had noticed for some months, and with a history of diarrhoea of some months' duration. She had never vomited, though she had suffered a good deal from wind and distension. Her appetite was quite good, and there was no feeling of distaste for certain kinds of food. No history of pain after food could be obtained, and indeed she had not been troubled with pain at any time beyond the discomfort associated with the flatulence and distension after meals. There was no history of haematemesis or melæna. The patient stated that she had lost weight latterly, but this was not marked. No history of peculiar dietetic habits could be obtained.

Condition on Admission.

On examination the patient appeared undersized and poorly developed for her age. She presented a somewhat infantile character, mammary development being almost nil, and the axillary and pubic hairs scanty. The general skeletal development was less infantile than these remarks would suggest. The state of nutrition was quite average.

The abdomen showed some general fullness. A distinct swelling could be seen in the left epigastrium, moving from under the left costal margin on inspiration. The mass was quite hard and nodular, and in size rather larger than a hen's egg. It was not tender. It was movable to a limited degree in the abdomen. The liver, kidneys, and spleen were not palpable.

Operation.

A laparotomy was done by Mr. Thorburn. A median incision was made in the epigastrium, and on inserting the hand into the abdomen the swelling was found to be contained in and formed by the stomach. The stomach was drawn up to the wound, and the tumour was found to be inside the gastric cavity and to fill it completely. An incision about 3 in. long was made into the stomach in a horizontal direction and the hair ball was extracted. The stomach was then closed with Lembert sutures and the abdominal wall sewed up in layers.

The patient made an uneventful recovery. The sutures were removed on the tenth day, and the patient left the hospital in three weeks.

Shape of the Ball.

The accompanying illustration gives a good idea of the shape of the hair ball. It is a perfect replica of the shape of the stomach, the muscular wall of which was contracted down on to it. It is a really noteworthy example of the shape of the full or nearly full stomach. It shows quite well the incisura angularis, the pyloric vestibule (which sags rather low), and the well marked off pyloric canal. Its dimensions were as follows:

| | |
|--|------------------------|
| Lesser curvature | 5 $\frac{1}{2}$ inches |
| Greater curvature... .. | 14 " |
| Longitudinal diameter | 6 $\frac{1}{2}$ " |
| Circumference of body (mid-point) | 7 $\frac{1}{2}$ " |
| Circumference of pyloric antrum | 8 $\frac{1}{2}$ " |
| (The weight in the dried condition was 11 $\frac{1}{2}$ oz.) | |

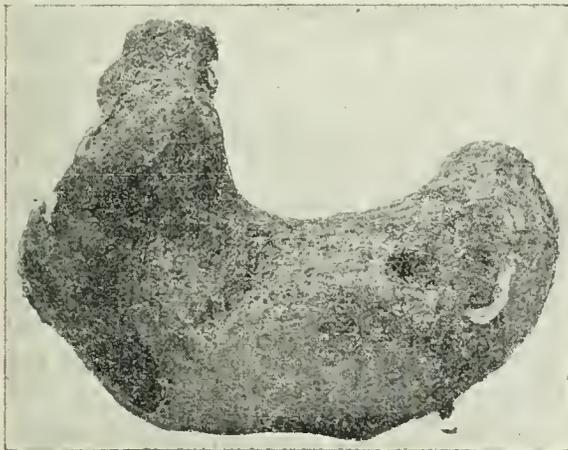

In appearance it was of a dull brownish-grey colour, composed of masses of hair fibres twisted and squeezed into a solid body, with a coating and admixture of mucus and food debris between the fibres of hair. It subsequently transpired that the hair composing this mass had been obtained indiscriminately from the hair-clad regions of the body, this accounting for the sparseness of hair noted above. The long hairs—the greater number which held the mass together, were derived, of course, from the scalp, whilst the plentifully interlaced shorter ones were of axillary and pubic origin. When taxed with her evident habit she admitted its existence on and off for several years.

REMARKS.

The diagnosis of the condition presented, of course, many difficulties, particularly as the patient denied absolutely the possibility of the presence of a foreign

body. No skiagram was taken or bismuth meal given owing to the absence of any marked history of dietetic upset or idiosyncrasy. Mr. Thorburn was, however, strongly impressed with the resemblance of the clinical signs and symptoms to a case of hair ball on which he operated some few years previously. An infinite variety of foreign bodies may be found in the stomach, some of which have been swallowed by the insane, in other cases by accident, and occasionally by people of a hysterical or degenerate type. To this list we must add people such as this girl whose case is now recorded—a girl without the classical hysterical stigmata but whose nervous balance is evidently in an unstable condition.

The absence of vomiting and the normal appetite are two of the outstanding features of this case. That the stomach should be able to perform the functions normally, that peristalsis should be apparently healthy and well co-ordinated is a very striking thing. In view of the recent work of Cannon and Washbourne on hunger, the fact that appetite should be normal is very interesting, whilst the feeling of fullness and flatulence after meals appears to be quite natural, though not inevitable, this condition being dependent rather upon how much gas is present in the stomach than upon the degree of "fullness" from solid contents. When one considers what a great obstacle a hair ball of such a size must have been to the performance of the gastric functions, it is surprising that

the "ball" was not expelled by the stomach when yet small enough to pass the pylorus.

In Mr. Thorburn's previous case loss of weight and vomiting were marked features, though the "ball" was only about the volume of a kidney. In the present case, despite the increased size of the foreign body, these symptoms were inconspicuous.

Butterworth gives an exceedingly interesting account of hair ball, and reports a full bibliography. At the time of writing (1909) there were 42 cases in the literature. The largest "balls" on record are one of 5 lb. 3 oz., which we believe is in the Museum of the Royal College of Surgeons of England, and that of Mornet d'Hautville, which weighed 6 lb. in the fresh condition and 2½ lb. when dry.

I wish to take the opportunity to express my indebtedness to Mr. G. Jefferson, F.R.C.S., for the assistance he has rendered me in the bibliography of the subject.

THE twelfth congress of the German Society of Orthopaedic Surgery is announced to meet in Easter week, on Thursday, March 25th, 1913, at the Langenbeckhaus, Ziegelstrasse, Berlin. The chief subject selected for debate is the treatment of chronic arthritis (arthritis deformans). Dr. Friedrich Kraus, Geheirat, will introduce the discussion, with observations on symptomatology, pathogenesis, and internal therapy; Dr. Ibrahim of Munich will read notes on chronic arthritis in childhood; and Dr. Preiser of Hamburg will read a paper on the orthopaedic treatment of that disease.

Reports of Societies.

LIVERPOOL MEDICAL INSTITUTION.

Thursday, January 23rd, 1913.

Mr. ROBERT JONES, F.R.C.S., President, in the Chair.

Fracture of Neck of Femur.

Mr. PUSHTON PARKER read a note on fracture of the neck of the femur, and showed specimens from two aged subjects, with lantern slides. The first patient was 82 years of age, and died ten days after the injury. The second was 72, and died ten weeks after the injury. The specimens showed true bony union. Mr. Parker said he preferred to treat them on a "Thomas" hip splint, though in some cases the "Thomas" knee splint answered.

The PRESIDENT said the specimens were worthy of attention, as the possibility of bony union was denied. In making the initial diagnosis an injury to the hip which produced eversion of the foot and some loss of power in the leg was quite sufficient. In treating these cases he used extreme abduction of the injured limb. By this means the broken surfaces were turned on to each other, muscular tension was released, and if an angle of 45 degrees were obtained the neck of the femur was fixed against the acetabulum. He reduced displacement by pulley or manual extension, then abducted the limb with the knee flexed. The limb was fixed in a special abduction frame, or where an injury occurred out of reach of apparatus good fixation could be obtained by plaster-of-Paris. Fixation should be kept up for at least two months, usually three months. Massage and passive movements were important; the patient could be trained to move the limb in the abducted position. In cases in which deformity had occurred and the limb was abducted with eversion he forcibly abducted the limb under an anaesthetic and kept it fixed for ten days, and then massaged.

Acute Yellow Atrophy.

Dr. NATHAN RAW read a note on seven cases of acute yellow atrophy of the liver, which demonstrated the relation of the disease to syphilis. All 7—namely, 4 males, of the ages of 23, 15, 40, and 27, and 3 females, 17, 23, and 26 years of age—had suffered from syphilis. In 4 of the cases leucin and tyrosin were demonstrated in the urine. The youngest of the female cases was pregnant.

Rectal Carcinoma.

Mr. K. W. MONSARRAT read a paper on carcinoma of the rectum. In choice of the operation to be performed it was necessary to consider the extent of removal required. Where the edge of the growth was defined and limited he had not been able to trace with the microscope the changes which had been described by another observer beyond the actual naked-eye growth. The inguinal glands were not liable to be infected except in cases involving the anal margin. As the peritoneal surface might be invaded, an abdominal section should be performed as a preliminary in all cases to make sure of this point. There was no necessity to remove any great length of bowel beyond the growth. In most cases he thought an inguinal artificial anus satisfactory. There was no doubt that the mortality from the operation was serious. He had lost 3 cases out of 13—2 from sepsis, 1 from syncope three months after.

Mr. F. T. PAUL said it was thirty-five years since he had first removed a rectal cancer, and he had found that the growth did not extend far in the length of the bowel. The microscope showed practically no infiltration beyond the naked-eye margin of the growth. He found that a sacral anus was more satisfactory than an inguinal anus, while a perineal anus was unsatisfactory. He did not consider an abdominal incision necessary. He did not think high and fixed cases, especially if involving the bladder, worth the risk of removal of the growth, especially as cases might live for years after an inguinal colotomy alone.

Mr. R. W. MURRAY thought the operation unsatisfactory, and even went so far as to believe these cases were best left alone until a colotomy had been performed. He had seen a large number of cases in Vienna, some of which

had been undertaken fourteen years ago, and he had been unfavourably impressed with the results of the formation of a sacral anus. He thought an inguinal anus the least harmful.

MR. DAMER HARRISON and Dr. NATHAN RAW also took part in the discussion.

MEDICAL SOCIETY OF LONDON.

Monday, January 27th, 1913.

SIR W. WATSON CHEYNE, President, in the Chair.

Exhibition of Clinical Cases and Pathological Specimens.

THE following were among the exhibits: Dr. F. PARKES WEBER: (1) A case of *Splenic anaemia* in a woman aged 30. Dr. Weber believed that the case was one of a clinical group of cases of "splenic anaemia" in adults which improve under arsenical treatment and do not necessarily develop into typical cases of "Banti's disease" with hepatic cirrhosis and ascites. (2) Case of probable *Tertiary visceral syphilis* with pyrexia and extreme cachexia. The patient, a woman aged 43, had been previously shown as a case of acquired chronic acholuric jaundice, with a blood picture resembling that of pernicious anaemia. There had been acholuric jaundice and splenomegaly, but no excessive fragility of the red blood corpuscles. Dr. J. L. BUNCH: (1) *Lupus erythematosus* in a girl, aged 14, benefited by carbon dioxide snow; and (2) a case of *Syphilitic resembling tubercle* in the neck and upper part of the thorax in a young woman. Mr. PAUL ROTH: A boy, aged 8, on whom he had successfully performed *Transperitoneal uretero-lithotomy*. The stone was oval, its diameters being $\frac{1}{16}$ and $\frac{1}{10}$ in. Mr. W. H. CLAYTON-GREENE: *Hair ball removed from the stomach* of a young woman, aged 23. Abdominal pain and vomiting had been accompanied by a large gastric tumour. This proved to be a hair ball, which extended from the cardia to the jejunum and formed a cast of the stomach and duodenum. Also a specimen of an enormous *Mucocoele of the appendix*, which had formed a large iliac tumour. Dr. LANGMEAD: Suprarenal glands from a case of *Addison's disease* in a boy of 10. They were almost entirely tuberculous. It was brought forward on account of its great rarity in children. Dr. P. S. LUKIS: *Acholuric jaundice* in a boy, aged 6½ years. The spleen and liver were enlarged, and the blood showed undue fragility and reticulation of the red blood cells. Mr. A. E. RAYNER, for Mr. C. A. BALLANCE: A case of *Bony tumour of the femur*, in which the question arose as to whether it was a simple osseous tumour or an osteosarcoma.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

Tuesday, January 28th, 1913.

Dr. FREDERICK TAYLOR, President, in the Chair.

Records of King Edward VII Sanatorium.

DR. NOEL D. BARDSWELL read a paper containing an analysis of 1,079 patients discharged between July, 1907, and July, 1911. In 1,027 of these cases the diagnosis of the disease was confirmed in the sanatorium, leaving only 52 not so confirmed. The bacilli were discovered in the sputum of 82.7 per cent. Of the 1,027 definite cases, 112 had been lost sight of and could not be traced; the remaining 915 had been traced up to October, 1912; 764 of the latter number had the bacillus on admission; in 151 no tubercle bacilli were found at any time. In 1912, 57.1 per cent. were well or alive, 42.8 per cent. dead. Dr. Bardswell presented the figures separately according to the stages of the disease. The condition in 1912 of the 151 in whom no bacilli of tubercle were found was as follows: 88.7 per cent. were well or alive; 11.2 per cent. were dead. Of the 764 in whom tubercle bacilli were found, 148 (19.3 per cent.) lost their bacilli before discharge. Of these 148, 124 were well or alive in 1912—that is 83.7 per cent. In 1912, of the 616 with tubercle bacilli present on both admission and discharge, 313 (or 50.8 per cent.) were well or alive, 303 (or 49.1 per cent.) dead. The author laid great stress on the criterion of diagnosis being the actual discovery of the bacillus in

the sputum; once that was departed from, all kinds of elements of uncertainty could enter to modify the figures and therefore a right conception as to the efficacy of curative measures.

Dr. HARTLEY commented on the large percentage of cases in which the tubercle bacillus was found, and asked whether intensive methods were employed. It was a pity that so large a number as 112 could not be traced.

Dr. AULAND spoke highly of this valuable contribution, especially when there was so much inaccurate statement and unjustifiable deduction prevalent as to the disease. He hoped definite evidence would soon be forthcoming as to the relationship between the cutaneous reaction and the complement-fixation test in tuberculosis.

Dr. CECIL WALL suggested the addition of one or two tables, including one giving the average expectation of life for the different ages dealt with, apart from tuberculosis, because many of the patients might presumably have been dead from other causes by the same date if they had not had the disease. It would also be of great value if Dr. Bardswell would draw up a table giving the duration of the disease from the date when the patient definitely felt unwell. The anatomical classification was not a reliable index to prognosis; a consideration of intensity of symptoms was much more informing.

Dr. PARKES WEBER agreed that the only safe criterion to take was the presence or absence of the tubercle bacilli in the sputum. Moreover, there were many persons going about in apparent health who harboured the tubercle bacillus, and who responded to tests for tubercle, yet who were not likely to be subjects of active pulmonary tuberculosis.

Dr. McCULLOCH spoke of the rarity of cases of the disease in Himalayan villages, which he was able to verify by a twelve years' residence there. He had been able to get very good results on tuberculous glands by x-ray irradiations.

THE PRESIDENT (Dr. Frederick Taylor) said it would be instructive if any one could compare the modern results of treatment of the disease with those of thirty years ago, at which latter period, no doubt, cases taken from the slums to the wards of a general hospital and given food to which they had hitherto been strangers, left very much improved, and their fever and cough abated.

Dr. BARDSWELL replied, and promised to add fresh tables.

SECTION OF PSYCHIATRY.

Tuesday, January 28th, 1913.

SIR GEORGE H. SAVAGE, President, in the Chair.

Insanity and the Neuropathic Inheritance.

DR. F. W. MOTT read a paper on this subject. He said there were individuals born of sound mental and physical stocks that no acquired conditions, such as disease, drink, and poisons, either engendered within the body or taken from without, nor head injuries, emotional shock, distress, and even combined misery and destitution, could render insane. There were others, in most cases subjects derived from a neuropathic stock, whose mental equilibrium might be disturbed by any one of these conditions, or even without any apparent cause, except the physiological conditions appertaining to the functions of the sexual glands. Between these two extremes all gradations of mentality were found, from the congenital imbecile and the insane adolescent dement at one end of the scale, to the potentially sound mind and body which no combination of acquired conditions could render permanently insane. Every case of insanity should be regarded as a biological problem, and the study resolved itself into the acquirement of a knowledge of what the individual was born with—Nature and what had happened after birth—nurture. The former could be ascertained by a study of the ancestral stocks. The neuropathic tendency might be differently manifested in different members of the stock. Just as bodily features were transmitted from one generation to another, so was temperament. Special racial and family characters were of later development, therefore were far less fixed, stable, and organized in the nervous system. Galton found that twins developed from one ovum, and therefore identical germ plasma, living in a different environment, remained similar in temperament and

character, whilst binocular twins, brought up and living in the same environment, remained dissimilar. Galton also made a statistical inquiry into the inheritance of good and bad tempers, and concluded that one set of influences tended to mix good and bad at haphazard, another tended to assimilate them, another tended to divide families into contracted portions; and in that way there was a tendency to revert to the normal average of the race. Morel had pointed out that nervous irritable weakness and neurasthenic predisposition might be the first evidence of degeneration of a stock. The signs of degeneracy might be manifested as self-centred narrow-mindedness in religious beliefs, fanaticism, mysticism, spiritism, and unwholesome contempt of traditional custom, social usages, and morality, a vain spirit of spurious art and culture, a false, self-loving vanity in the pursuit of a sentimental altruism, the intelligence being well preserved. Such qualities might be combined with latent or active genius; but the brilliant intellectual qualities of a degenerate were generally associated with either a lack of moral sense or of sound judgement and higher control. Dr. Mott declared that the world's history had been made by men who were either epileptics, insane, or born of a neuropathic stock: Alexander the Great, Julius Caesar, Napoleon, Peter the Great, Frederick the Great, Pitt, Earl of Chatham, Mahomet, the Apostle Paul, Martin Luther, Emanuel Swedenborg, and others. Among English poets, Cowper, Wordsworth, Byron, Gray, Burns, Chatterton, Thomson, were either insane or possessed the neuropathic temperament. The author then proceeded to describe the work which had been done in the pathological laboratories of the London County Asylums on heredity in relation to insanity, chiefly by means of a card system which he instituted four years ago concerning no less than 1,450 families, the total number of cases inquired into having reached 3,118. That showed the following facts: (1) In the insane offspring of insane parents daughters were much more numerous than sons. (2) Amongst the insane members of the same family (brothers and sisters), sisters were more numerous than brothers, which fact might be usefully correlated with the further fact that there were more women in asylums than men. More than half the residents of the London County lunatic asylums had been resident there more than ten years. Among the reasons for the preponderance of women inmates were that general paralysis, which was three times more frequent in men than in women, was a fatal disease; again, women were more likely to be insane because of the physiological emergencies connected with reproduction. Moreover, women had a more unstable nervous system or mental equilibrium. To those factors must be added, in his opinion, the enforced suppression, by modern social conditions, of the reproductive functions and the maternal instinct in women of emotional temperament. The author then proceeded to establish the principle of anticipation or antedating, and Nature's means of mending or ending degenerate stock, showing a number of pedigrees, one of which exhibited the elimination of unseemly elements in a stock in which there was a dual insane inheritance. It was generally admitted that in the pedigrees of general paralysis of the insane the neuropathic taint was not found to anything like the extent that it was in the pedigrees of patients suffering from neuroses, psychoses, and feeble-mindedness. This was not surprising, seeing that general paralysis was an organic disease due to the action of the syphilitic organism. He had been able to support his contentions by the investigation of upwards of 3,000 relatives of persons admitted into the London County asylums.

Dr. WHITE demonstrated a number of very instructive pedigree charts, and the manner in which the data were ascertained. It seemed to be the general rule that the abnormality on the mother's side was greater than that on the father's side.

Sir GEORGE SAVAGE (President) referred to some cases within his experience in which a man, after a head injury, slowly became weak-minded, and the children begotten after it were also weak-minded. He also spoke of the alternation of neuroses, gout or asthma alternating with insanity in several cases he had seen, while glycosuria and insanity were said to behave in the same way. Diabetics sometimes had insane or epileptic offspring.

Marriage between offspring of degenerate parents was not such a serious matter where the contracting parties did not themselves show a neurotic taint as where that did exist. This presence or absence of a neurosis also entered largely into the question of whether cousins should marry.

Dr. ROBERT JONES (Claybury Asylum) said he took the histories of 100 cases of general paralysis, and found that in 28 per cent. there was a history of paralysis of some kind in the progenitors, in some of whom it was called "spinal paralysis"; but he knew that in others it was general paralysis. And there was a history of some member having been insane in 38 per cent., while in 18 per cent. there was a history of drink in the parents; 12 per cent. gave a history of epilepsy, and 31 per cent. a history of tuberculosis. He considered that disorders of the ductless glands were responsible for much insanity. He believed in the transmissibility of general paralysis of the insane.

Dr. HYSLOP pointed out the protean character or conditions grouped as insanity, and the fact that in some cases the condition was due to a gross physical defect in the thyroid gland, for example; and he counselled caution in applying Dr. Mott's statistics in too sweeping a manner.

SECTION OF THE HISTORY OF MEDICINE.

A MEETING of this Section was held on January 29th, Sir WILLIAM OSLER, Bart., F.R.S., President, in the chair. Sir W. T. Thiselton Dyer, K.C.M.G., F.R.S., the Right Rev. Francis Aidan Gasquet, D.D., O.S.B., A. Rudolf Hoernle, Charles Louis Taylor, H. S. Wellcome, and Sidney Young, F.S.A., were elected Corresponding Fellows as "persons who have distinguished themselves in the subjects for the study of which the Section is established."

Medical Allusions in the Writings of Francis Bacon.

Dr. STEEVES read a paper upon medical allusions in the writings of Francis Bacon. The subject was considered under the following heads: (1) Bacon's mental attitude towards the profession, and the duties pertaining to it. (2) His views on public and domestic hygiene. (3) Remarks on disease in general and special diseases. (4) Medicines and special medical applications. (5) The special senses. (6) Generation; decay and death. The paper was discussed by Dr. RAYMOND CRAWFORD and Dr. LEONARD GUTHRIE.

Plague Banners.

Dr. CRAWFORD showed some plague banners by means of lantern slides in the epidiascope. He said that these banners were formerly carried in processions in times of plague. He traced back the custom of carrying such pictures in public as far as the time of Gregory the Great at the end of the sixth century. He alluded to the many wonder-working Madonnas that abound in Italy, and assigned them a place in the lineage of plague banners. He showed a fifteenth-century fresco from the church of S. Pietro in Vincoli at Rome, which depicted the carriage of a plague banner of the Madonna sheltering her suppliants beneath the folds of her robe. Passing to the gonfaloni of Perugia, he showed that such banners were not an exclusive product of the Umbrian school. They fall into three groups, according as the central figure of the banner is the Madonna, Christ, or a plague saint, usually St. Sebastian, on account of his local veneration. Examples of each type were exhibited and the salient features explained. Dr. SAMBON took part in the discussion.

Some Oddities in Nomenclature.

Mr. B. GLANVILLE CORNEY, I.S.O., read a paper on this subject. He said that in Rio de Janeiro during the epidemics of influenza which occurred in 1777 and 1802-3 the disease was called "zamporinion" and "corenuda." He also cited an epidemic of dengue which ran through Brazil in 1847 and was called "polka" at Rio and "rabo alerto" at Bahia. The term "zamporinion" was adopted from the name of a Venetian singer who was popular at Rio at the time, and has nothing to do with the Portuguese name for measles, "sarapao"—in Spanish, "sarampion"—which is directly derived from the Greek, the bright colour of the rash resembling that of a faded

vine leaf. "Corcunda" means hunchbacked, and came into popular use because of the bent condition in which patients were left at the end of each paroxysm of cough, which was said to be of a very spasmodic character and closely to resemble whooping-cough. Dengue was called "polka" because of a distinguished court beauty at Rio who was a native of Poland and was in great vogue at Bahia at the time of the epidemic. The same epidemic received the name "rabo aherto" because there chanced to be coincidentally an unusual glut of the fish of that name. Mr. Glanville Corney advanced the theory that an epidemic of cerebro-spinal meningitis was coincident with the Bahia epidemic and that whooping-cough played a part in the "corcunda" attack. He also alluded to the older folk names for influenza—namely, "le tac," "the new delight," and the "jolly rant," which have in turn displaced each other and have themselves been replaced by "the flue."

Eighteenth Century Obstetric Forceps.

Mr. ALBAN DORAN demonstrated by means of the epidiascope some eighteenth century obstetric forceps. He showed Grégoire's forceps. This is a heavy instrument weighing 1 lb. 9 oz., measuring 17 in. in length, with no pelvic curve, but with fenestrated blades. It differs from Grégoire's original type in its simpler lock, and in a mechanism to allow of one handle being used as a sharp crotchet, as in Freke's instrument. It is uncertain if Grégoire devised this modification since he never wrote on his own forceps, and Boehmer is the original literary authority. Orme-Lowder forceps: Very short, blades straight, broad, narrower at the free ends, which are $1\frac{1}{2}$ in. apart when the handles are closed; the fenestrae are wide. The evidence, again, is that of contemporaries, because Orme left no writings; Lowder admitted Orme's priority in some manuscript lectures. Kühn wrote the first published description of Orme's forceps in 1783. Mulder, a pupil of Orme and Lowder, published important evidence, and sketched their forceps himself. The inventors considered that the wide fenestrae and narrowing of the broad blades near the tips adapted their instrument to the fetal head. Lowder rejected Orme's leather covering for the handles. Mulder and Kilian differ as to the extent of the leather covering in Orme's forceps. The instrument exhibited seemed intermediate, being longer than Orme's and shorter than Lowder's, whilst the handles were lined with leather. Haighton's forceps were an exaggeration of the main features in the Orme-Lowder type, but there was no description of his forceps in his manuscript lectures. Blundell, Haighton's nephew, noticed Orme's and his uncle's forceps in his textbook, ignoring Lowder's. There is some uncertainty about the precise nature of variation in Haighton's instrument. David Davis designed forceps with even wider fenestrae. Conquest's widely fenestrated forceps had a screw-joint in one handle. Osborn's forceps: The instrument exhibited corresponded exactly to a drawing in the inventor's *Essays* (1792). It was a miniature Levret, a light, short forceps, with relatively slender blades bearing a pelvic curve; it was also broadest at the tips, which were $\frac{3}{4}$ in. apart when closed. The whole instrument, including the fenestrae, was covered with leather. Mulder's contemporary evidence and Denman's own writings awarded the priority to Osborn. Denman's forceps were similar, but the blades had no pelvic curve. Thynne retained the pelvic curve and made the blades proportionately longer, according to Mulder; Thynne himself left no description of his modification in the abstract of his lectures.

SECTION OF OBSTETRICS AND GYNAECOLOGY.

At a meeting held on January 2nd, Dr. AMAND ROUTH, President, in the chair, Dr. CUTHBERT LOCKYER read a paper on *Adeno-myoma of the recto-uterine and recto-vaginal septa*. The author first remarked upon the rarity of new growth arising in the connective tissue of the recto-vaginal septum, and described a case which had come under his own observation. The patient was a sterile married woman, aged 35. There had been menorrhagia for twelve months and a good deal of pain in the rectum, and latterly defaecation became difficult. There had been no bleeding from the bowel. A hard mass was felt in the posterior fornix, which

was attached to the supravaginal cervix and projected into the rectum, the rectal mucous membrane covering it being intact. The vaginal cervix was normal. Laparotomy showed that the body of the uterus and the appendages were normal; there was no cellular infiltration, and the growth, which was extraperitoneal, was firmly fixed to both rectum and uterus. The ureters were dissected out, the left being firmly incorporated with the growth; then the uterine arteries were tied and the parametric tissues divided as far out as possible. The bladder was then separated and the anterior vaginal wall divided. The rectum was divided between clamps above the growth, freed as low down as possible, and again divided, along with the posterior vaginal wall below the growth. The lower end of the rectum was closed and the upper end fixed in a separate opening in the left iliac region. Suprapubic and vaginal drainage was employed. The patient was making a good recovery. Microscopic examination showed that the growth resembled an adenomyoma of the uterus. Histologically it was comparatively benign, and might have originated in some vestigial remains of the Wolffian duct. An epidiascopic demonstration on the lighting of Continental operating theatres was given by Dr. MACNAUGHTON JONES, and short communications upon cases in which a foreign body was removed from the abdomen by laparotomy were read by Dr. RUSSELL ANDREWS and Dr. G. F. BLACKER.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF STATE MEDICINE.

Friday, January 17th, 1913.

Dr. T. P. C. KIRKPATRICK in the Chair.

Sanatorium Benefit in Ireland.

DR. R. J. ROWLETTE read a paper on this subject. He summarized the clauses of the National Insurance Act dealing with the sanatorium benefit, and sketched the machinery by which it is administered. He then defined the relations of the Insurance Committees and the county councils, and described the various agencies to be employed in a tuberculosis campaign. He concluded with an appeal to the profession to assist cordially in the working of the benefit. Dr. T. J. CROWE pointed out the disadvantages of the arrangement by which the dispensary was to be only a place for consultation. In Dublin most of the cases had just been sent up by the practitioners with letters asking them to be dealt with, and the rules laid down forbade the tuberculosis officer doing so. Dr. PATRICK HEFFERNAN said that there seemed to be great uncertainty as to the definition of domiciliary treatment. Sir JOHN MOORE agreed with Dr. Crowe that the Insurance Act had raised great difficulties in respect to tuberculosis. Provision was made, it had been pointed out, in the Act for extension to other diseases; although pneumonia killed between 40,000 and 50,000 people in England and Wales every year, there was no notification or sanatorium treatment provided in this country for patients recovering from it. With regard to the advanced cases the conditions were deplorable, and the Act had made no provision for them. If the Insurance Act provided for the remuneration of medical officers in connexion with the tuberculosis section of the Act, he thought the honorary staffs of hospitals should not consent to work those sections of the Act without fair remuneration. Dr. CROFTON considered that much advance would not be made in the treatment of the disease until institutions were provided completely equipped and having whole-time directors and assistants as in Germany. Dr. McDONALD, referring to his own experience, objected to examine patients apart from the practitioner in attendance, but the Commissioners insisted on his doing so. Dr. LAW said that the paper had shown how unsatisfactory was the Act. It was of the greatest importance that every case should be notified. How the expense of treatment was going to be met out of the money available was not clear. Advanced cases among the poor were an imminent danger to the whole community, which demanded compulsory segregation. The CHAIRMAN dwelt on the difficulties in working the Act and the way in which it was proposed to work it, but he thought that if the medical profession joined whole-heartedly it would

greatly aid in stamping out the disease. In the past, when a patient, a bread-winner, was met with in which there was hope for improvement, he perhaps could not afford to undergo the treatment, but under the present Act this difficulty would in part at least be removed. Dr. ROWLETTE, in replying, said that every effort would have to be made to confine dispensary officers to consultation work, but he saw no reason why one of the dispensary staff should not go in consultation to the home of the patients to examine contacts. Domiciliary treatment meant whatever treatment could be carried out in the home of the patient. The necessity for provision for advanced cases seemed most important, yet county councils were rushing into provision of sanatoriums and taking no care whatever of such cases. As to treatment, he pointed out that no general practitioner could be employed to attend his own patient without the manner of treatment being approved by the Local Government Board. Referring to the question of finance, the amount available for sanatorium benefit for the city of Dublin would be about £3,000. The corporation would have power to levy a 1d. rate, which would bring about £4,000, and if this were done the Treasury would add a further £4,000, making the total for providing treatment £11,000. He agreed with Sir John Moore about the honorary staffs of general hospitals. As to what constituted treatment under the Act, there was great difficulty in ascertaining the point. Food supplied on a doctor's order was at first held not to be treatment, but it had since been held to be treatment.

The Mental Deficiency Bill and its proposed Extension to Ireland.

Dr. W. R. DAWSON referred to Standing Committee B, by which up to the end of the year seven clauses had been considered and amended, providing for the constitution of the central authority (for England), the constitution and duties of the local authority, and defining the persons subject to be dealt with under the bill. After referring to certain amendments, Dr. Dawson remarked that on the whole the bill had gained greatly in Committee. The class of persons who had become mentally infirm from age or decay of their faculties had wisely been withdrawn. The local authorities were to be the county and borough councils respectively, but they were not to be obliged to provide accommodation unless one-half the net cost of maintenance was contributed by Parliament. The numbers to be provided for might be roughly estimated at 10,000, not including persons in asylums, but many of these were already provided for at public expense, so that their present cost would have to be deducted from the amount required to work the bill. As matters stood at present the bill was to apply to England and Scotland, but not to Ireland, which required such a measure far more than either of the former. It would not offer a complete provision, but would make a much-needed beginning, and if the present opportunity was lost, there seemed little chance of any legislation on this pressing matter for years to come. The CHAIRMAN said the matter had occupied the attention of the Medico-Psychological Society (Irish Branch) for a long time, and they had done a great deal to urge the extension of the bill to Ireland. Dr. LEPPER added that no one, unless he had worked amongst the insane of Ireland, would realize the importance of this measure to the country, where the insane population was yearly becoming greater, and he felt that that increase would go on until such a measure as the one referred to was introduced. He proposed the following resolution:

That the Section of State Medicine of the Royal Academy of Medicine in Ireland strongly approves of the extension of the Mental Deficiency Bill to Ireland, and recommends the Council of the Academy to adopt this resolution and forward copies to the Chief Secretary for Ireland, the Lord Chancellor, and to the Irish members of Parliament.

He considered that if the Section gave its support they would be doing much good to the country. Sir JOHN MOORE seconded Dr. Leeper's resolution, which the CHAIRMAN put to the meeting. It was declared carried unanimously. Dr. DAWSON referred to the method of treatment which children had to undergo in asylums, and said that he did not like to see children in asylums at all. Of

course, in the Stewart Institution they could only be detained if they were certified as lunatics. He saw no difficulty about the application of the Act to Ireland.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held in the Glasgow Royal Asylum, Gartnavel, on December 20th, 1912, the PRESIDENT (Dr. Freeland Fergus) being in the chair. A clinical and pathological demonstration was given by the staff of the asylum, in the course of which the SUPERINTENDENT (Dr. L. R. OSWALD) read a paper on, and demonstrated several cases of, *Dementia praecox*. Dr. R. M. MARSHALL discussed the differential diagnosis of dementia praecox from manic depressive insanity. Dr. F. MURCHIE made a short communication on *The eyes in dementia praecox*; and Dr. IVY MCKENZIE read note on *Dementia praecox and general paralysis: a comparison and contrast*.

At a meeting held on January 17th, Dr. J. CRAWFORD RENTON being in the chair, Dr. IVY MCKENZIE showed and described pathological preparations from the following cases: (1) A woman, aged 40, an inmate of the Glasgow Royal Asylum, Gartnavel, suffering from *Recurrent insanity with exophthalmic goitre, leucoderma, and bronzing of the skin*, also auriculo-ventricular tachycardia (230 per minute) and auricular fibrillation. *Post-mortem* examination showed disease of the thyroid gland and of the upper cervical sympathetic ganglion, and hypertrophy of the medulla of the suprarenals. (2) A man, aged 40, a dement, who died suddenly in Gartnavel Asylum with symptoms simulating intestinal obstruction, tympanites, faecal vomiting, etc. *Post-mortem* examination showed *Necrosis of the pancreas and necrosis of the mucous membrane of the small intestine*, involving the whole length of the bowel. Dr. DAVID NEWMAN read a short paper on *Certain urinary conditions in women, associated with frequent or painful micturition*, and demonstrated with the projectoscope the cystoscopic appearances presented in the early stages of tuberculous of the bladder, and in the various stages of colon-bacillus infection of the bladder. He pointed out that one of the slightest forms of colon infection of the bladder was seen frequently in infants and young children as the result of want of cleanliness in changing the child's napkins. The frequency of micturition might not be noticed in infancy, and for years afterwards the child suffered from nocturnal incontinence, which might persist until puberty or even later. Dr. J. A. WILSON read a paper on *Myopia: a review of 500 cases, with special reference to their etiology*. From an analysis of his cases he found: (1) Keratitis as the cause of myopia in 16 per cent.; (2) evidence of heredity in 54.8 per cent.; (3) cases without opacities and without evidence of heredity in 29.2 per cent. In the hereditary group were 17 cases with opacities; 65 cases showed monocular myopia, largely accounted for by keratitis and by heredity. Lenticular changes were found in quite young people. The evidence regarding near work as a cause was reviewed, and it was pointed out that for evident reasons German school hygiene had not lessened the amount of myopia.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held on January 31st, the PRESIDENT, Dr. Dobson, being in the chair. Dr. G. W. WATSON opened a discussion on *Tuberculin*, its place in modern medicine. Remarks were made on the varieties of tuberculin in common use, and the various methods of administration were outlined, with descriptions of the types of case suitable for each method. Dr. Watson was of opinion that the efficacy of tuberculin was so far proved that its use was essential in the proper treatment of most cases of tuberculosis of the lungs. He deplored the tendency under recent legislation to make the treatment of phthisis a speciality and to give it into the hands of the few rather than to obtain the skilled and enthusiastic co-operation of the whole of the profession. Dr. CHRISTY WILSON spoke of his experience of Béranek's tuberculin, and instanced cases in which it had proved of great value. Dr. BARRS spoke of the treatment as being still on its trial, and confessed that no convincing example of its usefulness had yet come within his experience. Mr. J. F.

DOBSON spoke of the value of tuberculin in the treatment of cases of surgical tuberculosis. He was in favour of the method of administration recommended by Wright. Dr. COPLANDS contributed some interesting information about tuberculosis in animals. Cases were shown by Dr. HELLIER, Mr. A. L. WHITEHEAD, Mr. CONSTABLE HAYES, Mr. J. F. DOBSON, Dr. C. OLDFIELD, Mr. COPLAND, Mr. MICHAEL TEALE, and Dr. WATSON.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

At a meeting on January 22nd, the President, Mr. W. G. LAWS, in the chair. Dr. L. W. MARSHALL opened the discussion on the *Medical aspect of education*. The first aim of teachers should be to produce physical fitness and then mental culture in their scholars. The attention of teachers should be drawn to the various parts of the body developed at different periods. Private tuition was bad. It was most important that the preparatory schools should be good, and such as gave great attention to the early development of the body. "Only" children were greatly to be pitied. From 4 to 7 years the Kindergarten system was the best. From the 7th to the 9th years neuroses developed and should be carefully watched. At this period, also, the teeth were changing, and sleep was apt to be affected. The cardio-vascular system developed about the 9th year. Discipline should be enforced from the 7th to the 9th years; more mental pressure might be applied from the 9th to the 13th years. The "will power" was now developing, and became confirmed after the sexual development at the age of 13 years. Miss SARAH GRAY laid great stress on eliminating all physical defects. The "nervous child"—that is, one of exalted sensibility in particular—should be carefully watched. The aim of teachers should be to (1) make the child a healthy animal, (2) avoid stimulation in every way, (3) provide for ample sleep, (4) allow the child a definite amount of daily leisure when it should amuse itself; and, lastly, not to overwork the child, especially between the ages of 9 and 13 years. Drs. S. E. GILL, J. S. BOLTON, and W. HUNTER continued the discussion.

HARVEIAN SOCIETY.

A CLINICAL meeting of the Harveian Society of London, held at St. Mary's Hospital on Thursday, January 30th. The following cases were shown:—(1) Dr. SIDNEY PHILLIPS: An abdominal case, probably tuberculous. (2) Dr. WILLCOX: Two anomalous cases of *Erythraemic goitre*, a case of *Chronic enlargement of joints resembling Charcot's joints*, and a case of *Perforating ulcer of the foot*. (3) Dr. REGINALD MILLER: *Post-pneumonic fibrosis of the lung*, and a case of *Endemic cretinism* fifteen years old. (4) Dr. GRAHAM LITTLE: A man with *Psoriasis* covering his whole body, and a woman with *Lichen planus hypertrophicus verrucosa*. (5) Mr. COPE: A case of *Syringomyelia*, and a case of recovery after *Rupture of the jejunum*. (6) Dr. WILLIAM HILL: A case of *Epithelioma of the Larynx*, and a case of *Stricture of the pharynx* after swallowing glacial acetic acid with suicidal intent. (7) Mr. BRYAN: A girl with a *Sarcoma of the lower jaw*, and a man with a large tumour just above the ankle of doubtful nature. (8) Mr. DUNCAN FITZWILLIAMS: A *Fibrolipoma* in a child, and a man with a large *Epithelioma*, growing rapidly from an old urinary fistula.

LONDON DERMATOLOGICAL SOCIETY.

At a meeting held on Tuesday, January 21st, Dr. MORGAN DOCKRELL in the chair, Dr. W. GRIFFITH showed a case of *Ichthyosis* in a boy aged 13, displaying the typical "crocodile hide" marked over the chest and back, where the thickened skin lay in large folds. He proposed treating him with thyroid extract. Dr. Griffith also showed another but milder case of ichthyosis. Dr. BUNCH considered 3 grains of thyroid extract three times a day to be a fair dose. The PRESIDENT, who had recently prescribed it freely, thought that a patient should take at least 9 grains a day, though he had himself often taken as much as 15. Dr. KNOWSLEY SIBLEY considered that recently too large doses of thyroid were administered. A grain

and a half once daily, only very gradually increased, seemed sufficient. Doses of $\frac{1}{2}$ and even $\frac{1}{16}$ grain were now often given. Dr. J. M. BUNCH showed a case of *Mycosis in the fungoid stage* in a woman aged 26. For about nine months she had been subject to a pinkish, yellowish, and slightly scaly eruption over her body. Dr. GRIFFITH showed a case of *Angioma serpiginosum* which had been completely cured in the electrical department. Dr. HAMPTON explained that it had been treated with solid carbon dioxide and x rays. Dr. SIBLEY showed several cases: (1) Of a man aged 28 with a considerable amount of keloid scar formation over his face and the back of the neck, the result of acne, which he was treating with benefit by hyperaemia. (2) A man aged 50 with an extensive eruption of lichen planus. (3) A man 28 years of age with some remarkable old standing lesions on his hard palate, and some few brownish, scaly, ringed-like patches on his skin, probably old syphilis. (4) A man aged 30 with a marked tertiary patch on his right cheek. (5) A woman aged 23 with condylomatous patches on her lips, chin, thighs, and genitalia. Dr. J. M. BUNCH opened a discussion on *Bullous eruptions*, in which he described in detail the various skin lesions which were the result of or accompanied by bullae. The PRESIDENT, Dr. GRIFFITH, and Dr. SAMUEL joined in the discussion.

Reviens.

GIBSON'S LIFE OF GAIRDNER.

THERE must be many not only of his old pupils and personal friends, but amongst the medical profession in all parts of the world, who will be glad to possess this *Life of Sir William Tennant Gairdner*,¹ and to find included in it a selection of his general and medical papers. But the work possesses an additional value to not a few as being the last production of the pen of the greatly beloved GEORGE ALEXANDER GIBSON, who, as the intimate friend and latterly the medical adviser of Sir William, was selected by the family for the honourable duty of preparing this memorial to one who was undoubtedly the most notable figure in Scottish medicine during the last half-century.

Gairdner came of a family which has many distinguished connecting links with the medical profession; the late Professor Sir Douglas MacLagan was a cousin in some degree, as was also the distinguished naval surgeon Sir Gilbert Blanc, while William Gairdner, the author of the well-known work on *Gout*, was his uncle. John Gairdner, the father of Sir William, was President of the Edinburgh College of Surgeons in 1830-31, and wrote many papers on the history of the profession, while his mother, Susanna Tennant, was a sister of Sir James Tennant, K.C.B., who commanded the artillery at Chillianwalla and Gujerat.

William Tennant Gairdner was born on November 8th, 1824; he was his father's second son, and in connexion with his family it is only necessary to add that a younger brother was the distinguished historian, James Gairdner, C.B., LL.D., D.Litt. Gairdner's education was received at the Edinburgh Institution and the university of his native city, which last he entered in 1840, taking his M.D. degree in 1845, evidently at the earliest possible age of 21. Among his contemporaries were many who became distinguished men, but the writer of this notice has heard some of them say that they looked up to Gairdner as their leader. After graduation he had the advantage for so young a man of accompanying Lord and Lady Beverley (afterwards Duke and Duchess of Northumberland) to Rome, where he remained a year; the mental impression then received was never effaced. On his return to Edinburgh he entered the Royal Infirmary as a resident, serving both as house-physician and house-surgeon during a period extending over two years, and the maturity of his mind is shown by the fact that he then prepared his papers on the pathology of the kidney. In 1848 he was appointed pathologist to the infirmary, and began to lecture on pathology with such success that the

¹ *Life of Sir William Tennant Gairdner*, K.C.B., M.D., LL.D., F.R.S., Regius Professor of Practice of Medicine in the University of Glasgow. By George Alexander Gibson, M.D., Sc.D., LL.D. Glasgow: James Maclehose and Sons. 1912. (817 pp. 12s. 6d.)

members of his first class gave him a copy of Bright's *Hospital Reports*, with a letter expressing their sense of the high value of his teaching; among the signatures appended to that letter are to be found the well-known names of James Warburton Begbie, Henry Duncan Littlejohn, Thomas Keith, Arthur Scott Donkin, and Alexander Fleming. In 1853 he became physician to the Infirmary; meanwhile he had published many of those papers which founded his reputation as a scientific physician; in the same year he commenced lecturing on the practice of medicine. In 1855 he was a candidate for the Chair of Medicine in Edinburgh, vacant by the death of Alison; but the choice of the curators, guided, it is said, by Sir James Simpson, fell upon Thomas Laycock, a physician of York. In 1862 he published his *Clinical Medicine*, and in the same year was appointed Regius Professor of the Practice of Medicine in Glasgow, henceforth to be his home and the centre of his educational and professional life until his retirement in 1900. Gairdner's interests were by no means limited to his profession, for he was keenly alive to questions of theology or philosophy, politics or literature, as his letters published in this volume bear witness: but into these channels his mind overflowed without prejudice to the main stream of his thoughts, which was always, even to the end of his life, directed to the advancement of the science of medicine.

Gairdner did not marry until he had reached the mature age of 46; he has left a family of four sons and three daughters to be a solace and support to Lady Gairdner in her widowhood.

He died at the age of 83, on June 28th, 1907, at his house at Colinton, near Edinburgh. For the last five years of his life he had suffered from the condition known as "heart-block," and the study of his own case in the light of new methods of research which Dr. Gibson was so well qualified to employ, gave him much food for thought. He ultimately passed away quite quietly in one of his fits of unconsciousness.

His many-sided mind is vividly illustrated by the papers reprinted in this volume. Among British physicians of his day Gairdner was indisputably the foremost academical figure; there was no teacher like him; he lived for his chair and his students, but his words reached a wider audience and his spirit inspired many who had never seen him or heard his voice.

All those who read Dr. Gibson's book will feel that they owe a debt of gratitude to the author for the admirable manner in which he fulfilled his task, and will join in regretting that it is now too late to offer him even a few poor words of thanks for this memorial to which he devoted so much care and labour.

THE CARRIER PROBLEM IN INFECTIOUS DISEASES.

UNDER the title of *The Carrier Problem in Infectious Diseases*, Drs. LEDINGHAM and ARKWRIGHT have prepared a useful historical summary of the main facts about infection by "carriers" in six important diseases. Nearly half the book, and distinctly the best part, is occupied by typhoid fever, the transmission of which by carriers is a subject of universally recognized importance, thanks largely to the investigations initiated by the late Professor Koelsch in 1902. The present survey of this problem is to a large extent a reproduction of Dr. Ledingham's excellent report to the Local Government Board, issued in 1910 (New Series, No. 45), and we are glad to see that his work is now given the opportunity of a wider publicity. Unfortunately little or no success has been attained in many of the attempts hitherto made to cure the chronic carrier of typhoid bacilli. The administration of drugs seems useless, or at least to have no more than a temporary effect. Sour milk treatment has been equally disappointing in the hands of Dr. Ledingham and some other observers; and cases of alleged cure by this method are, in Dr. Ledingham's opinion, open to the criticism that the permanency of the cure has not yet been fully established. The author gives us an interesting account of attempted

cures by surgical operation on the gall bladder, but here again he thinks the prospects of success are small in long standing cases, though a definite pronouncement must be postponed until the cases have been under bacteriological supervision for at least one or two years after operation.

Next in order of interest is the chapter on the cholera carrier. From a review of the data available, Dr. Arkwright concludes that about half the persons who recover from an attack of true cholera retain the vibrios for from ten days to a fortnight. Only 5 or 6 per cent. remain infective for over twenty-five days, but of these latter 1 or 2 per cent. continue to excrete the vibrio intermittently for two or three months. This raises the important question whether the danger of the cholera carrier is sufficiently great to justify a bacteriological examination of all passengers on ships arriving from cholera-infected ports. Dr. Arkwright tells us that at New York, between July and November, 1911, 26,455 passengers were examined bacteriologically for cholera vibrios; "150 were detained for further examination, and 26 (1 per cent.) were eventually proved to be carriers." In the last sentence the printer has apparently omitted a decimal point, as the above figures give an average of only 1 carrier per 1,000, a difference which is of very considerable importance in estimating the value of this irksome interference with the convenience of passengers and the interests of trade.

The lengthy chapter on diphtheria carriers covers well-trodden ground and calls for no special comment. The three other diseases which are dealt with are paratyphoid fever, epidemic cerebro-spinal meningitis, and dysentery. The collection, from various sources, of statistics as to carriers of the meningococcus has been made with great care, and will be much appreciated by epidemiologists.

ASTHMA.

DR. SIEGEL'S treatise³ contains the orthodox view on the nature of asthma. After surveying the experimental enquiries into the function of the bronchial muscles Dr. Siegel defines asthma to be "a reflex neurosis characterized by asthmatic attacks" (*sic*), and concludes that these are due to a combination of a bronchial spasm with an abnormal bronchial secretion, of which the former is the predominant factor and that organic lesions which may be discerned during life or which have been found at the *post-mortem* examinations hitherto recorded have no bearing whatever on the mechanism of the dyspnoea, this being a purely functional derangement.

Dr. Siegel's pathology, however, is not consistent with facts, and appears to have been constructed, as too commonly happens, not merely with preconceived notions but also on the basis of cases which he had seen in the intervals between, rather than during, the attacks. Had he actually observed a large number of the latter he could hardly have failed to notice, that just amongst the neurasthenic and the hysterical, whom he had in his mind, it occurs not infrequently that even at the height of the dyspnoea the air passages are perfectly pervious and that there is at the time not the slightest sign of any impediment to the ingress and egress of air. In these circumstances, whatever the immediate cause of the seizure may be, it is clearly not a bronchial spasm. True, in the majority of instances there is obviously an obstacle in the bronchial tree; but the nature of this obstacle can only be rightly inferred from the just appreciation of the clinical data. In that respect Dr. Siegel has completely failed. His notion, for instance, that the deformities of the chests of asthmatics are the consequence of their faulty attitudes during the paroxysms is amply disposed of by the facts, as Berkart has pointed out, that these deformities exist long before the onset of the first dyspnoeal paroxysm and that, if opportunities are given of examining the parents, or members of the same family who are not asthmatic, they also present deformities of the osseous system. A little reflection, moreover, would have convinced him that there are certain data which militate against his conclusion. He himself has observed that occasionally the obstruction is entirely limited to one lung—an observation which he

² *The Carrier Problem in Infectious Diseases*. By J. C. B. Ledingham, M.B., D.Sc., and J. A. Arkwright, M.D. International Medical Monographs. London: Edward Arnold. 1912. (Demy 8vo, pp. 326. 12s. 6d. net.)

³ *Das Asthma*. Von Dr. Wolfgang Siegel. Jena: Gustav Fischer. 1912. (Roy. 8vo, pp. 170. Mk. 4.)

claims to be original, but to which Berkart has called attention more than twenty years ago. Does the spasm affect, then, only one lung? And what about the results of the *post-mortem* examinations of the cases which have succumbed during the attacks? There were found dilated bronchioles filled with morbid exudation and with walls either atrophic or degenerated by interstitial connective tissue proliferation; yet, in spite of the progress of these lesions, which clearly preclude any active contractions of the bronchioles, the dyspnoeal seizures have maintained their types, and have increased in frequency and severity.

Equally unsatisfactory is the method of treatment which Dr. Siegel advocates. His book is avowedly intended for the use of practitioners who have had no special experience in dealing with asthmatics. In order to supply this deficiency he gives them exhaustive lists not only of the remedies and remedial measures commonly in use, but also of the numerous nostrums which industrial enterprise has placed on the market. Definite indications he can give only for a few of them; instead of them he over and over again advises the inexperienced practitioner to try them all—*ausprobieren*, as he calls it—on the chance that the one or the other may produce the desired results. It is difficult to conceive of anything more painful to read than such recommendation. To his credit, however, it must be said that he is averse from the haphazard operations on the nose. The proud edifice, he states, which has been built on their first introduction has entirely collapsed, as experience has shown that the successes have been few and the failures many. Dr. Siegel does not rely entirely on medicinal or other method of treatment. An indispensable element in the management of asthmatics is, he holds, the individuality of the practitioner—that particular tact which cannot be acquired but must be innate in the successful asthma specialist. Without this quality all efforts to combat the disease must, he maintains, remain vain. We are led to suppose that with this endowment and with the advantages of a salubrious climate such as that of Reichenhall where, moreover, there are cabinets for inhaling compressed air, the prospect of obtaining full mastery over what is otherwise one of the most intractable of complaints is very promising

SHORT TEXTBOOKS OF MEDICINE.

THERE are few works on the science and practice of medicine which can claim to have retained the favour of professional appreciation for such a long and uninterrupted period as thirty-two years. This highly satisfactory record has been achieved by Professor CARTER'S treatise on the *Elements of Practical Medicine*,⁴ and we congratulate the distinguished author on the appearance of the tenth edition of a work which has been so successful as to prove acceptable for nearly one-third of a century. Practical medicine has become so extensive as to make it a matter of much difficulty for any author to compress into one volume the main outlines of a subject to which enormous treatises have been devoted. Dr. Carter modestly declares that his book attempts to deal only with the elements, but he has succeeded in producing a trustworthy synopsis of the essential facts belonging to clinical medicine, and has marshalled his material in such a masterly way as to provide his reader with a bird's-eye view of the present position of knowledge in its relationship to the broad outlines of etiology, pathology, symptomatology, and treatment in their bearings upon the recognition and management of medical disorders. In common with all books that attempt the delineation of such an extensive subject as general medicine, Dr. Carter's volume suffers from the compression which is essential to the fulfilment of the plan of production. Much important detail is of necessity omitted, and, especially on the question of treatment—which is, after all, the practical application of research and knowledge to the requirements of the sick—the information afforded is too generalized to be of great value to the busy practitioner. Still, in regard to treatment, as to all the other factors that go to make up a complete picture of disease, the author succeeds in

giving the outlines of his story in terms of sufficient comprehensiveness to guide his readers along the true pathway of clinical investigation, and to direct them to an accurate appreciation of the methods of prevention and cure which, in the light of present knowledge, are most generally acceptable. For more detailed information recourse must be had to larger textbooks and to works more extensively devoted to the consideration of special subjects. The favourable criticisms that have been expressed concerning previous editions may be confidently reiterated concerning this tenth issue. The book has been carefully revised and many chapters rewritten, new information in connexion with the more recent advances in medical science and practice has been added, and the application of general principles to the recognition and treatment of disease has been elaborated at the sacrifice of details. This has been done with a view to keeping the volume within moderate compass and to fulfilling its purpose of being useful to students and junior practitioners as a guide and remembrancer rather than a textbook. Practically the whole of the re-editing has been undertaken by the author personally. This gives to the various sections of his work a level merit and plan of execution which is sadly wanting in many of the treatises produced after the present day fashion of multiplicity in authorship. We are able to recommend Dr. Carter's new edition as cordially as we have recommended its predecessors to the perusal of students and practitioners alike. They will find it a concise and reliable guide to practice, unencumbered by theoretical disquisition, but bristling with ascertained facts—in short, a *multum in parvo*, which records the outcome of the author's extended personal experience, and may be relied upon for accuracy and wise guidance. The book is pleasantly written, has the advantage of a copious index, and comprises a therapeutic guide illustrative of the author's experience in drug combinations.

Dr. FLEMING must be congratulated upon his success in preparing the second edition of his *Short Practice of Medicine*.⁵ The medical student preparing for his final examinations in medicine and the practitioner anxious to get at the centre of the many problems connected with medical diseases will be grateful to an author who, whilst giving the essentials, has skillfully avoided entering into vexed controversies. If Dr. Fleming has been ruthless in this direction and has not given as much attention to some of the more modern points of view, such for example as the unity of so-called rheumatic fever, the alleged benefit to be derived from the use of tuberculin in the treatment of pulmonary tuberculosis, and the toxic origin of cardiac hypertrophy, the reader must feel that although the author has set out to write an account in short compass of the practice of medicine, he is inclined to be critical and rightly so, for the readers of this volume will mostly want facts and not theories. On page 599, it is evident that the two sentences beginning "Schlösser" have got out of their place. We may call the attention of teachers of medicine to some of the very cogent remarks in Dr. Fleming's preface to the original edition. He has evidently formed a true estimate of the duties of a lecturer in medicine. He leaves to the student the duty of learning for himself from a textbook the general outline of each individual disease and provides in lecture form special points, clinical illustrations, and hints on treatment. This volume is admirably designed for such a scheme.

A LIBRARY OF THERAPEUTICS.

THE large *Bibliothèque de thérapeutique*, projected and edited by Professors A. GILBERT and P. CARNOT, of the Faculty of Medicine at Paris, is divided into three series and twenty-eight volumes. The first series, comprising fourteen volumes, deals at full length with the various therapeutic agents at our command; eight of these volumes have now come out. The third series, to be completed in eleven volumes, will describe the treatments applicable to the various diseases of the different

⁴ *Elements of Practical Medicine*. By Alfred H. Carter, M.D., M.Sc., Professor of Medicine, University of Birmingham; Emeritus Professor of Physiology, Queen's College, Birmingham, etc. Tenth edition. London: H. K. Lewis, 1912. (Crown 8vo, pp. 709. 9s. net.)

⁵ *Short Practice of Medicine*. By Robert Fleming, M.A., M.D., F.R.C.P.E., F.R.S.E., Lecturer in Practice of Medicine, School of the Royal Colleges, Edinburgh; Assistant Physician, Royal Infirmary, Edinburgh. Second edition. London: J. and A. Churchill, 1912. (Med. 8vo, pp. 849; 55 illustrations. 12s. 6d. net.)

systems of the body. The second series, with which we are now concerned, is divided into three volumes, and discusses the treatment of symptoms and signs. It is often difficult to decide whether a given symptom demands treatment or not, whether it should be encouraged or combated: what means (if any) should be applied to the end desired; the phenomena of inflammation may be quoted as an instance of this difficulty, or the occurrence of epistaxis in a patient with abnormally high blood pressure. The object of the second series is to throw light on these often difficult, or even insoluble, problems; and its first volume,⁶ on general symptomatic treatment, is written by a number of the most distinguished clinicians in France. To mention the separate chapters written by each of them is impossible; it is sufficient to say that the book contains a series of fairly detailed sketches setting out the general lines of treatment in such general conditions as fever, the infections and intoxications, developmental defects, senile involution, oedema, and the like. These sketches are well written, give much general advice, together with a few detailed prescriptions, and are thoroughly up to date. In addition, they contain very useful descriptions of the physiology and pathology of the various diseased conditions they describe. The volume may be warmly commended to the philosophical practitioner.

ELEMENTARY ZOOLOGY.

Among the many excellent scientific works that have emanated from the Oxford University Press during recent years, the *Manual of Elementary Zoology*,⁷ by Mr. L. A. BORRADALE, can by no means be reckoned the least important. As the author says in his preface, he has "endeavoured so to treat of the animals which are most often studied in courses of elementary zoology as to introduce the student by their means to the principal problems of the science." He has kept this object in view throughout, and the manual is one we can thoroughly recommend to those students, medical or other, who are commencing the study of zoology. After a clear but concise introductory chapter on the animal organism, the author departs from the usually accepted order of considering the animal kingdom and starts with the frog. By so doing he is enabled to describe in detail much of the minute anatomy of this animal, and so to demonstrate, as he goes along, the provisions that exist for carrying out the various physiological functions that he has previously referred to in his introduction. He then turns to the monocoelular amoeba and goes forward in an ascending scale through the polyps and medusae to the flat and round worms, on to the crayfish, mussel, lancelet, and dogfish, and so reaches finally the mammal, as exemplified by the rabbit. There are, in addition, chapters on reproduction and sex and on embryology, and an appendix of instructions for practical work. The book is of handy size, well printed, and profusely illustrated. Many of the illustrations are from the pen of Dr. Edwin Wilson, whose name is a guarantee of their accuracy. We must take exception, however, to Fig. 216—the skeleton of a pigeon—and point out that the outermost toe of a bird has three interphalangeal joints and not two only, as in the drawing. The error, though apparently slight, is unfortunate, because the only way of discriminating between the right and left foot of a bird, when detached from the body, is by counting the number of (interphalangeal) joints in the three front toes.

To write an elementary scientific primer which shall be lucid, accurate, and up-to-date is indeed a difficult task. Such a difficulty has been successfully overcome by Professor GRAHAM KEIR in his little work on *Zoology*,⁸ one of Dent's series of scientific primers. The three animal types selected are the amoeba, hydra, and the earthworm, a chapter being devoted to each. The structure and physiology are described in simple and clear language. Then follows a short and succinct account of the natural

groups of the animal kingdom which lie nearest to the main phylogenetic stem, such groups as the sponges and ctenodermis being rightly neglected. The remaining three chapters are devoted to the fact and method of evolution and to the mechanism of heredity and variation. These difficult subjects are dealt with in a very elementary fashion, but are nevertheless admirable examples of lucidity. To the beginner, and to all those who may wish to acquire an elementary knowledge of biological facts, this book may be safely commended.

NOTES ON BOOKS.

AN excellent book for mothers and nurses is Dr. BROCKBANK'S *Children: Their Care and Management*, whilst doctors will pick up from it many practical suggestions not to be gained in hospital work or found in more pretentious books. From the chapter on the hygiene of the expectant mother to the last, on first aid in the nursery, the book is a storehouse of information on child management and care. On artificial feeding, weaning, the care of the infant, clothes, the nurseries, diet, digestion, and development, attention to the calls of nature, the teeth, bad habits, the special senses, schools and holidays, Dr. Brockbank has something useful to say. Whilst the hygiene of the older child is not omitted, the care and management of the infant get the fullest treatment; and, fortunately, Dr. Brockbank has not considered beneath his notice details, trivial in themselves, but of the greatest importance to the child and those who have charge of it. He lays stress upon the value of drinks of water to young babies, and refers to the need for using accurate measures in the preparation and administration of food. In the chapter on first aid there is no reference to that not uncommon nursery emergency, croup; and for cases of drowning Sylvester's plan of artificial respiration is given in preference to Schäfer's, which obviates the need for inversion of the body. The book is the work of one who has had much practical experience in the management of infants and children. Messrs. James Woolley, Sons, and Co., Limited, Manchester, supply a handy "First-aid Box for the Nursery," fitted up in accordance with Dr. Brockbank's suggestions.

MEDICAL AND SURGICAL APPLIANCES.

Non-Cutting Dissecting and Surgical Forceps.
MR. GORDON G. COPELAND, B.A., M.B., (Toronto, Canada) writes: The forceps illustrated embodies two new principles—the special non-cutting tips and a grip-handle which does not tire the hand. The tip or end has been modelled after the human fingers. There are no sharp edges that can cut or damage a ligature held by them, or on which a knot is tied. It is designed to hold delicate structures such as vessels, nerves, tendons, and fine ligature material, and soft tissues generally. The length of the forceps is such that deep work, as in the pelvis can be done easily, whilst it is not so large as to be clumsy. Ligatures not infrequently cut through after they have been tied tightly down on a forceps with serrated edges. Either the ligature is allowed to slip, by the withdrawal of the forceps too soon to prevent the above accident occurring, or the operator takes the risk. I have tried a large number of knots that have been tied tightly down against an ordinary tissue forceps, and in each case the ligature has been damaged, most of all if it be soft catgut. The instrument is of special use in orthopaedic work, such as tendon transplantation, blunt dissection, keeping a running suture tight while the needle is taking a fresh stitch; and in operations on delicate and soft structures in general. The handle is a combination of the lateral corrugations and a longitudinal central groove. The curved depression allows the pulp of the fingers to fit in it and affords a broader bearing surface, which is much less fatiguing than any other type. This type of handle will no doubt be more generally applied to ordinary tissue forceps, and others. Messrs. Allen and Hanburys are the makers of this instrument.

An Anaesthetic Mask.

Mr. H. TORRANCE THOMSON, Anaesthetist to the Leith Hospital, writes: For several months I have used an anaesthetic mask which Messrs. Down Brothers made at my request. The mask proper is made after the pattern of one introduced by Kocher a few years ago. The feature of this is that the rim is notched to receive the bridge of the nose, so that accurate apposition of the mask to the face is possible. A perforated metal pipe arches over the vault of the mask internal to the gauze, with its inlet at the edge of the rim: through this a stream of oxygen, or of the vapour of chloroform from a Junker's inhaler, or of ethyl chloride, can be introduced. Superimposed on the mask is a second framework consisting of double parallel bars curved so as to arch antero-posteriorly and laterally to fixed points on the rim, and to intersect at the summit of the vault. These bars carry the ether chamber, which has a

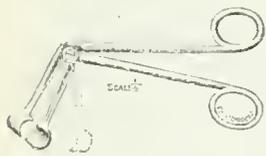

capacity of 2 oz., and a screw adjustment to regulate the size and rate of flow of the drop. The chamber is gripped by and can be moved in various di-

rections between the parallel bars, so that the drop can be brought to bear upon the mask in whichever of the ordinary positions the head may be placed. A flange springing from the rim of the mask gives a fixed point for the left thumb to act upon, and the fingers of the left hand command the lower jaw. The right hand is available for such purposes as testing the depth of the anaesthesia, examining the pulse, adjusting and refilling the ether chamber. If it is desired to administer a more concentrated vapour a petticoat of Gamgee tissue may be applied over the upper framework of the mask. The advantages claimed for the apparatus are: (1) That a steady, continuous, and easily regulated quantity of ether can be administered; and (2) that the right hand, being freed from the task of holding the dropper, is more available for the performance of other necessary functions.

Sterilizer Forceps for Vaccine Syringes.

Dr. J. F. HALLS DALLY (London) writes: It is a matter of common experience that injection syringes are frequently dropped and broken, or the fingers are burned in the endeavour to keep hold of a syringe the temperature of which has been raised to about that of the boiling point of water or of oil. Equally futile is it in many cases to attempt to lift a syringe out of the boiling liquid in a sterilizer by means of ordinary dressing forceps, since these are apt to lose their grip on the circular and slippery surface of the syringe or neck of needle. Where time is

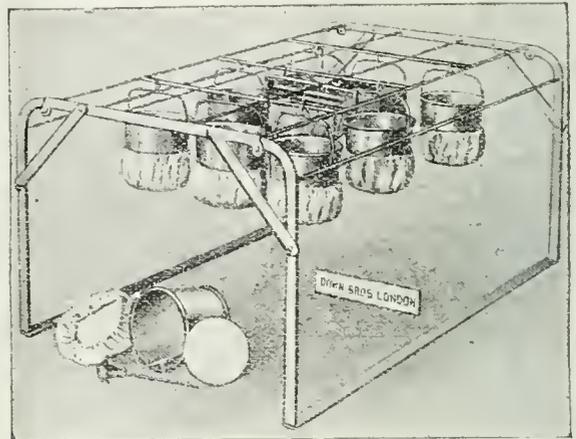

valuable, as, for instance, in the administration of tuberculin to many out-patients in succession, where it is not desirable to wait until the syringe has cooled, the pair of forceps shown in the illustration will be found of practical utility in avoiding these inconveniences. The

syringe with attached needle can be lifted out of the sterilizer without risk, drained of fluid, and then held securely whilst it is filled with the required dose. By this time the syringe is cool enough to be grasped by the fingers, and the injection may then be given, the piston being lifted out by its top in like manner. The forceps have been made to my design by Messrs. Allen and Hanbury, Limited, and are devised for use in departments for therapeutic inoculation. In addition to being serviceable for removing small vaccine syringes from the sterilizer, they can be employed also for use with hypodermic, serum, and exploring syringes of any capacity up to 25 c.cm., as well as more generally for operation instruments.

An Ice Cradle.

Miss K. C. BRADWOOD, Matron, Infectious Hospital, Mylands, Colchester, has designed the ice cradle illustrated in the accompanying drawing. The apparatus consists of a light folding body cradle, to the top frame of

which are attached a thermometer and set of eight ice pails, the bases of which are enveloped in flannel caps, which, by absorbing the moisture due to condensation, effectually prevent dripping. The pails can be detached singly or otherwise, and the number in use at any time thus regulated to the requirements of the case. The advantages claimed for it are: (1) Convenience in carriage and storage; the cradle folds flat when not in use. (2) Avoidance of all discomfort to the patient, who also need not be moved. (3) Economy of time and labour, as compared with that of other methods, such as baths, packs, etc. (4) It can be easily managed by one nurse,

The method of use is as follows: The patient wears a long flannel gown and bed socks or is covered with a thin blanket, and has a water bottle at the feet, and the cradle is placed over the patient, well up over the trunk, and the pails and thermometer put in position. Two blankets are arranged over the cradle to open in the middle so that no inrush of air shall accompany inspection of the cradle thermometer. As the patient's temperature falls one or more pails are taken out. The nurse in charge of the apparatus notes the cradle temperature every time the patient's temperature is taken, and keeps the pails replenished. This is only the work of a moment if a bowl of chipped ice and an empty bowl into which to drain the pails are brought to the bedside. The makers of the apparatus are Messrs. Down Brothers, Ltd., St. Thomas's Street, London, S.E.

The Finger-Grips of Forceps.

Mr. N. BISHOP HARMAN (London, W.) writes: The finger-grips or plates of forceps have many varieties of markings thereon to ensure a proper hold of the instrument. The old file-markings that were in almost universal use are now considered obsolete in these days of "aseptic handles," although it is curious to note that similar serrations still are retained as indispensable at the business ends of the blades! File-markings have been succeeded by various breadths and depths of flutings, or by a broad, shallow groove extending the whole length of the finger-plate. Neither of these grips prove satisfactory; they are barely sufficient when the fingers are dry, they are inefficient when the fingers are wet, and a hold is impossible when the fingers are slippery. For the last two years I have been using sundry eye instruments and forceps in which

the finger-grips were secured by cutting holes in the flat plates. My experience of them has been most happy. They are superior in security to even the old file-markings. The figure shows a pair of iris forceps of the pattern used as conjunctival forceps in my new squint operation of sub-conjunctival reefing. The holes are cut square edged and give a most sensitive grip; in fact, "grip" is a poor word in its suggestion of strenuousness. Even when the fingers are wet or purposely slippery it is possible to hold these slender forceps accurately. The holes lighten the instrument (a matter of some consideration in eye work) and they are obviously clean. The size of the holes can be made large in proportion to the size of the forceps. The forceps illustrated were made by Messrs. John Weiss and Son, of Oxford Street, W.

NOVA ET VETERA.

PROVERBIAL MEDICINE.

PROVERBS OF DIET.

As might be expected, many proverbs reflect the very general and often well founded belief in the therapeutic value of diet, and reference has been made (JOURNAL, January 25th, p. 178) to such maxims as "Diet ences more than the lancet" and "Use first Dr. Quiet, then Dr. Mercurian, and Dr. Diet"; but there are many other adages which illustrate and exemplify special aspects of this widespread and in many cases well founded belief, and to some of these proverbial expressions attention will now be directed.

To begin with Homer,¹ some have read into the phrase *Δαίς ἕιση* (an equal repast) an early Greek reference to care in dieting among the gods of Olympus, and the words have thus been used with something of proverbial force; but it has, on the other side, been maintained that the expression means no more than the "banquet equally shared." Even if this objection hold good, however, there is the maxim which has been ascribed to Theognis, according to which "Surfeit has killed many more men than famine" (*πολλῶν τοι πλείονας λιμοῦ κάρος ὄλεσεν ἄνδρας*); and Hippocrates² had an aphorism that "Everything in excess is inimical to Nature" (*πάν γὰρ τὸ πολὺ πολέμων τῇ φύσει*).

The direction thus given to proverbial wisdom about food by the Greek writers was maintained by those who came after them, and the result is the long list of adages which warn against excess in eating and drinking. Some of these express the danger thus arising by more or less arresting comparisons; thus, Theognis's maxim finds modern equivalents in "Surfeit slays more than the sword" (a Scottish proverb from Ray's collection), "Surfeits slay more than swords," and a Latin counterpart in "Non plures gladio quam cecidere gula." Two other Latin proverbs put the same idea in different words: "Multo plures satietas quam fames perdidit viros" (Many more men die of surfeit than of hunger), and "Multos morbos multa fereula fecerunt"³ (Many diseases are the result of dinners of many courses). Amongst G. H.'s (George Herbert's) "Ontlandish Proverbs" there is one which says, contrasting the evil effect of over-eating at suppertime with the good results following Galen's practice, "By suppers more have been killed than Galen ever cured"; and of this there seems to be a Danish equivalent which also contains one of the previous comparisons, namely, "Flere Folk dræbes af Nadver end af Sværd" (More people are killed by supper than by the sword). A laconic adage says, "Much meat, many maladies"; an outspoken one says, "Quick to the feast, quick to the grave"; an unpollished one declares that "The glutton digs his grave with his teeth"; a military one foretells that "A double charge will rive a cannon"; and a far-seeing one announces that "Feastings are physicians' harvests."⁴ Hernan Nuñez⁵ gives a Spanish proverb which again emphasizes the danger of heavy suppers by contrasting their evil influence with the curative effects of medicine, namely, "Mas malo la Cena che enro Avicena" (The supper kills more than Avicenna cures); this maxim has what all require to ensure complete success in the world of proverbs, rhyme. Rhyme is not indeed an essential part of a wise saying, but it fixes it in the public mind like a nail, and it may actually give it a longer life than will a large amount of contained wisdom.

Another group of maxims is concerned with the setting forth of the other side of the truth—namely, the good effect upon the health which spare diet, and especially a light supper, has. Gurney Benham⁶ has succeeded in gathering together quite a number of these: There is "Light supper makes long life"; there are two Spanish ones—"Come poco y cena mas poco" (Dine lightly and sup more lightly), and "Come poco y cena mas, duerne en alto y viveras" (Dine lightly and sup more so, sleep high up and live long); there is an Italian one "Chi

ben sena ben dorme" (Who sups well sleeps well) which seems to contradict the others, unless, as is very likely, we understand the first *well* as meaning *wisely*; and there is a mediæval Latin proverb which contains a double rhyme: "Ex magna coena stomacho fit maxima poena, ut sis nocte levis, sit tibi coena brevis" (From a great supper comes a great pain, that you may sleep lightly sup lightly). "Light suppers make clean sheets" is a saying quoted by Ray (1670); it is intelligible enough to the medical if not to the lay mind.

There is a hint of the high mental and spiritual possibilities following upon fasting in Milton's well-known lines in *Il Penseroso*:⁷

And join with thee Calm Peace and Quiet,
Spare Fast, that oft with gods doth diet,
And hear the Muses in a ring
Aye round about Jove's altar sing;

And, as Masson says, this was a favourite Miltonic principle (*vide* his *Elegia Scita*, lines 55 to 66). According to another proverb "spare fast" brings also advantages of a more mundane nature, and a somewhat feeble rhyme commands us to "eat less and drink less, and buy a knife at Michaelmas."⁸ It is conjectured that the knife is for the carving of the goose, which was brought on the day of St. Michael by the tenant to induce his landlord to be lenient regarding the rent; the date is September 29th, when the bird is at perfection, as Churchill sings:

September, when by custom (right divine)

Geese are ordained to bleed at Michael's shrine.

A sinister suggestion is that the knife is for the fasting man to end his life with; but we put the thought away from us, relying upon Sir William Gull's dictum, "First get your patient hungry, and then keep him so."

Horace⁹ has a satire on the advantages of simple fare: "In you," he sings, "consists the pleasure of the treat, not in the price or flavour of the meat" (*non in caro nidore voluptas summa, sed in te ipso est*); in the next line he adds, "seek relishes by sweating toil" (*tu pulmentaria quaere sudando*); and, a little further on, come the words: "Hear now what blessings, and how great, a frugal diet brings, and first of all you'll be in health" (*accipe nunc victus tenuis quae quantaque secum afferat, in primis valeas bene*). *Optimum obsonium labor*¹⁰ ("Labour gives the best relish") is a Latin proverb, which Horace possibly had in mind as he penned his satire; and "Hunger is the best sauce" is the English maxim, whilst a French one says "Il n'est sauce que d'appétit";¹¹ an Italian one rhymingly says, "L'asino che ha fame mangia d'ogni strame"¹² (The hungry ass will eat any kind of litter), and another Latin one puts it pithily as "Fabas induleat fames"¹³ (Hunger sweetens beans). "The stomach," wrote Seneca, "is not a hard creditor," *parro dimittitur, si modo das illi quod debes, non quod poles* ("a small amount satisfies it, provided you give it what you ought, not what you can").

But one might continue proverbializing almost without end upon the text, so to say, that a man "ought to feed by measure and defy the physician"; it must suffice now to throw together, out of our notebooks, the following more or less familiar maxims. Here they are, let the reader choose: "The sparing diet is the spirit's feast"; "a little sufficeth nature"; "leave off with an appetite"; "leverdo table avec l'appétit"; "keep a corner for a friend"; "enough is good as a feast, and better than a surfeit"; "enough is too much"; "tis best eating when one's hungry"; and "full bellies make empty skulls." Herrick (in his *Hesperides*) has the lines:

Go to your banquet then, but use delight
So as to rise still with an appetite.

Sir Philip Sidney,¹² also, may be quoted: "The rules of health and long life are Moderate diet, open air, Easy labour, free from care." One proverb descends to particulars, and says, "Moderation produces clear complexion."

Some powers of clinical observation would seem to lie behind the lines:

Eat till you're cold,
And you'll live to grow old.
Eat till you're hot,
And you'll die on the spot;

¹ Homer, *Iliad*, Bk. XV, line 95.

² Hippocrates, *Aphorisms*, II, 51 (Sydenh. Soc., p. 714).

³ Seneca, *Epistolarum*, 95.

⁴ Kay, J. R., *Public Health*, xviii, p. 566, 1906.

⁵ Nuñez, Hernan, *Reflexions o Proverbios*, Valladolid, 1555.

⁶ Gurney Benham: *Book of Quotations*, p. 317.

⁷ Milton: *Il Penseroso*, Works (Masson's edition, i, p. 374).

⁸ Howell: *Paroimologia*, quoted by Lean, *Collectanea*, I, p. 505.

⁹ Horace, *Satires*, Bk. II, Sat. II, lines 19-20, 70-71.

¹⁰ W. F. H. King, *Classical and Foreign Quotations*, p. 402.

¹¹ *Ibid.*, pp. 233, 285, 176.

¹² Lean, *Collectanea*, vol. I, pp. 478, 503, 504, 505; vol. IV, pp. 23, 30, 36, 17.

and behind the saying, "cold after eating is a sign of long life." We think of the coolness of the skin due to the natural determination of blood to the stomach on the one hand, and of the flushed face of indigestion on the other hand, and we get the vision of long life and eupepsia in the one case and of gastric disability and apoplexy in the other.

There are, however, two sides to every truth, and it is possible to think too much about eating and drinking, for, after all, in whatever sense we take it "we live not to eat but we eat to live" (*non vivas ut edas, sed edas ut vivere posses*), or, as the French put it, "il faut manger seulement pour vivre, non vivre pour manger." This maxim goes back to Socrates, about whom it was reported, "they live that they may eat, but he himself eats that he may live" (*οἱ μὲν ἕσθαι ἵπ' ἐσθίοντες, αὐτὸς δ' ἐσθίει ἵνα ζῆ*).

Truly, "it seems to me," said Imlac to Rasselas (in Johnson's famous tale),¹² "that while you are making the choice of life, you neglect to live," and it is obviously a gigantic blunder *propter vitam vivendi perdere causas*; so also with eating, as Hans Busk (the elder)¹¹ put it into rhyme, there are those who "by little eating hope to grow the stronger, and starve themselves to death to live the longer."

But whilst it may be freely admitted that over-anxiety about what and how much food is to be eaten is not good, yet the proverbs against gluttony carry the day both in respect to number and force; and many fashionable physicians of the present time might do wisely to give to the well-fed and free-living patients who consult them the penetrating advice which Dr. John Abernethy, with some degree of masterful roughness and with almost brutal plainness of speech, administered to the wealthy Londoners of a century ago. Boldly combining dietetic treatment and ergotherapy, Abernethy shouted to his would-be patient, "Live on sixpence a day—and earn it." There is a saying that "the fire of London was a punishment for gluttony" (Bohn); and another seventeenth-century adage had reference to the *Devonshire man's disease*, which had become somewhat epidemic. "This malady, agreeing in at least one of its symptoms with the ergophobia of the present day, was thus described:¹⁵ "Che's not zick nor che's not well; che can eat and drink most woundily, but che cannot work."

The Wisdom books of the Hebrews put some of these maxims in their own way and with their own imagery. Thus, in Proverbs (xxvii, 7) we read, "the full soul loatheth an honeycomb; but to the hungry soul every bitter thing is sweet." Here the literal rendering of *loatheth is trampleth upon or treadeth under foot*, an even more powerful figure; it appears in the Vulgate as "anima saturata calcabit favum; et anima esuriens etiam amarum pro dulci sumet." A Latin echo is found in Horace's *j-junus raro stomachus vulgaris tenuit*¹⁶ ("a hungry stomach does not often despise coarse food"). In Ecclesiastes (x, 16, 17), too, morning feasting is condemned in the well-known proverb, "Woe to thee, O land, when thy king is a child, and thy princes eat in the morning! Blessed art thou, O land, when thy king is the son of nobles, and thy princes eat in due season, for strength and not for drunkenness!" "For strength" ought, perhaps, to be "in strength," that is, with self control. In another book (Isaiah v, 11) a special woe is declared unto "them that rise up early in the morning that they may follow strong drink"; and, indeed, morning feasting is held generally to be the extremity of gluttony and intemperance.

Other proverbs refer to the state of mind in which food is taken, and, generally speaking, to the hygienic accompaniments of eating. Thus, there are the familiar passages (Proverbs xv, 17; xvii, 1), "Better is a dinner (or dish) of herbs where love is, than a stalled ox and hatred therewith"; "Better is a dry morsel and quietness therewith, than an house full of feasting with strife." "Mickle corn, mickle care," is a Scottish proverb reflecting the Biblical "great treasure and trouble therewith" (Proverbs xv, 16). Another Scots saying tells us that "Welcome! is the best dish in the kitchen." So also Shakespeare (*Comedy of Errors*, Act v, scene i, lines 73,

74) makes the abbess say to Adriana, "Thou say'st his meat was sauced with thy upbraidings; unquiet meais make ill digestions"; and the advantage of having a jester to aid digestion was appreciated by the diners of the Middle Ages. "It is good to be merry at meat" is one of Ray's *English Proverbs*, and one of George Herbert's is "a cheerful look makes a dish a feast"; the latter collector of maxims has another saying which emphasizes the importance of peaceful surroundings at meal times, namely, "a little with quiet is the only diet." "Cease your chatter, and mind your platter" epitomizes the whole matter.

Other proverbs bring out the advice to eat sparingly but often, and not to have an unvarying diet. "Little and often; a good potcary's shop" is a sixteenth-century saying, from Bullein's *Bulwarke of Defence*; "often and little eating makes a man fat" is one of Ray's *Collection*; and "better meais many than one too merry" comes from Davies's *Satyrical Epigrams*. Proverbs, however, are apt to be paradoxical, and one which says "sometimes a riot's as good as a diet" seems in opposition to those which have been referred to above; but there is no real opposition here, only another aspect of the truth, for every one knows that too restricted a diet may do harm by not bringing into action all the gastric powers, and that in such circumstances a good mixed meal may work wonders, astonishing no one so much as the poor dyspeptic who has fancied himself incapable of any digestive exertion. It is true that another reading of "a riot's as good as a diet" has been found in the sinister recommendation to eat so heartily once a month as to bring on a vomit; but happy is the man whose dietetic history has in it no such dislocating events, "happy the people whose annals dietetic and political are vacant." But a monotonous diet is also to be avoided; "a man must not always eat one sort of meat" said Rowley in *All's Lost by Lust* (1633), and "shift of meat is good" is from Thomas Bacon's *Boke of Matrimony* (1542); and "he who eats but of one dish never wants (that is, lacks) a physician" is a somewhat enigmatical presentation of the same truth. "Variety's the very spice of life, that gives it all its flavour," wrote Cowper in *The Task*; the Latin proverb is *juvunda rerum vicissitudo*; and there is a Greek saying (from Euripides's *Orestes*), *μεταβολή παντῶν γλυκεία*, or "the variety of all things forms a pleasure."

Proverbs in various languages gather round the well-known advice, "After dinner sit awhile; after supper walk a mile," which has been altered slightly by Beaumont and Fletcher (in *Philaster*), to suit the fair sex, into "Women should talk an hour after supper; 'tis their exercise." The advantage of rhyme (that excellent thing in proverbs) attaches also to the sayings in foreign languages which express this advice. Thus, the Latin proverb is *Post epulas stabis vel passus mille meabis*; the Venetian one is *Dopo pranza sta, dopo cena va* ("After dinner rest; after supper walk"); and the German one is, *Nach dem Essen sollst du stehen, oder tausend Schritte gehen* ("After dinner you must stand or walk a thousand paces"). The dinner referred to in these proverbs would be the midday meal, and the wisdom of putting no strain upon the body after eating freely in the hot part of the day is easily accepted; supper should be followed by an interval of time so as to ensure that digestion is completed before sleep is sought, and in the cool of the evening the time may be safely occupied by exercise. "If you would be ill, sup and go to bed," is another way in which this truth is expressed; the proverb that says, "Who goes supperless to bed, all night tumbles and tosses," is in apparent contradiction to it; but it is easy to see that what is here meant is the restlessness which follows fasting, supper taken at a suitable and sufficient time before retiring to rest being rewarded by quiet slumbers. The waning digestive powers of old age are perhaps hinted at in the saying, "He wrongs not an old man who steals his supper." Codrington, in his *Collection of Proverbs* (1672) gives the secret of long life: "To rise at six and dine at ten, to sup at six and go to bed at ten, will make a man live ten times ten"; but Hastings Gilford¹⁷ has collected together some facts about centenarianism which shake the stability of this view, and seem to show that power to pass the fourscore years is

¹⁷ Hastings Gilford, *Disorders of Post-natal Growth and Development*, p. 545, 1911.

due to an "inherent faculty of persistence of life," which is independent of environment, and even of habits.

The superiority of diet over medicinal means is borne out by a number of proverbs—some familiar, others less known. Thus there are: "Better pay the butcher than the doctor"; "Better wait on the cook than the doctor"; "The poor man's physic lies in his garden"; "Kitchen physic is the best physic"; "A good cook is half a physician"; and "The cook's boy in the kitchen . . . was the best physician among the doctors, for by his kitchen physic the sick was cured."¹⁸ There is much truth in this; and many of the constipated patients who are ever trying new purgative medicines would do well to bear in mind that the apertients which are to be had in the grocer's, the greengrocer's, and the baker's shop are safer and better in the long run than those which are purchased at the chemist's.

But it is time to bring this reading in proverbial medicine to a close, leaving the proverbs which laud or reproach certain special articles of diet—for example, alcohol, cheese, salad, etc.—and other allied matters for another occasion.

NOTIFICATION OF ALL CASES OF TUBERCULOSIS.

NEW GENERAL ORDER: ENGLAND AND WALES.

The new General Order of the Local Government Board in England, the short title of which is the Public Health (Tuberculosis) Regulations, 1912,* which extends the principle of compulsory notification to all forms of tuberculosis, came into force on February 1st.

In a circular letter accompanying the Order it is pointed out that more than half of the deaths from non-pulmonary tuberculosis are those of children under 5 years of age, and that it is probable that a much higher percentage of the total number of persons suffering from non-pulmonary tuberculosis are children of this age. The hope is expressed that the notification of these cases will facilitate the investigation of sources of infection and assist in securing improvement in the conditions under which the children live. The circular points out that the Insurance Act contemplates the provision of treatment on a comprehensive scale for persons suffering from tuberculosis, and reiterates the general agreement of the Board with the recommendations of the report of the Departmental Committee on Tuberculosis. That committee expressed the opinion that any scheme which is to form the basis of an attempt to deal with the problem of tuberculosis should be available for the whole community, and recommended that the unit area for administrative action should generally be the county or county borough area, or in some cases groups of counties and county boroughs.

The Order directs that notification is to be made on the strength of evidence other than that derived solely from tuberculin tests. There are two forms of notification—primary and supplemental. Primary notification is to be made on a special form to be supplied by the authority, and is required in respect of every case of tuberculosis, whatever organ be affected, unless the practitioner has reasonable grounds for believing that the case has already been notified. Primary notification of every new case of tuberculosis is to be made on the specified form by every private practitioner, district medical officer of a Poor Law union, medical officer of a tuberculosis dispensary, and by medical officers of hospitals. Notifications in respect of hospital patients are to be sent in the case of out-patients to the medical officer of health for the district in which the patient's residence at the time of notification is situated, and in the case of in-patients to the medical officer of health for the district in which was the usual place of residence of the person before his admission to the hospital.

In the case of patients in Poor Law institutions or sanatoriums who have been already notified, particulars will be entered weekly on a general form showing all the patients admitted during the week. Supplemental notifications will be made on a form giving particulars of all the patients admitted during the week, and a similar form will be made up weekly of patients who have been discharged during the week.

A school medical inspector is required to notify all cases of tuberculosis which come to his notice in the course of inspections at public elementary schools. These notifications will be made on a general form to be sent in at the end of each week, and will be transmitted to the medical officer of health for the district within which the children's homes are situated. The fee to be paid to a private practitioner is 2s. 6d., to the medical officer of a hospital or Poor Law institution or to a district medical officer 1s. for a primary notification. The medical officer of a Poor Law institution is to receive a fee of 1s. for the first name on each weekly list and 3d. for each additional name.

The medical officer of health is required to keep a register with full particulars of each notification received by him, and to send to the medical officer of the county at the end of each week a statement of all notifications received during the week. Any notification addressed to him in error he is to send on to the proper district, informing the notifying practitioner that he has done so. The medical officer of health by himself, or by one of his officers, is to make such inquiries and to take such steps as may be necessary or desirable for investigating the source of infection, for preventing its spread, and for removing the conditions favourable to it. "It is contemplated," the circular continues, "that for the purpose of carrying out the requirements of this article a visit to the home of the patient will generally be necessary, and the medical officer of health will doubtless avail himself of the co-operation of the notifying practitioner. When a case is notified, inquiry should be made to ascertain the state of health of all other members of the household." The necessity of close co-operation between the medical officer of health and the tuberculosis officer of the dispensary which serves the district is insisted upon. It is suggested that the county tuberculosis officer or some other officer of the dispensary should undertake the duties or some of the duties of the medical officer of health under the Order, and for this purpose act as an officer of the sanitary authority under the direction of the medical officer of health.

A circular addressed to the board of guardians and managers of asylums and school districts points out that medical officers appointed by Poor Law authorities are not required to fill up counterfoils, as under the previous regulations, or to submit an account of fees claimed, and the sanitary authorities are not empowered to demand any such account. Relieving officers and superintending officers of Poor Law institutions, who are not medical officers, are not required to notify under the new Order, and are therefore relieved of the obligations in the Regulations of 1908, which, as well as other tuberculosis Orders and Regulations, are revoked and replaced by the new Order.

SCOTTISH POOR LAW MEDICAL OFFICERS' ASSOCIATION.

The annual meeting of the Scottish Poor Law Officers' Association was held at the St. Enoch Hotel, Glasgow, on January 31st, with Dr. GILBERT CAMPBELL in the chair.

The report of the committee stated that much correspondence had been involved in giving possible applicants for appointments particulars of the conditions of appointments, area of district, character of roads, probable value of private practice, average outlay for expenses, and house accommodation. It had the satisfaction of announcing that no case of dismissal of a medical officer by a parish council had come to its knowledge—a fact which appeared to show that the councils were more careful in the treatment of their medical officers than had been the case in the past. Two instances were given in the report of the ungenerous and unsympathetic treatment to which medical officers are exposed at the hands of local and central authorities. In one case the parish was for a time without a medical officer, and a medical practitioner in the neighbourhood found it necessary to attend several paupers and rendered an account to the parish council; payment was refused, the inspector covering himself by saying that he had given no written instructions to the medical man. It was pointed out that the action of the inspector, though it may have been legally right, was morally wrong. Advice was given to the medical practitioner which it is believed led to an adjustment of the matter. In the other case it

¹⁸ Lean's *Collectanea*, vol. i, pp. 478, 504, 506, 1902

was found that the parish council advertised its appointment at a salary of £30 a year, the fact being that this sum was made up by £30 from the parish council and £50 from a medical aid association. The committee had had a correspondence with the Local Government Board on this subject, without, however, any satisfactory result. Many inquiries had been received with regard to the Insurance Act, the chief question being what was to be done in the case of an insured person living 10, 20, or 30 miles from the medical officer. The advice given was that the inquirers should notify the Insurance Commissioners that while they were ready to attend insured persons within a radius of 2 miles, in all other cases provision must be made by the insured person for attendance as a private patient unless the Insurance Commissioners granted an adequate mileage fee for each visit.

The report was adopted unanimously.

The report of the committee on the conditions of medical service in Highlands and Islands was referred to the Committee of the Association for consideration.

Considerable discussion took place with regard to the action of the City of Glasgow Corporation in respect of the notification of pulmonary tuberculosis. The new regulations issued some time ago by the Local Government Board in Scotland had assigned a fee of 2s. 6d. to Poor Law medical officers for each notification. The city of Glasgow refused to pay more than 1s.; but the Scottish Poor Law Medical Officers' Association recommended its members not to accept, and the secretary, Dr. W. L. Muir, was instructed, if no satisfactory arrangement was reached, to raise an action against the Corporation in the Sheriff's Court.

The usual votes of thanks brought the proceedings to an end.

LITERARY NOTES.

The Poetry Review, which with its new name seems to have won new vigour, has in its February number a paper by the editor controverting the eustomary doctrine that Shakespeare was an optimist who took a detached view of life, and looked on it with a humorous smile for the foibles of mankind. For Mr. Stephen Phillips he was a burning spirit in revolt against the injustice of fate. The author has not given himself space enough to develop his thesis, and does little more than indicate the line of evidence he is prepared to call; but the note is suggestive, and will appeal especially to the disciples of Mr. Frank Harris. The same number contains an eloquent article on the melody of Moore by Dr. H. Macnaughton-Jones, who sets out to show Moore's versatility "in his double gift of melody and power of illustration by contrasts." Moore, Dr. Macnaughton-Jones says, felt an indivisible link between the music and the words, and in an endless variety of allegory brought to his aid all that in nature and life stirs the memory and recalls friendships, scenes, and personalities.

In his second instalment of the Scott-Baillie Letters, which appears in the January number of the *Edinburgh Review*, the librarian of the Royal College of Surgeons deals with the serious illness of Sir Walter Scott, attributed by a writer in these pages to gall stones, though Scott himself set it down to gastric cramp. Scott's illness, which first manifested itself acutely on the night of March 5th, 1817, figures at some length in his correspondence, and is familiar to all readers of Lockhart's *Life*. In February, 1819, the great writer suffered from so terrible an attack of pain that his end was thought to be near. "We find," says Mr. Plarr, "Charlotte Sophia Scott, his eldest daughter, who was soon to be married to John Gibson Lockhart, writing in her delicate Italian hand to Joanna Baillie to say that her father had not been able to take up his pen because he had been dangerously ill, and was still very weak." To this letter there is a remarkable and unexpected addendum in the handwriting of Scott himself, and, as this joint composition has not been reprinted in the *Edinburgh* we take this opportunity of publishing it here for the first time. The letters, of course, are from the Scott-Baillie collection in the library of the Royal College of Surgeons, to which they were presented by the son of Matthew Baillie. The future Mrs. Lockhart writes:

My dear Mrs. Baillie

I am sorry to be obliged to give you a very poor account of Papa's health, the spasms never leaving him for more than twenty-four hours at a time. We took the liberty of making Doctor Clarkson who attends him here write his case to your brother (Dr. Matthew Baillie) to request his advice. Papa would have wrote himself, but he has not been able to write for some time, for he has really been dangerously ill and is still very very weak, and is so very much disheartened with the constant return of the spasms that it is quite miserable, but we are in great hopes that the spasms are not so dreadfully violent these two last days. That is the only thing that comforts us. He sends you a letter from Mrs. Siddons [daughter-in-law of Sarah Siddons] he ought to have sent you long ago, but he has been so ill that he quite forgot it.

Dear Miss Baillie, I hope soon to be able to write you a better account of Papa than I can do at present and I hope that you will excuse the shortness of this letter, but I have so few minutes to spare from attending Papa and so tired from being up almost every night that I must conclude with subscribing myself in haste

Very affectionately yours

Charlotte Sophia Scott.

Abbotsford Friday 26th 1819

[The following is in Sir Walter's handwriting:]

Turn over

Dearest friend

I cannot let Sophia's dolorous epistle go without adding a few lines to say that I think I am now getting really better. The combat between the medicines and the disease having been carried on entirely at the expense of my body corporate I feel after so long and obstinate a conflict as I suppose the town of Saragossa did when it had been so desperately attacked and defended. I have no apprehension of any great danger, but till of late the agony was intolerable and lasted six, seven, and eight hours without intermission. The fever is now much milder. I have reason to thank God for placing me in circumstances so much above my deserts in every respect and am much too grateful for the blessings which have attached themselves to me in every respect than disposed to murmur under the natural evils of humanity. Kind love, my dear friend, to your sister, Mrs. Baillie, the Dr., and believe me always, well or ill, most affectionately yours

W. S.

... My hours have been divided betwixt pain and stupidity.

In the following April Sir Walter believed himself to be face to face with death. He took a solemn leave of his children, but later, his symptoms having improved, we find him writing to Dr. Matthew Baillie, the brother of Joanna and Agnes Baillie and nephew of John and William Hunter, in a strain of relieved tension. The letter, never before published, takes high rank among the confidences of ailing genius to medical science.

Dear Sir,

The Greeks were, I believe, allowed to consult Esculapius by proxy while they were patients, but on recovery were expected to pay their grateful thanks in person. I need not say how much I was obliged by your kind attention to Mr. Clarkson's letter, which gave us all much confidence, which in the extremity of pain and subsequent exhaustion I really could not have drawn from less authority than yours.

The quantity of opium and anodynes of all kinds I was obliged to swallow during these paroxysms, often with little effect, was truly frightful. But, thank God, the last returns of the pain have been of a description so mild as to yield to the hot bath alone. I begin to sleep at nights, and crawl out on my pony by day, and my bowels seem to be regaining their natural state. I had hoped to have seen you, Mrs. Baillie, and my excellent friends your sisters this spring, but that is now impossible. Some time in the year, however, I may come up for the purpose of getting my son settled in the army.

Believe me, my dear sir,

Very sincerely,

Your obliged and grateful servant,

(Signed) WALTER SCOTT.

Abbotsford, 17th April.

Dr. Baillie wrote his interesting unpublished memoirs in August, 1818, while in attendance on George III at Windsor. In these he mentions a number of lifelong friends, but had he written after the date of Sir Walter's letter he could not have failed to describe his intercourse with his illustrious compatriot. As long ago as 1813 he had been instrumental in obtaining for Sir Walter a lock of Charles I's hair when that monarch's body was exhumed and identified at Windsor Castle. Scott had some gold mohurs melted down to form a setting for the relic, and in December, 1818, we find him dispatching twenty brace of ptarmigan to the doctor. Matthew Baillie predeceased his famous patient by ten years, dying in 1823 of old man's consumption induced by a too strenuous attention to duty. He was, indeed, a model physician, one of the finest type of a bygone school, and Scott in nowise exaggerates when

he writes to Joanna Baillie on the subject of her brother Matthew's death in October, 1823:

We have, indeed, to mourn such a man, as, since medicine was first esteemed an useful and honoured science, has rarely occurred to grace its annals, and who will be lamented as long as any one lives, who has experienced the advantage of his professional skill, and the affectionate kindness by which it was accompanied. My neighbour and kinsman, John Scott, of Gala, who was attended by our excellent friend during a very dangerous illness, is mingling his sorrow with mine, as one who laments almost a second father; and when in this remote corner there are two who join in such a sincere tribute to his memory, what must be the sorrows within his more immediate sphere of exertion!

FRIENDLY SOCIETIES AND THEIR AGED AND INFIRM MEMBERS.

IN the JOURNAL of February 1st, p. 251, we dealt somewhat fully with this question, but make no apology for returning to it in view of its importance, and especially as an interesting instance of action by one of the important friendly societies has just come to our notice. Section 15 (2) of the National Insurance Act states that:

"The Regulations made by the Insurance Commissioners . . . shall require the adoption by every Insurance Committee of such system as will secure:

- (c) The provision of medical attendance and treatment on the same terms as to remuneration as those arranged with respect to insured persons, to members of any friendly society which, or a separate section of which, becomes an approved society who were such members at the date of the passing of this Act, and who are not entitled to medical benefit under this part of this Act by reason either that they are of the age of 65 or upwards at the date of the commencement of this Act, or that being subject to permanent disablement at that date they are not qualified to become insured persons:"

It may be of interest to note the annotation following this section of the Act in the book *National Insurance*, by Carr, Garnett, and Taylor (second edition), which has a preface by the Right Hon. D. Lloyd George, M.P.:-

There is an interesting history attached to this paragraph (c), as the persons here alluded to are not insured persons under the Act. The subsection is the result of a mutual arrangement between the British Medical Association and the friendly societies. The persons must have been members of a friendly society on or before December 6th, 1911, though they need not have reached the age of 65 or become permanently disabled until July 15th, 1912, or up to January 1st, 1913, if the Act does not commence till then.

It is quite evident, and it is strongly impressed upon the memories of those who were present at the time, that, at the time the above-mentioned "mutual arrangement" was arrived at, the friendly societies were extremely anxious that the operations of the Act should not prevent them from fulfilling the obligations which they then felt they were under to their old members who would not be insurable under the Act. The representatives of the Association agreed that these old and disabled members should not be charged any more than insured persons for their medical attendance, although it must be obvious, from a merely business point of view, that they might well be charged at a much higher rate. Friendly societies all over the country are now, however, trying to evade this obligation by attempting to induce medical men to undersell one another and to take these old members at less than the Insurance Act rate. This has apparently failed in London, and the following letter, which has been sent to a member of a friendly society lodge in London, is an example of meanness which it may be hoped is not likely to be followed:

February 3rd, 1913.

Dear Sir and Bro.,

In reply to yours to hand, Dr. ——— has ceased to be surgeon to the Court, his notice resigning having expired.

The Court have no surgeon now, and you must find your own doctor in future, and pay him yourself.

Of course you will not in future be charged the 1s. per Qr. for surgeon. You can thank Lloyd George for this.

(Sgd.)

Yours, fratry., _____ Sec.

No one will think us anxious to excuse Mr. Lloyd George from any of his responsibilities in regard to this Act, but this seems to be an instance of attempting to put

upon his shoulders a responsibility which clearly lies elsewhere. The friendly society has probably received for many years the contributions of the unfortunate member and now that he has reached a time of life when he is most likely to require medical attendance, it calmly informs him that he must shift for himself, and that it washes its hands of all responsibility for his medical attendance. The fact is, of course, that medical attendance can easily be got for such old members of friendly societies if the societies are prepared to pay a fair price for it, but they have been so accustomed to getting it at charitable rates that they cannot bring themselves readily to pay the fair price. We trust that full publicity will be given to this miserable attempt of one of the largest friendly societies in the kingdom to evade its responsibilities to the very class of members who should have most claim on the sympathy and fraternal feeling which, we have always supposed, was the basis on which friendly societies have been built up.

CONTRACT MEDICAL ATTENDANCE ON UNINSURED PERSONS.

THE State Sickness Insurance Committee of the British Medical Association had under consideration, at its meeting on February 6th, the question of fees and other conditions concerning attendance upon uninsured persons, a matter which had been referred to it by the Council.

The Committee adopted the following minute:

That in general in considering the necessity for obtaining the approval of the State Sickness Insurance Committee mentioned in a minute of the Council of January 29th, 1913 (see SUPPLEMENT, page 131), the following principles must be adhered to:

- (a) Free choice of doctor.
- (b) Remuneration not less than that given in respect of insured persons—that is, 9s. including medicines.
- (c) Persons earning over £160 not to be treated under contract terms at all.
- (d) Juveniles (under 16) to be treated at special rates.

That the Committee realizes that the conditions in certain areas will not allow of the above terms being obtained; and that in these circumstances the approval of the State Sickness Insurance Committee for a scheme involving a less payment may be given provisionally when the local profession can show that the economic conditions in the area demand it.

That one of the conditions necessary for the approval of schemes at lower rates of payment shall be the inclusion amongst the rules of a statement that the approval by the Association has been given to the rates only because of special economic conditions.

MOTOR CARS FOR MEDICAL MEN.

Small Cars.

IN the notice of the Bayard cars published in our issue of January 25th, p. 177, there were several slight errors. In addition to the 8-h.p., 10-h.p., and 14-h.p. cars mentioned, the company also supply 11-h.p., 12-h.p., and cars of higher power than the 14-h.p. referred to. The engines of the 8-h.p. and 10-h.p. cars are monobloc, while the engines of the 14-h.p. cars are cast in pairs; the 8-h.p., 10-h.p., and 11-h.p. have three speeds. Wire wheels are fitted only to the 8-h.p. and 10-h.p. as standard cars. The wheel bases of the 8-h.p., 10-h.p., and 14-h.p. cars are 7 ft. 5 in., 8 ft. 3½ in., and 9 ft. 5 in. respectively, and the size of the cylinders of the 8-h.p. car is 65 by 120. The foot-brake acting on the back wheel is used only in the 12-h.p. cars.

THE report presented to the annual meeting of the Royal Infirmary, Sunderland, stated that there was urgent need to rebuild the administrative block erected in 1868, which had become inadequate to the needs of the institution. The amount received from workpeople during the year was £7,778 out of a total of £12,555. The children's hospital, opened on March 26th, had already received 795 patients into its wards, and the number of patients treated at the Heatherdene Convalescent Home was 575, an increase of 166 on the previous year. Dr. Rowstron had been appointed honorary assistant physician to the infirmary, and his place at the Children's Hospital had been taken by Dr. Herbert Bruce Low, and Dr. Heslop had been re-elected assistant surgeon to that institution.

British Medical Journal.

SATURDAY, FEBRUARY 8th, 1913.

THE DOCTOR IN POLITICS.

LORD ILKESTON, who played a conspicuous part for many years in Parliament, was an example of one who attained high distinction both in medicine and politics. Staunch to his political colours, he did not give up to party what was meant for his profession. Allusion is made elsewhere to the work he did on behalf of the profession in Parliament, but necessarily it is impossible to relate in detail all that he did during a parliamentary career extending over twenty-seven years.

It may be interesting, however, and perhaps stimulating even at this time of day to recall the strong views to which he gave expression some thirty years ago as to the duty of medical men to render service to the State in public capacities. In his presidential address delivered at the annual meeting of the Birmingham and Midland Counties Branch of the British Medical Association, on June 28th, 1883, he dealt with the political powerlessness of the medical profession, indicated its causes and suggested remedies. After pointing out that the tendency of the Legislature for some years before had been to give more and more attention to social and sanitary questions, he referred to the Medical Act of 1858, which when he spoke it was expected would shortly be amended, and which was, in fact, amended in 1886. The position then existing was, he said, the result of more than a quarter of a century's education on the part of the Association and of its Medical Reform Committee. "As far back even as 1831 the profession had begun, under the leadership of that honoured veteran, Dr. A. P. Stewart, to demand an improved educational course, and in 1833, at the second annual meeting of the Association, medical reform was discussed in Dr. Barlow's address. From the beginning even until now we have consistently and continuously pleaded 'that instead of having sixteen modes (now nineteen) of entering the profession, one only should be adopted, and that the profession at large should be represented on its Medical Council.' In 1840 these demands were first drafted into shape in Mr. Wakley's bill, and then session after session attempts were unsuccessfully made to pass some measure. The history of these attempts from 1837 to 1858 forms about as depressing a piece of reading for any one jealous of the position and influence of his profession as I can well imagine, except the dismal diary of our struggles and failures from 1858 till now. In both periods we have a similar catalogue of petitions presented and forgotten; of deputation-courtesies received and dismissed; of Select Committees and Royal Commissions framing laborious reports; of remonstrances unheeded; of hopes raised and disappointments reached. When at the end of the first twenty-five years' campaign we did at last obtain the Medical Act of 1858, we won neither of the essentials demanded by the Association: neither a single mode of entering the profession, nor direct

representation on the General Medical Council. Direct representation, we were told, could not be granted till a register of the profession was made to enable it to vote. For a quarter of a century the register has been complete, the medical practitioners of the United Kingdom have contributed from their narrow means £150,000 for the support of a council to represent and defend the interest of the colleges in opposition to the wishes of the profession; and, as a result of our taxation, to leave us the worst governed medical body in Europe." He went on to say that after an experience of the Act extending over some seven or eight years a sense of its failure caused the Medical Reform Committee to resume its work, and in 1859 a petition, signed by some 10,000 practitioners, was presented, in which direct representation and a uniform mode of admission to practice were demanded as essential reforms. As the Medical Council showed itself indifferent to the demands of the profession, reform was sought through parliamentary channels. "Year after year medical bills have been introduced and withdrawn because we as a profession have had no adequate medical representation in the House." Warned by the long weariness of waiting, he said, broken by repeated disappointment and defeat, the Association had accepted the bill drawn up as the result of the labours of its Medical Reform Committee, and especially of its Chairman, Dr. E. Waters of Chester, giving four seats in a Council of eighteen for the representatives of the 24,000 practitioners in the United Kingdom. "Surely," he said, "such small success, after such long labours, must convince us of the political impotence of the profession to which we belong."

He made an appeal to the profession to take its due share in the public work of the communities in which it lived. "The nature of our daily work is to many of us," he said, "so absorbing in its interest and demands so much of our time for calm, careful reflection and for scientific investigation that we turn with the dislike of philosophers from the noise and dust of the forum. With some of us possibly there may be a lurking fear that pronounced opinions on political and social questions are apt to injure a doctor in public estimation and so to lessen his professional influence and his pecuniary profits. In the sad quietude of the sick chamber, where the finer issues of life and death have to be weighed, the brawling politician would jar on the sensitive nerves of the sufferer. Truly; but we need not be brawling politicians; nor need we allow political questions to so occupy our thoughts as to interfere with that absolute concentration of mind on the case of every patient which is essential to the most perfect performance of our work. Every man needs some variety in the direction and subject of his thoughts; as a class we are apt from lack of this variety to become, as compared with other classes, rather narrow-minded and wanting in sympathy with the great movements going on around us."

What Lord Ilkeston said so well in 1883 has its application to-day, and it suggests again the question that has so frequently been discussed, Why are there not more doctors in Parliament? It would be a very decided benefit to the profession if it had a larger share in the making of laws and in the management of affairs, and it would be even more beneficial to the public if the special knowledge of medical men were placed more directly and more fully at its service in matters concerning the suppression of disease and the preservation of the public health.

In regard to the duty which the medical profession owes the public in this respect, we may quote what

was said by Mr. Cleveland, then President of the United States, at the celebration of the New York Academy of Medicine of its semicentennial anniversary. After paying the profession the conventional compliments demanded by the occasion, he went on to point out certain evils, such as the imperfect isolation of some communicable diseases, the want of adequate protection against dangers to health from unwholesome water and noxious surroundings, and the practically unchecked prevalence of quackery, and he hinted that, although the doctors were not responsible in a professional sense for these results of the insufficiency of the laws, or of laxity in their execution, it was doubtful whether as citizens they were doing all in their power to remedy the situation. "We cannot but think," he said, "that the discoveries and improvements in the medical practice which we now enjoy are dearly bought if the members of the profession in their onward march have left behind them their sense of civic obligation, and their interest in the general public welfare. We cannot accuse you of utter neglect of your duty to the country, and yet we cannot keep out of mind the suspicion that if your professional work in exposing evils were more thoroughly supplemented by labour in the field of citizenship, these evils would be more speedily corrected. If laws are needed to abolish abuses which your professional investigations have unearthed, your fraternity should not be strangers to the agencies which make the laws. If enactments already enforced are neglected or badly executed, you should not forget it is your privilege and duty to insist upon their vigorous and honest enforcement. Let me also remind you of the application to your case of the truth embodied in the homely injunction—if you want a job well done do it yourself. If members of your profession were oftener found in our national and State legislative assemblies ready to advocate the reformatory measures you have demonstrated to be necessary, and to defend your brotherhood against flippant and sneering charges of impracticability, the prospect of your bestowal upon your fellow men of the ripened results of your professional labour would be brighter and nearer." These words may find an application in this country not less than in the United States. It may be hoped that the profession will lay to heart another remark of Mr. Cleveland to the effect that "no object of personal ambition and no activity of professional life should be permitted to withhold from our government the tithe of devotion and service due from its thoughtful and intelligent citizens."

This injunction applies not only to Parliament, but to other elected bodies which discharge important duties in the body politic. Dr. Cuff reminds us, in a letter published this week, that there never was a time when the obligation on medical men to take their due share in local administrative work was more imperative. Dr. Cuff declares that doctors are conspicuous by their absence from county councils, town councils, rural councils, and all bodies in which the local government of the country is vested. Though this exaggerates the extent of the default, there is a great measure of truth in the general accusation, and the approaching county council elections afford an opportunity for making it good. It is true that the methods of the party canvasser may be distasteful, and that the successful candidate may find that his new duties as a councillor make serious calls upon his time and energy. But we may recall Bacon's words in the preface to *Maxims of the Law*: "I hold every man a debtor to his profession; from which as men of course do seek

countenance and profit, so ought they of duty to endeavour themselves by way of amends to be a help and ornament thereunto."

PLACENTA PRAEVA AND PRE-MATERNITY TREATMENT.

PROFESSOR PAUL BAR has been writing on the subject of placenta praevia,¹ and what he has to say on that matter is always worthy of attention. There are, however, certain statements embedded in this particular article which are in danger of being overlooked because their position is not prominent and because they are not emphasized. Yet they are, as we take it, of extraordinary importance.

Professor Bar has been dealing with the somewhat sombre matter of the maternal mortality in placenta praevia, and he has found that his hospital statistics give him a death-rate of 9.2 per cent.; in other words, in 153 cases of placenta praevia he lost 14 mothers. These deaths were spread over the period from 1897 to 1912, but they were not all in the same hospital though all in Paris. Professor Bar was in charge of the Saint-Antoine Maternity from 1897 to 1907, but from the latter year to the present time he has been at the Clinique Tarnier. Naturally enough he has been comparing the results obtained in the two hospitals, and he has found that whilst in the former he lost 10 mothers from infection following the placenta praevia, in the latter he had lost none from this cause.

This difference obviously calls for inquiry, and even for close scrutiny. Of his 153 cases of placenta praevia, 108, or about two-thirds, were treated in the maternity department of the Saint-Antoine Hospital, and 45, or about one-third, in the Clinique Tarnier. The total maternal mortality, as has been said, was 14; 4 of these deaths were due to the haemorrhage, whilst 10 were caused by infection and its sequelae. In placenta praevia, therefore, the mother runs more risk to her life from infection than from haemorrhage and the acute anaemia induced by it. This conclusion is printed in italics, and quite rightly, since it is a very important fact for the obstetrician to bear in mind; but why should all the infection-deaths have occurred in the one hospital?

We gather that Professor Bar's methods of dealing with placenta praevia did not undergo any essential change when he went to the Clinique Tarnier; and there is no hint that the two institutions differed in any way in their sanitary conditions. There were, however, two marked differences in the management. In the Saint-Antoine, in cases of urgency, the resident doctor or student (he is called *l'élève de garde*) had to do the best he could for the patient; in the Clinique Tarnier, under similar circumstances, the chief physician or his substitute did what was needful. Professor Bar does not place great weight upon this difference, indeed he puts it after the other, although we can easily see that with the best will in the world the learner of practical obstetrics could hardly render as much assistance as the practised senior. It is on this other difference that he lays stress, and it is on it also that we would insist.

When patients came to the Saint-Antoine suffering from some pathological state connected with pregnancy, no special pressure was put on them to induce them to remain in the hospital. In other words, they were probably told to come back when the pains had begun. At the Clinique Tarnier, on the other hand, many pregnant patients came for advice;

¹ *Arch. mens. d'obstét. et de gynéc.*, Ann. I, No. 10, pp. 162-176, 1912.

and it was very rare for a woman, when counselled to stay in the hospital, to disregard the recommendation. Now, what was the result? In the one hospital, where no effort was made to hospitalize (so to say) morbid pregnancies, placenta prævia cases were rushed into the wards, bathed in their blood (as Professor Bar says), having had several floodings, and having suffered several attempts at treatment, including in all probability a packing of the vagina. In the other hospital there was always a chance that the diagnosis of placenta prævia would be made in the course of the pregnancy; that the patient would be in what we call in Britain the prematernity or pregnancy ward, and that therefore she would be within reach of the best treatment when the first sign of hæmorrhage appeared. In the former case the patient may be infected before she reaches the hospital; in the latter, there is a far better chance of making the whole process aseptic. In the Parisian statistics one can hardly fail to find a remarkably strong argument in favour of the idea of providing all maternity hospitals with prematernity or pregnancy wards, an idea which was pressed upon the profession by Dr. J. W. Ballantyne of Edinburgh in this JOURNAL² as long ago as the early part of 1901.

Two questions may be asked: Can placenta prævia be diagnosed in pregnancy before the occurrence of hæmorrhage? and did the facilities for the treatment of pregnancy cases in the Clinique Tarnier diminish the deaths from hæmorrhage? With regard to the former, the answer is, Yes. If on abdominal palpation the head be felt at brim of the pelvis, and if on vaginal examination, made at the same time, the cervix be found to be thicker than usual with a soft substance lying between the fingers and the presenting part, then the diagnosis, even if there have been no slight premonitory bleedings, is fairly certain. To the latter question Professor Bar's statistics cannot give an answer. There were four deaths in all due to hæmorrhage, and two of these occurred in the first half and two in the second half of his fifteen years' experience. We cannot affirm that the risks from the bleeding will be less, although we think that logically they ought to be so; but we have the sure evidence that the risks of septic infection are much reduced.

We wonder in how many maternity hospitals in this country prematernity or pregnancy wards have been established since the plea for such things was published in these pages in 1901. We know that in the same year the Edinburgh Royal Maternity Hospital set aside first a bed and later a ward for pregnant patients suffering from the maladies of gestation, and we know that reports³ of the cases dealt with there have been from time to time put on record, but it would be interesting to know how many other hospitals have adopted an idea to which Professor Bar has given support in a manner all the more striking because apparently unintentional

FAULTS IN THE CONSTITUTION.

THE resolutions of the Special Representative Meeting in January with reference to the need for an alteration in the regulations of the Association in order that it may be possible to obtain more quickly than at present the decision of the Association in cases of urgency, and requesting that the postal vote

should be utilized on such questions, or such as are concerned with any suggested future line of policy, were referred by the Council at its quarterly meeting last week to the Organization Committee, with instructions to treat the matter as one of urgency. Recent events have shown the necessity of proceeding with this matter without further delay. Action will be facilitated by the fact that the difficulty which has now arisen was foreseen and the whole subject very fully discussed five years ago. The letter which Dr. Henry Davy of Exeter addresses to us this week will be read with interest, for he writes from a very full acquaintance with the subject. As President of the Association in 1907-8, he endeavoured to reconcile conflicting opinions, and after discussion between some of those who had taken a leading part in drawing up the draft of the Charter and representatives of the opinion that it was defective in the respects indicated above, a compromise was provisionally reached which was embodied in resolutions moved on behalf of the Cardiff Division at the Annual Representative Meeting in Sheffield in 1908 by Dr. Maclean. The first amendment proposed that the referendum whenever taken should be by means of voting papers to every individual member of the Association. The mover pointed out that under present circumstances probably not more than 10 per cent. recorded their votes, since they could only vote by attending a meeting of the Division. This, he declared, was an unsatisfactory condition of things. The proposal to introduce the principle of a postal referendum into the regulations of the Association embodied in this motion was, however, rejected by 63 votes to 34, and the present system, to which the term "referendum" has been applied, was retained. It is, Dr. Davy says, "nothing more than an appeal by the Council from the decisions of meetings of Divisions, as expressed by Representatives instructed at these meetings, back again to the meetings of the Divisions." It is not a referendum in any sense known to any national constitution, and would be laughed out of court if proposed as part of the political organization of this country.

Dr. Davy in his letter refers also to the mode of election of Representatives by the members of Divisions. At present a Division can elect its Representative either by the votes of those members who happen to be able to attend a general meeting, or it can, if it so decide, make the election by voting papers sent to each member of the constituency. It was proposed as part of the compromise at Sheffield that the election should always be by voting papers, but this also was rejected at that time.

Another point made by Dr. Davy is that the existing rule, according to which a Representative is instructed by a meeting of his constituency, does not work satisfactorily, since the instruction may be given at a meeting attended by a very small proportion of the members of the Division, and the Representative may therefore be called upon to vote at the Representative Meeting without having any opportunity of ascertaining the opinion of the majority of his constituents, and therefore possibly contrary to their wishes. Dr. Davy suggests a method by which this difficulty could be met. Upon its feasibility we are not prepared to express any opinion. What seems obvious is that some means must be found by which every member of the Association shall be able to exercise his legitimate influence in determining the policy of the Association, and no scheme can be successful which does not take fully into account the special conditions of medical life, and the fact that the

² BRITISH MEDICAL JOURNAL, vol. i, 1901, p. 813.

³ BRITISH MEDICAL JOURNAL, i, 1903, p. 65; *Journ. of Obstet. and Gynec. of the Brit. Empire*, xv, 93, 169, 190; *Internat. Clinics*, vol. iii, 1911, p. 511.

exigencies of his calling and the distance he may have to traverse may prevent him from attending a meeting at a stated hour and place.

The Association has been placed in a false position, and has suffered in consequence in the eyes of the public and the profession alike. Means should speedily be taken to prevent the occurrence of such a misfortune again. The public has laughed at what it looks upon as another proof of its doctrine that doctors are not good men of business. Dr. Davy explained the position to the public in a letter to the *Times* published on January 17th, and our contemporary, in commenting on the matter, wrote: "The actual difficulty in which the Association finds itself must be attributed largely to a faulty constitution. No doubt the underlying causes go deeper than mere methods of administration; but if a postal referendum had been taken instead of relying on Divisional and Representative Meetings the true situation would have been more clearly revealed and the danger have been avoided. . . . The inference is obvious that, before taking any other decision, it would be wise to ascertain the real trend and strength of opinion among the members by an individual vote. We presume the Representative Body has power to do this." The Representative Body, however, has not got this power, and the Association under its present constitution has no constitutional means of ascertaining the opinion of the majority of its members.

THE MOTIVES OF THE PROFESSION.

On Sunday last the Bishop of Manchester, preaching in his cathedral on behalf of the hospitals of the city, said that medical practitioners knew the poor as no other profession—not even the clergy—knew them; and he had, he said, been "filled with great indignation to witness how little has been understood the attitude of the medical profession towards the Insurance Act, as if they had never worked without payment, as though they had never treated cases out of sheer charity. It has been assumed too often that the whole profession has been haggling after sixpences, whereas, so far as I can judge, they have desired only that the work which they had under the Insurance Act should be thorough and not scamped work, and that the diseases of the poor should receive the same careful attention as the diseases of the rich. In all this they had in reality been fighting the battle of the poor, and they deserve the gratitude of the nation for the endeavour which they have made to secure conditions under which medical attendance under the Insurance Act should be a reality and not a sham. This is, at all events, my impression, and, in justice to the profession to which we are all indebted, I am bound to record it." The Insurance Act, he went on to say, brought no relief for diseases requiring special medical or surgical treatment, and none to the uninsured, among whom were many who most needed it. Hospitals and dispensaries would continue to be necessary for most of the worst cases and for the most needy classes, and for the present the Act had not diminished the work of the hospitals. The loss to the nation would be great if the hospitals ceased to be voluntary institutions; it would no doubt be possible to provide excellent infirmaries at the public cost. The workhouse infirmaries were in many respects admirable, but it would, he said, be a poor day for the national life when the self-denial of the nation took the form of rates and taxes. The Bishop showed a true insight into the motives by which medical practitioners are inspired, and it is pleasant to record the sympathetic attitude of a distinguished member of a sister profession.

MEDICAL SERVICE IN THE HIGHLANDS AND ISLANDS OF SCOTLAND.

Medical men in the Highlands and Islands of Scotland owe a debt of gratitude to the member for Orkney and Shetland—Mr. J. Cathcart Wason—who, in his place in the House of Commons and at public meetings, has taken every opportunity to show the disabilities under which medical practice is carried on in the Highlands and Islands. In a letter published elsewhere in this issue Mr. Cathcart Wason draws attention to two points—namely, security of tenure and the doctor's house. It is an anomaly that in England parochial medical officers have fixity of tenure and medical officers of health have not, while in Scotland the position is reversed. As Mr. Cathcart Wason points out, Scottish Secretaries have always refused to sanction any change in the arrangements. The Poor Law Medical Officers' Association of Scotland has over and over again agitated to have fixity of tenure granted, but the demand has never been met. If fixity of tenure—with, of course, the right of the Local Government Board to institute an inquiry where it might deem it necessary—was one of the conditions of parish medical appointments a better class of candidate would be forthcoming. At present the parochial medical officer is at the mercy of a board, one or two members of which may have had some social quarrel to which the doctor is unwittingly a party, and in a spirit of revenge may deprive the doctor of his appointment. This is known to have happened more than once in the Highlands and Islands. The outstanding grievance to which Mr. Cathcart Wason refers is that in many parishes it is difficult, and often impossible, for the doctor to get a house, or even to get suitable accommodation, in the village or hamlet where he practises, befitting a man in his position. The evidence given by the witnesses before the Committee is quite in keeping with the facts which are within our knowledge. We are pleased to learn, from Mr. Wason's letter, that it is proposed to introduce a bill to deal with the matter; the measure, we are sure, will meet with the sympathy and support of the members of the House of Commons, as many of them—when visiting the Highlands in pursuit of sport—must have been struck by the very meagre accommodation provided for medical men in comparison with the houses erected for the army of clergymen who have invaded the Highland parishes during recent years. It will be seen that a supplementary estimate for the present financial year, issued last week, allots a sum of £10,000 for mileage and other special charges in the Highlands and Islands of Scotland. Thanks to the efforts of Mr. Cathcart Wason and other Scottish members of Parliament, the outlook for medical men in their districts is becoming brighter.

THE FEAR OF ANAESTHETICS.

DR. DUDLEY W. BUXTON has published in the *Contemporary Review* an excellent article designed to allay the fear of anaesthetics, a fear aroused in the minds of many laymen by the rather large number of cases of death under chloroform which occurred during some past years. The personal equation of the human being, he says, must always render the use of a powerful anaesthetic a delicate and intricate matter. Danger cannot be completely eliminated from empirical methods, but he points out that the recent report of the Special Chloroform Committee of the British Medical Association has done much to lift the premier anaesthetic "from the limbo of empiric practice to a more rational and scientific level"; but there is still need for legislation which shall check the wanton abuse of one of the most important discoveries of modern times. In the opening part of the article, which is entitled "Sleep and her twin sister, Death," Dr. Buxton traces rapidly the evolution of anaesthetics from the nepenthes of Helen to chloroform. He mentions Humphry Davy's statement that nitrous oxide might be used as an

anaesthetic in minor operations, which is of course familiar to all students of the subject, but the fact remains that after the effect of the substance had been clearly pointed out no one paid the smallest attention to it for over forty years. Nothing could be more definite than Humphry Davy's statement, which we quote once more, as many people, even at the present time, seem to be unacquainted with it. In 1800 Davy, in experimenting with the gas, found that it relieved pain, and gave his experience in the following words: "The power of the immediate operation of the gas in removing intense physical pain I had a very good opportunity of ascertaining. In cutting one of the unlucky teeth called *dentes sapientiae*, I experienced an extensive inflammation of the gum, accompanied with great pain, which equally destroyed the power of repose and of consistent action. On the day when the inflammation was most troublesome I breathed three large doses of nitrous oxide. The pain always diminished after the first four or five inspirations, the thrilling came on as usual, and uneasiness was for a few minutes swallowed up in pleasure. As the former state of mind, however, returned, the state of organ returned with it." In his book *Researches, Chemical and Philosophical, Chiefly Concerning Nitrous Oxide and its Respiration*, Davy pointed out the possible applications to which the anaesthetic gas might be put by surgeons. We again quote his own words: "As nitrous oxide in its extensive operation appears capable of destroying physical pain it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." It will be seen that nothing could be more definite than this. Eighteen years later, in 1818, a paragraph in the *Journal of Science and the Arts*, probably written by Faraday, drew attention to the fact that "when the vapour of ether is mixed with common air and inhaled it produces effects very similar to those occasioned by nitrous oxide"; but this plain intimation of the anaesthetic properties of ether also fell on deaf ears. Dr. Crawford W. Long of Jefferson, Jackson County, Georgia, guessing, possibly from this hint of Faraday, that ether, which was then in use in what were called "ether frolics," might deaden the sense of pain under the surgeon's knife, tried it in practice in 1842 with success. He did not, however, apparently take much pains to make this discovery known, and from this we should gather that he did not appreciate its importance. It is to an American dentist named W. T. G. Morton that we owe the successful application of ether in surgery. He had long been looking for an anaesthetic, and the use of ether was suggested to him by Dr. Charles T. Jackson, a distinguished chemist of Boston. To him belongs the credit of having got this great discovery accepted, just as to Simpson belongs the glory of having introduced and popularized the use of chloroform, the trial of which was suggested to him by Mr. David Waldie. It is, as Sydney Smith somewhere says, not the man who gives the first hesitating hint of a new truth, but he who shouts it from the housetop, and gets people to listen to him, who is the real discoverer. Dr. Buxton refers briefly to the psychology of the anaesthetic dream sleep, a subject on which we have often dwelt, giving particulars from the well-known story of Oliver Wendell Holmes's supposed discovery of the riddle of the universe, which resolved itself on his awakening into the cryptic formula, "A strong smell of turpentine pervades the whole." Dr. Dudley Buxton pleads strongly for the scientific use of chloroform by exact methods. "The subject," he rightly says, "is no longer a mere handicraft but a science; and the art which it teaches is based upon physiological knowledge and experiment." An attempt has been made recently to get a law passed forbidding the use of anaesthetics by any person not possessing a medical qualification; but, so far, nothing has been done in this direction, and thus, Dr. Buxton says, "the menace of a grave danger to the public remains."

THE SUPPOSED INFERIORITY OF THE FIRST AND SECOND BORN.

IN a memoir published in 1907,¹ Pearson described the results of an inquiry which tended to show that the earlier born members of families were more likely to develop phthisis than their younger brethren; he also concluded that the fertility of phthisical stocks was, if anything, above the average. Very similar results were reached by Heron in his analysis of asylum data.² Both these conclusions, if established, would be of considerable importance, and it is not, therefore, surprising that they have been questioned. We have received a copy of an essay by Mr. T. B. Macaulay, a former President of the Actuarial Society of America,³ who is of opinion that Pearson's results depend upon statistical fallacies and are consequently worthless. In Mr. Macaulay's judgement, the first conclusion, namely, that elder-born children are more likely to develop the disease in question, is due to the fact that, partly owing to phthisis being a disease which develops mainly in adult life, partly because sanatorium patients are usually adults, the diseased members of the families studied, who formed the starting point of the inquiry, were past childhood. But since a man of 40, if he have brothers and sisters, is more likely to be the eldest in family than a boy of 15 with the same number of brethren, a selection of persons above 15 years of age will contain a higher proportion of eldest sons than the population at large. Mr. Macaulay's argument is vividly expressed in the following sentences which we quote from his address to the Eugenics Congress. He remarks: "I can begin with this very audience now before me. It is certain that very many of you have younger brothers and sisters who are yet but boys and girls. The percentages of elder born among you will therefore certainly be decidedly in excess of those for the younger born. Would I be justified, however, in assuming from this that the composition of this audience proves that first and second born children are mentally superior to their younger brothers and sisters? It would be very pleasant if I could pay you that flattering compliment, but truth compels me to say that all that such statistics would really prove would be that children and babies are too young to attend this congress." Mr. Macaulay seems to have overlooked the fact that not only children and babies were excluded from the congress but also persons of any age who happened to be dead. If we had a gathering confined to survivors of the Balaclava charge and then considered only those veterans who had living brothers and sisters, we should no doubt discover an overwhelming proportion of eldest sons. But if we do not draw such a line, it is not obvious that the percentage of first-borns among men of 80 should be greater than among children of 1 month, unless there be correlation between longevity and order of birth. The argument, therefore, is sophistical. Mr. Macaulay's second objection to Professor Pearson's work, namely, that the fertility of stocks when determined from the children is artificially increased, since the large families are relatively more likely to be represented in a sample of children than are the small families, has recently been advanced by Weinberg⁴ in a slightly different form. It is well known that when fertility is estimated from data based on the statements of children as to the number of their brethren, the mean fertility per family may be over-estimated, owing to the weighting of each family with the number of children it contains. Pearson⁵ specially considered this point some years ago. If it be possible,

owing to the possession of complete pedigrees, to sort out the children into their respective families, so that any family is not counted more than once, and if sterile marriages be excluded from the normal data used for comparison, the force of the objection is notably weakened. As will have been gathered from the foregoing remarks, we are not greatly impressed by the cogency of Mr. Macaulay's arguments, but this is not to say that the conclusions of Pearson and Herou are self-evidently just. The importance of the matter is so great that we hope the staff of the Galton laboratory will consider some of the difficulties ordinary readers are likely to meet with in studying their results. Thus the sanatorium patients dealt with by Pearson seem each to have come from a separate family. It is not, *prima facie*, obvious that the proportion of first-borns among the tuberculous members of these families should be the same as that prevailing among all the members of the stocks taken together. The conclusion may be correct, but it certainly seems to require further elucidation. The matter is, however, a technical one, and cannot fittingly be discussed in these columns. We have only noticed the subject because it illustrates the intrinsic difficulty of statistical problems having a direct bearing upon public health teaching.

THE PORTRAYAL OF THE BLIND IN JAPAN.

From earliest times the blind have been favourite subjects for the artist's brush, and portraits of the blind alone do much to reveal the standard of painting at various epochs. The subject was treated with great realism by the Greeks, but the most relentless realism was displayed by the Dutch painters. With the exception of the Dutch school, however, Japanese artists are, according to Professor Greeff,¹ the most faithful portrayers of blindness in its many aspects. In an interesting paper he brings out many curious features of the life of the blind in Japan, and of their portrayal by Hokusa, who was born about the year 1759. He ranks in European opinion as Japan's greatest painter, yet he appears to have been ignored by his contemporary fellow countrymen, and to have died in poverty and obscurity. After middle age he issued a series of sketches representing life in Japan, and he depicted as many as twenty-four distinct types among the blind. His vivid realism lays him open at first sight to the charge of caricaturing. But Professor Greeff thinks that such an interpretation is unjust, and that the artist has caught true, but possibly fleeting, expressions of the blind. Some appear happy and scarcely affected by their blindness, others bear the stamp of sorrow and resignation, others look stupid, and others again are portrayed as idiots. Their attitude, gait, and expression betray the action of a common affliction on characters of widely different type. Massage is an accomplishment commonly acquired in Japan by the blind, whose sense of touch is naturally well developed; and, as massage has been in common use since the eighth century, the blind masseur is well established. Massage is to-day prescribed for almost every form of illness, and it is commonly employed after baths or exercise. It is therefore not surprising that even the smallest villages in Japan can boast a blind masseur, and that he has been frequently depicted in the exercise of this art. Professor Greeff reproduces two such scenes depicted by Japanese artists, who evidently have caught characteristic expressions of both the masseur and his subject. The former, in one sketch, wears an expression of grim determination as he apparently digs his elbow into the small of the back of his subject. The latter's quaint expression of resignation scarcely suggests pleasurable sensations. In the other sketch, the masseur's expression denotes extreme despair and exhaustion, while the fatuous and languishing expression of his subject suggests the placid contentment of a pig being tickled.

¹ *Deut. med. Woch.*, January 2nd, 1913.

THE ANALYSIS OF COLOUR VISION.

PROFESSOR A. W. PORTER and Dr. F. W. Edridge-Green reported recently to the Royal Society the result of further researches into the question of the negative after-images and successive contrast with pure spectral colours. The object was to ascertain the appearance of pure spectral colours after the eye had been fatigued by light of a known wave length or situated in a portion of the spectrum between two known wave lengths. They used lights of only moderate intensities for a short time, and their experiments thus differed from those of Burch, who used lights of extreme intensity, or from those of Edridge-Green and Devereux Marshall, who used very weak lights for a prolonged period. The eye was kept rigidly fixed during the fatiguing process, and a very clear after-image was produced. The results obtained could all be explained on the Edridge-Green theory. It was found that the complementary to the exciting light was never strengthened in the spectrum on the screen by the after-image, and the after-image was not surrounded by the primary colour as it should be according to the Hering theory. According to the Young-Helmholtz theory, the effect of fatiguing the eye with a monochromatic region should cause the uniform grey band to vary in colour and luminosity across its breadth, but this did not occur. On the Helmholtz theory the after-image should change colour on fading because of the varying amount of fatigue of the hypothetical colour sensations, but this was not the case. Regions like the violet, after fatigue to red, should be very little affected, but they were the most affected. The fatigue light should most affect the region used for the fatigue, but again this was not the case. Yellow should change to green after fatigue to red, or to red after fatigue to green, but this was not so. These facts, as well as some others, are used by the authors to still further disprove the theories of Hering and of Young-Helmholtz and as arguments in favour of the Edridge-Green theory, which does explain all these phenomena.

TUBERCLE BACILLI IN THE BLOOD.

PROFESSOR LYDIA RABINOWITZ,¹ whose careful and exact work on tuberculosis always claims the serious attention of pathologists, has recently published some interesting details in regard to the presence of tubercle bacilli in the blood of consumptives. She points out that twenty-two years ago Virchow expressed his conviction that tuberculin "mobilized" tubercle bacilli. Orth, at that time in Göttingen, came to an almost identical opinion, and showed that the action of tuberculin was to produce a reactive change in the tuberculous foci which led to the liberation of the bacilli and their appearance in the circulating blood. Several investigators confirmed this observation, but others, including Ehrlich, Guttmann, and Kossel, had only negative results. Professor Lydia Rabinowitsch states that she did not succeed while working at the old Koch Institute in demonstrating bacilli in the blood; this, she now thinks, was due to the methods then in use. Utilizing the Stäubli-Schnitter method, she has recently obtained positive results in guinea-pigs and rabbits infected with tubercle bacilli three or four weeks previously, in whose blood no bacilli could be found. The animals were then treated with tuberculin and the existence of bacilli in the blood was demonstrated both microscopically and by inoculation into fresh guinea-pigs. This result was obtained with small as well as with large doses of tuberculin, although not with the same regularity. Some years ago she examined with Jessen of Davos the blood of a number of phthisical patients, and found that bacilli could be detected in the blood in about 33 per cent., but the effect of tuberculin was not then investigated. The importance of the presence of tubercle bacilli in the blood after the absorption of tuberculin

¹ *Berl. Klin. Woch.*, January 20th, 1913.

is self-evident, and calls, therefore, for further observations in order that its significance may be thoroughly understood. No satisfactory deduction can be drawn until it has been established whether tubercle bacilli are usually absent from the blood in tuberculosis. Some at least of the negative results have been due to inefficient methods, and before a definite step forward can be made it will be necessary to ascertain whether some method cannot be devised which will reveal with certainty the presence in the blood of even a few bacilli. It may then appear that they are always or frequently present in tuberculous infection with pyrexia. It seems possible that the bactericidal action of substances contained in the serum may limit the life of the bacilli in the blood under ordinary conditions, and in this case the number of living bacilli might be extremely small. Professor Rabinowitsch raises the question whether the acid-fast bacilli found are true tubercle bacilli, for such organisms have been found in apparently healthy persons. Baemeister and Rüben have put forward the view that they are not tubercle bacilli at all, chiefly because of the results obtained when the blood has been injected into rabbits. Professor Rabinowitsch has no difficulty in demonstrating that this argument is untenable, and that the point cannot be decided by experiments on rabbits. There is already experimental evidence that tuberculin can liberate a sufficient number of bacilli to render their recognition in the blood by existing methods possible in a majority of cases. Further, we have evidence to the effect that in man tubercle bacilli may under circumstances which have yet to be determined be present in the blood. Before we are justified in considering the effect of this observation on the therapeutic value of tuberculin, further evidence is required in regard to the presence or absence of tubercle bacilli in the blood when no tuberculin has been employed. We understand that investigations in this direction are at present being carried out.

TUBERCULOUS PERITONITIS AND STERILITY.

ABDOMINAL surgery, more accurate registration of hospital cases, and bacteriological research have taught us a great deal about tuberculous peritonitis, especially in women. General opinion, based on recent practice and observation, seems to hold that surgical measures are inadvisable unless the tuberculous disease is limited to one organ, so that the knife may pass through perfectly healthy tissues and the ligatures lie safely in those tissues. Otherwise grave complications may probably ensue. It is also believed that although extensive tuberculous deposits may disappear under medical treatment, the functions of the internal organs may be very seriously disturbed. That this is not invariably the case is shown by a very definite instance reported recently by M. Delassus,¹ where the diagnosis was confirmed by two abdominal sections. The patient was a pale, sickly lady aged 29, who had been married five years. There was no family history of tubercle, but she grew thin and weak and ascites developed. M. Delassus found that there was no evidence of thoracic disease, but that ill-defined solid deposits could be felt in the abdomen and Douglas's pouch. They were not tender. The abdomen was tapped. For a few weeks daily injections of 5 cc. of sodium creodylate were administered with good general results, but the peritoneum filled up again, although the patient grew stronger. M. Delassus opened the peritoneal cavity by a median incision and found tuberculous deposits widely disseminated; the omentum was infiltrated, and on the surface of the uterus and Fallopian tubes were characteristic nodosities. There were no adhesions between the intestines. Nothing was removed. Six months later, as fresh effusion had occurred into the peritoneum and

incisional hernia had developed, M. Delassus, in January, 1911, operated again and found that the peritoneum presented the same appearances as before; it was dried and closed. After convalescence the patient became pregnant within eighteen months of the date of the second operation and was delivered of a living child. In September, 1912, she was in perfect health. No bacteriological examination was made, but there seems to be little or no doubt that the peritonitis was tuberculous. There were none of the signs of the more purely inflammatory forms of peritonitis, such as multiple adhesions, and the after-history showed that the solid bodies were not disseminated malignant growths. There appeared to be no obstruction of the tubes, which so often complicates any disease of the upper part of the female genital tract, and necessarily involves sterility, not only because the passage of the ovum is thus impeded, but also because destructive inflammatory changes occur. The case seems to prove the possibility of gestation after tuberculous peritonitis, so that no patient who recovers should be held as hopelessly sterile, though marriage could hardly be advised in the instance of a single patient. In the case of any married woman it is important to note the relation of tuberculous peritonitis to pregnancy, as there is some difference of opinion as to the same relation of pulmonary tuberculosis, which instead of being extremely rare is one of the commonest of all grave diseases, and does not act as an immediate check on conception and pregnancy. The case is incomplete in one respect, as it affords no evidence as to whether the local changes in gestation act beneficially on the adjacent peritoneum or whether the tuberculous disease may not become more active than ever after the pregnancy has ended—a phenomenon not unknown in phthisis.

THE INFANT'S CRY.

"The infant does not speak," says Dr. Rousseau-Saint-Philippe,¹ "he is *in fans*." Etymologically, he must not speak; but he cries, and we find his language in his cry. It is part of the physician's business to learn his language, and so to interpret the child's sensations. The infant comes into the world with a cry, and the writer quotes Longel, who declares that this first cry is a shout of triumph, for the bonds of intrauterine existence have been burst by the unknown force which dominates all the phenomena of life. There is, however, a more prosaic reason for this initial cry—namely, the contact of the child's body with the cold atmospheric air. The healthy babies cry loudly, while those which are congenitally weak cry feebly and little, and the doctor should be on his guard in the case of the silent and the sleepy ones. It is, of course, always important to find out the cause of crying; but there are babies who cry for no real cause, and these are the screamers ("les ériards"), generally the offspring of defectives, alcoholics, and neuropaths, and likely to grow into neuropaths themselves by and by. But there is usually a real cause. Among the external ones are what may be called "the four p's" (p's in French, at least)—the pricks of parasites, such as fleas, lice, and bugs (puces, poux, punaises), and of pins badly placed; but there are others—such as the tightness of clothes, the presence of diapers soiled with faeces or urine, hot bottles, extremes of temperature, and especially very hot days. The internal causes are harder to find, but it is of great importance to discover them. Fortunately, the commonest, which is hunger (and perhaps thirst), is the most easily cured; it ceases when the child has had the breast. If it does not so cease, it may mean that the milk is poor or scanty, and then weighing the infant will clear up the diagnosis. But it may be due to other causes, of which the second in frequency, according to Dr. Saint-Philippe, is internal discomfort due to

¹ *Bulletin de la Soc. d'Obstét. et de Gyn. de Paris, Lille, etc.*, November, 1912, p. 828.

¹ *La clinique infantile*, xi, p. 17, January 1st, 1913.

dyspepsia, and especially to dyspepsia with colic. Crying now is increased by giving the breast; it comes on suddenly and ceases abruptly when wind or a stool is passed; if it be the result of a full bladder, it disappears with micturition. The third of the internal causes is pain, and again the intestinal tract may be at fault; but now it is more than discomfort—it is sharp suffering, as in cases of enteritis, and particularly, says Saint-Philippe, of athrepsia, as was pointed out long ago by Parrot. Of course many causes of pain may exist, among which teething and local maladies of the bones and skin may be named. A fact of some importance is, as was pointed out by Dr. Genaro Sisto, of Buenos Aires, that persistent crying, in the absence of other causes, may be due to hereditary syphilis: if it be, it ceases with the commencement of the specific treatment. Much, then, may be learnt from the cry.

OBSERVATION AND JUDGEMENT.

THE address delivered at the inauguration of the present winter session of the Royal Veterinary College, London,¹ by Major-General F. Smith, C.B., C.M.G., F.R.C.V.S., has been printed. In it he called attention to the necessity of bearing in mind the relation of observation to judgement when treating man or animals. Observation depended largely on the personal factor. There were, he said, many varieties of observation, and probably no man possessed them all to an equal extent. There were some people who never forgot a face—the mental picture formed was ineradicable; some never forgot horses they had once seen, others could never remember them. There were people so unobservant as to locality that they did not recognize a street they had often seen before, and others who never failed to remember one along which they had once passed. Similarly there were men who could see clinical features and differences when they were pointed out, but failed to find them for themselves, yet the recognition of these differences in practice was of the utmost importance, and there were even commoner features in connexion with the sick or their surroundings, which some utterly failed to notice. He aptly turned attention to Zadig and the queen's dog, the most often quoted passage from Voltaire's witty story, and transformed Zadig into a veterinary surgeon, who, by his common-sense powers of observation, reported on the state of the regal stables and their inmates after simple inspection, during which he never spoke a word nor asked a question nor received any spoken information. This report showed that the stables and the horses were, to say the least, in a highly unsatisfactory condition. Judgement, Major-General Smith declared, was infinitely more difficult than observation, and required a longer apprenticeship. The mental analysis of symptoms and evidences constituted the essence of judgement, which was directed by experience and the application of the senses. His advice to the student of the diseases of horses was such as students of disease in man may consider with profit, for infants, like animals, are "dumb," and there are also men and women who seem unable to give any precise account of their symptoms and thousands more who mislead us by their false conclusions, which is worse. "In order to be good practitioners I urge you," he said, "to train your observation and judgement, and be, as far as possible, independent of outside help in the diagnosis of disease. Look and see. . . . The absence of speech is no very serious disadvantage excepting in cases of lameness, and though the truth-saving advantages of a dumb patient may be neutralized by the untruthfulness and gross inaccuracies of those in attendance, the observant practitioner can silently afford to neglect most of what he hears."

THE SEMON LECTURES.

WHEN about three years ago Sir Felix Semon, in the full vigour of his faculties and the high tide of professional success, announced his intention to retire from active practice—a resolution made more often than it is carried out—his brother laryngologists all over the world, in Germany, Hungary, Austria, Russia, Scandinavia, Denmark, the Low Country, France, Italy, Spain, and America resolved to express their esteem for the man and their respect for his scientific achievements and for the work he had done to raise the status of the speciality to which he had added distinction. The presentation, which was accompanied by a sum of money subscribed by British laryngologists, was made at a banquet in July, 1909, at which the late Sir Henry Butlin, who was in the chair, after referring to Semon's achievements in the science and art of laryngology, and to his success in establishing the *Centralblatt für Laryngologie*, said that it was only after reading the tributes paid to him on that occasion by laryngologists and laryngological societies all over the world that he had seen him in his true aspect—"the defender of the laryngological faith throughout the world, the constant protector of all oppressed bodies of laryngologists; the man whose name is spoken with affection and respect in every place where laryngologists do congregate." Sir Felix Semon determined to devote the money gift which he had received on this occasion to the advancement of laryngology, and we had the pleasure of recording in June, 1911, that the Senate of the University of London had gratefully accepted his offer to transfer to the University the sum of £1,040 presented to him, for the foundation of a university lectureship and medal in laryngology. The first lectures under this foundation were given by Dr. Peter MacBride, formerly lecturer on the diseases of the ear, nose, and throat in the University of Edinburgh, at University College. At the first, on January 22nd, when Sir Rickman Godlee, President of the Royal College of Surgeons of England, was in the chair, the subject dealt with was Sir Felix Semon's personal history, his career, and the circumstances which influenced it. The second, on January 24th, when Dr. Watson-Williams occupied the chair, dealt with his work and its influence on laryngology, with special reference to general palsy, laryngeal paralysis, and malignant disease.

THE SENSORY FIBRES OF THE PHRENIC.

THE sensory fibres of the phrenic nerve, discussed by Dr. Kidd in a paper recently noticed in this JOURNAL (January 11th, 1913, p. 86), have been investigated by Dr. G. C. Mathison¹ in the performance of a series of experiments upon the innervation of respiratory muscles. Part of the evidence for the existence of these sensory fibres he obtained was indirect, part direct. The indirect evidence was furnished by the rise in the carotid blood pressure resulting from electric or other stimulation of the central end of the cut phrenic nerve in anaesthetized dogs, rabbits, and cats; no rise, but even a fall, was observed when the anaesthesia was deep and produced by chloroform. Similarly, pinching and stretching the pericardium evoked a rise of blood pressure, which was distinctly lessened but not entirely abolished by section of the phrenic nerve in the neck; the pericardium has apparently a further sensory supply. In curarized dogs, pinching the peripheral muscular portion of the diaphragm on the thoracic side also produced a rise of blood pressure not entirely abolished by section of the phrenics; Mathison argues that this structure also, therefore, apparently possesses a further sensory supply, probably through the intercostal plexus. Stimulation of the central end of the cut phrenic was never found to produce anything in the nature of an expiratory reflex,

¹ The Sensory Fibres of the Phrenic Nerve. By G. C. Mathison, M.D. *Review of Neurology and Psychiatry*, London, 1912, x.

¹ *Journal of Comparative Pathology and Therapeutics*, January, 1913.

and it is probable, therefore, that sensory impulses passing up the phrenic nerves play little or no part in the normal regulation of the respiratory movements. The direct evidence that sensory fibres travel in the phrenics of the dog was furnished by dissection. On the right side these fibres leave the phrenic nerve near the diaphragm, and ascend in two strands along the inferior vena cava to be distributed to the pericardium, one branch going to the auricular portion, an arrangement corresponding with that described by Luschka in man. Two branches given off from the left phrenic as it goes behind the heart pass to the pericardium.

ROYAL DENTISTS.

The choice of a hobby is largely a matter of individual temperament; and, whereas one man will seek refuge from fatigue and worry in books or music, or some other sedentary occupation, another can only find refreshment for mind and body in severe manual labour. The need for some wholesome relaxation, however, is felt by high and low alike; and even kings have not disdained to occupy their leisure hours in working with their hands like the meanest of their subjects. Louis XV, one of the idlest of men, strove to dissipate his continual boredom by means of a private printing press set up for him in his apartments at Versailles by Quesnay, Madame de Pompadour's favourite doctor; and Louis XVI, his grandson and successor, became in course of time a skilful locksmith. Neither of these monarchs, however, was as versatile in his amusements as the ill-fated hero of Flodden, King James IV of Scotland, who was not only an amateur carpenter and blacksmith, but a dentist to boot. The accounts of his private expenditure, extracts from which are given in Miss Green's *Lives of the Princesses of England*, prove that although he indulged his eccentric tastes at the expense of those who surrounded him, James knew how to console his victims for the sufferings they endured at his hands. That the royal dentist's involuntary patients were well paid for their complaisance is shown by the following extract, quoted by Miss Green, though one wonders why the unfortunate Kynnard was less generously treated than the anonymous "fellow" who preceded him, and if the latter proved a more refractory patient than the barber:

| | £ | s. | d. |
|--|---|----|----|
| Paid for a psalter, three compasses, a hammer, a tursace to take out teeth, and two pair of beads, to the King ... | 0 | 7 | 8 |
| Item, to one fellow because the King pullit furht his tooth ... | 0 | 14 | 0 |
| Item, to Kynnard, the barber, for twa teith drawin furht of his hed be the King... .. | 0 | 14 | 0 |

This bald statement of the old accountant is oddly reminiscent of Major Drury's amusing story of the savage potentate who, like the Scottish king, was afflicted with "a mania for experimental surgery," and cheerfully sacrificed the teeth of his unhappy courtiers in the pursuit of his most inconvenient hobby.

TRANSMUTATION OR SYNTHESIS?

At the meeting of the Chemical Society on Thursday Professor Norman Collie, of University College, and Mr. Patterson, of Leeds University, described recent experiments they had made independently which show that on subjecting hydrogen to bombardment by the cathode rays both neon and helium make their appearance. The essential point appears to be that these elements are produced under conditions which exclude the possibility of their appearing in the apparatus as impurities, a suggestion which it will be remembered was put forward when Sir William Ramsay, a few years ago, stated that under the influence of radium emanation various transmutations occurred. In the new experiments neon and helium are collected in relatively large quantities—that is, in terms of thousandths or tens of thousandths of a cubic centimetre.

Another interesting feature of the discovery is that whereas the most familiar instance of transmutation—namely, that seen in the breakdown of the radium atom—is an instance of a highly complex atom resolving itself into simpler and more stable constituents, the present case is one of the formation of elements which must be regarded as being among the simplest known. They are the first to appear in the nascent stars, and it is only when these have cooled down—as in the case, for instance, of our own sun—that the existence of the other more complex elements known on the earth can be determined by the spectroscope. It is difficult to avoid drawing the conclusion that in these experiments we may be witnessing the occurrence, on a small scale, of the conditions under which the worlds of the universe came into being.

Medical Notes in Parliament.

Medical Service in the Highlands and Islands.—Mr. Ainsworth asked the Secretary for Scotland, on February 4th, whether his attention had been drawn to the necessity of an improved medical service for the Highlands and Islands of Scotland, and also to the fact, as made clear by the report of Sir John Dewar's Committee, that the rateable value of the Highland counties was insufficient to meet the demands of modern local government, especially as regards medical service; and what steps he proposed to take to remedy the present state of affairs in these counties.—Mr. McKinnon Wood said he had carefully considered the report of the Committee, and his knowledge of the Highlands and Islands led him to agree entirely with their view that an improved medical service was urgently needed. The report had also received the sympathetic attention of the Government. A special item for the current year dealing in part with the matter appeared in the Supplementary Estimates, and the whole subject was receiving the most careful consideration.—Mr. Cathcart Watson asked the Secretary to the Treasury, on February 4th, if he was aware that doctors in the Highlands and Islands were under liability to attend insured persons without receiving any adequate compensation for journeys by land and sea which might often occupy twenty-four hours or more; and, in view of the fact that doctors only accepted service under the National Insurance Act believing that they would receive reasonable consideration, if he would take an early opportunity of stating what provision will be made.—Mr. Masterman said that the Supplementary Estimates included provision of £10,000 for mileage and other special charges in the Highlands and Islands of Scotland in connexion with the medical attendance and treatment of insured persons.—The Marquess of Tullibardine inquired if that was the full sum which was going to the service, or was there to be a larger sum later on for those other points which were not strictly under the Insurance Act.—Mr. Masterman replied that the report of the Committee was now under consideration.

Royal Commission on Vivisection.—The Home Secretary stated, on February 5th, that he was now in a position to give practical effect to nearly all the recommendations of the Royal Commission on Vivisection. The new administrative arrangements were already far advanced. The inspectorate would be increased to four by the appointment of two additional inspectors, and the present senior inspector would be made chief inspector for the whole country. The new inspectors would be qualified medical men who would give their whole time to the work, and the appointments would be made at an early date. It was also proposed to constitute, in accordance with the recommendation of the Commission, an advisory body to guide the Home Secretary in the exercise of his powers, and the Royal Society and the Royal Colleges of Physicians and Surgeons had consented to assist in the selection of the members of this Committee. He proposed to publish the names in due course, and hoped that the committee would be constituted at an early date.

England and Wales.

[FROM OUR SPECIAL CORRESPONDENTS.]

LONDON.

THE MILK SUPPLY.

In its quarterly report as to action taken under the London County Council General Powers Act, 1907, relative to the milk supply, the Public Health Committee reported to the Council on February 4th that during the three months ended December 31st, 1912, 720 samples of milk were taken at London railway termini. The examination of 772 samples (some taken in the previous quarter) was completed, and 51, or 6.6 per cent. proved tuberculous. Of 3,589 cows examined at various farms throughout the country, 15, or 0.4 per cent., were found to be suffering from tuberculosis, and the sale of milk from these cows in the county of London was stopped. The Committee stated that since the Act came into operation on July 1st, 1908, the examination of 10,638 samples of milk had been completed, 1,071, or 10.1 per cent., proving tuberculous. Of 55,947 cows examined, 637, or 1.1 per cent., were found to be affected by tuberculosis of the udder.

Commenting on the announcement that the Milk and Dairies Bill, 1912, had been dropped, the Public Health Committee reviewed the efforts it has made every year since 1907 to obtain powers to deal with contaminated milk, the Council's proposals being withdrawn time after time on a promise of general legislation by the Government. In view of the urgent necessity for action, the Committee regarded it as a matter for extreme regret that another session had passed without any real efforts being made to deal with the subject of the milk supply, and that the Prime Minister had stated that he was not prepared to give any pledge that facilities would be afforded for the Milk and Dairies Bill in the next session of Parliament.

TUBERCULOSIS DISPENSARIES AT LAMBETH.

The Lambeth Borough Council, at a meeting held last week, adopted the general outlines of a scheme for the establishment of tuberculosis dispensaries in the borough. It is proposed to establish a central dispensary in Effra Road, Brixton, close to the Town Hall, to be entirely under the control of Dr. J. Priestley, M.O.H., and an assistant tuberculosis officer. A branch dispensary for patients living in the northern part of the borough will be established at St. Thomas's Hospital. The governors of the hospital are prepared to establish and maintain a branch dispensary where all persons, both those insured under the National Insurance Act and those not so insured, may be treated for tuberculosis. The department will be controlled by the governors and staff of the hospital and independent of control of all outside bodies except such administrative control as devolves on Dr. Priestley, as medical officer of health for the borough. The governors have appointed Dr. R. C. Wingfield, medical officer in charge of the department, and beds in the hospital will be placed at his disposal for the treatment of suitable cases. He will not visit homes in the borough for the purposes of treatment.

With regard to the whole scheme when presented to the council, Dr. J. Baird proposed that it be referred back to the committee for further consideration with a view to rediscussing the other commitments the council were bound to take up under the scheme of the Local Government Board. The provision of the dispensaries was only a part of the scheme, and they were bound to provide sanatorium treatment. Mr. W. Gough-Cook seconded. Mr. J. E. Wood protested against any further delay. Mr. Frank Briant, a member of the London Insurance Committee, said he failed to see to what further financial burdens the council was committed by establishing the dispensaries. The London County Council had practically agreed to take over one of the institutions of the Metropolitan Asylums Board for a sanatorium, and the borough council would not be called upon to establish one. The resolution to refer the report back to the committee was defeated.

Dr. J. McKeith proposed that the resolution of the council adopted at a previous meeting relating to the

establishment of a branch tuberculosis dispensary at St. Thomas's Hospital be rescinded, and that the Public Health Committee consider and report as to the establishment and maintenance by the council itself of a branch dispensary in North Lambeth. The council had previously declined to invite voluntary aid in the establishment of dispensaries, and had agreed that they should be under the control of and maintained by the borough council. Under the scheme for the establishment of the branch dispensary at St. Thomas's Hospital the council gave up its right of control over the tuberculosis officer, who would have the treatment of a large number of patients. The council had decided not to have voluntary assistance, and yet patients would be compelled to go to St. Thomas's Hospital to be treated as charitable cases. Let the hospital have its own tuberculosis department, but the council, for the sake of economy, should not shirk its responsibilities. Dr. J. Baird seconded. Alderman Evans said that the governors of St. Thomas's Hospital had offered the council all the facilities and help they could, and the council, considering what it would have to contribute in other ways in general expenses, was extremely fortunate in being able to accept the offer. He failed to see what more could be secured than the acknowledgement by the governors that the whole scheme was to be under the administration of the medical officer of health. Mr. Frank Briant said that rejection of the offer of the governors of the hospital would be to the detriment of the hospital itself and the students attending it. Mr. J. E. Wood pointed out that it would cost the council £5,000 to fit up a dispensary similar to that at St. Thomas's Hospital. The resolution proposed by Dr. McKeith was defeated by a large majority.

MANCHESTER AND DISTRICT.

SANATORIUM BENEFIT IN MANCHESTER.

The Manchester Sanitary Committee has just issued a lengthy report dealing with tuberculosis in Manchester, and it would appear that it has at last, after numerous abortive proposals, arrived at a scheme for sanatorium benefit which may be accepted. At the next meeting of the City Council the Finance Committee will propose that application be made to the Local Government Board for sanction to borrow the sum of £44,945, which is estimated to be the capital cost of the scheme. The population of Manchester is about 720,000, and according to the report of the Special Committee on Tuberculosis, which recommends one tuberculosis dispensary for every 250,000 of population, there ought to be three dispensaries in Manchester. It is considered, however, that one central dispensary will be much more convenient and economical, and will allow of better combination of the public health work and clinical work, and it is proposed that the Hardman Street Dispensary should be used for this purpose, being extended, as required, to accommodate both the public health and the dispensary staffs. It will be used as a receiving and clearing house, a centre for diagnosis, observation, and treatment, a centre for examination of contacts and after-care, an information bureau and educational centre. The existing staff of five physicians will be retained at salaries of £250 a year each, and they will act as consultants to general practitioners. There are also to be four whole-time tuberculosis medical officers, the senior to receive not less than £500 a year, and to be independent of the medical officer of health in clinical matters, and the junior officers to receive £300 a year. The staff of the Consumption Hospital will attend at Hardman Street as usual, and two of the whole-time officers will attend in the afternoons of the first five days of the week. In this way, if patients are seen on an average once a fortnight, it will be possible for 840, or even 1,000, to be seen regularly and without undue hurry. Eight nurses are to be appointed as a minimum, and, if more are required, arrangements are to be made with the District Nursing Association; some extra clerks will also be necessary. Recommendations for sanatorium benefit are to be made through the medical officer of health, the senior tuberculosis officer being appointed as his deputy for the purpose, but the whole-time staff are to be in administrative subordination to the medical officer of health.

If the advice of the Special Committee on Tuberculosis were taken, that there should be one sanatorium for every 5,000 population, about 150 beds would have to be provided in sanatoriums, and the same applies to beds in other institutions. But it is stated that the incidence of tuberculosis in Manchester is greater than in the rest of the country, in the proportion of nearly 3 to 2, so that more than the average number of beds will be required. At present there are 150 beds at the Baguley Sanatorium, and it is proposed to double these by adding 100 for men and 50 for women, giving a total of 300 beds which would be available for moderately advanced cases. There are also to be 62 beds at the Crossley Sanatorium for early cases only. In addition, arrangements are to be made to take over from the South Manchester Guardians the Abergele Sanatorium, where there are at present 50 beds. This gives a total of 412 beds available if the arrangements are carried out in full. It was originally proposed to provide for the treatment of surgical cases at the Manchester Royal Infirmary, the Ancoats Hospital, the Children's Hospital, and the Swinton House Schools, but these proposals have had to be dropped—at any rate, for the present—owing to the expense and difficulty of making arrangements.

From the point of view of infection, tuberculosis of the lungs is regarded as the most dangerous form of the disease, entailing the greatest expense in prevention and treatment, but the recent Order of the Local Government Board, which came into operation on February 1st, and makes all forms of tuberculosis compulsorily notifiable, was anticipated, and allowance is made for the additional expense that will be entailed in investigations and administration consequent on the Order.

It is recommended that two special committees be formed—one a committee of medical men, whose business it will be to devise methods of tracking down the disease and securing early diagnosis. It is suggested that it might consist of a medical representative from each of the principal voluntary medical institutions, three representatives of medical practitioners, Professor Delépine (Director of the Public Health Laboratory), Dr. Niven (Medical Officer of Health), and the senior whole-time tuberculosis officer. The second committee, to be called the Tuberculosis Care Committee, is to be a fairly large one, containing representatives of the university, the corporation, the Insurance Committee, the clergy, and medical practitioners, representative employers of labour, and representatives of numerous societies for social welfare, such as the Charity Organization Society, the City League of Help, and others. This committee is to consider, among other things, how to assist needy families when the breadwinner is in a sanatorium, and to provide for consumptive patients who cannot continue at their ordinary work some suitable employment in which they may engage without danger to the health of others. It is proposed to place the sum of about £500 at the disposal of this committee for the provision of food and clothing.

It is estimated that the total capital expenditure will be about £44,945, and the annual expenditure about £39,600. The income of the Manchester Insurance Committee under the head of sanatorium benefit will be about £15,000 a year, of which £6,000 is to be retained for domiciliary treatment and £700 for provision of food and clothing, and the remaining £8,300 is to be handed to the corporation for the treatment of the insured suffering from tuberculosis at the dispensary or in institutions. This leaves a sum of £31,300 to be provided, half of which will be defrayed by the Treasury and the other half out of the rates. It is expected that a saving of £7,000 may be effected by the transference of fever cases from Baguley to Monsall, and that a number of minor savings are possible, but when everything is taken into account the scheme will probably entail a total increase in the Manchester rates of at least £5,000 a year.

LIVERPOOL.

DEATH OF DR. CARTER.

FOLLOWING SOON on the death of Dr. O. T. Williams we have this week again to record the death of a distinguished Liverpool physician. Dr. Carter died on February 2nd after a short illness. For some four years he had retired

from the Professorship of Materia Medica and from his various hospital appointments, but he maintained a lively interest in medical life and progress in Liverpool till the end.

CHANGES IN THE SCHOOL.

The death of Dr. Williams has caused a vacancy on the medical side of the Royal Infirmary. Already there are three strong candidates in the field.

The impending retirement of Mr. Damer Harrison from the Northern Hospital will cause a further change in the teaching staff in Liverpool.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

COMMITTEE ON THE EXTENSION OF MEDICAL BENEFITS TO IRELAND.

IN reply to Mr. John Redmond, in the House of Commons on February 4th, Mr. Lloyd George stated that he had appointed a committee

To consider and report as to the advisability of applying to Ireland the provisions of the National Insurance Act, 1911, with respect to medical benefit, and as to the alterations, legislative or otherwise, which, in the event of such provisions being applied, would be desirable in the systems for affording medical relief at the present existing.

The members of the committee are Lord Ashby St. Ledgers, chairman; Mr. Hugh T. Barrie, M.P. (London-derry N.), Mr. Joseph Devlin, M.P. (Belfast W.), and Mr. J. C. R. Lardner, M.P. (Monaghan N.), Mr. J. Bradbury, of the Treasury, Mr. J. T. Stafford, medical member of the Local Government Board for Ireland, Mr. J. A. Glynn, and Dr. W. J. Maguire, chairman and medical member respectively of the National Health Insurance Commission for Ireland, and Mr. W. L. Micks, a member of the Congested District Board for Ireland. In reply to Mr. Booth, who asked whether the Committee would simply have to report whether the medical benefit system in operation in England should be applied to Ireland or would have power to suggest some alternative system, Mr. Lloyd George, while declining to express any opinion, stated that the Committee would have to consider the Irish position as a whole, and he thought it probable that it would have to adapt it in some way or other to the conditions existing in Ireland.

The Committee has been asked to proceed speedily with its inquiry, because, if the extension of medical benefit to Ireland is recommended, a bill to amend the Insurance Act will be introduced by the Government next session, which will begin next month. The Committee met on the day of its appointment and arranged to take evidence from the urban districts in the north of Belfast on February 17th and 18th, to meet in Dublin on February 19th, 20th, and 21st, where evidence will be taken from Dublin, Cork, Limerick, and Waterford. The first part of the inquiry will be directed to ascertain the extent of the demand for medical benefit in the urban areas, and whether it should be at once instituted. The inquiry as to the rural areas will not, it is said, be made until after Whitsuntide.

Need for Representation of the Poor Law Medical Officers.

The members of the County Cork Branch of the Irish Medical Association, at a meeting held last week, passed a resolution calling on the Committee of Council of the Irish Medical Association at once to take steps to secure that representatives of the Irish Poor Law medical officers be placed on the Committee appointed by Mr. Lloyd George to consider the question of the extension of medical benefits to Ireland, as the question was very urgent, and vitally affected the interests of those officers. They also requested that members of the Irish medical profession should be put on the proposed committee.

The medical practitioners of South Tipperary have decided that in that district it will be regarded as an unprofessional act for any medical man, either in private or Poor Law practice, to give certificates for sick benefits to insured persons pending a final settlement of the

question—this to include workhouse hospitals, county infirmaries, and any other hospitals.

MIDWIVES.

The Women's National Health Association has outlined a scheme for midwives employed under the Local Government Board. If a board of guardians appoints as midwife for a dispensary district a woman having the qualifications laid down by the Insurance Commissioners for a midwife attending women on behalf of whom the maternity benefit is to be applied, the Women's National Health Association will endeavour, through its branches or through special committees to be formed for the purpose, to bring up the midwife's salary to £1 a week, with bicycle and allowance for uniform, on certain conditions; the principal conditions are that the midwife so appointed works under the local branch of the Women's National Health Association in her spare time; that she attends to the mother and baby for a month after birth, giving special care and attention to the care and management of babies; and that she takes no private practice save that provided for the wives of insured persons or women who are themselves insured.

The Kenmare Board of Guardians wrote to the Local Government Board asking the Board's advice on the scheme, and the Local Government Board has replied advising the guardians to wait for further information before agreeing to the fundamental alteration in the duties and present system of control and remuneration of the dispensary midwives.

TREATMENT OF SURGICAL TUBERCULOSIS.

Under the auspices of the Women's National Health Association two lectures were given in Dublin last week explaining the work that is being carried on at Lord Mayor Treloar's Cripples' Hospital and College, at Alton, Hants. The lectures were delivered by Dr. Gauvain, Medical Superintendent of the Home, and Sir William Treloar. An unfortunate misunderstanding arose about the first lecture, for which invitations were sent by the Women's National Health Association to all the Dublin doctors. As it was advertised in the public press along with the other lecture, and was given in the theatre of the Royal Dublin Society, with the Countess of Aberdeen in the chair, it was naturally supposed that it was to be a public lecture, and the medical profession took exception to a lecture entitled "The Conservative Treatment of Surgical Tuberculosis of the Bones and Joints" being delivered by a doctor to a general audience. In spite of a prominent notice in the paper on the morning of the lecture, saying that only medical men had been invited to attend, there was a very small audience, only about forty doctors being present. The lecture was extremely interesting, as showing what could be done for surgical tuberculosis by conservative methods, when neither time nor money were spared. Dr. Gauvain explained his methods, and illustrated them by lantern slides and cinematograph films. There was a short discussion after the lecture. It is a pity that the lecture was not delivered at the Royal College of Surgeons, which would have assured a good attendance, and it is to be hoped that Dr. Gauvain will understand that no discourtesy to himself was intended by the absence of the majority of the profession. In the evening Sir William Treloar explained how he founded the home, and explained the working of it, illustrating his lecture with lantern views showing the patients at work and play. This lecture was well attended, and Lady Aberdeen, who presided, expressed the hope that a similar home would be started in Ireland. Already there is an institution for Belfast carrying on similar work, with homes in Belfast and Bangor.

THE ROYAL COLLEGE OF SURGEONS IN IRELAND.

On February 1st, being Charter Day, the Royal College of Surgeons held its annual dinner. The President of the College, Dr. R. Dancer Pinfrey, occupied the chair, and the guests included His Excellency the Lord Lieutenant and the two new Fellows on whom the Honorary Fellowship had just been conferred in the board room of the college—Surgeon-General Sir Launcelot Gubbins, K.C.B., M.V.O., K.H.S., M.D. (hon. causa), and Sir Berkeley George Andrew Moynihan, F.R.C.S.

Sir Launcelot Gubbins, speaking after dinner, referred to the sections of the Officers' Training Corps raised both by the College of Surgeons and Trinity College, and said that he had been much struck with their physique and personal appearance. He also spoke of the great improvement that had taken place in the general health of the army in the last ten years. Whereas in 1901 there were 170,000 cases of disease and 1,700 deaths, in 1911 (although the strength of the army was greater by 30 per cent.) the numbers were 90,000 and 800. He mentioned especially the striking decrease in the numbers of remissions and deaths on account of enteric fever and in the numbers of men invalided from India. An important cause of this improvement was the better training of officers and the increased attention paid to hygiene. During the course of the evening an enjoyable selection of musical items was rendered by the Leinster Male Voice Quartet—Messrs. J. Barklay Walker, W. C. Lewin, J. Gerard, and Dr. Wm. S. Haughton.

A DOCTOR'S FEE.

At Portadown last week, in a case under the Workmen's Compensation Act, it was stated that the doctor who attended the plaintiff would not give evidence unless a fee was put in his hand, and that the man was unable to pay it. The judge said it was a pity the doctor had not given evidence, for he could have given him a guinea for his attendance; he went on to say that they often heard about the benevolence of the medical profession, but it would seem that a good deal of it was only on the surface. It is a pity that a man in the position of a judge should have made such a remark. We know nothing about the facts of the particular case, but we do know that in cases under the Workmen's Compensation Act the fee of one guinea is often ridiculously inadequate for the doctor's time and trouble in attending court, and unless the doctor looks after his own interests very carefully he may not get even that. We are glad to note that a solicitor remarked that medical men did much for charity, and that in some cases they were imposed upon.

INSANITARY CONDITIONS IN DUBLIN.

At the annual meeting of the Dublin Chamber of Commerce the Chairman drew attention to the insanitary conditions under which the poor of Dublin lived. He said that the commercial community, he was sure, were willing to bear its share in the cost of remedying this state of things, which was a stigma on the city, provided the remedy was carried out in a businesslike way, with forethought and without extravagance. The tenement occupiers, he said, had the remedy in their own hands, as they possessed a majority of votes in many of the city wards. Besides being the first and greatest sufferers from the epidemics engendered by bad sanitation, the tenement occupiers were the largest ratepayers in the city in proportion to their incomes, though this was concealed from them by the system of compounding for rates.

CARRICK-ON-SUIR MEDICAL OFFICERS' SALARIES.

The Carrick-on-Suir Guardians, at their last meeting, had a motion before them to increase the salaries of the five dispensary doctors of the district. The doctors had a solicitor present to put forward their claims, and Dr. McCormack, Local Government Board Medical Inspector, was also present to advise the guardians. Some of the guardians present asserted that Dr. McCormack had a brief for the doctors and that the guardians would refuse to be dictated to by the Local Government Board. The guardians therefore refused a hearing to both Dr. McCormack and the solicitor of the dispensary medical officers, and the motion for the increase of salaries was defeated by 23 to 19 votes.

PREVENTION OF DISEASE.

The Oughterard District Council, at its meeting on January 23rd, unanimously adopted a resolution expressing deep concern at the frequent recurrence of fever in the union owing to the defective sanitary conditions under which the people live, conditions they are unable to remedy with the resources at their disposal owing to the poverty of the union and the high rates prevailing. Drastic remedies are required, involving an outlay entirely

beyond the powers or resources of the council. In the district are hundreds of insured persons and hundreds of persons suffering from tuberculous disease. But no lasting benefit can be expected from the National Insurance Act or from the Tuberculosis Act, because when patients are sent to hospitals or sanatoriums and cured they have to return to the same insanitary surroundings, with the result that they develop the same disease again. No remedy can be permanent until the housing question is seriously taken in hand. The resolution concluded as follows:

In our opinion the proper authorities to take remedial measures in unions like ours, where congestion, poverty, insanitary conditions, and their usual accompaniments of typhus, typhoid, and tuberculosis exist, are the Congested Districts Board, the Local Government Board, and the Irish National Health Insurance Commissioners. We urgently call on these bodies to form a committee of inquiry to investigate the conditions which prevail in this union, with a view to having proper remedial measures taken to put an end once and for all to these deplorable conditions, which are a disgrace to any civilized Government. We pledge ourselves that this council and each individual member thereof will assist by every means in our power any such committee of inquiry, and we are confident that when the members of the above-mentioned bodies become fully aware of the true conditions which prevail they will see the urgency of having the necessary remedial measures adopted with the least possible delay.

PRESENTATION TO DR. BLAKENEY.

On Saturday, January 25th, a number of Rosecommon gentlemen waited on Dr. and Mrs. Blakeney at the Infirmary House, Rosecommon, and presented them with an illuminated album and a purse of sovereigns. The presentation was on the occasion of the doctor's marriage.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

RECENT EXTENSION OF THE EDINBURGH ROYAL MATERNITY HOSPITAL.

DURING the past months a considerable extension has been made to the Edinburgh Royal Maternity and Simpson Memorial Hospital, and a number of improvements have also been effected in the internal arrangements and lighting of the institution. One of the existing defects of the hospital was lack of proper accommodation for the nurses in training as well as for the sisters and staff nurses engaged in the work. Formerly, when only ten or twelve pupils could be trained at one time the accommodation was not much below the necessary amount, although the nurses' quarters were badly lighted and far from cheerful. When, however, the hospital began to train as many as twenty or even twenty-three or twenty-four pupil nurses at once, all the defects and inconveniences became more obvious, and every difficulty was increased. Welcome relief came when the directors purchased the neighbouring building, which had been used as a residence for medical students, and was called the Milne Murray Lodge. Very few alterations were needed to convert the lodge into an ideal residence for the nursing staff; it was already united to the hospital by a bridge; the bedrooms were large, airy, and well lighted, and there were also sitting and reading rooms. There were in all sixteen bedrooms, three of which were double, so that nineteen nurses were accommodated in the extension, a few others remaining in the hospital itself. The supply of hot water was improved as well as the heating of the building.

Through the transference of so many of the nurse pupils to the new block, space was given in the hospital itself for sundry much needed improvements. A more spacious board room was made available for the meetings of the managers and medical board, a ward for sick nurses was provided, and a large dining hall in which all the nurses could take their meals together was found. Small wards for special purposes were added to those already existing for the pregnancy cases (Hamilton or pre-maternity ward), and for patients in the first stage of labour.

Further improvements were made possible by reason of the helpful action of a number of ladies in Edin-

burgh and the neighbourhood, who arranged for a performance of *Penelope* at the King's Theatre. The proceeds of the performance (a *matinée*) were given to the hospital, and were used for the construction of a new operating theatre with the most recent equipment and appliances for the installation of the electric light throughout the building, and for the furnishing of the nurses' sick room, etc. Minor alterations were also carried through, with the result that the institution is now much more worthy of the name "Simpson Memorial" which it bears, and much better adapted for the important work which is carried on in it.

MEMORIAL TO THE LATE DR. G. A. GIBSON.

The late Dr. George A. Gibson's friends (and he had many) all over the world will be glad to hear that a movement is on foot to found a suitable memorial to him. Last week Dr. Graham Brown, President of the Royal College of Physicians of Edinburgh, presided over a meeting, summoned by a notice in the newspapers, in the hall of the college. Lieutenant-Colonel Sir Joseph Fayer, Bart., Sir William Osler, Bart., Sir Clifford Allbutt, K.C.B., Sir Alexander Simpson, Sir Halliday Croom, Sir William McCormick, Sir James Affleck and others sent apologies for absence; and Sir Thomas Clouston, Sir Robert Philip, Dr. Byrom Bramwell, Professor Alexis Thomson, Professor Noël Paton (from Glasgow), Mr. Victor Noël Paton, W.S., Mr. George Berry, and many others were present. The meeting lasted a short time, and cordially expressed approval of the proposal to found a memorial. The motion to this effect was proposed by Dr. Byrom Bramwell and seconded by Mr. Hodsdon. A committee was then appointed to carry the proposal into effect.

PARIS.

Salvarsan and New Arseno-Mercurial Drugs.—Febrile Reaction after Injection of Salvarsan.—Pregnant Syphilis Treated by Salvarsan.—Transposition of Viscera.

On January 17th, at the meeting of the Medical Society of the Hospitals, the results of treatment of syphilis with the new arsenical compounds of mercury were discussed. Drs. Beurmann and Tanon related the successes which they had obtained with the drugs numbered 1116 and 1151. The authors claim that these two new drugs give more satisfactory results than salvarsan (606). The new drugs, they said, influenced the chancre as well as the secondary and tertiary lesions, and at the same time had no unfavourable effect upon the circulatory and nervous systems. The dose of the new drugs varied between 40 eg. to 5 eg. dissolved in distilled water containing 12 grams of sodium carbonate per litre. In practice, a small ampoule containing the 1116 or 1151 is inserted into a larger ampoule containing the soda solution. The whole is sterilized and can be kept for a considerable period without undergoing alteration. When required for injection the small ampoule is broken by shaking, and the solution in the large ampoule is then ready for immediate injection.

At the same meeting Dr. Jeanselme read a report by Dr. Jacquet and himself on the febrile attacks which may follow salvarsan injection. They have come to the following conclusions: (1) That the fever following the first injection is not a toxic fever; (2) that the febrile reaction occurs only in patients who show active virulent syphilitic skin lesions or lesions on the mucous membrane; (3) that injection of salvarsan cuts short a syphilitic febrile reaction, but has no effect on the febrile disturbances from other causes (typhoid, phthisis); (4) that a febrile reaction takes place only when a large initial dose is given and only after the first dose, and that it is due to the wholesale destruction of the spirochaetes, which does not take place when small doses, often repeated, are given, or where mercury treatment is carried out. In syphilitic cases which have previously undergone a course of

mercury, no febrile reaction follows the injection of salvarsan.

Dr. Jeanselme made another communication, on the treatment of syphilitic pregnant women with salvarsan as a prophylactic measure for the child as well as for the mother. During the past two years he has carried out this line of treatment with very encouraging results; the cases in which the patient had previously always miscarried are probably the most interesting. Fourteen women who showed marked active syphilis, and who were treated by weekly doses varying from 30 to 40 c.cm., gave birth to children who showed no signs of congenital syphilis, and were well up to weight and apparently healthy. Two women who had had repeated abortions carried the child to full term, and gave birth to apparently healthy children. Dr. Jeanselme contrasts these cases with the results obtained in similar cases treated with mercury.

The transposition of the viscera, though perhaps not extremely rare, has probably never been demonstrated in the same way as in a woman in Paris at present, whose case was reported to the Medical Society of the Hospitals by Drs. Podelvin and Dufour. Dullness was found in the left hypochondrium, and the heart sounds were best heard to the right of the sternum. By x-ray examination the heart and liver were found transposed; the patient was given a bismuth meal, and another x-ray photograph taken, which showed that the stomach lay on the right side, and the pylorus towards the left; the caecum was in the left iliac fossa, and was well seen after the bismuth had passed through to the large bowel. The cerebral functions are normal, and the patient is not left-handed.

Correspondence.

THE CONSTITUTION OF THE ASSOCIATION.

SIR.—There seems to be a consensus of opinion that the Insurance Act must be amended at an early date if it is to be worked as a practical scheme by the profession. There seems also to be an equally strong consensus of opinion that the Representative Meeting has clearly demonstrated that it may completely fail to represent the majority of the profession.

Many of those who are best acquainted with the constitution of the Association have long thought that this might happen, for a constitution under which a large proportion of the busiest general practitioners throughout the country were bound to travel distances of from six to forty miles in order to have a voice in

- (a) Electing their Representative,
- (b) Instructing this Representative as to how he was to vote,
- (c) To give his vote on any question referred to him for a referendum,

was bound to result in causing a very large number of these general practitioners to have no voice in the policy of the Association.

That this is so is clearly seen by the voting at the meetings called in the Divisions last December. In these divisional meetings 2,000 voted in favour of working the Act, 11,000 voted against doing so, but the opinion of some 14,000 or 15,000 members was never ascertained at all. Yet, in spite of not knowing the opinion of this large proportion of members, the policy of the Association was declared at the ensuing Representative Meeting. How little binding was this "declared policy of the Association" was shown by the way in which it was repudiated by the members of the Association within a week or two of its declaration.

Now, the British Medical Association is the only body which can speak with a wide amount of true authority for the bulk of the practitioners throughout the country, and it has already done a great deal of good work for the profession generally. There is no doubt that the present terms under which the Insurance Act is being worked are far better than the terms originally proposed; and for this improvement the profession has to thank the British Medical Association. I have nothing but admiration for the work which has been done by leaders in the Asso-

ciation like Mr. Verrall and Dr. Macdonald, and the whole profession owes them a great debt of gratitude for the work they have done.

But the Association can never be really successful in formulating a policy for the profession until every general practitioner, however busy, has an opportunity of recording his opinion as to what the policy of the Association should be before it becomes its declared policy.

There seems to be a considerable body of members who think that everything will be solved by allowing the Council of the Association to obtain a postal referendum. There is no question that by granting this power to the Council a very great reform would be effected, for the present mode of taking a referendum is no referendum at all. The process now called a referendum in the existing regulations is nothing more than an appeal by the Council from the decisions of meetings of Divisions, as expressed by Representatives instructed at these meetings, back again to the meetings of the Divisions. A true referendum as defined in the Concise Oxford Dictionary is:

Referring of certain political questions or of such questions under certain circumstances to the electorate for direct decision by a general vote on the single question.

The present process does not refer the question "for direct decision by a general vote," and to apply the term "referendum" to the present process is a misnomer, a pretence, a sham.

But the crux of the whole question cannot be settled by a postal referendum alone. The question is, How can the busy general practitioner, living from six to forty miles from his Divisional centre, have a voice in the policy of the Association before it becomes the declared policy? for if he is deprived of his opportunity of giving his voice as to this declared policy he will never feel bound to carry it out.

I would suggest that the following changes in the constitution of the British Medical Association could easily be carried out, and would effect the necessary reform:

1. That every Division should choose its Representative by a postal vote.
2. That a Representative should speak and vote at a Representative Meeting in accordance with the wishes of his constituents, but that a plan should be devised to replace the present haphazard system under which a Representative may receive "instructions" from a meeting attended by perhaps less than 10 per cent. of the members of the Division. I suggest that it should not be competent for a Division meeting to "instruct" the Representative of the Division unless at least two-thirds of the members of the Division are present at the meeting. A decision of the Association is a very serious act, and the Council in preparing the agenda which it issues for the information of members should state in plain and unmistakable language the matters on which formal decisions fixing the policy of the Association are to be invited. If a sufficient number of members of a Division cannot attend the meeting of the Division, then the Representative of the Division who has been elected by the postal vote, which gives every member a choice in his selection, should be free to speak and vote in accordance with his judgement after hearing the arguments in the Representative Meeting.
3. That the Council have the power of taking a postal referendum on the principle embodied in the Swiss Constitution on all matters which they cannot settle by a two-thirds majority.

I venture to submit these suggestions to the consideration of the members of the Association, not in any spirit of hostile criticism, but because I am sure that no "declared policy of the Association" can succeed until it is supported by the actual vote of the majority of the members. It has been this want of support by the majority which has paralysed the work of the Association in the immediate past, and it will paralyse it again in every crisis and negotiation which may arise. It is of no use to obtain the opinion of 14,000 members if the opinion of another 14,000 members is not known.—I am, etc.,

Exeter, Feb. 1st.

HENRY DAVY.

MEDICAL MEN IN PUBLIC LIFE.

SIR.—Insurance Committees will within the next two months be fully formed; the bodies who will have much say in their final constitution are the county councils. The coming March will bring elections of county councils upon us. I have watched in vain for a sign that this situation is appreciated. The present position of our profession is, I venture with all humility to suggest, in some considerable part due to the fact that we do not take our due position or accept our responsibilities in the body politic, neither by our own presence at its councils nor by influencing the election of candidates whose feelings may harmonize with ours. County councils, town councils, rural councils, all bodies in whom the local government of the country is vested—in these the doctor is conspicuous by his absence. If medical men will not come out into the arena of public life and take up some of the duties themselves (surely many might secure election), at least they may exert much influence to secure the success of candidates who have the will, as they will have the power, to mitigate in some small measure the situation created for the profession by this unspeakable Act. I venture once more, Sir, to suggest that we shall not better our position by indifference in the coming contests. Lack of time we should not plead, so clear is the call of duty. Opportunity is here. "The heart that seizes quick hold of opportunity can achieve." No new truth this, nor dimmed because of past neglect. I am, etc.,

ROBERT CUFF,

Chairman, North Riding (Yorks) Medical Committee,
Scarborough, Feb. 4th.

MEDICAL SERVICE IN THE HIGHLANDS AND ISLANDS OF SCOTLAND.

SIR. It is quite clear from the report of the Committee on the Highlands and Islands Medical Service that the conditions of life prevailing in many districts is quite out of keeping with modern requirements. The Insurance Act has been of inestimable benefit to the Highlands and Islands in drawing public attention to the prevailing conditions.

I had the opportunity of bringing the matter before the Chancellor of the Exchequer, and was cordially supported by my friend and colleague, Mr. Macpherson, M.P. for Ross and Cromarty, and the Chancellor, in reply, promised that the cases we brought forward would receive sympathetic consideration and attention. In pursuance of that promise he appointed the Committee which has now issued its report, and we understand that a special grant will be made to make adequate provision for both doctors and nurses; but in the meantime we are extremely anxious, as it is, of course, absolutely impossible for doctors to attend insured persons in anything like the terms of the Act.

Doctors have other grievances, which are dealt with very ably by the report.

Security of Tenure.

The first is with reference to security of tenure. Doctors for many years have protested vainly against the injustice of being summarily dismissed by a parish council without any appeal. Twelve years ago I presented a memorial to Lord Balfour, signed by practically all the Scottish unofficial members of both parties, praying for this very reasonable request, and although we know of no objection, Scottish Secretaries have persistently refused the demand. The report will, I trust, give doctors hopes of a reasonable amount of fair play.

Doctors' Dwelling-houses.

A very serious difficulty is again with reference to doctors' houses. The paragraph of the report is worth quoting in full:

THE DOCTOR'S DWELLING-HOUSE.

39. The provision of a dwelling-house for the doctor that would be satisfactory both as regards accommodation and situation is of extreme importance.

Complaints were frequent that the house provided is ordinarily too small, as in many cases neither wind nor water tight, is insanitary, and lacking in even the most elementary conveniences of civilized life.

40. Moreover, instead of being centrally situated and so affording ready access to all parts of the practice, the doctor's residence is occasionally found in the remote corner of a large

parish and distant some 15 to 20 miles from half his patients. The main reason given for this anomaly, which seriously affects both the cost and readiness of medical attendance, is that the parish council, however willing in the matter, have not the requisite statutory powers to build or buy a suitable doctor's house.

41. On this question, Mr. Maxwell, Secretary of the Local Government Board, writes:

"In some parishes it is difficult for the medical officer to find a suitable house. It has, unfortunately, been held that parish councils have no power to provide a house for the medical officer out of the poor rates. But for this restriction, it is probable that most parishes would ere now have provided a house for the medical officer. I consider the provision of a suitable house is second in importance only to the provision of an adequate salary."

There was evidence that the local proprietor or agent is occasionally responsible for this difficulty. Mr. Tulloch (Eday) says:

It is the trouble with the house that is the great difficulty. . . . There were proposals made to build one. The first thing was to go to the proprietor's agent for a site. At first they were favourable, and then they refused and would not give a site.

And Dr. Moir (Inverness):

I know of a case where a doctor had the use of a house, and the relations between the doctor and the factor became strained and he was asked to move.

"In marked contrast," the report says, "are a school board's powers in regard to sites and buildings."

To give effect to this legislation is imperatively demanded, and it is proposed to introduce a bill dealing with the matter, which it is hoped will receive unanimous support.

The case mentioned of Eday is bad enough, but Papa Westray is even worse, for there we have raised sufficient money to build a house, but up to now have been unable on any terms to obtain a site for the house, as the person representing the landlord or mortgagees has persistently refused to either grant, sell or lease any ground. The Islanders with extreme difficulty have, in one way or other, contrived to secure the services of a doctor, but it is only by the kindly action of the Scottish Local Government Board that they have been able to do this, as the same person who, unfortunately, is in charge of the Island, used every effort to deprive the Island of the services of the doctor.—I am, etc.,

J. CATHCART WASON,
M.P., Orkney and Shetland.

House of Commons, Jan. 30th.

P.S.—Since writing the above I am very thankful to learn that an interim grant of £10,000 has been made for the Highlands and Islands.

FEES TO PRIVATE PATIENTS.

SIR.—The conditions of practice are being so greatly altered by the operation of the Insurance Act, at least in most localities, that, it appears to me, a corresponding change should now be made by the whole profession in the scale of fees for private patients.

The *raison d'être* for the old sliding scale no longer applies with the same force. Medical men are no longer expected by the public to act from charitable motives. The basis of the Act is the repudiation of charity, and is a demand for a business arrangement.

Let the profession respond in the same spirit. I appeal, therefore, to the Association to confer a much-needed and long overdue boon on the profession by the compilation of a scale of fees, as well as a capitation rate, of a more generous nature than that which has heretofore existed.

The justice of the move will be admitted by the public, and the present unanimity and temper of the profession can be relied on to enforce it. The time is ripe, *carpe diem*. Next year it may be too late.—I am, etc.,

London, N.W., Feb. 3rd.

W. COUDE ADAMS.

THE SIGHT TESTS OF THE BOARD OF TRADE.

SIR,—I have examined the sight tests of the Board of Trade and find them most unsatisfactory, and not in agreement with modern science.

Form Vision.

In the form vision test the letters are printed on canvas, to which a piece of wood is attached. In the normal position this rolls up at the bottom, and has to be held

down by a tag by the examiner. I have never before seen anything so primitive. For curiosity I ascertained whether these tests were obtainable at the ordinary opticians. I tried two or three of the leading ones in London, and found they were not on sale or on their lists. The objections to this kind of test are as follows: The surface is liable to crack, and the letters become distorted. It is very difficult to obtain a flat surface by the method used, in fact when I was being examined the surface was to a certain extent concave, and therefore an astigmatic effect was produced. I found I could read the letters better by tilting my glasses, so that the images formed of the test types on my retinas were astigmatic. The effect of this is that men having a defect of the eyes might read the test types better than a man without this defect. The arrangement of lighting was lateral and very defective, and as the daylight varies considerably men would not be examined in similar conditions.

The method to be adopted should be that which is employed by nearly every ophthalmic surgeon. The letters should be printed on a smooth white surface, preferably white porcelain. The letters should be the standard size—that is, the letter should subtend an angle of 5 minutes on the observer's retina, and each part of the letter should subtend an angle of 1 minute. I do not know whether the size of the letters I saw was correct; the letters, however, could be easily measured with the aid of a sextant. The illumination should be constant and uniform and free from all points of glare. It should be by diffused daylight when possible, the source of the light to be opposite the type and not placed laterally, as is the case with the Board of Trade. The lighting should be such that a normal sighted person should be able to read all the letters at the required distances with the greatest ease.

It is obvious that any standard must be arbitrary, and efficiency is only compatible with a high standard. Whether the standard given is too high can only be decided by a series of experiments. This would take a considerable time.

Colour Vision.

The Wool Test.—This has not been improved. The method of dividing the wools into sets is a very bad one, and the non-use of colour names makes the test very defective and unreliable. There are numerous colours which ought to be present and are absent. The test as used is very confusing to a normal sighted person. I think the test will be even less efficient than it has been previously. Normal sighted persons will be rejected and colour-blind ones passed as before.

The Lantern Test.—This lantern is an imperfect copy of my lantern and lacks many of its essential features. It is a paraffin lantern which shows one or two small lights simultaneously which are reflected from a mirror. Its chief defect is that it lacks any means of regulating the luminosity of the light; only two colours and white are used in the lantern, so that a man knows beforehand that he will only be shown these three lights. The method of having two lights is not a good one, and is one that I have carefully investigated. Change of colour due to simultaneous contrast is likely to cause the rejection of many normal sighted persons, and those with slight and unimportant defects of colour perception. On the other hand, in my opinion many colour-blind persons who have practised themselves in distinguishing between the three lights employed, particularly if with one of these lanterns or one of similar construction, whilst in reality very dangerous persons and liable to cause accidents at sea, will be passed.

The Classification of Colour Blindness Recommended by the Committee.—This method is absolutely erroneous. I have examined two colour-blind persons on this method, and found that they appeared normal sighted. I have also examined a normal sighted person who appeared very colour blind on this method. The method is strictly analogous to endeavouring to ascertain whether a man had a good musical ear by measuring the distances at which he could hear different notes. The two things are quite distinct.

It is curious that whilst one Government department (the Admiralty) uses such very efficient methods, another should use methods which are so imperfect and unscientific. A thorough inquiry into the methods of the Board of Trade

by unbiassed persons is needed in the interests of the mercantile marine and the nation.—I am, etc.,

London, Jan. 29th.

F. W. EDRIDGE-GREEN.

THE SUPPORTS OF THE UTERUS.

SIR.—On p. 225 of the BRITISH MEDICAL JOURNAL for February 1st there is a review of Liepmann's Atlas of Gynaecological Anatomy. In the course of his remarks the reviewer writes: "When we turn to prolapses all is still obscure." And again, "We cannot understand how the uterus loses or frees itself from its supports until we thoroughly recognize what these supports may be, and as yet the problem is not thoroughly understood."

Surely his position is unduly agnostic, for many gynaecologists have ceased to regard prolapses as "obscure," and various anatomists now demonstrate the "supports" which have so long been wrapped in mystery. During recent years the whole subject has been cleared up in the *Journal of Anatomy and Physiology*, in the *Transactions of the Royal Society of Medicine*, in the *Journal of Obstetrics and Gynaecology of the British Empire*, and in various books. There are still some who ignore the available information, and fail to realize that this problem has been settled; therefore contributions to its discussion are still required. One of these, curiously enough, is mentioned on the same page with the review in question. Thus—Dr. M. Moritz read a paper on the fracture of the so-called ligaments of Mackenrodt. By means of dissections and drawings he conclusively showed these so-called ligaments to be perivascular tissue surrounding the vessels supplying the uterus and not separate ligaments.—I am, etc.,

Manchester, Feb. 4th.

W. E. FOTHERGILL.

MEDIAEVAL MEDICINE.

SIR.—Of course I appreciate very much that lengthy discussion of my Old Time Makers of Medicine in the issue of the JOURNAL for December 28th, 1912. May I be permitted to make just one comment?

When I began ten years ago to study mediaeval medicine and surgery I was amazed to find how many anticipations of what I had been used to think of as modern were to be found in the old textbooks. That amazement has grown with the years and each year presents new reasons for its continuance. Instead of exaggerating it always seems to me that my ignorance has up to the present time made me make too little of these old masters. I am learning every day to appreciate them more.

Take the single department of intestinal surgery. The operations for the radical cure of hernia were many. They were performed in the Trendelenburg position with the patient on a board slanting against the wall of the operating room. The *Iconographie de la Sypétrière* published a picture of this mode of operating taken from an old-time book. In wounds of the large intestine, especially when transverse, it was suggested by the Four Masters that the trachea of an animal should be put into the intestinal lumen and the intestine brought together over it. The wound was then brought near the abdominal wound in order to provide for drainage if necessary, which these old surgeons understood very well. The commentator on the Four Masters expressed the positive opinion that in time the trachea will be absorbed or discharged. Dr. Lutz, in the *Interstate Medical Journal* for November, calls attention to the work of Dr. Pfolsprundt in the fifteenth century. He suggested in intestinal transverse wounds the insertion of a silver tube with blunt ends larger than the middle over which the cut ends of the bowel were to be fastened. What was to happen to this forerunner of the Murphy button Pfolsprundt does not say. But he assures us that a patient so treated might survive from forty to fifty years. His technique for plastic surgery, as for the making of a new nose, is perfect in every detail. In every other matter of surgery that he touches there is the same practical character.

Of course there are the textbooks, but most of us sincerely hope that we will be judged by the textbooks and only the best among them. But fortunately Time's winnowing can usually be depended upon.

Compare for a moment the declaration of Theodoric in 1266 that pus is unnecessary and due to mistakes in

treatment, and Nussbaum's expression just six centuries later, about 1869, when before Listerism came to him he declared that he would close his hospital because he could not avoid purulent processes. Can we say too much of the man who had solved that problem six centuries before? More knowledge is all that is needed for enthusiastic admiration and not merely complacent recognition of the work of the Middle Ages.—I am, etc.,
New York, Jan. 14th. JAS. J. WALSH.

The Services.

C AND H.

It may be of interest to some readers to learn that the two distinguishing letters C and H have recently been introduced into the official *Monthly Army List*. These letters signify "Crimea" and "Mutiny," and are prefixed in Gothic lettering to those officers on the active and retired lists who served in either or both of these campaigns.

Altogether there are 2 officers on the active list and 186 on the retired list distinguished by the letter C, and 3 on the active and 402 on the retired lists by the letter H. Fifty officers have both.

Medical officers to the number of 36 (including one quartermaster) are on the list, there being 8 with C, 20 with H, and 8 with CH.

A full list of these retired officers follows:

C.H.

- Boustead, Surgeon-Major R., M.D., [F]. Also served in China (60), Abyssinia (67), and Soudan (85).
 Home, Surgeon-General Sir A. D., V.C., K.C.B., [R]. Also served in China (60), New Zealand (63-65), and Ashanti (73-74).
 Innes, Honorary Deputy Surgeon-General C. A., M.D.
 Jackson, Honorary Deputy Surgeon-General Sir R. W., Knt., C.B., [R], [F]. Also served in Ashanti (73-74), Zulu (79), and Egypt (82).
 Loughurst, Surgeon-Major A. E. T., M.D.
 Reade, Surgeon-Major-General Sir J. B. C., K.C.B., K.H.S., [R]. Also served in Afghanistan (72-80).
 Rendell, Surgeon-Major W. J. Also served in Bhootan (65).
 Sinclair, Deputy Surgeon-General E. M., C.B., M.D., [L]. Also served in South Africa (81).

C.

- Cattell, Deputy Surgeon-General W. Also served in Afghanistan.
 Fletcher, Surgeon-Major W.
 Gorman, Honorary Major L., Quartermaster (retired), Army Medical Staff, [R]. Also served in Canada (66-70), Zulu (79), and Egypt (82).
 Gulland, Honorary Surgeon-General A. D., M.D., [R]. Also served in China (60), and Hazara (61).
 Lawrence, Honorary Brigade-Surgeon H. J. H. Also served in Soudan (85).
 Read, Honorary Brigade-Surgeon C. C. Also served in Soudan (85).
 Rose, Honorary Deputy Surgeon-General H. J. Also served in China (60), and Afghanistan (78-80).
 Saunders, Honorary Deputy Inspector-General G., C.B., M.D.

H.

- Bidie, Surgeon-General G., C.I.E., M.B., K.H.S., [R].
 Bradshaw, Surgeon-Major-General Sir A. F., K.C.B., K.H.P.
 Also served in Afghanistan (79), Zhob (84), and Hazara (91).
 Collins, Honorary Brigade Surgeon F., M.D.
 Colvin-Smith, Surgeon-General Sir C., K.C.B., M.D., K.H.S., [R], [F]. Also served in Burma (52), and Egypt (82).
 Don, Honorary Deputy Surgeon-General W. G., M.D. Also served in Baltic (55).
 Fairweather, Deputy Surgeon-General J., M.D. Also served in North-West Frontier (57).
 Giraud, Surgeon-Major-General C. H., R. Also served in China (60-64), and Zulu (79).
 Hopkins, Honorary Brigade-Surgeon E. Also served in North-West Frontier (63), Afghanistan (78-80), and Soudan (84).
 Hoisted, Honorary Brigade-Surgeon I. Also served in Burma (85-87).
 Joynt, Deputy Surgeon-General C., M.D. Also served in Persia (57), and Abyssinia (67-68).
 Landale, Deputy Surgeon-General J.
 Loch, Deputy Surgeon-General J. H., M.D.
 Mackinnon, Honorary Brigade Surgeon C.
 Planck, Surgeon-General C.
 Sexton, Brigade-Surgeon E., M.D. Also served in China (60), and Abyssinia (67-68).
 Smith-Wynne, Deputy Surgeon-General W. A.
 Thornton, Deputy Surgeon-General Sir J. H., K.C.B., M.B. Also served in China (60), Cosayah (62-3), Bhootan (65-6), Egypt (82-85), and Hazara (85).

Veale, Brigade-Surgeon T. S., M.D. Also served in Bhootan (65-6), and Afghanistan (79-80).

Watson, Deputy Surgeon-General G. A. Also served in Afghanistan (79).

Wyndowe, Deputy Surgeon-General S. J., M.D.

[F] signifies the bestowal of a foreign decoration.

[R] signifies the possession of a reward for distinguished service.

K.H.S. and K.H.P. denote the Honorary Surgeons and Physicians to the King.

Medico-Legal.

WORKMEN'S COMPENSATION ACT.

Two Deaths from Pneumonia.

A CASE decided in the Court of Session, Edinburgh, on January 25th, raises an important point under the Workmen's Compensation Act.

Judgement was given by a bench of seven judges in a stated case under the Workmen's Compensation Act between the Alloa Coal Company, Ltd., and Mrs. Margaret Walls or Drylie and others. The question in the case was whether John Drylie, a brushing contractor, who was employed at the Brucefield Pit of the Alloa Coal Company, and who contracted a chill, which was followed by pneumonia, had met with an accident, arising out of and in the course of his employment. On September 25th, 1911, while Drylie was at work, water began to accumulate at the pit bottom, owing to a defect in the pump. The pump was stopped in order that the defect might be remedied. Drylie and his two companions became alarmed when they found the water rising, and they decided to leave the pit. When they arrived at the pit bottom they were heated, and had to stand there up to the knees in icy cold water, and with a draught of cold air falling down the shaft on them for about twenty minutes until the cage descended. On arriving at the pithead Drylie remained for about twenty minutes or half an hour, and on reaching his house complained of chill. He was at his work off and on until September 29th. Two days later he was told that he was suffering from pneumonia, and he died on October 8th. The Brucefield Pit was a wet pit, but it was unusual for water to accumulate to the depth of 2 ft.

Sheriff-Substitute Dean Leslie found that the pneumonia from which Drylie died was due to the chill which he got on September 25th; that his remaining at the pithead in his wet condition and his working on the days following, and his wetting on these days, had not a favourable effect upon the illness; and that the pneumonia was a natural sequence of the chill. He held that Drylie's death resulted from injury by accident arising out of and in the course of his employment, and found that the widow and her three children were entitled to compensation amounting to £265 3s. 8d.

The Court, Lord Salvesen dissenting, held that the appellants had failed to show a case for disturbing the decision of the arbiter, and dismissed the appeal with expenses.

Lord Dundas, who gave the leading opinion, said this case seemed to be near the line which separated liability from non-liability for compensation by an employer. The Sheriff-Substitute had decided that it lay on the side inferring liability, and his lordship did not see any reason for disturbing his decision. His lordship thought one might postulate, as the result of all decisions, that they must have a definite accident of some sort, not necessarily an occurrence extraneous to the workman, involving something unusual, unexpected, and undesigned to which the injury or death could be unequivocally, or at least by a reasonably inferred use of causation in fact, attributed; and also, probably as a corollary, that death from disease, apart from the industrial diseases specially mentioned, was not an accident unless the disease which caused death could be definitely collocated in the relation of effect and cause with some unusual, unexpected, and undesigned event arising at an ascertained time out of the employment. He thought the elements of an accident were present in this case.

The other judges, excepting Lord Salvesen, concurred.

Lord Salvesen, who dissented, said this case was one of the most important that their lordships had had to determine under the Workmen's Compensation Act, as it was the first in which an arbiter had decided that a death which resulted from pneumonia following on a neglected cold was a death resulting from injury by accident. If their lordships decided the case in accordance with the views of the Sheriff-Substitute, it opened up an endless vista of legislation under the Workmen's Compensation Act, and covered cases which could hardly have been considered by the framers as falling within the Act. His lordship was unable to reach the conclusion that the deceased met with an accident which caused him an injury by accident within the meaning of the statute.

A few days after the case reported above was decided in the Court of Session another appeal was heard, in which the condition of water in the pit was held to be "normal."

The appeal was in respect of the claim of John Brown, miner, Rutherglen. He was at work in No. 2 pit, Gilbertfield Colliery, on June 26th, 1911, where, in consequence of a wreck in the shaft, all the men in the pit were ordered to ascend to the surface. They proceeded towards the shaft of No. 2 pit, by which they were usually raised to the surface. They were met by an official, who told them to proceed by the communication

road to the shaft of No. 1 pit. Here they had to wait at a mid-landing for about an hour and a half, and a very strong current of air blew in on Brown and his fellow miners. After reaching the surface Brown complained of feeling cold, and ran part of the road home to try to recover warmth. The next morning Brown went down the pit, but he was unable to start work on account of illness, due to the chill incurred on the previous day. Pneumonia supervened, and he died on July 3rd, 1911. The Sheriff-Substitute found that Brown died from the effect of injuries by accident received by him on June 26th, and awarded compensation to the respondent.

The Divisional Court reversed this decision, deciding that Brown's death was not due to an accident arising out of or in the course of his employment. There was nothing abnormal, it was held, in the circumstances in which the deceased and the other men found themselves at the shaft No. 1, as it was the down-cast shaft, and the current of air was always blowing there. The case was entirely distinguished from the Drylic case, inasmuch as in that instance there was the abnormal condition in the presence of water, which had not been there before and in which the men had to stand. In the present case the conditions were entirely normal.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following degrees have been conferred:

M.D.—B. P. Campbell.
M.B.—J. W. Adams, W. B. G. Angus, A. C. Johnson,
B. C.—J. W. Adams, W. J. Carr.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

A COMITIA was held on Thursday, January 30th, Sir Thomas Bartow, Bart., K.C.V.O., President, being in the chair.

Admission of Members.

The following gentlemen having passed the required examination were admitted Members of the College:

Anthony Feiling, M.B. Camb., L.R.C.P.; Nathan Mutch, M.B. Camb., L.R.C.P.; Robert Hunter Steen, M.D. Lond.; Francis Martin Rouse Walshe, M.D. Lond.

Licences Granted.

Licences to practise physic were granted to ninety-eight candidates who had passed the necessary examinations.

Diplomas in Public Health.

Diplomas in Public Health were granted jointly with the Royal College of Surgeons of England to the following:

F. J. Ayre, L.R.C.P., M.R.C.S., L.S.A., St. Mary's and Cardiff; H. Balme, F.R.C.S. Eng., L.R.C.P., M.R.C.S., King's College; Jamasp Cursetji Bharucha (Lieut. I.M.S.) L.R.C.P., M.R.C.S., L.M. and S. Bombay, Bombay and King's College; Elsie M. Chubb, M.D., B.S. Lond., Royal Free and University College; W. E. Cooke, M.B., Ch.B. L'pool., Liverpool; A. Ferguson, M.B., B.S. Lond., L.R.C.P., M.R.C.S., St. Bartholomew's; C. A. Gill (Capt. I.M.S.), L.R.C.P., M.R.C.S., University College; H. Hilliard, L.R.C.P., M.R.C.S., St. George's and University College; J. E. Hodgson (Major R.A.M.C.), L.R.C.P., M.R.C.S., Manchester and R.A.M. College; H. M. H. Melbush (Capt. I.M.S.), L.R.C.P., M.R.C.S., St. Bartholomew's and University College; A. L. Otway (Capt. R.A.M.C.), M.B., B.Ch., B.A.O. Dubl., Dublin and R.A.M. College; P. Rose, L.R.C.P. Lond., Guy's and University College.

* Under the Medical Act, 1876.

Communications.

The following communications were received: (1) From the Secretary of the Royal College of Surgeons of England, dated December 12th, 1912, and January 10th, 1913, reporting proceedings of the Council of that College on December 12th and January 9th respectively. (2) From the Clerk to the Privy Council, dated December 19th, 1912, enclosing a programme of the Fourth International Congress on Physio-Therapeutics to be held at Berlin from March 2nd to March 30th next, and stating that should the College nominate a representative the Lord President of the Council would ask the Foreign Office to give him credentials as delegate of His Majesty's Government. Dr. A. E. Garrod was nominated as representative of the College. (3) From the Colonial Office, dated January 3rd, 1913, with enclosures, concerning the appointment of some distinguished medical man to represent His Majesty's Government at the tenth session of the Australasian Medical Congress, to be held at Auckland, N.Z., February 9th to February 14th, 1914. The matter was left in the hands of the officers of the College. (4) From the Home Office, dated December 20th, 1912, asking the opinion of the College on an application from the Liverpool Infirmary for Children for permission to use the prefix "Royal." A favourable reply was returned.

Appointment of Councillors.

Sir E. Cooper Perry, Dr. F. W. Andrewes, Dr. E. H. Starling, and Sir J. Rose Bradford were elected Councillors.

Representative on the Central Midwives Board.

Sir Francis Champneys was appointed the Representative of the College on the Central Midwives Board for one year from pril 1st next.

Discussions on the Insurance Act.

Dr. F. J. Poynton brought before the College certain difficulties in the position of Fellows of the College who are hospital physicians due to the altered conditions that have arisen with the establishment of the medical panels. He said that these difficulties related to the hospitals and their honorary physicians, to the doctors on the panels and to the patients themselves. The main difficulty was the matter of determining which patients were suitable for hospital relief, and which for treatment by the doctors on the panel; there was some danger of patients being sent to and fro between the hospital and the doctor. It would often be onerous for the physician to out-patients to decide the question, and he was afraid the result would be that the hospital would be blamed whatever happened. He hoped the College would keep a sympathetic eye on the difficulties he had mentioned.

The President observed that the difficulties should be settled locally at the various hospitals. Two committees had already been appointed to consider the circumstances of the Insurance Act.

The Treasurer (Sir Dyce Duckworth) placed reliance on the lay management of the hospitals, and referred to the plan adopted at St. Bartholomew's Hospital.

Some further discussion took place, but no resolution was proposed.

Dr. H. Sainsbury, in accordance with notice, called attention to the medical working of the Insurance Act to the resolutions passed at a meeting of the Joint Committee on November 13th, 1912, and urged upon the College the necessity for a further consideration of the present situation with a view to further action. (These resolutions were published in the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of November 16th, 1912, p. 551.) Dr. Sainsbury urged that the majority of doctors were working the Act under compulsion, and labouring under a strong sense of injury; that the conditions were temporary and could be adjusted; and that in three months some further decision would have to be reached. He hoped that the resolutions passed by the College would not remain as mere pious opinions, but that they would be acted upon. The general practitioners were the backbone of the profession, and they had never stood in greater need of guidance than at present. On grounds of freedom of action and development of character, and on the grounds of the interest of the insured, he urged that the College should give the matter its continued attention. He moved the following resolution:

That this College do summon a meeting of the Conjoint Committee at the earliest possible day to further consider the resolution passed on November 13th, 1912, and to report to the College.

This was seconded by Dr. F. J. Smith, who referred to the methods which had been adopted to force doctors to go on the panel, and trusted that the College would be roused to a sense of its responsibilities to the Licentiate. The resolution was carried.

Reports.

A report from the Committee of Management dated December 3rd, 1912, recommended that Radley College and King Edward VII School, Lytham, which had been visited by members of the Committee and reported on as fulfilling the requirements of the Board, be added to the list of institutions recognized by the Examining Board in England for instruction in chemistry and physics, and that the course of laboratory instruction in public health at the University of Cambridge be added to the laboratory courses recognized by the Royal Colleges for their diploma in public health.

The report was adopted.

After some further formal business the President dissolved the Comitia.

CONJOINT BOARD IN SCOTLAND.

The following candidates passed the quarterly examinations held in Edinburgh which concluded on January 25th:

FIRST EXAMINATION.—Umanath Rao Hattiangadi, I. Davies, L. H. Peries, J. T. W. Gale; and four passed in Physics, three in Biology, and one in Chemistry.

SECOND EXAMINATION.—A. G. McKee, J. L. Hendry, P. Chisholm, A. G. Bee, C. E. S. Runciman, F. H. A. Stegmann, R. V. Clarke, H. A. G. Dykes, J. Fitzpatrick, Elfrida H. B. Coghill, J. P. Fairley, J. H. B. Blackburn, H. R. Fisher; and three passed in Anatomy and one in Physiology.

THIRD EXAMINATION.—Florence W. Heyworth, S. A. Faulkner, J. Cooran, Krishnarao Abhaji Deodhar, J. R. Fleming, E. C. Brooks, W. S. O'Loughlin, C. Poshan, A. W. Cochrane; and two passed in Pathology, and five in Materia Medica.

FINAL EXAMINATION.—E. W. Ingle, W. Laird, Baljipet Seshachalam, J. Williamson, P. Giuliani, Isabel Quabrough, W. A. S. George, E. Clubb-Beeckley, T. Sheehan, J. E. Rees, H. W. Ward; and six passed in Medicine, two in Surgery, thirteen in Midwifery, and nine in Medical Jurisprudence and Public Health.

THE Royal Academy of Medicine, Turin, offers for competition the thirteenth Riberi prize, of the value of 20,000 francs. All who desire to submit scientific researches in medical science for competition are requested to announce their intention before December 31st, 1916. For information and forms of application competitors should apply to the Secretary of the Royal Academy of Medicine, 18 Via Po, Turin, Italy.

Obituary.

THE RIGHT HON. LORD ILKESTON, P.C., M.D.,
F.R.C.P., D.C.L., LL.D.,

CONSULTING PHYSICIAN, GENERAL HOSPITAL, BIRMINGHAM; EMERITUS
PROFESSOR OF MEDICINE, QUEEN'S COLLEGE, BIRMINGHAM.

It is with the deepest regret we have to announce the death of Lord Ilkeston, better known to the profession as Sir Walter Foster, which took place at his residence in Grosvenor Road, London, on January 31st. Some sixteen months ago Lord Ilkeston began to suffer from symptoms pointing to obstruction of the bowel, and at the beginning of October, 1911, lumbar colotomy was performed by Sir Anthony Bowlby. He bore the operation well and made a good recovery. He continued to follow with the keenest interest the shifting scenes of professional life during the last year. During the last month or two, however, it became more and more clear that he was failing, and he suffered a good deal of pain. Some weeks ago hæmorrhage from the bowel took place, and although he rallied from the immediate effects of the loss of blood he gradually sank, facing the end which he knew to be inevitable, as he had borne his illness, with unruffled fortitude. When the disease, the true nature of which he had himself suspected from the beginning, was positively pronounced to be malignant, he heard the decision with perfect calmness. He sent for a friend to whom he conveyed the news as coolly as if he had been announcing that he was going out of town, and discussed the details of the operation and the chances of success in a manner which showed that he perfectly realized the situation, and was prepared for whatever fate had in store for him. He passed easily into conversation about other things—remembrances of his professional life at Birmingham, the men he had known, his relations with Mr. Chamberlain, and so forth, showing all his old practical insight into affairs and his power of portraying a personality with one or two touches. The Greek philosopher discoursing with his friends before drinking the hemlock was not more free from any unmanly fear.

Balthazar Walter Foster was the son of Balthazar Foster of Beaulieu, Hampshire, and Marian Green of Cambridge. He was born in 1840, and was therefore in his seventy-third year when he died. He has so long been a conspicuous figure in the medical and political world that probably most people who did not know believed him to be older. It must be remembered that he entered on active professional life at an age when most students nowadays are struggling with their preliminary examinations. Till the onset of his last illness he was remarkably alert in his movements and bright in manner; even in appearance he did not seem his age.

At the age of 8 or 9 he went with his family to Ireland. He was educated at the Drogheda Grammar School, where he had a brilliant career, gaining at the age of 13 all the three medals, in classics, science, and English. His first intention was to enter the ministry, and before leaving school he read through the undergraduate course of theology. Changing his mind, however, he decided to enter the medical profession, and accordingly went up to Dublin in October, 1857. There he was a student at Trinity College and at the school of the Royal College of Surgeons. He was the best anatomist of his year, and was made prosector to the professor, John Hatch Power, whose junior colleague was Professor Alexander Macalister, now of Cambridge. Early in 1860 he obtained the licences of the Colleges of Physicians and Surgeons in Ireland. He obtained the degree of M.D. from the University of Erlangen in 1864, was admitted a member of the Royal College of Physicians of London in 1865, and was elected a Fellow in 1873.

As soon as he was qualified he applied, in answer to an advertisement, for the professorship of practical anatomy and the post of medical tutor at Queen's College, Birmingham. But owing to his youth he had so little hope of success that he was actually on his way to present himself for examination for a commission in the navy when he

received a telegram announcing that he had received the Birmingham appointment. This changed his whole career. On his arrival to take up his duties he discovered that he was also to hold the post of assistant physician to Queen's Hospital. Therefore he was a hospital physician and a professor of anatomy before he had completed his 21st year. In 1864 he became full professor of anatomy in succession to Furneaux Jordan. In 1866 he left Queen's College to join the Sydenham College as professor of anatomy and medicine. Strong efforts were then being made to bring about an amalgamation of the two schools, and this was achieved in 1868, when the School of Medicine was reconstructed by Act of Parliament. In the meantime Foster had become full physician to the Queen's Hospital, an office which he retained till 1868, when he was appointed physician to the General Hospital. He was also appointed professor of medicine in conjunction with James Russell. That position he held from 1868 till 1890, when he became Emeritus Professor and consulting physician to the General Hospital. In addition to these appointments he was consulting physician to the Birmingham Hospital for Skin and Genito Urinary Diseases, and to the Kidderminster Infirmary.

He acquired a large private practice as consulting physician, and published various writings on professional subjects. He gave special attention to diseases of the heart, and his best-known contribution to medical literature was a book on the sphygmograph which appeared in 1866. His interest in the heart is symbolized in the coat of arms designed for him when he was made a peer; a picture of this appeared in the JOURNAL of June 24th, 1910. Among his other publications are: *The Use of Ether and Etherised Cod-liver Oil in the Treatment of Phthisis* (1868); *Method and Medicine* (1870); *The Prince's Illness: Its Lessons—a Lecture on the Prevention of Disease* (1872); *The Therapeutics of Diabetes Mellitus* (1872); a collection of lectures and essays entitled *Clinical Medicine* (1874); *Comparative Mortality of Birmingham and other Large Towns* (1875); *Diabetic Coma, Acetonaemia* (1879). He was the author of the article on valvular disease of the heart in *Quain's Dictionary of Medicine*; and of papers on the treatment of pleuritic effusion (*Birmingham Medical Review*, 1881).

From an early part of his professional career he had been active in the work of the British Medical Association. He was elected co-secretary of the Birmingham Branch in 1872, and was one of the secretaries of the annual meeting held at Birmingham in the same year. He was Vice President of the Section of Medicine at the annual meeting held at Bath in 1878. In 1883-4 he was President of the Branch, when he delivered an address on the political powerlessness of the medical profession, which did much to arouse doctors to a feeling that if ever they were to be a force with which the politicians had to reckon they must organize themselves into a united body. In 1884 he was elected President of the Council, an office in which he displayed great zeal for the better organization of the profession. During his term of office the Association took new premises in the Strand, and Foster interceded himself in getting its head quarters made a freehold. In 1886 he was elected one of the first direct representatives of the profession on the General Medical Council, and for ten years, in conjunction with Dr. Glover and Mr. Wheelhouse, he fought the battle of reform against the apathy or active opposition of the Council. Of this fight he bore the brunt. Although the work was generally distasteful and too often thankless he struggled on, often beaten but never allowing defeat to dishearten him. By his tact, resourcefulness and quiet but resolute persistence he succeeded not only in gaining for the cause which he championed a hearing that could not have been won by violence, but in carrying many useful reforms. To his efforts the appointment of the Penal Cases Committee was largely due. He always laid the greatest stress on the importance of maintaining a high standard in medical qualification, and in particular he did good service by denouncing laxity in the conditions of granting diplomas in public health at that time. When his period of service came to an end in 1896 he did not seek re-election, but in the following year when a by-election unexpectedly occurred, he was induced to stand again, but he was not returned. Not long before, at the

annual meeting, his services to the profession and those of his colleague, Mr. Wheelhouse, had been recognized by the award of the Gold Medal of the Association. He was—with the exception of Mr. Andrew Clark—the last survivor of those distinguished men on whom the Association has bestowed this signal honour.

He delivered the Address in Medicine at the annual meeting of the Association held in Birmingham in 1890, taking as his subject the public aspects of medicine. It was a remarkable address, the orator tracing the evolution of preventive medicine through the scientific work of the profession, and foretelling the advent of a day "when the State shall awaken to the value of such services, and recognize in the trusty dispenser of a nation's charity, or the wise saviour of a city's health, servants of the State more worthy of its honours than the successful soldier or the astute diplomatist." He was President of the Section of Public Medicine at the annual meeting held at Nottingham in 1892, and of the Section of State Medicine at the London meeting in 1910.

At a comparatively early period of his career Foster had begun to take an active part in public affairs outside the profession. He was elected to the Birmingham Town Council in 1855, and served on that body for five years. It was also in 1855 that he entered Parliament as member for Chester. When he sought re-election after the great split in the Liberal party in 1886 he was defeated by a narrow majority. In the same year he received the honour of knighthood in recognition, as Mr. Gladstone expressed it, not only of his medical eminence, but of his services to the great town of Birmingham and his political work. In 1887 he was returned for the Ilkeston Division of Derbyshire, which he continued to represent till 1910, when he gave up the seat, which he had won by an enormous majority, in favour of Colonel Seely, now Secretary of State for War, who had failed to secure re-election elsewhere.

In Parliament, while faithful to his political constituency, he never forgot that he was one of the representatives of the larger constituency of his professional brethren. He took a prominent part in the discussion of all questions affecting directly or indirectly the interests of medical practitioners. He rendered invaluable service in the passing of the amended Medical Act of 1886, and he was largely instrumental in obtaining direct representation of the profession on the General Medical Council. As the advocate of the redress of various grievances of medical officers he earned the gratitude of the Army Medical Department. His defence of the late Captain Fowler, the victim of one of the grossest acts of injustice ever perpetrated even by the War Office, was a fine instance of his courage in standing up against a Government at that time all powerful, which only escaped defeat by using the party machinery at full pressure. In connexion with the Public Health (Scotland) Bill, the Midwives Bill, and the Poor Law Officers' Superannuation Act, Foster showed sleepless vigilance in safeguarding the interests of medical practitioners.

He became Parliamentary Secretary to the Local Government Board in 1892. On his appointment to that office a dinner was given in his honour, which was attended by more than a hundred and fifty members of the profession from all parts of the kingdom. Among them were many of the leaders of the medical profession and the men prominent in the Association at that time. It was felt, as several speakers on the occasion said, that the appointment marked an important epoch and indicated a public recognition of the parliamentary work done by the Association for the furtherance of public health and the welfare of the State. In his speech Sir Walter Foster, as he then was, referred to the fact, mentioned by the President, Dr. Withers Moore, who was in the chair, that he had served in nearly every office of the Association, and in the discharge of these functions he had had his education for public life in the State. He added that as an officer of the Association he had learned some other arts. He had been for a long time a member of the State Medicine Committee, and in that capacity had learned something about the State medicine which it was then to be his lot to administer. "That Committee of State Medicine," he said, "was after all the nursing mother of sanitary science in this country, and helped to do much to place the law of public health in

the position in which it stands to-day." He went on to say that he had also been a member of the Medical Reform Committee, and during the many struggles they had had for medical reform he had learned the arts of an agitator which might be useful.

He held the office of Parliamentary Secretary to the Local Government Board till 1895. In that capacity he proved himself a first-rate administrator, and did excellent work in periods of difficulty, notably in strengthening the system of defence against cholera in 1892 and again in 1894. Here, too, he lost no opportunity of improving the position of medical officers of health and parish doctors and increasing the influence of the profession. In 1893 he presided over the Select Committee on Death Certification, but the Ministry to which he belonged went out of office in 1895 before an opportunity of legislation on the lines recommended by the Committee occurred. To the disgrace of both parties nothing has yet been done to give effect to these recommendations, and both the report of the Committee over which Foster presided and that of the Coroners Committee, which reported much to the same effect in 1910, seem to have been consigned to the official pigeon-hole, the limbo of legislative stillbirths.

Foster's political career was very successful till the Liberal Party returned to power in 1905, when he was trodden down by hungry generations of younger aspirants for office. It was generally expected that he was to have been President of the Local Government Board. We believe that, as a matter of fact, he was to have been First Commissioner of Works, but was set aside to make room for Mr. Lewis Harcourt. He was offered the Deputy-Chairmanship of Committees, but declined that post as inadequate to his deserts. His constituency felt so much that his claims had been ignored, that it insisted on some recognition being given. As there was no opportunity of a post of suitable rank, he accepted a peerage in 1910, taking the title of Lord Ilkeston at the expressed wish of the constituency he had represented for twenty-three years. He had been a Privy Councillor since 1906.

Of his multifarious activities in other directions an idea may be formed from the following enumeration of public positions held by him at different times in addition to those that have been mentioned. He had held the office of President of the British Medical Benevolent Fund and was the first President of the Irish Medical Schools' and Graduates' Association. He was Chairman of the National Liberal Federation from 1886 to 1890, President of the Allotments and Small Holdings Association in 1892, and President of the Land Law Reform Association, 1899, 1908. He was a J.P. for the county of Warwick. In addition to the distinctions already mentioned, he received the honorary degree of D.C.L. from the University of Durham in 1893, and that of LL.D. from the University of Montreal in 1897. Ilkeston conferred upon him the freedom of the borough in 1904.

Lord Ilkeston married Emily, daughter of Mr. W. L. Sargent, of Edgbaston, and by her had one son, the Hon. Stephen Foster (now Lord Ilkeston), and three daughters, two of whom survive him. To his widow, who helped throughout his married life with encouragement and support, and who ministered to him with the most self-sacrificing devotion in his illness, the sympathy of the profession and of his many friends outside it will go out in her bereavement.

The funeral took place at Brookwood Cemetery on February 3rd. A memorial service held at St. Margaret's, Westminster, was attended by a number of friends, including Earl Spencer, Lord Shaw of Dunfermline, Lord Southwark, Lord Rotherham, Colonel Seely, M.P., Mr. John Burns, M.P., Mr. Eugene Wason, M.P., Sir Edward Coates, M.P., Sir Henry Cotton, Sir Herbert Raphael, M.P., Sir James Reid, Bart., Sir David Brynmor Jones, M.P., Sir Horace Monro, Secretary to the Local Government Board, and Sir R. Douglas Powell. The Royal College of Physicians was represented by Sir Thomas Barlow, Sir Dyce Duckworth, Dr. Sharkey, Dr. Percy Kidd, Dr. Samuel West, Dr. W. Hale White, Dr. Liveing, Dr. Ormerod (Registrar), and Mr. Fleming (Bedell); the British Medical Association was represented by Mr. E. B. Turner, Member of Council, who attended at the request of the President, and Mr. Gny Elliston, Financial Secretary. The Land Law Reform Association, the National Liberal Federation, the Ilkeston Division Unionists

Association, the Ilkeston Division Liberal Association, and the Women's Imperial Health Association were also represented.

The Right Hon. ROBERT FARQUHARSON, M.D., writes:

When Walter Foster deserted medicine for politics many of his friends, myself included, thought that he had made a mistake, for his position in the North was unassailed and unassailable. Not only had he the largest consulting practice, but he was a successful lecturer and clinical teacher; he had written largely and well on the heart and other important matters, and his professional income must have been very large. But he always had a love for public life, and was prepared to make sacrifices to embark in it. Chamberlain and he were great friends in earlier days; he enjoyed the intimate confidence of Schmadowitz, prince of organizers, and on one occasion, if I remember aright, he was president of the National Liberal Federation, the highest honour to which an outsider can aspire. So the road was plain and simple towards higher honours, and he moved along it with perfect success. At first he represented Chester, but when the *débâcle* came he was swept out of his seat and had to take refuge elsewhere, and Ilkeston opened its embracing arms and took him in and held him with unceasing and increasing devotion until he was called away to the "other place." He very quickly caught on in the House, for he spoke early but not too often, and he had a remarkably attractive House of Commons manner, which, like the bedside manner he must have possessed to perfection, is, I fancy, born, not made, though, of course, it may be partially acquired by practice. To this was added a rich and well modulated voice, through which ran a strain of the brogue which bespoke Hibernian readiness in debate and retort—a clear, balanced mind, which thought out his subject carefully and communicated his views in well-arranged and judicious language, neither too brief nor too copious, but satisfactory at the moment and standing the test of subsequent reflection. Like a wise man, although he occasionally took part in general discussion, he confined himself mostly to his own subjects, on which he became a recognized authority, and the House always filled up when he rose to speak of them. In 1894, when Sir Henry Fowler was President of the Local Government Board, he passed that wide-reaching and eminently successful piece of legislation, the Parish Councils Bill, and in the following letter he generously acknowledged the eminent services of Sir Walter Foster, then his chief lieutenant:

Local Government Board, 15th January, 1894.

My dear Foster,

I cannot let the passage of our bill be completed without conveying to you my cordial thanks for the valuable, unflinching, and pleasant assistance you have so ungrudgingly rendered to me in my arduous task. I know that on several points you would have preferred to see the provisions of the bill more in accordance with the views of several of our friends behind us, but you have so fairly recognized the difficulties of the Government, and the wisdom of obtaining substantial and unprecedented advantages, and you have so loyally discharged your duty as a member of the Government, that it would be the height of ingratitude if I did not express my appreciation of your conduct, etc., etc.¹

When the next Liberal Government was framed it was inevitable that a place should be found for him, and the Local Government Board was ideally fitted to bring out his best powers. I think he was the first medical man who held parliamentary office under it, and the wisdom of the choice was quickly shown, for both in and out of the House he was emphatically the right man in the right place, and spoke on vaccination and vivisection and all matters concerning public health with a convincing authority which was recognized and appreciated. When the Tories succeeded the Liberals and we were in the throes of the disastrous South African war, Sir Walter patriotically placed his services at the disposal of the Government to go out and bring order out of chaos and try to save the numerous valuable lives which were being preventably sacrificed by want of sanitary co-ordination. But with the infatuated obstinacy which regulated the proceedings at head quarters during that dark and dreary time, his valuable aid was rejected,

and history now tells the mournful tale of what might have been. When the next Liberal Government was framed Sir Walter and his friends were disappointed to find that no place had been found for him. Doubtless there were difficulties in the way—a Cabinet portfolio had to be found for John Burns, and Sir Walter as a senior man could not serve under him at the Local Government Board. But he accepted the situation loyally, and manfully continued to do his useful work as a private member, and when translated to what has been sometimes called the lethal chamber he determined that he would stir up the stagnant waters and introduce fresh life into the gilded chamber, which only requires to be wakened up to impress its mass of sterling ability on the minds of the people. He moved or seconded the Address with marked ability, and was beginning to feel his feet and stand firmly on them when the blow fell. And it was with regretful surprise that we heard of his serious illness, for he was a surprisingly young-looking man for his age, with abundant hair barely flecked with grey, a buoyant mind and walk, and all the appearance of a constitution that would long defy the ravages of time. But here, again, his abounding vitality and elastic nature and Christian resignation came to his aid. When I went to see him not long after the operation and asked how he was, he characteristically replied, "As well as a man can be who has got a hole in his side," and I consoled him by reference to the case of a mutual friend, high placed officially, who led an active life, even hunting occasionally, after a colotomy which was still kept open; and he confidently looked forward to regaining his seat in the House of Lords and joining occasionally in debate. But it was not to be. Gradually the shadows grew deeper around, and although brightened by an occasional gleam of hopeful sunshine, as when radium seemed to cause some arrest of the advancing disease, they closed in upon him at last, and the end came; and perhaps, under the circumstances, we cannot regret that the curtain fell. It would be unthinkable to imagine bright, breezy, active, likeable Walter Foster as a chronic invalid, incapacitated by bodily and perhaps mental infirmity from taking part in the *Sturm und Drang* of forceful political life, where he worked so long and so well. The drama of his strenuous and useful career is over, and nothing is left us but to render our true and respectful sympathy to his devoted wife, who shared his joys and his sorrows, exulted at the mark which her lost husband made in two great and essential departments of human activity, and brightened his later hours by her energetic cheerfulness; and I think she may be consoled for her heavy loss by the reflection that his work has not been in vain—that he has alleviated human suffering and lengthened human life, and that he leaves behind him the high and inspiring example of how a good man can live and how he can die.

Professor SAUNDREY writes:

My recollections of the late Lord Ilkeston carry me back a great many years. When I came to Birmingham in 1876, although he was under 40, he was already one of the leading consulting physicians in the city and district, and held the position of physician to the General Hospital, and of Professor of Medicine in Queen's College Medical School. He impressed me at the time as being a man not only of remarkable ability but far ahead of his local contemporaries in knowledge of recent scientific medicine. He had already published a number of important papers, which had carried his name far and wide, his pioneer work with the cardiograph being of considerable originality. I have often heard his "bedside manner" spoken of as being perfect, and unquestionably he had a large practice in bedside consultations, his carriage being constantly seen all over the city. When I came upon the Council of the British Medical Association, he was its President as the title then was, and there never was a better chairman; for many years we used to look back to those days as affording a model to all times of the orderly dispatch of business. The Council used to meet in Exeter Hall, which was a long, narrow room, in which it was difficult for those who sat at the lower end to make themselves heard, or to take any proper share in the proceedings; the duties of the chair were not lightened by these circumstances, and it says much for him that so many should have carried away so strong

¹ *Life of Lord Wolverhampton*, p. 272.

an impression of his merits. After he entered Parliament, in the early eighties, he necessarily had to give up a good deal of practice, and his life thenceforth was devoted in a much greater extent to the public. His monument must be the Medical Act of 1886, which he carried successfully through Parliament; it will always be remembered as enfranchising the medical profession and widening the General Medical Council by making it no longer almost exclusively representative of the licensing bodies. Quite appropriately Sir Walter Foster, as he then was, became one of the first group of direct representatives of the medical profession in the Council, a post he held until 1896, and there can be no question that the choice of a man of his ability and position as one of the first direct representatives gave these new members a standing in the Council which they might otherwise have taken years to attain. There is no need to recall the incidents of his rejection at the 1896 election, but after that time he was no longer in a position to represent the medical profession. He had given up his posts in Birmingham and had removed to live in London. Except for the short period from 1892-5, when he was Parliamentary Secretary of the Local Government Board in Mr. Gladstone's last administration, his career was that of a member of Parliament sitting in opposition. On the return of his party to power many hoped that the medical profession would be recognized by his appointment to the Presidency of the Local Government Board, but that was not to be, and the Government was the weaker for his exclusion. It is impossible to doubt that had Lord Ilkerton been taken into the confidence of the Chancellor of the Exchequer many of the mistakes of the Insurance Act would have been avoided.

J. F. J. SYKES, M.D., D.Sc.,

MEDICAL OFFICER OF HEALTH, ST. PANCRAS.

THE announcement of the death, on January 30th, of Dr. J. F. J. Sykes, from peritonitis after an operation, has come as a shock to many friends who knew his ceaseless activity in the office which he held.

John Frederick Joseph Sykes was born at Brighton sixty years ago, and was educated in that town, at Guy's Hospital, and at the University of Edinburgh. He took the degree of M.D. Edin. in 1878, and the diplomas of L.R.C.P. Lond. and M.R.C.S. Eng. in the same year. He studied also in Paris and Frankfurt. He graduated B.Sc. Edin. in 1880, and took the degree of D.Sc. in Public Health in the same university in 1893. From an early stage of his career he devoted himself to public health work, and for some years was assistant examiner in hygiene to the Science and Art Department. The chief work of his life was done as Medical Officer of Health of St. Pancras, an appointment which he received in 1885. He gave himself to the duties of this arduous office with zeal; and very much of the more general work which he accomplished was, as it were, a by-product of his special duties. He early directed attention to the insufficient control with respect to the burial and identification of deceased persons and the verification and certification of deaths, and gave evidence before the Select Committee on this subject which sat in 1893 under the chairmanship of Lord Ilkerton (then Sir Walter Foster), whose death we have also the regret to record in this issue. Dr. Sykes interested himself in 1889 in the question of the provision of hospital accommodation for diphtheria in the metropolis. In 1895 he drew attention to the risk of the spread of puerperal fever by midwives, and in the same year gave evidence on the spread of disease in barrack schools before the Poor Law Schools Committee. To complete this brief note on his work with regard to infectious diseases it may be said that in 1901 he took the lead in obtaining the provision for the notification of chicken-pox during the prevalence of small-pox. He was President of the Society of Medical Officers of Health, and had previously been President of its metropolitan branch. He took great interest in the work of the Royal Sanitary Institute; was a member of its council almost continuously from 1883, and at various times served on the Congress, Examination, Referee, Education, Museum, Finance, and Parliamentary Committees. He was the Chairman of the Congress Com-

mittee from 1892 to 1897, and was honorary or recording secretary of one of the sections of the congresses of the Institute from 1884 to 1904. He was a Fellow of the Royal Statistical Society, and was by that society awarded the Howard Medal in 1900. In 1901 he gave the Milroy Lectures before the Royal College of Physicians of London on public health and housing. He was the author of a work on *Public Health Problems* in the Contemporary Science Series, and wrote a handbook of *Home Hygiene* for the St. John Ambulance Association. He was Secretary of the Section of Architecture in relation to hygiene at the International Congress of Hygiene and Demography in London in 1891, and was a delegate to the next following congress held at Budapest in 1894. He was a member of the Epidemiological Society, of the Société Française d'Hygiène, of the Société d'Hygiène Publique of Paris, and of the Deutsche Verein für öffentliche Gesundheitspflege.

DR. ARTHUR NEWSHOLME, Medical Officer to the Local Government Board in England, writes:

Although in the time available I cannot hope to do justice to Dr. Sykes's memory, I avail myself of your invitation to add my personal tribute to the high value of his life and his work.

The outstanding characteristic of Dr. Sykes was the extremely and sometimes almost painfully thorough fashion in which he dealt with every problem with which he was faced. While current it formed the subject of his constant thought, it was investigated from every viewpoint, and the results of his work were presented with conscientious completeness. To the superficial reader or hearer he may sometimes have appeared unnecessarily to labour one or other point of detail, but this was the defect of the quality of thoroughness which gave importance to his opinions and his conclusions. He had an original mind, exceptionally fitted for analysing public health problems; and had not his time been over-full of and his energies sapped by the vast mass of minor administrative detail daily requiring his attention, his contributions to the advance of our knowledge would have been more numerous even than they were. Notwithstanding the clog of excessive administrative work, he impressed the mark of his mind on several important subjects. His work on *Public Health Problems* did not, I believe, have the circulation it deserved; but it well repays study, even at the present time, nearly every chapter embodying broad-minded and original suggestions on the wide aspects of public health problems. The book on *Housing and Public Health*, giving the substance of his Milroy Lectures on this subject, contains some of his most thoughtful work; and the chapters on "Construction and Misconstruction" and on "Usage and Misusage" should not be neglected by any medical officer of health to whom urban housing is a pressing problem. Dr. Sykes was the pioneer of the school for mothers in this country, and in inaugurating this work he not only realized fully the importance of the educational element in the hygiene of infancy and childhood, but also the great value which attaches to the yoking of voluntary with official efforts directed against excessive child mortality.

But my chief wish in writing these lines is to add my tribute of grateful appreciation of Dr. Sykes's life and work. His memory is among the precious possessions of his friends, and public health is the poorer because of his—as it appears to us—too early rest from work.

DR. R. M. BEATON (Chairman of the St. Pancras and Islington Division of the British Medical Association) writes:

Quite recently Dr. Sykes was in our midst, going out and in and doing his duty—then a sudden attack, an operation, and in a week he is gone. The suddenness startled those of us who heard of his illness and of his passing in quick succession, and even now we can hardly believe that the alert, active presence which has so long and so well watched over the health affairs of St. Pancras is gone from us. It was in his capacity as medical officer of health that I knew him best, especially during the last ten years. For the greater part of this period I was associated with him as a member or Chairman of the Public Health Committee of St. Pancras. I found him a most devoted officer, courageous in the exposition of his views, and fearless in the carrying out of his duty. He was a

man of many ideas, some of which possessed him, and when this was the case he never spared any effort to make himself complete master of the particular subject. Nothing gave him greater delight than to expound his favourite views to an individual or a committee, and he would do this with an elaboration of detail which often amazed and sometimes puzzled his hearers. I was frequently struck with the original lines of thought and argument by which he would seek to prove any case he expounded, as well as by the earnestness of his manner and ring of conviction in his voice. United to his fondness for detail he had a wide outlook and took a long view of things. Often his ideas were rejected, but he laboured on with much enthusiasm and great hopefulness. He has left his mark for good on St. Pancras. Now he rests from his labours and his works do follow him.

CHARLES ORTON, M.D.DURH., F.R.C.P. EDIN.,

CONSULTING PHYSICIAN, NORTH STAFFORDSHIRE INFIRMARY.

The announcement of the death on January 16th of Dr. Charles Orton, consulting physician to the North Staffordshire Infirmary, at the age of 73, has caused much regret throughout the profession in the Pottery districts. He received his medical education at King's College, London, and Edinburgh, became M.R.C.S. Eng., and L.S.A. in 1862, and F.R.C.P. Edin. in 1881, taking the degree of M.D. Durh. in the same year.

He was one of the old pupils of the old North Staffordshire Infirmary at Etruria, and was house-surgeon there in 1862. After commencing practice at Newcastle-under-Lyme, he was appointed one of the honorary medical officers of the infirmary, an appointment which he retained until 1889, when he became consulting physician. He took part in the formation of the Staffordshire Branch of the British Medical Association in 1874, was its president in 1883-4, and from 1882 to 1888 one of its representatives on the old Parliamentary Bills Committee. His address as president of the Branch was on the effects of our present system of education on the health of our children. He was surgeon to the 4th Battalion of the North Staffordshire Regiment (Prince of Wales's), and retired with the rank of surgeon-major.

In 1870 he visited the seat of the Franco-Prussian war with Mr. W. D. Spanton, when they wrote an account of their experiences; he also wrote an essay on the medical wants of the Potteries. He had a wide practice in and around Newcastle-under-Lyme until he retired, for he was highly esteemed as an able practitioner and man of culture, qualities which, combined with his kindness and hospitable disposition, won him the universal respect and esteem of his professional brethren. When he gave up practice, he spent some time abroad, chiefly at Florence and Rome, and then settled in Hastings, but a few years ago removed to Bradley Court, Wotton-under-Edge, a delightful old manor house, with an interesting history. Here he died after a very short illness, leaving a widow and three daughters, one of whom is the wife of Mr. Douglas Coghill, formerly M.P. for Stoke, and another is married to Mr. W. B. Yarde, formerly one of H.M. Inspectors of Education. He was buried at Wotton-under-Edge.

Mr. W. D. SPANTON sends us the following appreciation of his friend's life and character:

I am glad to have the opportunity of saying a few words concerning my old friend Charles Orton. It has been my pleasure to have had an unbroken friendship with the late Dr. Orton for more than half a century; and, during the many changes we have both taken part in, nothing has ever disturbed it.

Dr. Orton married Miss Kate Leslie, of Aberdeen, forty-seven years ago, and they had a family of three daughters, all of whom are now living. His brother Dr. John Orton was a surgeon-major in the Indian army, and died several years ago.

Dr. Orton was a proficient artist, and had some skill in sculpture, while he was especially fond of outdoor sports of all kinds, cricket particularly; and in later life whilst resident in Rome took an active part in the work of the Archaeological Society there.

We were long associated on the active staff of the North Staffordshire Infirmary, and he was always ready

to take energetic action in any matter which conduced to its welfare and efficiency. He never wrote much or took a prominent part in public medical matters, but he could always be relied on to come forward to help a colleague or do anything to uphold the best traditions of our profession, for he was trained in the old school of masters and apprentices, as I was, and believed more in levelling up than the more modern style of levelling down. His pleasant manner, his perfect uprightness, and his loyalty to his chosen profession as well as to his friends are the most marked characteristics I can recall; and although for many years he had passed out of the region of active work, except sometimes in Italy in the winter, he will be greatly missed by all his old friends.

JOSEPH BAYLEY, M.R.C.S., L.S.A.,

MEDICAL SUPERINTENDENT AT ST. ANDREW'S HOSPITAL,
NORTHAMPTON.

We deeply regret to record the death of Dr. Joseph Bayley, which occurred at Bryn-y-Neuadd, Llanfairfechan, on January 19th.

Dr. Bayley, who was in his 78th year, had been ill for some eleven weeks; on November 2nd he went to Llanfairfechan to pay one of his periodical visits to the Welsh branch of the institution, and was taken ill whilst staying there. His death removes one of the most highly respected residents of Northampton, a man of conspicuous ability in his profession, and an exceptionally successful organizer. His life-work was bound up with the institution with which he was so honourably associated for forty-eight years in Northampton.

Joseph Bayley was born on January 17th, 1836, and was the son of Dr. Joseph Bayley, of Odiham, Hampshire. He was educated at Reading School, and proceeded to King's College, London, where he completed his education. He took the diploma of M.R.C.S. in 1857, and that of L.S.A. in 1858. He entered the Royal Navy as a surgeon, and on the outbreak of the Crimean war gallantly responded to the call for volunteers. He served with the Baltic Fleet on board H.M.S. *Colossus*, one of the first-class line of battleships during the Crimean war, and was present at the bombardment of Bomarsund, and at Kronstadt. For his services he received the Baltic medal. At the conclusion of hostilities he was appointed surgeon on H.M.S. *Shannon*, a vessel of the frigate order. He did not continue long in Her Majesty's Service, resigning his commission to enter the Lunacy Service. He was first appointed assistant medical officer at Leicester County Asylum. He afterwards became assistant medical officer at the Salop and Montgomery Asylum, Shrewsbury, under Dr. Oliver, whose daughter he married. On the death of Dr. Oliver he was appointed superintendent of the Shrewsbury Asylum, and in 1865 he was appointed medical superintendent at St. Andrew's Hospital, Northampton. Here for close on half a century he devoted himself to the welfare of the institution which under his skilful administration became one of the leading asylums of its kind in the country. In the management of the hospital itself no less than in the treatment of patients he was most successful, and St. Andrew's became recognized as one of the largest and best places for the treatment of patients of the upper and middle classes.

When Dr. Bayley went to Northampton the asylum possessed about 100 acres of land; St. Andrew's Hospital now has, including the Welsh Estates, over 1,000 acres. The buildings themselves have been enlarged time and again, new houses and blocks of buildings being added, private residences in the vicinity acquired, and, in fact, the whole hospital has been so completely remodelled that it now possesses hardly a feature in common with the institution of half a century ago. The average number of private patients admitted annually has risen from 20 to about 100, and the total number of inmates is now about 450.

In the care of the patients Dr. Bayley always laid special emphasis on the importance of pleasant surroundings and recreations. The grounds at St. Andrew's are beautifully laid out with terraces, avenues of fine trees, picturesque walks and groves, and broad meadows and lawns. Some twelve or thirteen years ago hockey, tennis, cricket, and croquet lawns were laid down. Bryn-y-Neuadd was acquired in 1900. The patients were

encouraged to participate in outdoor athletic games, and the effect was very marked. Dr. Bayley himself was interested in all forms of sport. He used to run his own pack of harriers at Northampton, and he also went in for coursing, owning some fine greyhounds. He was also a cricketer in his younger days. His interests, however, apart from athletics and sport, were mostly confined to the development of St. Andrew's Hospital.

Dr. Bayley was an actor in amateur theatricals in his youth, and many admirable performances were given by members of the staff and patients, even operas of the calibre of *Il Trovatore* being undertaken.

His work—and the continual development going on over a long period of years—proves him to have been a shrewd, capable, far-seeing man, possessing exceptional grasp and well-directed outlook, a man of large organizing power and practical enterprise, and a good judge of other men. Clear of perception and of ready decision, he may have seemed sometimes a little quick-tempered; but at heart he was one of the best of men, and friends and officials who survive him can alike testify gratefully to many acts of kindness and consideration.

An old friend and professional colleague writes: Now that Dr. Bayley's lamented death has terminated a long and much-valued friendship, I cannot refrain from giving expression to the feelings of admiration which I have always entertained for his attainments as a physician and his skill in that branch of the profession which he had adopted and for so long practised. In the ranks of the alienists his death creates a distinct loss which it will be difficult to fill, for it was to the eminent position he occupied and which was so widely recognized, that the success of St. Andrew's as a hospital for the care and treatment of the mentally afflicted was due more even than to the unusual talent for organization which he undoubtedly possessed, and to the watchful care which he gave to the working of the institution which he may be said to have created. St. Andrew's before his time was a struggling institution with scarcely any but local connexion. It is now the favoured resort to which patients from all parts of the kingdom, of all degrees, are sent—a tribute indeed to the skill of the superintendent and to the widespread nature of his reputation. It has happily been Dr. Bayley's lot to complete the work to which he had devoted his lifetime, and to put the hospital into so finished a state that it may reasonably be expected to maintain in the future the position it has now long held as one of the best and most useful institutions of its kind in the United Kingdom. As a man and as a physician his kindness of heart was at all times manifested, and his anxious care for the well-being, and if possible the cure, of those committed to his charge was a marked feature in his relations with their relatives and friends, and added no little to the favour with which the hospital is regarded. Dr. Bayley was a man of great determination, and having once made up his mind as to the right course to pursue, was not to be turned aside from his purpose. In his early days at St. Andrew's he had to meet many difficulties, but he did not give way, but by tact and firmness overcame them.

This is scarcely the place to speak of Dr. Bayley in his private relations—they were most happy; he made many friends, who now feel how great is their loss, and no enemies; while the former live his many amiable qualities will not be forgotten.

THE LATE DR. GIBSON.—The University Court of the University of St. Andrews, at a meeting on February 1st, adopted the following minute:

The University Court deeply regret the death of their former colleague, George Alexander Gibson, M.D., LL.D., etc., Edinburgh. They desire to put on record their sense of the great loss caused thereby to science, medicine, and Scottish culture. They recognize how great was his distinction as a physician, an original investigator, and a learned and accomplished writer on many branches of medicine.

They recall with thankfulness his valuable services as member of University Court, and the constant kindness, courage, and courtesy which he showed in all the relations of life. They grieve over the bereavement of his widow and family, and direct that a copy of this minute be sent to them as an expression of sympathy.

DR. JAMES WATERSTON, J.P., of Sunderland, died on the morning of January 22nd, having reached the advanced age of 85. He was a man of remarkably strong physique and followed his profession up to within a few weeks of his death, although he had been ailing for some time. A native of Edinburgh, he was educated at Heriot's Hospital, and took the diploma of L.R.C.S. in 1848. He commenced his professional career as medical officer to a vessel on a voyage to the Arctic region; it was shipwrecked, and he was with difficulty rescued. He practised for a time in Haltwhistle, and was later on in Gateshead during the period of the great cholera epidemic. Then he settled at Sunderland and practised there for more than half a century. He was connected with the Royal Infirmary for many years. Dr. Waterston was Chairman of the Sunderland Division of the British Medical Association in 1905. Twenty years ago he was appointed a Justice of the Peace, and attended most assiduously to work on the Bench. He always declined to become a candidate for municipal honours. He was a staunch Liberal in politics and a member of the committee of the Liberal Club. Dr. Waterston was twice married, and leaves one son and two daughters.

DEPUTY INSPECTOR-GENERAL ANTHONY GORHAM, R.N., died at his residence, Glen Jerne, Clifden, Ireland, on January 26th. He took the degree of M.D. of the Queen's University, Ireland, in 1866, and entered the navy in the following year. He received a decoration and special promotion to the rank of Staff Surgeon for his services in Perak in 1876, and after serving in nearly all quarters of the empire, including China, India, Mediterranean, and the various home stations, he retired in 1900 with the rank of Deputy Inspector-General of Hospitals and Fleets, having declined the offer of further promotion in the service. The deceased officer, who was not married, was one of a numerous family of doctors, two of whom, Dr. P. C. Gorham, of Clifden, and Dr. J. J. Gorham, J.P., of London, attended his funeral on January 30th. A younger brother, Dr. John Gorham, died a short time ago in South Africa.

A GLOOM was cast over the Edinburgh School of Medicine for Women at the close of the past week by the sudden death of Miss AGNES ROTHE, a young Danish lady who had taken some of her medical classes in Glasgow, and was completing her course in Edinburgh. The death occurred with startling suddenness at an early hour on Saturday morning. Miss Rothe had been quite well on the previous day; indeed, she had been present at the meeting of the Women Students' Medical Society on Friday evening, and had been in good health and spirits then; about 3 o'clock on Saturday morning she awoke with severe hæmatemesis, and in a few minutes thereafter she passed away. She was living in the Muir Hall of Residence in George Square, and she was able to summon one of her comrades to her assistance; but, as has been said, the fatal issue was almost immediate.

Medical News.

THE anniversary dinner of the Medical Society of London will be held at the Whitehall Rooms, Hotel Metropole, on Wednesday, March 5th, at 7.30 p.m.

THE annual meeting of subscribers to the Royal Medical Benevolent Fund will be held at 15, Wimpole Street, W., on Tuesday, February 18th, at 4.30 p.m.

WE are asked to state that any old student of Charing Cross Hospital who wishes to attend the annual dance at the Royal Palace Hotel, Kensington, on February 13th, should communicate with the honorary secretaries at the hospital.

A "MASQUE of Learning, Mediæval and Modern, being a Pageant of Education through the Ages," devised by Professor Patrick Geddes, will be presented in the Great Hall of the University of London on March 11th and the following evenings of that week, as well as on Saturday afternoon, March 15th.

SIR SQUIRE BANCROFT will give a farewell "reading" of Dickens's *Christmas Carol* on the afternoon of Tuesday, March 11th, at the St. James's Theatre. Sir Squire Bancroft's first public reading was in aid of the Middlesex

Hospital, and the final reading will be given for the same great charity, on the weekly board of which he has served for twenty-five years.

A COURSE of lectures and demonstrations arranged by the Child Study Society will be held during February, March, April, and May at the house of the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W. The first lecture will be given on Thursday, February 13th, at 7.30 p.m., when Dr. James Kerr will speak on brain mechanisms and handwriting. The chair on this occasion will be taken by Sir James Crichton-Browne.

A TABLET with the following inscription has been fixed over the "Coronation Aerial Post Bed" in the King Edward VII Hospital, Windsor: "This bed was endowed by a donation from the fund realized in aid of charities by the 'Coronation First United Kingdom Aerial Post, A.D. 1911,' organized by Mr. D. Lewis-Poole and Captain Windham, by sanction of His Majesty's Postmaster-General, for the conveyance of mails by aeroplane from London to Windsor, and from Windsor to London, in September, 1911, to commemorate the Coronation of Their Majesties King George V and Queen Mary."

THE next Special Post-graduate Course on the diagnosis and treatment of pulmonary tuberculosis at the Brompton Hospital will commence on March 3rd, and will continue for a fortnight. Each morning there will be demonstrations and practical work in the laboratory, and each afternoon there will be clinical demonstrations in the general and special out-patient departments, and in the wards. In connexion with the course a series of public lectures will be given at 4.30 p.m., and on Friday, March 14th, there will be an expedition to the Frimley Sanatorium. The syllabus of the course, the list of lecturers, and other particulars may be obtained on application to the Dean at the hospital.

THE Scottish Red Cross unit, which was stationed at Uskub during its period of service, returned to Glasgow on January 23th, after an absence of eleven weeks. The unit consisted of eighteen members, under the command of Major H. E. M. Douglas, V.C., D.S.O., R.A.M.C. On arrival at Uskub the Welsh unit was joined with it, and they were given a disused Turkish hospital: 137 beds were made, and 637 patients were treated, many being enteric cases. One member of the Welsh unit died of enteric fever, but the Scottish unit was fortunate in having no casualties. The medical officers with the Scottish unit were Dr. H. C. R. Rankin and Dr. C. Stewart Black. Several medical students were among the orderlies.

THE Obstetrical and Gynaeological Section of the Royal Society of Medicine has arranged to hold a discussion on "ventrifaction" of the uterus on Thursday, March 6th, at the Society's rooms, 1, Wimpole Street. The subject will be divided into three parts: (a) Indications for the operation, to be opened by Dr. W. S. A. Griffith; (b) varying technique of the operation, to be opened by Dr. Henry Briggs, Liverpool; and (c) clinical results of the operation, to be opened by Dr. A. E. Giles. It is requested that any one desiring to take part in the discussion will communicate with the honorary secretaries, Dr. Walter Tate, 32, Queen Anne Street, W., or Dr. T. Watts Eden, 26, Queen Anne Street, W., not later than Saturday, March 1st.

A SERIES of reports on blackwater fever in the Tropical African Dependencies, recently presented to Parliament, gives a general idea of the prevalence of the disease. It is interesting to note that in Northern Nigeria, out of eight cases in which details were obtained, all, with one exception, had been living in native-built houses. Of four other cases in which details were not supplied, three lived in native houses and one died in a canoe on the Gongola river. Native houses for Europeans, it is stated, have mud walls, but the floors are usually cemented; the wood used in building is the ordinary forest timber, unseasoned; the roofs are made with bamboo or the midribs of the palm, and roofed with the usual grass thatch. There is no reason to suppose that the usual blood-sucking flies are more attracted to these houses than to the ordinary bungalow, but they are more liable to the ravages of the white ant, common throughout the country. This question of the native house seems an important one and should be further inquired into. The idea now seems to be gaining ground that those who do not take the daily dose of 5 grains of quinine are more liable to blackwater fever than those who do, the conclusion being that blackwater fever is a manifestation of malarial toxicity. Recently much work has been done as to the etiology of this interesting disease, and Colonial reports such as the above should prove valuable, especially from the epidemiological point of view.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 429, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 429, Strand, London, W.C.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Artiology, Westrand, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*.

TELEPHONE (National):—
2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

COUNTRY DOCTOR asks for advice in the treatment of a girl other than operative of a case of enlarged thyroid in a girl aged 18. The enlargement is increasing in spite of thyroid extract and external remedies; there are no other symptoms.

HORNY SCAR.

M. desires suggestions for the treatment of a large scar of upper arm, contracted after a burn in infancy, which has for a few years taken on a horny character. Patient is a female over 40 years old, and her arm is contracted into a flexed position. The horn is heaped up at one part to a thickness of $\frac{1}{2}$ in., and a certain amount might be removed mechanically. Other parts are divided up, showing tender cracks in the skin. In other places the scar is studded with small horns as the sole of a boot is with nails.

ANSWERS.

PORTABLE TYPEWRITERS.

A SURGICAL correspondent writes in reply to a recent question on the subject to recommend the Corona, made by the Folding Standard Company, U.S.A. The price is ten guineas. In its case (which looks like a small dressing case) it measures 11 by 9 $\frac{1}{2}$ by 4 $\frac{1}{2}$ in. and weighs 8 $\frac{1}{2}$ lb. Its working is delightfully easy. It is truly portable, for it can be used without removing it from the case; when that is open, and the paper carrier turned back, it is ready for work. I frequently write with it when sitting in an armchair with the machine on my knees. After this eulogy I had better add I know nothing of either makers or sellers of the machine.

LETTERS, NOTES, ETC.

CORRECTIONS.

IN the paragraph on foul breath, in the JOURNAL of February 1st (p. 264, line 13 of paragraph), the words "offensive breathing" should read "oppressive breathing."

A misprint occurred also in Dr. Clippingdale's note on a royal hoax, which appeared in the same issue of the JOURNAL (p. 264, col. 2). The authority on which the note is based was Lady Llanover.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|-----|
| Eight lines and under | ... | ... | ... |
| Each additional line | ... | ... | ... |
| A whole column | ... | ... | ... |
| A page | ... | ... | ... |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postis restante* letters addressed either in initials or numbers.

APPENDICITIS:

A PLEA FOR IMMEDIATE OPERATION.

By EDMUND OWEN, F.R.C.S.,

SURGEON TO THE FRENCH HOSPITAL, AND CONSULTING SURGEON
TO ST. MARY'S HOSPITAL, LONDON.

IN April of last year a short paper of mine in the *BRITISH MEDICAL JOURNAL*, in which the word *quickness* was associated with the disease appendicitis, drew forth a good many letters. But the correspondence drifted into a wordy warfare in which the main object of the paper became somewhat obscured. When controversial ammunition seemed to be running short, the Editor closed the discussion, and announced that the subject would be reopened at an evening's debate before the Medical Society of London. And may the hope be expressed that in the forthcoming discussion, speakers will be so good as to confine their remarks as closely as possible to this question—"Is the best result in the treatment of appendicitis to be obtained in the greatest number of cases by immediate operation or by temporizing?"

The question of *when* to operate in a case of appendicitis is often one of extreme anxiety. The general practitioner finds it difficult; so may the operating surgeon. The only person to whom, in my experience, it appears as a simpler matter is the "illustrious" physician. He likes to take time in making up his mind; but whilst he is musing the fire burns. He sometimes prefers to see the presence, or even to await the development, of nearly all the classical signs of appendicitis before giving his consent to an operation, and his help in such circumstances is apt to be an embarrassment to the family doctor and to the surgeon, and to prejudice the patient's prospect of recovery. I have deliberately used the word *illustrious* in connexion with the physician, so that no physician may take it to himself that there is anything personal in the matter—unless, indeed, he deems himself to be really "illustrious." Perhaps, after all, the *illustrious* physician does not actually exist, any more than the illustrious surgeon—that he is but a figment of imagination—so no slur can possibly be conveyed by my words on any individual Fellow of the Sister College.

I will go so far as to say that patients with acute or subacute abdominal troubles ought not to be considered as medical cases at all. I remember some years ago a physician to a children's hospital writing upon the subject of intussusception, and speaking slightly of what he called the *apothecosis* of surgical measures in the treatment of that disease. But if every child with intussusception were submitted to operation as soon as the diagnosis was made, much of the terror of this disease would be removed. Surely it is safer to deal with an intussusception directly and gently with a surgical finger and thumb, than to try and unravel the intestinal sheathing by forcible and blind distension of the large intestine. But that is not the question for this evening, and I drag it in only to strengthen my claim that true progress in acute abdominal disease is in the line of quick surgical assistance. Acute or subacute disease of the appendix is no more a "physician's case" than is one of septic gangrene of the foot, whitlow, or strangulated hernia, to each of which diseases, by-the-by, appendicitis has considerable pathological resemblance.

"UNNECESSARY" DEATHS.

If we look around the circle of our personal friends and acquaintances, say of the last twenty years, we can scarcely fail to realize the fact that a considerable number—or, at any rate, several—have dropped out as the result of blood poisoning started by disease of the appendix. Several colleagues and friends of my own have thus needlessly perished. Indeed, medical men, who in my opinion, ought to enjoy an exemption from all disease, have paid a heavy toll to appendicitis. Not a few have been rescued by prompt operation, but too many have not accepted for themselves that definite line of treatment which, in like circumstances, they would unhesitatingly recommend to those for whose health they were responsible. But

unfortunately, medical men make, as a rule, bad patients—bad in this sense, that they do not readily hand themselves over, bodily and entirely, to their *confères*, and bad also in that the *confère*, when he has undertaken entire charge, is apt to hesitate to insist upon an extreme measure lest his views should fail to meet with the full acceptance of his friend. The adjective which I have applied to most of these deaths as "unnecessary" would not so readily be applied to a death from typhoid fever, cancer of the liver, or pneumonia, for instance, but it was unnecessary in that if only an early operation had been resorted to no calamity would probably have taken place. In Surgery, as in the affairs of the State, what is to be desired is the greatest good for the greatest number; and if we could have back amongst us those friends whom uncontrolled appendicular disease has taken away, and could start treatment afresh, and begin it by early removal of the inflamed appendix, many of them no doubt would still be with us. But, unfortunately, the nature of our work is such that we cannot have our failures back and try them over again in a different manner. The barrister who is not satisfied with the result which his conduct of a case has received from any particular Judge, can take the case up to another court and have it tried over again, altering his treatment, may be, and securing, perhaps, a different verdict. But there is no Court of Appeal for the surgeon who has been unsuccessful in his management of a case. It behoves him, therefore, so to act that he may take no needless risk when entering into a contest with his great Adversary, the Man with the Scythe. Nearly all these deaths, I insist, were unnecessary, and the imaginary illustrious physician would himself admit, as he looks back, that not a few of the cases which he has seen in consultation might have been saved if earlier operation had been resorted to. Though there is no Court of Appeal open to the unsuccessful operator, the physician must feel that *his* branch of the Profession is less closely shut in, and I can scarcely imagine the physician, in his practice, being placed in a position of such intense anxiety as is the operating surgeon when he is suddenly called upon to insist upon the necessity of an operation in a case of appendicitis, whilst surrounded by a group of the patient's friends and relations unconscious of near danger, and expecting to hear smooth words.

UNCERTAINTY CONCERNING ACTUAL CONDITION OF
APPENDIX.

Appendicitis is different from most other acute diseases in this, that one cannot tell exactly what is the state of affairs without making an incision. The senses are prevented in their working, in that the deeply-lying appendix is unapproachable. In the case of pneumonia, bronchitis, or heart disease the ear tells precisely what is wrong and how things are going; when the liver, the kidney, or the bladder is in trouble the sense of touch imparts valuable or precise information, whilst in most cases the eye gives important help. But an inflamed appendix can no more be felt than seen, and it is impossible to inform oneself of its exact condition. Holmes, the poet and physiologist, suggestively remarked that one cannot tell what wood a table is made of until he lifts up the cloth. And so it is with the disease in question: one cannot tell the exact state of the appendix until it has been exposed to view by operation.

I should think that no part of the body has caused so many surgical surprises as the appendix. In one case the symptoms of disease have been uncertain, or definite but slight; and when the surgeon exposes the appendix he finds it mortified. In another case he thinks that he can distinctly feel it in the iliac fossa; but in the operation not only is it absent from its proper situation, but, after half an hour's anxious search, he finds it in the depths of the pelvis or tucked up behind the liver.

In other cases, where the symptoms have been unmistakable and even acute, much to his surprise, the surgeon finds nothing worse than a little catarrhal inflammation in the vermiform process. But the commonest surprise of all is the discovery of a perforated appendix when the symptoms have been slight and the operation has, by good fortune, been undertaken early. I think that the time will come, and that shortly, when these perilous associations of appendicitis will be obviated;

* A paper read before the Medical Society of London, February 10th, 1913.

this, however, can only be by a general agreement that no case ought to be allowed to drift, but that operation should be resorted to as soon as the presence of disease is recognized.

THE "QUIET STAGE."

It is generally considered that operations done on about the fifth or sixth day of the disease have a particularly high mortality. The explanation is simple: precious time has been lost. It does not mean that the surgeon is not to operate on the fifth or sixth, or any other day: it means that the disease has gone on developing from, perhaps, an apparently simple beginning, that by this time, as likely as not, an abscess has formed, and that the surgeon's chance is by so much the worse. Further, it does not mean that if the operation is postponed to the seventh, or eighth, or to any other day, the chances of recovery would be better. With, or without operation the patient may die; but the surgeon must do his best without regard to omens or statistics. It is out of the question now that he could advise waiting for the oncoming of the "quiet stage" before operating. The quiet stage in such a case may be nothing less than the silence of death itself. There would be no "fifth" or "sixth" or any other ominous day in the course of an appendicitis if operation had been promptly resorted to. And as for the so-called "quiet stage," I think it a misfortune that the specious term has ever been applied to appendicitis. But it has a great attraction; and even in medical conversation it is often spoken of as if there were actually a period in the course of the disease in which all urgent symptoms, local and general, passed away, and Nature seemed to be pausing in order that the surgeon might have a free and unhampered chance of putting a happy end to the trouble. Of course, in many cases the urgent symptoms do so clear up, but who is to know whether in any individual case they are going to subside or to rush forward with hurricane speed? No one can possibly tell; and it is because of this uncertainty that recourse to immediate operation offers the greater safety. One hears people talking of the oncoming of the quiet stage in appendicitis as if it were as clearly marked in the pathological timetable as is the crisis in pneumonia, or the fall of temperature in a remittent fever. It may prove, however, but a Will-o'-the-wisp.

WALLING OFF OF THE APPENDIX.

Associated with the theory of a "quiet stage" in the general run of cases of appendicitis is that of a "walling off" of the area of disease. In some cases there is, no doubt, a walling off, and it is pleasant when operating on them to find the appendix shut off and lying handy in a small abscess. But in hurricane cases there can be no attempt at a walling off. Nature seems to be taken by surprise and robbed of all chance of building up protective earthworks. One could scarcely expect a gangrenous appendix to glue itself to neighbouring coils of bowel, or to cause the production of helpful plastic lymph. In these furious cases there is usually no attempt at "walling off," so the germ-laden, sero-purulent exudation may be found tracking across to the opposite side, or draining down into the pelvis. There is evidently no more chance for a "walling off" than for the on-coming of the "quiet stage."

A FOOL'S PARADISE.

There is apt to be a Fool's Paradise stage in appendicitis, and it may come early or late in the course of the disease. Its occurrence is somewhat in this manner: A patient has been complaining of pains in the abdomen for a day or two, with some slight tenderness in the right iliac fossa; the pulse has been, perhaps, at about 100 to 120, and the temperature at 101° F. After a baddish night the man wakes up and finds that the pains have gone, and that he is better in every way. The pulse has dropped, may be, to 90; the temperature is a degree lower, and the man's appearance is much better. His nearest relation, who has been in to see him, is delighted with his improvement. The nurse also recognizes a great change, and the family doctor admits that since his visit of the previous night a marked alteration has taken place.

But in spite of all this, the lower part of the right rectus remains motionless or rigid; there is still a resistance in

the other muscles over the iliac fossa, and some tenderness on pressure over the caecal region still remains. The patient is not actually better; he is worse. The state of his pulse and of his temperature is of no real clinical value—it is, on the other hand, actually misleading, and the sensations and the aspect of the patient are certainly not to be taken as indications of improvement in the presence of persistent rigidity of the lower part of the abdominal wall. What exactly has happened to produce this sudden change one cannot say. As likely as not, the swollen appendix has given way to internal pressure, and some thick muco-purulent fluid, or even a solid concretion, has escaped. Or it may be that an abscess in, or close to, the appendix has burst its bonds. At any rate, some deeply seated tension has been relieved and quiet has been restored—at least for a time.

This remission of symptoms is not seen in the course of every case of appendicitis, but it is fairly common, and its occurrence is apt to be fraught with great danger, especially if it so happens that the consultation with the physician has been arranged for that particular morning.

Of all those who are in connexion with the case, the surgeon is the least likely to be deceived. The continued rigidity of the abdominal muscles (which probably is still marked) is evidence to him that the storm-warning must not be lowered, although some heavy clouds have been rolled away and the sky looks brighter. He is still anxious to open the abdomen and so to assure himself; but in the altered circumstances he may be tempted to give way. Indeed, unless he is unusually firm—obstinate, his friends call it—he will give way. And perhaps by night the urgent symptoms have returned, the patient breaks out in a sweat, or has a rigor, and after a loss of twenty-four precious hours, leave to perform the necessary operation is given. The surgeon then finds a diffuse abscess, and possibly the patient is so bad that he dare not venture to search for the ruptured appendix. How greatly does he then regret that he did not open the abdomen as soon as the diagnosis was definitely made!

If only the figures from Nature's clinical case-book could be shown upon the blackboard of how many times, say in the last year, the abdomen was opened too early in appendicitis, and how many times too late, there would be no need for me to be appealing for more resolution and promptness in the treatment of this disease.

ANGER OF WAITING.

In the correspondence to which I have referred, Dr. F. J. Dixon urged that it was better "to take a little increased risk by waiting than subject a great many patients to unnecessary operations." But unfortunately the man who is waiting cannot measure or control the risk to which he is subjecting his patient. A delay of a few hours in one case may prove fatal; in another case it may do no harm; but as one cannot possibly tell in which it may be harmful, delay is best avoided altogether. Dr. Dixon rightly hopes that the surgeon would not be in such haste to operate as to open the abdomen for a passing attack of colic. Such haste as that would, indeed, be blameworthy; but if in any ease at a consultation held a few hours later, it could not be positively settled whether the appendix was in trouble or not, the greatest safety would be found in looking at it. In a case of doubt, localization of the symptoms of "colic" in the right iliac fossa should render one anxious to exclude appendicitis, and this can be done only by making a small incision.

Mr. Paterson wrote that fifteen hundred deaths take place in England and Wales every year from appendicitis—"unnecessary deaths," I have called them. If all of these cases could be diagnosed and operated on straightway, how many could be saved? Why not every one? And the only reason that can be urged against their all having the benefit of an immediate operation is a vague fear that, if the practitioner were to make it part of his working creed that such treatment was advisable, he and his surgical associates might be regarded as needlessly enterprising, or "too fond of the knife"—to use a common expression. But if, as would happen as the result of their treatment, pretty nearly every one of their cases got well, it would not, after all, greatly matter.

When every practitioner holds these views the Golden Age in Surgery will have begun to dawn. And then the operator who has his fair share of cases of appendicitis

throughout the year will be able to say at the end of it "I have not lost a single case, because I have got them all early"! And this will be by the family doctor, the physician and the surgeon all agreeing that as soon as over the diagnosis is made that an appendix is inflamed it should be removed; and that if there is doubt about the diagnosis it must be settled by the making of an incision, the making of the incision being part of the scheme for arriving at a sure diagnosis—just as one employs the rays in an obscure case of hip injury.

APPENDICITIS AND THE PUBLIC.

But before this improvement can take place public opinion will also have to be educated. At present the greeting given by the friends to the surgeon who has been called in is apt to be, "We do hope that you will not think it necessary to operate." The mention of the word "appendicitis" has already caused alarm in the household, and the people have heard of so many deaths from that complaint after operation that they are inclined to attribute the fatal result to the operation rather than to the disease. Our Profession recognizes the fact that it is not well for the Public to be kept ignorant on medical matters, and from the platform and by the newspapers much useful medical knowledge is being constantly and widely imparted. Thus, on such questions as the Listerian method, hygiene, food and drink, tuberculosis, and infection the public have learnt much, and the time has now come that they should be told something about the danger of delay in appendicitis; that in the case of acute or obscure pain in the abdomen they ought at once send for their doctor, and if he advises that a surgeon be called in, no opposition should be urged to the proposal of an operation. They should be made to understand that it is not the operation but the delay in performing it to which a fatal result should be generally attributed.

Not long since I was called to operate on a boy from a large school with whose obscure abdominal pains the Matron had deemed herself competent to deal! Persons with abdominal pains are not cases suitable for treatment by Matrons or First Aiders; for every case of the kind the doctor should be *at once* called in. If after making his examination he is able to say that the complaint is not serious, so much the better. If, on the other hand, he finds the appendix at fault, the case at once becomes serious; and neither he nor anyone else can say how serious it may prove if it is allowed to drift.

TWO SERIES OF CASES.

In imagination let us take a hundred cases of appendicitis, from the beginning of their manifest infection, and form a rough estimate of the course which they will run, basing our guess on what we have seen in other instances. It might be fair to suggest that 30 of them would probably get well with what is called "medical treatment." This might be too large a proportion, but it may pass. Of the 70 remaining cases perhaps ten might have subsequent slight local troubles, from which they also may get quite well without active help, whilst an equal number might have recurring attacks which rendered them chronic dyspeptics, or even, from time to time, suddenly and most inconveniently took them from their occupation and threatened them with disaster. At last, finding the appendix a constant source of worry and anxiety, they had it removed when the trouble was in the "quiet stage." Accepting this estimate, there are still 50 cases left which will not fall into any one of those three groups. Five or six of them, perhaps, will go on with alarming rapidity, and when a day or two later the abdomen is opened—tardily opened, I will say—the appendix will be found gangrenous or perforated, with, may be, an unsuspected abscess in its neighbourhood. It matters not who the surgeon is who operates, some of those patients will certainly die, the proportion being settled, apparently, by blind chance. Of the remaining serious cases which do not run a hurricane course, some will be associated, perhaps, with subphrenic abscess, some with pelvic abscess, some with diffuse suppuration of the abdomen, with intestinal obstruction, or with septic intoxication. The list of the later complications of neglected appendicitis is long and appalling, and they claim a large number of victims. They ought all to have been avoided. It is impossible even to make a guess of the actual figure

of the fatal cases, so, being unknown, let it be called *a*—an *x* percentage out of the fifty is lost.

Now, by way of contrast, let another hundred cases of appendicitis in the earliest stage be taken, and let every one of them be operated on as soon as the diagnosis is made. By the light of our former series, it is at once seen that 40 cases have been submitted to operation which would have recovered without surgical aid. I admit it. But has any harm been done by operating? Have any people been wronged by the operation or any surgical principles violated? At any rate, those people, 40 of them (for they have all recovered), will not run the risk of having appendicitis again—and that is something to be thankful for. Then, by the early operation, we have put right those cases of slight relapsing forms of the disease; these ten people have been saved the misery of an annoying chronic dyspepsia—which is a common, and often unrecognized, complication of a lurking appendicitis. We have made those twenty persons absolutely safe and happy. There yet remain 50 individuals who, in the other series, became the subject of local and diffuse abscess in the abdomen and pelvis, or were attacked by some form of blood poisoning. We have got them also safe, every one. And we have not lost a single case out of the hundred—because the appendix was removed as soon as it was found to be diseased. What a contrast between the two series! Yet in the beginning the patients were all alike—all apparently simple cases of appendicitis. There can, I think, be no difference of opinion on the subject—*x per cent.* of the first lot of cases was lost because of want of surgical enterprise, whilst not a single death occurred in the second series. So that early operation in appendicitis gives *x per cent.* the better result.

Then, why is it that early operation in appendicitis is not the rule? The reply may be that it is all very well to talk about *series of cases*, but when the family doctor is in attendance on any particular case and is surrounded by anxious parents and apprehensive friends, he has to disregard the average and think only of the *individual*. That, in other words, circumstances alter cases. Still, if circumstances do alter cases, they ought not to disturb the principles on which surgical cases should be treated. But hitherto there has been no principle laid down by general professional consent and teaching in England as to what should be the rule and guide in the treatment of appendicitis. But it must come ere long. And when it comes it will be, I think, in some such form as this, "As soon as it appears fairly certain that the appendix is inflamed it should be removed by operation." The rule of treatment should be made as definite and rigid as is that for the treatment of a strangulated hernia or a cancer of the breast.

STEALTHY APPENDICITIS.

There is a small group of cases of appendicitis of extreme interest and importance to which special attention should be drawn in a paper of this sort. Two or three of them, I dare say, might be found in every hundred cases, and they come like a thief in the night. Let me give an imaginary clinical sketch of one of them:—An athletic young man who has never known a day's serious illness, has been for a long bicycle ride, and, returning home, has eaten a hearty supper, and gone to bed dead tired. In the night he wakes up feeling very ill; he vomits, and then, finding himself much better, goes back to bed and falls asleep. But in the morning he is not inclined to get up, and as he complains of pain, his mother calls in the doctor, and, meeting him in the hall, says that the boy had eaten something for supper which made him sick; that he is better now, but she hopes the doctor will not let him go to the office that day. He looks fairly well, and he is lying flat on his back with his knees not drawn up; his pulse-rate is scarcely quickened, and his temperature is but slightly above normal. May be, his face is a little flushed and anxious; he has some slight tenderness in the right iliac fossa but there is no swelling to be made out. Perhaps there is some rigidity of the neighbouring muscles. He is strictly dieted, and a fomentation is applied all over the abdomen. In the evening he is not so well, but he has not vomited again, and he says that the fomentations have eased his pain. The doctor is by no means happy about him, but he says some cheering words, and promises to come round early in the morning

to see him. The patient passes a very restless night, and when the doctor examines him he finds that there is a marked contraction of the lower part of the right rectus and more tenderness in the fossa. An operation is talked about, but, for some reason or another, it is not done till the evening. A gangrenous and perforated appendix is then removed, and a large quantity of foul sero-purulent fluid wells up; a drainage tube is inserted, and fomentations are reapplied.

What is the prognosis? Is it not quite likely that the lad will die? We all meet with these cases, quiet and deceiving in their origin, and formidably quick in their course. The surgeon wishes that he could have been called in the day before; but if he had been called in would he have been allowed to operate? If his rule had been to urge operation in every case as soon as he suspected the existence of appendicitis, and he had been allowed to follow it, he would certainly have increased the chances of recovery of this man. For aught that one knows, every early case of appendicitis may be going to turn out like this—no one can tell. Probably it is always a question of the virulence of the germs or of the vulnerability of the tissues—or both—which determines the pace at which the local changes will work out. And as one cannot possibly have any knowledge on either point, it will be far safer that the surgeon should act as if he suspected in each case that he had virulent germs and vulnerable tissues to deal with. He should banish all hesitation.

"WHEN TO OPERATE IN APPENDICITIS."

Supposing that there is a surgeon here who does not hold these views in connexion with the treatment of appendicitis, and some one asks him, as a matter of information, what are his guides as to when an operation should be advised, he may not find it easy to reply. The pulse and temperature may be normal, and the patient's aspect may be good although the disease is far advanced, and there may be no fullness in the iliac fossa and but slight resistance, yet the case is in urgent need of help. It is unsurgical to wait for some beacon-flash telling him when in any particular case he should advise operation, and I think that he would find it difficult to satisfy his questioner. On the other hand, if he held the opinion which has been forced upon most of us, he would simply reply, "I would urge operation as soon as ever I suspected that the appendix was inflamed." That is a clear answer; it cannot be misunderstood.

And amongst the many great advantages of the early operation is this, that no risk is run of the need of any of those secondary procedures which are apt to be called for if the case is allowed to drift on to suppuration. After the early operation the wound is closed once and for all; no drainage tube is used, and there is no fear of a future ventral hernia or of a bulging at the scar, of inflammatory adhesions or intestinal obstruction.

"LOOK AND SEE."

It is constantly argued that if the appendix is removed as soon as it is believed to be inflamed, some cases will be submitted to operation in which, after all, no disease of the appendix is discoverable, and that many others will be so dealt with which might probably have got well without any active surgical help. This I fully admit; but it is the only argument which can be raised against the early operation. However, the admission by no means weakens my appeal. We sometimes hear the same sort of criticism made in the course of our practice by persons who have no claim to express any opinion of value in the matter—"This boy," says a proud mother, "had an attack of stomach-ache last month, and the doctor wanted to have him operated on. But his father wouldn't allow it, and the boy has been perfectly well ever since!" That valiant decision exalted the man in his wife's opinion, and at the doctor's expense: but my sympathy is all with the doctor. And it is more than likely that if the boy got another attack of the kind, and the father again stayed the surgeon's hand, the result would be disastrous, and the father might regret that he had ever stood in the way of operation.—The conclusion of an attack of appendicitis is not infrequently associated with regret.

Let me briefly give a clinical sketch of the imaginary case just mentioned:—The boy had been sitting on damp

grass watching a cricket match, and next day he was seized with acute catarrhal appendicitis. The doctor found him with a pulse of about 120; his respirations were quick: he had vomited, and he complained of pain and tenderness in the right iliac fossa. The doctor, perhaps, had recently had a case with like symptoms in which, when an operation was tardily resorted to, a mortified appendix was found in a stinking abscess, and the patient had snuk. He dreaded a repetition of the scene, and he was anxious to be in time on this occasion. And he was right!

It is because of the two-fold uncertainty which must always be associated with appendicitis—uncertainty as to the actual state of the disease, and uncertainty as to the course which it will take—that the surgeon should be anxious to *look and see*. But, as it is, there is no general agreement as to what should be the exact procedure. One medical man may urge treatment by rest and opium, because he has seen several patients get satisfactorily over an attack when thus dealt with. Another may insist that treatment should be by castor-oil or Epsom salts, because he has known it answer well; and a third will swear by starvation, fomentation, and enema. And no one can affirm that in any case the adoption of one of these methods may not meet with success. But after dealing with a few more cases on such lines he would scarcely fail to be pulled up short, and to find his faith rudely shaken.

A whist-player with five trumps in his hand may win the trick although he leads from his short suit, but a fuller acquaintance with the game will prove to him that it is not safe play. In the course of time the experience of the many has been crystallized out into *Rules*, which intelligent players find it to their advantage to observe. And so is it in Surgery: out of the experience of the many, definite principles of practice are constantly being laid down to become in due course accepted as *Rules*. And, judging from what one sees and hears, the Rule is gradually being established in this country that a case of appendicitis should be operated on as soon as ever the diagnosis is made—within the first twelve hours, if possible—that the patient will then not only get well, *almost for certain*, but will get well very quickly.

EXPLORATORY INCISION.

But would it really be a terrible calamity if an incision were made over a suspected appendix in a case in which it was not actually affected? For my own part, I give the question an unhesitating "No." A cleanly-made opening into the abdomen can do no harm, and I look forward to the time when it will be no unusual thing to hear that such and such a surgeon has been looking into an abdomen, or, to be more precise, has been passing his finger into an abdomen for this purpose, and that, after all, there was nothing wrong with the appendix. The dread of advising an incision in a case where the appendix might be found little or not at all affected, is greatly exaggerated. The surgeon's reputation as a diagnostician is of far less importance than the safety of the patient, and if his fruitless act be called a *mistake*, at any rate, it is a mistake on the right side. The surgeon who is haunted by the fear of making a mistake has made an unfortunate choice of his Profession. I can remember the time when a surgeon was afraid to cut into a mass of inflamed tissues lest, by chance, there should be no pus found. He preferred to "wait for fluctuation" (the expression even yet sounds familiar). But now that one understands the danger of acute inflammation and of tension, one unhesitatingly makes a free incision into an area of acute cellulitis so as to end painful disease and diminish the risk of sloughing, and of other effects yet more serious. But the same surgeon is still apt to be content to dally with, and hover helplessly over, an inflamed appendix because he is not "quite sure." In politics the motto "wait and see" may suffice: for the surgeon in a case of possible appendicitis it should be "*Look and See*," and Medicine and Surgery will not be in a satisfactory state as regards the treatment of appendicitis until the prompt making of a small iliac incision becomes part of the routine treatment. An inch incision through the abdominal muscles will suffice if it is made quite early, but an incision of 6 in. or more may prove ineffectual if it is delayed.

I have long since made up my mind what I shall do if I, in my turn, become the subject of appendicitis—I shall forthwith call in a surgical friend, and if he says "Yes, I think that the appendix is at fault," I shall ask him if he would mind my getting another surgeon (not a physician) to come and see me with him for the purpose of confirmation; and on the diagnosis being confirmed, I shall beg him *at once* to operate. And if these principles were adopted in all cases of appendicitis, would not the mortality of the disease be lowered by more than 90 per cent.? I think so.

I have not hurriedly formed the opinion that the greatest safety in appendicitis is in the early operation. And certainly I did not start with that opinion: I have been steadily driven to it. I have seen a fair share of cases of appendicitis, with some of which I have been associated from the beginning of the attack; to more I have been called in when the disease had already made considerable headway, and for others my help has been asked only towards the close of the chapter. And my deliberate opinion is that if it were generally recognized that safety lay in prompt operation, the present high death-rate in the disease, as I have already said, would be greatly lowered.

At various times in our professional life we have to study our bearings, take soundings, and re-shape our course. How greatly thus has our treatment of cancer of the breast, for instance, improved in recent years, for even if there is a slight margin of doubt in that diagnosis we now urge immediate and complete operation. There is no waiting for the appearance of signs which shall render the diagnosis so clear that there is no chance of mistaking a chronic inflammatory thickening for a malignant infiltration; the patient and not the tumour is now given the benefit of the doubt, and the improvement in our results has, in consequence, been most remarkable. In diphtheria, too, antitoxin is injected without a moment's delay; and in the case of suspected renal calculus the kidney is explored for a likely stone even if the x rays fail to reveal its presence.

MISLEADING CONDITIONS.

Whether all the views advocated in this paper prove acceptable or not, there is, at any rate, one point which ought to receive a more general recognition: it is the reference to the fact that there may be a comparative absence of clinical signs in the presence of advanced and perilous disease in the appendix. It does not at present seem to be universally realized that the pulse and temperature of a person may be normal in spite of the appendix being gangrenous or perforated; that in some of these stealthy and rapid cases there is absolutely no fullness in the fossa; and that if the chief pathological change in the appendix is gangrene, there need be very little local tenderness—for there is no sensation in dead tissue; that as there is no sensation in a mortified appendix, there need be no reflex rigidity of the abdominal muscles covering the fossa; that there being no excitement of pulse or temperature, and little or no local pain or tenderness, the patient may make light of his trouble and that his aspect may be deceptively cheerful. Thus, in the most dangerous class of cases of appendicitis there may be but little either to cause anxiety or to attract serious attention. Every operating surgeon will bear one out in this, and will agree that, for the happiness of all concerned, the family doctor should never sit pondering over his case of suspected appendicitis, but should *at once* call in surgical aid. If the surgeon then says that because he is not sure he would rather wait a little, at any rate, whatever happens, the doctor will not afterwards have anything to reproach himself with. But I do not think that there are many surgeons who would counsel delay; we have all seen enough of the danger of waiting.

In no respect, I think, has improvement in surgical treatment in the last quarter of a century been more marked than in that of strangulated hernia. Taxis and the hot bath happily have become things of the past. The general practitioner sends his patient into the hospital without hesitation or delay, or calls in the surgeon for immediate operation: and instead of there being now a high death-rate from strangulated hernia, statistics would show a most remarkable improvement. And what, in my opinion, is wanted at the present time is a similar

waking up of the profession with regard to the treatment of appendicitis.

We have heard of the sailor who, when his ship was in action, saw an unexploded shell, with a time fuse attached, land upon the deck. He did not wait to see the development of events, but, taking the shell up in his arms, dropped it over the ship's side out of harm's way. An inflamed appendix is a shell with a lighted time fuse, and though in any case it may happily fail to explode, it is far safer to lift it out at once and drop it overboard.

In the course of this paper scarcely a word has been said as regards alternative methods of treatment, for, in my opinion, *there is no place for the discussion of general measures until after the inflamed appendix is out.*

Whilst waiting for leave to operate, nothing whatever should be given by the mouth, and no fomentation or water-dressing should be used, because wetting the skin spoils the antiseptic effect of the tincture of iodine, which should at once be freely and widely painted over the region in preparation for operation. But there will be plenty of scope for treatment after the appendix has been removed, and especially so in those cases in which the blood or the peritoneum has already been poisoned by absorption.

The discussion at the present time should be directed towards the solution of the important question as to whether immediate operation or temporizing ought to be the rule in the treatment of appendicitis. If the answer is in favour of immediate operation, such subjects as that of the choice of anaesthetic, the routine washing out of the stomach before the patient leaves the table, the administration of opium, or of purgatives, may well be referred to; but the main question should first be settled. And in a meeting such as this the answer will be likely to prove useful towards the drawing up of a Rule for the guidance of the practitioner in the treatment of every case of appendicitis.

THE FUNCTION OF THE APPENDIX AND THE ORIGIN OF APPENDICITIS.

BY

EDRED M. CORNER, M.C., F.R.C.S.,

SURGEON TO THE CHILDREN'S HOSPITAL, GREAT ORMOND STREET,
AND TO ST. THOMAS'S HOSPITAL, IN CHARGE OF THE SURGICAL
ISOLATION WARDS AND OUT-PATIENTS, ETC.

SHORTLY after his death, which took place so lately, a paper by Mr. C. B. Keetley was published in the *Annals of Surgery* about the function and value of the appendix. Both he and Sir William Macewen regard the appendix as an actively useful and valuable organ not to be sacrificed lightly. Their opinions are based largely upon clinical, and therefore complicated, observations. Other observers, such as Mr. W. J. Mayo, incline to the other extreme—that the value and function of the appendix is so small that it is absolutely inconsiderable when compared to the dangers which it may cause. When the enormous number of people are considered who have had their appendix removed and are in perfect health, one cannot but sympathize with the latter view put forward. Yet as a matter of scientific interest the appendix has a function; and, when removed, that function is undertaken by neighbouring tissue, and the patient is relieved of a passive tube containing actively poisonous material. This view I advocated in the Erasmus Wilson Lectures delivered before the Royal College of Surgeons in 1904,¹ and, in view of Mr. Keetley's recent death, shall content myself with restating them. This is done in four sections: The natural history of the ileo-caecal region, the physiology of the appendix, the development of the appendix, and the pathology of chronic typhlitis and appendicitis.

The Natural History of the Ileo-caecal Region.

Food in the mouth is reduced by the action of the teeth to a more or less pulpy condition, in which state it enters the stomach, where it is further broken into fragments by the action of the hydrochloric acid, pepsin, and churning muscular movements. The casein of our primitive natural food—milk—is precipitated and also fragmented. The

pylorus, the smallest portion of the alimentary canal, allows or should allow, no large pieces to pass into the duodenum. The work of the stomach and mouth may be regarded as chiefly, if not entirely, preparatory to chemical digestion and absorption and to partake of the physical nature of fragmentating the food. The more perfect the work of the stomach the more completely will the food be reduced to a molecular condition, and consequently the more perfectly will it be adapted for the chemical action of the bile and pancreatic secretions. The next twenty odd feet of the small intestine are given over to these chemical changes and the absorption of nutriment. The products of digestion having reached the ileo-caecal valve, it is the duty of that sphincter only to allow water, soluble material, and very small pieces of indigestible debris to enter the caecum. There are similarities in the physiologies—that is, homologies—between the pylorus and the ileo-caecal valve. The former is the portal between fragmentation on one hand, and chemical digestion on the other; the latter stands between chemical digestion and specialized absorption on the one hand, and possibly excretion and the absorption of water on the other. The stomach prepares food for the small intestine, the caecum for the large.

Fluid or semi-fluid material is passed from the small intestine through the ileo-caecal valve into the caecum. The latter is not adapted for the carriage of fluid by peristalsis; it is too large and thin-walled to contract efficiently unless it is tightly distended like the bulb of a Higginson's syringe. In addition, in man gravity works against it. As a result, the faeces must remain in the caecum until the absorption of water from them and the addition of mucus have rendered them of the proper consistency for their transit along the large intestine. Hence it is easy to understand why the caecum is so often the most capacious part of the large bowel, and why at operations, particularly for intestinal obstruction, surgeons so frequently find it distended out of all proportion to the rest of the alimentary canal, the bowels being full of fluid.

Hence, just as there is a natural pause for food in the stomach, so is there another for the products of digestion in the caecum; and in both the contents are prepared for their course in the succeeding part of the alimentary tract. To turn to the pathological significance of this halt, pause, or rest, it will be seen at once that the caecum is the breeding ground for bacteria *par excellence* of all parts of our intestine. The enumerations of the colonies from different parts of the alimentary tract bear this out, and have proved that colonies of bacteria are more frequent by hundreds and thousands here than in any part of the intestinal tract, even after a period of starvation. And it is only to be expected that this difference will show manifold increase when food is taken. It is now very easy to understand why Nature has established so large a storehouse of lymphoid tissue in the ileo-caecal region—to furnish leucocytes and protect the body from the bacteria, to which region the appendix is an intestinal "tonsil," an index of the fermentative processes which are going on within the caecum, a culture tube for the bacteria therein contained. Hence the very great frequency of its inflammation—appendicitis.

It will now be seen that there is strife between the micro-organisms and lymphoid tissue in the caecum of every living being. Hence the gradual disappearance of the lymphoid tissue as age advances. If the strife becomes a little more severe than it is ordinarily in health some inflammation about the ileo-caecal region will result, such as after a dietetic indiscretion. In the very great majority of cases this inflammation in the ileo-caecal region shows itself as appendicitis. In consequence, appendicitis may be regarded as a result of an exaggeration of the fermentative processes natural to the ileo-caecal regions of all.

The Physiology of the Appendix.

It has long been taught that this organ was functionless, and that most probably in this lay its apparent incapability to resist the attacks of disease. That it represents the terminal portion of the caecum, which has become differentiated in development, is undeniable. But that it is functionless is undoubtedly untrue. Like the rest of the intestinal mucous membrane, that of the appendix has numerous glands, whose secretion has apparently an insignificant digestive action on all foods.

As little, if any, contents of the caecum ever enter the appendix, any digestive action it has must be of the smallest, whilst its absorption of products of digestion cannot be greater.

To sum up this phase of intestinal physiology: In the small intestine the products of digestion are fluid, and are being continuously passed onwards by peristalsis; the caecum is the first great "resting place" for these products since they have left the stomach; the large intestine, as its name implies, is of greater calibre than the small, and is more suited for the carriage by peristalsis of solid than of liquid faeces; the caecum being rendered less mobile owing to its peritoneal attachments and, in man, having to work semifluid material against gravity, the products of digestion have to remain in it until their consistence has become such as allows of their easy passage along the large intestine; the change in consistence is made by the deposition of mucus from the glands of the large intestine and the absorption of water. In consequence, the caecum of the child loses its tapering form, and becomes larger by the formation of pouches between the taeniae muscularis. During this pause further quantities of digested material will be deposited in the caecum and dilate that structure, possibly delaying the dispatch of the first "faecal" contribution. Hand in hand with these processes will go the fermentative changes of myriads of micro-organisms, to whom the temporary stagnation offers opportunity of multiplication. Hence the far greater quantity of bacteria in the large than in the small intestine. The temporary delay in the passage of the intestinal contents, the absence of a secretion like that of the stomach, the presence of large quantities of active micro-organisms and their products, point to the necessity for the development of a protective armament on the part of the host to counteract them. Hence the large development of lymphoid tissue in the terminal and most dependent part of the caecum, that is, the appendix, and its specialization, not degeneration. The need of the presence of this "intestinal tonsil" is apparent in the caecal region. The comparative absence of lymphoid tissue in the rest of the large intestine is explicable, as it is in the caecum that the faeces should have been brought up to the proper consistence to allow of their passage along the colon, and in consequence there should be no more considerable periods of "rest"; and as the faeces become dryer and harder, there will be less fermentative action.

Hence it may be said that:

(a) Lymphoid tissue is the characteristic feature of the caecal apex. The vermiform appendix of man is represented in the vertebrate kingdom by a mass of lymphoid tissue, situated most frequently at the caecal apex.

(b) As the vertebrate scale is ascended, this lymphoid tissue tends to be collected together into a specially differentiated portion of the intestinal canal, the vermiform appendix.

(c) The vermiform appendix of man is not, therefore, solely a vestigial structure, though it undoubtedly represents the terminal part of the caecum. On the contrary, it is a specialized part of the alimentary canal, Nature having made use of a disappearing structure and endowed it with a secondary function by giving it lymphoid tissue to protect the body against the micro-organisms in the ileo-caecal region.

Development and Life-History of the Appendix.

The development of this organ illustrates the previous contentions, and can be studied both in the individual—ontogeny—and in the animal series—phylogeny. That of the human fetus will be given first.

Up to the third month of intrauterine life the diverticulum of the primitive intestine, which subsequently becomes the caecum, is of uniform calibre throughout. At this period its growth becomes unequal, the terminal portion failing to increase in size at the same rate as the proximal. The inequality thus established becomes more and more marked as time goes on. At birth the terminal part of the caecum, or the appendix as it is called, forms a tapering prolongation of the caecal diverticulum.² It is not until later that a definite line of demarcation is to be seen between the two structures. The fetal type of caecum is, therefore, an inverted cone whose apex imperceptibly shades off into a prolongation of the

appendix.³ It will now be seen that the appendix represents the terminal portion of the original caecum.

Turning to the animal series for suggestions to aid in the explanation of this phenomenon, it is found that a distinct appendix is only seen in man, anthropoid apes, lemurs, and the opossum. On the other hand, it is common to find a lymphoid structure at the distal portion of the caecum, which undoubtedly represents the appendix.⁴ In the latter series of examples the caecum and its lymphoid appendage conform to the human fetal type. It is quite a later phase, both in ontogeny and phylogeny, that the caecum loses its conical form by the development of pouches between its three thin muscular bands. And it is by that the appendix becomes distinctly separated.

As age advances the appendix undergoes changes both in position and structure. In the fetus it is situated along with the caecum under the liver, and later it descends into the iliac fossa. Sometimes it remains in its fetal position, or it may be arrested at any part of its descent. An examination of the appendices for different decades shows that they are both relatively and absolutely longest and thickest between the ages of 10 and 30. The walls during this same period are packed with lymphoid nodules. After the latter age the appendix begins to undergo a slow involution both in length and thickness. The lymphoid nodules disappear also, though more slowly and uncertainly.

Robert Morris⁵ has directed attention to the association of pain, intestinal and general symptoms with this involution. The change is certainly of a chronic inflammatory character, such as would be expected to occur in nearly every one who has an appendix, and is the result of the continued irritative action of bacteria throughout years. Still more recently Sir Berkeley Moynihan and Mr. Paterson have redirected attention to the occurrence of appendix dyspepsia, its more modern name.

The situation of the appendix in the pelvis is an acquired feature, associated with intestinal dyspepsia, constipation, pregnancy, visceroptosis, etc.

Pathology of Chronic Typhlitis and Appendicitis.

It is a matter of more or less common knowledge in the profession that, as years pass by, changes are found in the appendices of people who have never had a clinically recognizable attack of appendicitis. How much these changes are physiological it is impossible to decide, and it is not very important, because, whatever they are, they will interfere with the normal performance of the work of the appendix, and so lead to evil results. One of the best known of the changes is the disappearance of the lymphoid follicles that are so plentiful in early life. Is this disappearance pathological or physiological. Yet if sections are cut of appendices removed from people over 60, or even older, these follicles sometimes can be found in abundance. The persistence in these cases may be due to individual variations in the rate of ageing, or perhaps more probably they indicate that the disappearance is of more pathological than physiological import.

In considering the physiology of the appendix, it has been shown that the caecum is the first great place of rest, pause, or stasis for the products of digestion after they have left the stomach, and, as a result, the appendix, serving as an index to the chemical and bacteriological processes which occur there, is well supplied with lymphoid tissue. One well-known property of lymphoid tissue is that by producing leucocytes it is actively protective to its possessor against foreign invaders. Situated in a blind tube in whose lumen are represented types of the organisms inhabiting the large bowel and their fermentations, the lymphoid follicles must have a great deal of work to do, more even than the tonsils, to which the appendix has been likened. It is well-known that the tonsils undergo fibrosis or chronic inflammation without the occurrence of an acute attack. In a like manner do similar changes occur in the appendix, but unfortunately there is a very marked difference. Fibrosis of the appendix interferes with the efficiency of its peristaltic action and the tube becomes incapable of emptying itself. By these means a vicious circle is established; the more pabulum which remains the more will bacteria flourish, and the more likely is it that the chronic inflammation will progress, and the organ become still more incapable of

performing its own evacuation. Such a condition may be aptly called appendicular constipation. The inspissation of the contents will lead to the formation of an appendicular calculus or faecal concretion, which may be likened to scybala elsewhere in the large intestine. It may be assumed that the presence of concretions indicates the existence of pathological change. And their association with chronic inflammation explains the fact that they are frequently found by the surgeon and the pathologist in cases which have never had a clinically recognized attack of appendicitis.

The results of chronic appendicitis may be at times far more extensive than this. The fibrosis, with its subsequent contraction, leads to further disappearance of the lymphoid follicles and impairment of the muscular action. The appendix consequently becomes an inert breeding ground for micro-organisms, and if they escape into the caecum the multiplication is continued there. The caecum will be affected sooner or later by the continued escape into it of toxic material elaborated in the appendix, and as it is necessary that the products of digestion remain there until they are of suitable consistency to be passed on into the ascending colon, those toxic materials will become still further elaborated and give rise to chronic typhlitis. Again there is the vicious circle, as the inflammatory condition will impair the contractile power of the caecum, and so lead to further bacterial growth and further chronic inflammation. In this way a colitis may be established throughout the entire length of the large bowel.

Our life-history as regards the micro-organisms in our intestines is of interest. Before birth the meconium in our bowel is sterile. With the first taking of its food the baby is introduced to their action and begins a lifelong education from his alimentary tract. In this connexion it is of great importance to note that the frequency of appendicitis is greatest between the ages of 10 to 20, the decade of the first habitual excesses in human life. After 30 years of age the lymphoid follicles are disappearing and the patient is becoming immune; but, should appendicitis occur after 30, the suppurative complications, abscess and peritonitis, are more frequent than they are at earlier ages. Indeed, in the fifth and sixth decades of life appendicitis with obvious suppuration is more common than appendicitis without obvious suppuration.⁶

The report presented to the annual meeting of the Women's Imperial Health Association, held at its office at 7, Hanover Square, stated that schools for mothers had been started in Lambeth, North Kensington, and Tottenham, and that a juvenile health crusade was enlisting children. The caravan tours, which had proved successful in the past, had been continued. During the year Sussex had been visited and certain places in Kent and Surrey. The London parks caravan worked during the summer at Battersea Park, Clapham Common, Wandsworth Common, and Tooting Common. During the year no fewer than 310 lectures had been delivered under the auspices of the association, many of them illustrated by lantern slides and cinematograph films.

In response to the wish of the Dresden branch, a general meeting of the Deutsche Gesellschaft zur Bekämpfung des Kurfuschertums (German Society for the Suppression of Quackery) decided on January 18th, 1913, to remove its headquarters to Dresden. Dr. Seifart, the first chairman, who has carried out his energetic duties for upwards of ten years, has repeatedly intimated his wish to resign, and during the last few months has pressed the Executive Committee to accept his resignation. The Executive paid a warm tribute to the untiring work of the chairman. It regretfully accepted his resignation. A new Executive Committee, consisting of Wirkl. Geh.-Rat Exzellenz Professor Dr. Fiedler, Gehelmrat Professor Dr. Schmorl, Professor Beythlen, Medizinalrat Thiersch, and others, has been elected. Dr. Neustätter (of Dresden-Hellerau) has been elected Provisional Chairman and Business Manager, to whom all communications, inquiries, etc., concerning the German Society for the Suppression of Quackery should be addressed.

A Lecture ON CARCINOMA OF THE COLON.

DELIVERED AT THE CANCER HOSPITAL,

BY

JOSEPH CUNNING, M.B., B.S. MELB.,
F.R.C.S. ENG.,

SURGEON TO THE ROYAL FREE HOSPITAL; SURGEON TO THE CANCER
HOSPITAL; SURGEON TO THE VICTORIA HOSPITAL FOR CHILDREN.

THERE are certain clinical aspects in the study of carcinoma of the colon which I propose to bring before you.

In the first place, let me say that the stage of complete obstruction is still unfortunately the most common at which the surgeon meets it. A typical instance is the following case:

A patient was admitted to the Royal Free Hospital with a distended abdomen, persistent vomiting, and inability to pass either faeces or flatus. The abdomen was opened in the mid-line. A hugely distended caecum presented, and on it was a patch of gangrene about half the size of one's palm. There was just sufficient time to pack around it with gauze before the caecum burst, flooding the wound with pints of liquid, offensive colon contents and running on to the floor. A Paul's tube was then fixed in the opening, and the patient made an uninterrupted recovery. Some weeks later the abdomen was reopened and a carcinoma of the sigmoid excised. At a third operation the caecal fistula was closed.

The most striking lesson to be derived from this case has always seemed to me that the gangrenous condition of the caecum and its early rupture, thus preventing any further abdominal exploration, was the means of saving his life. This brings me to the point. What should be done when a patient's abdomen is very distended and obstruction is complete? If a growth can be felt from the rectum or vagina, colostomy of the sigmoid may be performed. If not, the abdomen should be opened to the right of the mid-line, and if the caecum presents it should be opened without further exploration. If it does not, the first distended coil found should be used for the purpose of drainage.

You may say that without a proper exploration of the abdomen a strangulation under a band, or some other form of intestinal obstruction, may be overlooked. Even so the chance of the patient living is greater the less the intestines are handled, for consider their condition. They are filled with offensive liquid faeces, their walls are oedematous and brittle, the elasticity is diminished, the peritoneal covering cracks and splits even with gentle handling, allowing toxins and germs to invade the peritoneal cavity. Colostomy without an exploration for the cause of the obstruction, in very distended cases, brings about far better results than when a search is made.

The safest method of performing a temporary colostomy for drainage purposes is by using the curved clamp invented by Sir Thomas Smith (Fig. 1). A portion of the lumen

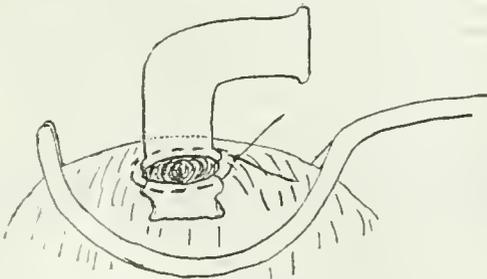

Fig. 1.

of the distended colon is emptied and then clamped. An incision is made and a purse-string suture inserted around it. A Paul's tube is now slipped in and the purse-string stitch tied around it. The clamp is then removed, and the gush of fetid faecal matter is carried well clear of the wound into a receiver by means of the rubber tube attached to Paul's apparatus.

We now come to the case of carcinoma of the colon in which obstruction has not become complete.

Here we have very typical symptoms, but which are often overlooked, either because the patient does not go to his doctor, or because the symptoms are improperly recounted, or because the symptoms are treated without any attempt at finding the cause.

Let us look at a typical specimen of the commonest type of growth, that of the sigmoid, and you will notice there is very little to be seen on the outside. The appearance is that of a string having been tied around the bowel. If we look at the interior we will see that the growth is of both an ulcerative and a cicatrizing nature.

Now any form of ulcer in the colon gives rise to frequency in the calls to empty the bowel. The excessive secretion of mucus and the call to get rid of it makes the patient think he has diarrhoea.

As the colon becomes narrowed by the shrinking of the growth, colicky pain is induced by taking food or drinking hot fluids, both of which stimulate peristalsis. This the patient attributes to "wind."

The most typical symptoms, then, of the early stage are the frequent passage of loose motions and mucus with blood occasionally, and colicky pain on taking hot drinks or food.

If these symptoms persist in spite of diet, bismuth, and rest in bed, an examination with the sigmoidoscope is called for. Failing definite evidence with that, the only means of settling the diagnosis is by exploration of the abdomen. I must here admit that in four cases of those I have explored with these symptoms the disease has been chronic appendicitis and not growth; but as their troubles have disappeared with the removal of the diseased appendix, the mistake was a good one.

A still later stage, and one during which no mistake should be made, is that in which there is gradually increasing constipation and *visible peristalsis*.

The picture of visible peristalsis once seen is never to be forgotten. If the abdomen is watched during one of the attacks of pain, coils of hypertrophied intestine will be seen standing out and raising the abdominal wall in waves. Visible peristalsis always means obstruction, and there should be no hesitation in opening the abdomen when this sign is present.

I was once asked to go to the country to fix a movable kidney which was causing pain in a patient whom I had never seen but who had been recommended to have the operation by a surgeon who devotes a good deal of attention to kidneys. While examining the lump which she had in the right kidney region she had one of her attacks of pain, and I was able to observe very well-marked peristalsis. I received permission to open the abdomen instead of fixing the kidney, and the condition I found was a chronic intussusception lying in the ascending colon and forming a lump which had been mistaken for the kidney. I was able to reduce the intussusception, which originated from a tumour of the ileum, causing the intestine to be invaginated into itself, and so producing chronic obstruction. The growth, with a good length of intestine, was excised, and the patient is now well, some eighteen months later.

Cases are not all of a straightforward character. An ulcer of the intestine, from whatever cause, may lead to an attack of localized peritonitis, and this is not uncommon in connexion with the chronic cases, especially in the region of the caecum. Invasion of the wall of the intestine occurs through the base of the ulcer, and what follows is exactly the same as in a case of appendicitis—namely, adhesions, a localized abscess, or general peritonitis. Most of the lumps found in these cases are due to this complication, the mass consisting mainly of inflamed adherent omentum and not of actual infiltration of the growth.

These cases may exactly resemble attacks of recurrent appendicitis, and one very interesting example, whose caecum I show you, was like that.

The patient was the wife of a doctor, and the subject of chronic phthisis. Some months before she was taken ill with pain in the right iliac fossa, vomiting, and constipation. A lump appeared in the region of the appendix, and for a day or two it was doubtful whether she had not an abscess, but all her symptoms cleared up in the course of a few days, and the lump gradually vanished. Two or three months later a second attack came on resembling the first. It was deemed advisable, as soon as she had recovered from this attack, to remove the appendix. On opening the abdomen and exposing the region of the appendix and caecum it was found that instead of a merely diseased appendix there was a much more formidable condition to be dealt with, namely, tuberculous disease of the appendix, caecum, and ascending colon. In this case there is no doubt that her attacks of localized peritonitis were not due to tubercle, but to

secondary infection by the *B. coli*. A portion of the ileum, the caecum, and the ascending colon were removed; the ileum was then joined to the transverse colon, and I am glad to say she is now going about feeling perfectly well.

The interest of a case of hyperplastic tubercle of this kind is that it may very easily be mistaken for carcinoma.

Another case I will relate to you illustrates very well the condition of a localized abscess in connexion with carcinoma of the colon.

A woman of 53 was admitted to the Royal Free Hospital complaining of abdominal pain. She soon developed a lump in the region of the sigmoid flexure which quickly became adherent to the abdominal wall and was clearly inflammatory in origin, but it was recognized that there was something more behind it—either a new growth or possibly a foreign body which had perforated the intestine. The abscess was opened, and a quantity of foul-smelling pus was let out. The major portion of the cavity was in the muscle of the abdominal wall, but there was a small sinus leading deeper into the abdominal cavity. This was allowed to drain for about two weeks, during which time no faecal matter escaped, and the discharge became very small in amount.

I then opened the abdomen by incisions which surrounded the abscess cavity. The lump which could be felt before the operation proved to be what I show you—a carcinoma of the colon with an ulcer which has perforated its wall, the great omentum, which has exercised a protective influence by becoming stuck over it. The abscess has then progressed through the omentum into the abdominal wall. An interesting feature is that the portion of colon involved turned out to be the transverse, although it was fixed in the region of the sigmoid. I was able to remove the whole mass, including practically the whole of the great omentum, 8 in. of the transverse colon, and the corresponding portion of the mesocolon.

Another case of similar interest was the following:

I saw with Mr. Boyce Barrow a lady suffering from pelvic peritonitis. Her symptoms rapidly cleared up when an abscess discharged itself through the vagina; but ten days or so later she developed intestinal obstruction of the mechanical type. On opening the abdomen the cause of all her troubles was found to be a carcinoma in the last six inches of the ileum which had perforated, forming a localized abscess at the bottom of Douglas's pouch; this it was which had discharged itself through the vagina. We were able to excise the growth with the caecum, ascending colon, and glands, and she went home well.

One other case of mine was of interest. The abdomen was opened for a growth causing chronic obstruction, which proved to be in the ascending colon, but she also had an entirely separate and irremovable growth in the stomach.

TREATMENT.

In the treatment of cancer of the colon, apart from those with complete obstruction and very distended abdomens, dealt with at the beginning of this lecture, there are various problems to be solved when the abdomen is opened.

I.

If the growth is removable, is there a sufficient amount of obstruction to render it a dangerous operation to immediately resect the growth and unite the divided ends?

This is a point where grave consideration is necessary, and a wise decision may make all the difference between life and death.

If the intestine is distended and contains fluid faeces, and especially if purgatives have been unwisely and

unsuccessfully given shortly before the operation, the intestine above the growth is likely to be oedematous and brittle and hold the stitches badly. In this condition a temporary colostomy is the wisest choice, however aggravating such a measure may be for both surgeon and patient.

If a temporary colostomy has to be performed, what situation shall be chosen? This depends upon the site of the growth. If it is in the sigmoid, descending or transverse colon, then the caecum is the best place in which to make the safety valve. If the caecum is involved (though caecal growths are usually discovered before obstruction occurs), then the fistula must be made into the ileum.

The site of a temporary colostomy should be planned, if possible, as much away as possible from the site of the incision for the subsequent removal of the growth, for the skin in the immediate vicinity of the colostomy is likely to be irritated by the fluid nature of the faeces in the caecum, and impossible to sterilize when the abdomen is opened again. As a rule, there is not much difficulty in obtaining such a site, but in one of my cases it would have been wiser to have substituted the old-fashioned lumbar colostomy of the ascending colon, such was the uncontrollable irritation of the skin of the whole abdomen.

II.

The next point to be considered, supposing there is no sufficient obstruction to render immediate resection dangerous, is, Can the growth be completely removed? If it cannot, then can any form of anastomosis be planned to short-circuit the growth and so avoid the otherwise inevitable obstruction? If the growth is so low in the sigmoid that this is not feasible, we are allowed no alternative but to leave the patient with a colostomy.

Another point arises here. If the patient has a removable growth but infected glands extending into such a situation that it is not possible to remove them, should nothing more be done and the abdomen closed? I say No.

The patient is certain to come to a painful end either from obstruction or peritonitis. This may be avoided if the growth in the intestine can be completely removed. Of course, death will ensue from spread to the liver, but an end of this kind much more resembles the "decline" of the novelist, and entails no suffering, but only an increasing anaemia and weakness, ending in death.

The operative measures designed to radically cure by complete excision, not only of the growth, but of the lymphatic areas into which it has spread visibly, or is likely to have spread microscopically, have been much extended of late years. Formerly the bowel was cut across much too near the growth. Now we know that there is no risk in removing many inches of the intestine. The whole colon may even be removed, though this is rarely necessary.

Carcinoma of the Caecum and Ascending Colon.

As will be seen from the diagram (Fig. 2), the caecum and ascending colon are supplied by one artery, the ileo-coelic, the right colic usually coming off as a branch from it. The lymphatic vessels and glands follow the course of this artery. The plan adopted is to tie the ileo-coelic at its origin from the superior mesenic just at the lower

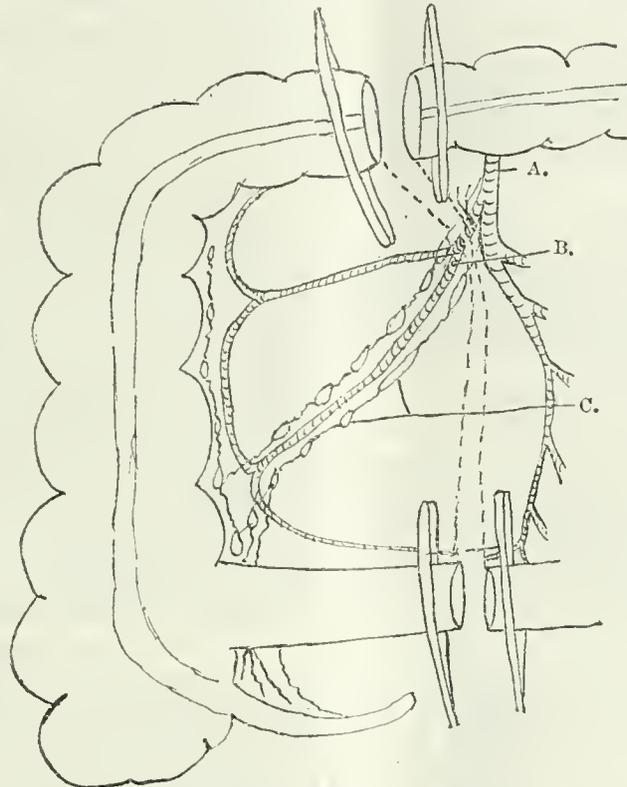

Fig. 2.—Diagram showing blood supply and lymphatics of caecum and ascending colon. Dotted lines show division of posterior layer of peritoneum, mesentery of the small intestine and mesocolon, with clamps on the bowel. A, Superior mesenteric artery. B, Ileo-coelic artery, with right colic artery coming from it. C, Lymphatic glands.

border of the transverse portion of the duodenum. The peritoneum, fat, and glands are then stripped downwards and outwards to the caecum and ascending colon. The ileum is clamped 8 in. from the caecum and divided. Clamps are similarly applied to the transverse colon at a movable and convenient point, and it and the transverse mesocolon severed. It now only remains to divide the peritoneum on the outer side of the ascending colon, and the removal is completed. The cut ends of the divided

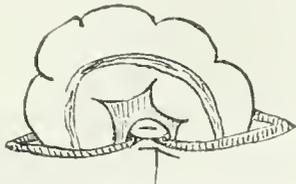

Fig. 3.—Colostomy performed by uniting the whole thickness of the abdominal wall through a hole made in the mesentery.

intestine are then closed and a lateral anastomosis performed. The advantages are that the operation is practically a bloodless one, the lymphatics and glands are removed in one piece with the growth, while the subsequent junction is easy as movable portions of the intestine are to be dealt with.

Transverse and Descending Colon and Sigmoid.

Similar measures are adopted, due attention being paid to leaving uninjured the blood supply of the remaining parts of the colon. When the growth is so low in the sigmoid that no junction is possible after excision, then the rectum must be removed as well as the sigmoid by the combined abdomino-perineal operation.

Closure of Temporary Colostomy.

I now come to the question, how to close a temporary colostomy.

1. The spur may be removed painfully and tediously by crushing with a clamp or enterotome.
2. Excision of the opening or the portion of the intestine into which the opening has been made.

The plan I practise is to incise the skin at a distance of 1½ to 2 in. from the margins of the colostomy (Fig. 4). This

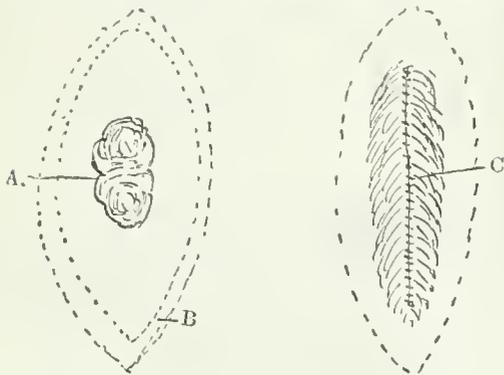

Fig. 4.—A, Colostomy. B, Incision in skin. C, Island of skin sutured over colostomy.

island of skin is dissected up towards the opening, and its edges sutured together with strong silk, so that it forms a watertight covering for the opening. This gets rid of two difficulties:

1. The leakage of faecal matter during the operation.
2. The septic skin around the opening.

The abdomen is then opened at some little distance to avoid the adhesions in the immediate neighbourhood, and it is then easy and quick, by sacrificing a little of the muscle of the abdominal wall, to completely free the opening. Clamps are then applied and the colostomy cut away. If it is the caecum, the edges of the wound are then united by a double row of stitches. If there is so little lumen left that there would be a stricture after repair, then that portion of the intestine is excised and end-to-end anastomosis performed.

It but remains to describe formal and permanent colostomy. Every one has his own plan, and many are

good. The one I like best is to bring the colon through the outer part of the left rectus a little below the umbilicus. A hole is made through a bloodless portion of the mesentery, and the whole thickness of the abdominal wall is then united through this opening. A few days later the colon is opened in the ordinary way.

THE RESULTS OF EXCISION OF THE HIP-JOINT IN 34 CASES OF SUPPURATING TUBERCULOUS DISEASE.*

By CHARLES A. MORTON, F.R.C.S.,

PROFESSOR OF SURGERY, UNIVERSITY OF BRISTOL; SENIOR SURGEON TO THE GENERAL HOSPITAL AND THE CHILDREN'S HOSPITAL.

This is a consecutive series of 34 cases of excision of the hip-joint with 35 operations (as in one case both hip-joints were excised) for tuberculous disease, but I have performed also 3 other operations on the hip-joint. One was a sequestromy of the head and neck of the femur for necrosis, and the other two were arthrectomies for tuberculous disease. The total number of operations for tuberculous disease of the joint is therefore 37. In no case have I operated for tuberculous hip disease until there was evidence of suppuration in the joint, nor do I think it is desirable to operate before suppuration occurs. I recognize, of course, that some surgeons consider that all that should be done in suppurating tuberculous hip disease is to scrape out the abscess sac; but I agree with those surgeons who maintain that it is better, when once operation has to be performed, to do more than this, and remove as much of the diseased tissue of the joint as possible. In my comments on the series of cases I shall point out what bearing the cases have on this view.

I have written to inquire about all the cases there was any hope of reaching that were operated on during the last twelve years. It seemed hopeless to try and get at those operated on longer ago than this. Some of those operated on within the last twelve years I have been able to examine lately; with regard to others, I have had to be content with reports from the mothers. Most of the cases were young children, some were over 12, a few were adults, and 1 case operated on this year (1912) was 57. I have had no death from the operation in the whole series.

THE OPERATION.

All my operations have been performed by the anterior incision, which starts just below the anterior superior spine and runs downwards, passing between the sartorius and the tensor fasciae femoris, and then between the rectus and gluteus minimus. Very often the abscess is opened in reaching the joint by this route. The neck is divided with an Adam's saw, and the soft parts around it cut with scissors. There is often much difficulty in turning out the detached head. I have found that the now almost obsolete perineal lithotomy scoop is a useful instrument for this purpose. Lion forceps crush the soft head too much, but sponge-holding forceps will sometimes be useful.

I then cut away with scissors curved on the flat all the tuberculous tissue I can. Occasionally I have been able to remove in this way quite large pieces, but it is a very different matter from doing an arthrectomy of the knee, in the performance of which it is so easy to see all the diseased tissue. In excision of the hip one has to be very largely content with free scraping of the diseased soft tissues, and scraping and gouging away diseased bone in the acetabulum; and, of course, sequestra are searched for and removed. In my first 24 cases I found sequestra in 10; in most of the cases several were present either in the head or acetabulum, most often in the latter. One sequestrum measured 1 in. by ½ in. The frequency with which sequestra are present in these cases is, I think, one reason in favour of excision rather than simply scraping out the abscess. No doubt many of these sequestra would in time disintegrate and come away, but I am sure their removal would tend very materially to hasten the process of recovery. In all cases the abscess sac, as well as the

* A paper prepared for the discussion on The After-Results of Major Operations for Tuberculous Disease of the Joints, in the Section of Diseases of Children, at the Annual Meeting at Liverpool.

interior of the joint, is scraped and flushed with I in 10 biniodide solution, and earbolized iodoform is applied to the wall. I have always drained for as long as discharge came away.

EARLY RESULTS.

All cases were drained, but within two months in most cases all discharge ceased and the wounds healed. This is more than I think we can expect if we simply deal with the abscess sac, and is, I think, the great advantage of excision as compared with methods in which the abscess alone is dealt with.

LATE RESULTS.

In nearly all cases flexion to a right angle was possible, but lateral movement was not usually as good as flexion, and in some cases was quite limited, but in one of the cases movement was almost perfect in all directions. Shortening was usually present to the extent of 2 to 2½ in. in cases seen some years after the operation, but may not be more than 1 in. for some time after the operation. In one case it was 4 in. nine years after the operation, the position of the trochanter indicating how the stump of the neck had become forced up on the dorsum ilii. In some cases the limp was slight, but in others, some years after the operation, it was marked, even when the shortening had been compensated for by extra thickness of sole of the boot. There seemed to be a marked want of stability about the joint. But even in these cases the patient could walk a considerable distance. In some of the cases with more stable joints they could walk many miles, and one boy was said to be able to climb trees just like other boys. It seems to me that to remove the head of the bone must tend to instability of the joint from displacement on the dorsum ilii, and that therefore we cannot expect as stable a joint after excision as after an operation which simply deals with the abscess. Yet it seems to me that it is so desirable to get away as much of the disease as possible when we have to operate, that this fact would not make me abandon excision in favour of simply dealing with the abscess. This instability of the joint after excision can, of course, be prevented by inserting the trimmed top of the great trochanter into the acetabulum after removal of the head, but this is likely to be followed by ankylosis; and it seems to me that it might be quite doubtful whether in the course of years a patient was better off with an unstable or an ankylosed hip-joint. Moreover, the joint may become ankylosed in a position of flexion and adduction.

I cannot say whether the range of movement is as good after recovery when simply the abscess is dealt with and the head of the bone is not removed, because in the only two cases in which I did not remove the head (the two cases of arthroctomy) I did not see the cases years after; but I should not expect as good a range of movement. I know that some surgeons who treat suppurating cases of hip disease by dealing with the abscess only say that in all after recovery movement is good, but, as I have said, with the exception of my two cases of arthroctomy I have done excision in all my suppurating cases, and therefore I cannot express any opinion about it. All I can say is that in some cases after excision the range of movement possible is astonishing, that flexion to a right angle is almost always possible, and that in many cases lateral movement becomes fairly free also.

With regard to the amount of shortening after recovery from the two forms of operation, Mr. Barber says: "How often have we seen patients treated on splints for years recover without abscess, and yet with two or three inches of shortening"; but I must say I should expect to get greater shortening in some cases after excision than one would be likely to get after simply draining the abscess, because I have seen the stump of the neck displaced so high up on the dorsum in some cases many years after the excision.

We must, however, remember that two very potent causes of marked shortening exist apart from excision of the head—wearing away of the head by the disease, and the production of a "wandering acetabulum," which would allow of much the same displacement of what was left of the head on the dorsum ilii as occurs after excision of the head.

In one of my cases deformity recurred eight years after operation, and was removed by weight extension. There

was no recurrence of the disease. Recurrent deformity was only rarely present in my series of cases.

CASES OF EXCISION OF THE HIP-JOINT.

1. C. R., aged 13; operated on in November, 1894. By December there was no discharge, and the wound was "almost healed." An abscess subsequently formed in the gluteal region. This was operated on in February, 1895, and was healed in April. In February, 1895, there was no deformity, could flex to half right angle, but there was no lateral movement; 1½ in. shortening; had not yet walked on it.

2. M. T., aged 10; operated on in March, 1896. Wound healed in April. In 1898 abscess formed in connexion with cavity at base of trochanter; this was scraped out, and soon healed. On examination in October, 1897—that is, eighteen months after operation—the patient could then walk freely with some limp; 1 in. shortening; could flex to right angle, but hardly any lateral movement. When examined again in 1899, there was 1½ in. shortening. There were lateral movements as well as flexion possible. In 1907—that is, eight years later—had to have weight extension for recurrent flexion and adduction, but movement was still fair, and no signs of recurrence of the disease.

3. G. P., aged 5; operated upon in March, 1897. The wound became infected with tubercle, and did not heal for many months. There were tuberculous iliac glands four years later. At this time—that is, four years after operation—the hip was noted as "sound, with remarkable freedom of movement."

4. M. L., aged 9; operated upon in July, 1897. Wound healed in August. Six years after operation abscess was found in connexion with cavity in upper end of femur, which healed in a year, and then remained well for six years, and then another abscess formed in connexion with another cavity in the same situation containing sequestra. Sinus was known to persist for at least another year.

5. W. T., aged 31; operated on in July, 1896. Wound healed in August. Seven months after operation the position of limb was normal; slight flexion, extension, and rotation out possible, but no lateral movement. There was no pain with movement, and could bear weight on limb in walking without pain. There was 2 in. shortening.

6. F. S., aged 11; operated on in March, 1897. The wound did not heal until late in summer, and the patient was sent to convalescent home in November. There was no late note of this case.

7. A. R., aged 9; operated on in November, 1897. Wound healed in December. Some superficial breaking down of scar which soon healed. This case was sent to the county workhouse. There was no late note.

8. M. B., aged 4; operated on in March, 1898. Wound healed in May. The patient died from tuberculous meningitis in May, 1898, associated with suppurating mastoid. On *post-mortem* examination firm adhesions were found in joint.

9. C. M., aged 6; first operation in December, 1897. The wound had "almost healed" in February, 1898. No note of when quite healed. Disease came in the hip on the other side, and this was excised in November, 1900. The wound had healed in December. A year after the first excision the note says: "Good position; fairly free flexion and lateral movement; 1 in. shortening." The range of movement became very great later. The patient went back to the workhouse from which it had been admitted, after second excision. There was no further note.

10. G. S., aged 12; operated on in May, 1897. Wound healed in July. A year later an abscess formed behind trochanter. There was no communication with hip. There was painless movement in joint. This soon healed. A sinus was found in the scar of excision three years after operation and was present when last seen six months later. Eighteen months after operation the patient could flex hip to right angle and adduct a little but not abduct. Position good; there was 2½ in. shortening.

11. E. Y., aged 14; operated on in May, 1898. Healing had taken place in June. An abscess formed more than a year after, and the patient was lost sight of at that time. Five months after operation there was a little movement possible; there was 1 in. shortening.

12. H. C., aged 15, was operated on in June, 1898, for recent septic sinuses. Rapid healing of the excision wound took place, but when discharged in August one of the old sinuses still discharged. There was no late note of this case.

13. S. G., aged 16; operated on in April, 1899. A sinus persisted in the position of the wound, leading to acetabulum. A year later a fresh abscess formed, and when the patient was last seen a sinus persisted.

14. B. E., aged 6; operated on in January, 1902. Wound healed in February. In April the patient was found to have tuberculous disease of the metatarsal bone. This was operated on and healing took place. A note made in April says the hip was sound, but no late note was made, and a letter of inquiry this year (1912) was returned through the Dead Letter Office.

15. A. D., aged 13, was operated on in February, 1902. The wound had almost ceased to discharge in March, and was healed in May. In October very fair movement in hip in all directions. Examined two and a half years after operation, the patient could then flex to right angle, and fair lateral movement. There was 2 in. shortening, and even with sole 2 in. extra thickness limps a good deal.

16. L. T., aged 5; operated on in June, 1902, and wound healed in July. A sinus formed in the scar, and persisted for months.

In June, 1905, an abscess formed from disease in the upper end of shaft. The joint was not affected, and the abscess healed in a few months. But a letter written this year elicited the information that after I lost sight of her she had two further "operations," and was never able to walk, and died last year (1911), that is, nine years after the excision. On examination two years after the operation, the patient could then flex to right angle, but there was very little lateral movement. There was 1½ in. shortening.

17. L. H., aged 10. This was a case in which septic sinus and fresh abscess were present before operation in March, 1903. The sinus persisted when last seen that summer.

18. A. M., aged 4, was operated on in July, 1903. The wound did not heal until the beginning of 1904. In 1907 there was abscess from disease of the ilium, which healed in 1908 but left the joint fixed. A letter of inquiry in 1912 was returned through the Dead Letter Office.

19. A. F., aged 8; operated on in May, 1903. The patient died in August with pneumothorax.

20. G. H., aged 8; operated on in August, 1903. Healing had taken place by October. The wound broke down and discharged twice after it healed, but when last seen it was only a superficial granulation patch. A letter of inquiry sent in 1912 was returned through the Dead Letter Office.

21. M. P. was operated on in May, 1903. Wound healed in July. In January, 1904, a gluteal abscess was operated upon, and as a sinus persisted was again operated on in 1905. No further relapse had occurred when examined eight years later. In 1905 the patient had fair movement in hip without pain, and sinus could not be traced to hip or to any bone here. Examined in 1912, nine years after operation, he limped down on affected side very much; there was 4 in. shortening, and only compensated for ¾ in.; movement of flexion and adduction very good, but abduction very limited. Trochanter raised to level of anterior spine.

22. B. H., aged 6; operated on in February, 1904. Wound healed by March. There was no further note of this case. A letter written in 1912 was returned through the Dead Letter Office.

23. Mr. B., aged 35, suffered from phthisis. He was operated on in July, 1904. In August there was only a small granulation patch on scar, but later a sinus formed and persisted. The patient died from hæmoptysis in 1905.

24. P. A., a child, operated on in August, 1904. The wound had healed, all but superficial area, in September, and had quite healed in October. An abscess formed later in autumn and sinus persisted. The patient was again operated on in May, 1905, and bare bone found in the shaft of the femur several inches below the joint. The joint deformity recurred in 1907, and the limb had to be straightened by weight extension, and then an abscess formed, and sequestra were removed from the acetabulum; there was then no sign of disease about the neck of the femur. In August, 1906—that is, two years after the operation—she could flex to right angle, and there was some lateral movement and rotation; ¾ in. shortening; there was not much limp. The patient died from general tuberculosis one month after operation on acetabulum, the symptoms of general tuberculosis starting a fortnight after operation.

25. G., aged 16, operated on in July, 1904. The wound had healed in August, 1904, but some deformity persisted. A sinus subsequently formed, healed, and then recurred, and in October, 1906, sequestra discharged. The sinus persisted for several years. The mother wrote in 1912 to say the sinus had been healed for two years, and that with a high-soled boot she does not limp much.

26. E. P., aged 27, operated on in November, 1906. The wound had healed in December. When examined eighteen months after operation there was fair movement in all directions. On examination in 1912, six years after operation, there was very free flexion and fair lateral movement, but she limped down on the affected side very much. There was 2½ in. shortening, but this was compensated by a high sole. She required a crutch for outdoor walking.

27. E. S., aged 9; operated on in April, 1907. The wound had healed in June. A sinus formed in the scar in July, 1908, and a soft patch of bare bone was found in the acetabulum; the stump of the neck was well covered in. In February, 1910, nearly three years after the last operation, the joint was quite sound and movements almost as free as usual. There was 2½ in. shortening. The mother wrote in 1912 that the child was in good health and only limped slightly, but that two abscesses had formed since 1910.

28. A. T., a child, was operated on in July, 1907, and healing had taken place in August. The mother wrote, in reply to a letter in 1912, that the child had had no relapse; she walked with a stick. In February, 1910, she died, after an illness of nine days, with some affection of the "back passage."

29. J. W., aged 9; operated on in August, 1907. The wound healed in September. There was no further note of this case. A letter of inquiry in 1912 was returned through the Dead Letter Office.

30. F. E., aged 12; operated on in April, 1907. The wound healed in June. In June, 1908, there was superficial ulceration in the scar. A note made in May, 1908, says: "Moderate movement in all directions. Some eversion; 2½ in. shortening." There is no note when the ulcer in scar healed; but the mother wrote in answer to a letter in 1912 that the patient was very well, and often did a 5-mile walk easily, but limped a little.

31. B. H., aged 3; operated on in December, 1907. The wound "healed rapidly." The patient had an attack of scarlet fever with breaking down of the wound, which did not heal

until May, 1908. By October, 1908, there was almost perfectly free movement in all directions; 1 in. shortening. An abscess formed in the scar in December, 1908, and sequestrum discharged, but healing had taken place by January, 1909. Examined in 1912—that is, five years after operation—there was quite a normal range of movements, but limbs much down on the affected side from instability of hip. There was 2 in. shortening, compensated for by high sole.

32. G. D., aged 12, was operated on in February, 1909. There was a septic sinus present. Healing had taken place in May, 1909. When seen again in April, 1910, the scar was sound, and there was fairly free movement in all directions; 2 in. shortening. In answer to a letter in 1912 the patient's relations reported that he could walk "wonderfully well," and climb trees like other boys, and was "not very lame," by which was probably meant that he did not limp very much.

33. E. C., aged 13, was operated on in April, 1910. The wound healed without any suppuration. The patient died with symptoms of tuberculous meningitis in June, 1910.

34. M. B., aged 57; operated on in February, 1912. Primary union took place, but a superficial ulcer formed in the scar; there were no complications.

CASE OF EXCISION OF HEAD OF FEMUR FOR ACUTE NECROSIS.

M. F., aged 12, was operated upon in August, 1908; sequestration of head and neck after acute necrosis. In March fair movement of joint. A sinus near trochanter had recently healed after scraping.

TWO CASES OF ARTHRECTOMY OF HIP FOR TUBERCULOUS DISEASE.

1. G. B., aged 5, was operated on in August, 1904. Healing had taken place in September. The patient was readmitted in December, 1904, with some swelling about the joint, but no abscess, and was discharged in Thomas's splint in February. An abscess was found three months later, which was opened by a dector, and eventually a piece of bone was discharged. The patient died with symptoms of tuberculous meningitis three and a half years after arthrectomy.

2. M. S., aged 6, was operated on in March, 1906; soft tuberculous tissue was scraped away from around head and acetabulum. In May the wound was quite superficial, but an abscess formed in the gluteal region, which was opened and scraped out. In June a tuberculous abscess formed in the arm, and was operated on, and in August the same condition was present in the other arm. There was then a persisting sinus into the hip. There was no further note of this case.

NOTE ON A SERIES OF FIFTY-FIVE CASES OF SUPRAPUBIC PROSTATECTOMY, WITH FOUR DEATHS.*

By ANDREW FULLERTON, M.D., F.R.C.S.I.,

SURGEON IN CHARGE OF OUT-PATIENTS TO THE ROYAL VICTORIA
HOSPITAL AND TO THE BELFAST HOSPITAL FOR
SICK CHILDREN.

THE operation of prostatectomy has done so much to relieve the distress of a large section of elderly men that it is well to review the risks that they run in subjecting themselves to the ordeal. Many of my medical friends have told me that they hesitate to recommend what may, perhaps, prove to be an execution rather than a cure. The object of this paper is to bring forward the results of my own experience. In the June number of the *Practitioner* Mr. Hugh Lett, of the London Hospital, makes the following statement:

The operation of prostatectomy cannot be looked upon as a trivial one, and I am strongly of opinion that, if statistics of this operation were compiled from the registers of a large number of hospitals, the mortality would prove to be not far short of 20 per cent., and possibly higher.

I am of opinion that a much lower percentage must be attained if the operation is to be more generally accepted by the profession and the public. I have up to the present operated on 55 cases with 4 deaths—a percentage of 7.2. The patients have not been specially chosen, but have been taken as they came, excepting only those who were obviously unfit for any operative procedure, however slight. The list includes patients from the age of 53 to the borders of 80—patients well preserved and relatively strong and patients broken down and exhausted, patients who were obese and patients who were emaciated, patients with fair

* Read at a meeting of the Ulster Branch, British Medical Association, in Belfast.

arteries and good hearts, and patients with marked degeneration of vessels and advanced cardiac disease.

The condition of the kidneys is perhaps the most important consideration, and marked renal inadequacy would prove an insuperable barrier to operation.

Some years ago I operated on a man, aged 53, for severe prostatic hæmorrhage. He weighed 20 st., and most of the fat was in the omentum and abdominal wall. I had to have a foot-stool to reach his abdomen, and I had to put my whole hand into the bladder to reach the prostate. He had had several attacks—called “weak turns”—said by his medical adviser to be due to his heart. Notwithstanding all this he made an excellent recovery, and is at present in full employment in a responsible position in a mill.

In 1908, I operated on an old man—a sexton—aged 78 years, for recurrent attacks of hæmorrhage with excruciating pain due to the clois. His arteries were hard and tortuous and he had a double aortic murmur. In addition, he had cystitis with a good deal of mucus in the urine. His doctor was very anxious that something should be done to relieve him, so in fear and trembling I removed his prostate, the operation from the skin incision to the delivery of the prostate lasting one and a half minutes. He made a good recovery and is now, at the age of 82, in good urinary health.

In 1909 a gentleman, aged 73, had, ten days before I saw him, a severe cardiac attack in which the pulse fell from its normal rate of 72 to 40 per minute. During this attack he became pale, blue, and collapsed, and his hands and feet were “dead” as far as the wrists and ankles. He recovered from this attack, but the pulse-rate remained at 40. When I saw him, ten days after this seizure, he had complete retention, and any attempt to pass a catheter was attended with bleeding and blocking of the eye of the instrument. Suprapubic puncture failed to relieve him, no urine being obtained, though the bladder was obviously full. On the same day I removed a huge sugar-loaf shaped prostate weighing 17½ oz. under ethyl chloride given by Dr. Fielden; the operation lasted fifteen minutes. After some anxious days, during which shock, hæmorrhage, and hypostatic congestion of the lungs almost claimed their victim, the patient began slowly to recover, and he is to-day free from all urinary trouble, though his heart still beats at the rate of 40, and he suffers much from dyspnoea on exertion. With the prostate I removed a beautiful specimen of mulberry calculus.

This case was published in the BRITISH MEDICAL JOURNAL of May 22nd, 1909, and I was rather severely taken to task by a correspondent for my conduct of it, but “the proof of the pudding is in the eating,” and my patient has had three years of comparative health and complete freedom from urinary trouble. He takes a lively interest in his own case, and occasionally invites a passing student to view his prostate in a glass jar at the Queen's University. I have given these few examples to show that grave general trouble need not necessarily be a barrier to operation.

The causes of the deaths in my series were as follows:

The first, an old gentleman aged 75 years, apparently in good health, with clear urine of good specific gravity, free from pus and albumen, died on the third day with symptoms of uræmia. I was not prepared for this result as I had had him examined as to his general condition by one of my medical colleagues before operating on him. There was more than the usual amount of bleeding, and, as a precaution, I packed the prostatic cavity with gauze.

In the second case, a gentleman aged 54, who had had repeated attacks of hæmorrhage with great pain, death took place six weeks after operation from perinephritic abscess.

This I attributed to an unsuspected collection of phosphates and débris in the bladder which failed to come away with the irrigation. I now make it a practice, if in doubt, to insert my finger down to the base of the bladder and the prostatic pouch to satisfy myself that all foreign matter has been got rid of. In the third case death was due to spinal anaesthesia.

The patient, a man aged 68, had a weak heart and a double aortic murmur. His medical attendant declined to take the risk of giving him a general anaesthetic. I was asked to give him spinal anaesthesia, which I did with disastrous results. 1 c.cm. of a 15 per cent. solution of novocain with 1 mg. of strychnine was injected. Anaesthesia was excellent, but the patient immediately began to vomit and became grey, cold and collapsed. After a slight rally the prostate was removed, but the patient continued to vomit and died the same night.

I have included this as a death from prostatectomy, though I feel sure I should be justified in attributing it to the anaesthetic.

The fourth case was a gentleman aged 66. He had been up to his last illness an alcoholic subject. He was taught to pass the catheter and had been doing this for some months every two hours day and night. The urine at the time of my seeing him was very foul and the bladder was intensely inflamed and irritable. I kept him in a nursing home and washed out his bladder for ten days with practically no improvement. As a last resort I removed the prostate and a phosphatic calculus.

The former weighed 6 drachms and the latter was about the size and shape of a pigeon's egg. For some days the patient did well, but soon the surface of the wound became foul and sloughy, the pulse increased in rate, the tongue became furred and covered with aphthae, which also appeared on the mucous membrane of his lips, cheeks, and gums; his temperature rose a little in the evening, he complained of thirst, and he lost flesh and colour. He died at the end of twelve days with all the symptoms of an acute septic intoxication, with pinched face, sunken eyes, cold extremities, and rapid thready pulse, retaining his faculties almost to the last, the picture recalling that of a patient dying from acute general peritonitis.

On reviewing this case I do not know whether it would not have been better to have simply drained the bladder, reserving the prostatectomy for a later date. I have no doubt that he infected his bladder with the catheter, and I always feel that this is the great risk in allowing a patient to enter catheter life. On the other hand, some of my patients have been dependent on the catheter for years, as in the following case, who, but for an accident, would probably have gone on with the use of the instrument to the end of his days.

A farmer, aged 73, had had trouble with his water for fifteen years. For ten years he had had to use the catheter several times a day, being unable to pass urine without. About six weeks before I saw him he was using a well-worn gum-elastic catheter, when, as he describes it, the skin came off and remained inside. After this he had great pain, and when I saw him he was passing the catheter every fifteen minutes. With the cystoscope the outer shell of a catheter could be seen curled up inside the bladder, which was much inflamed. I made an attempt to remove the foreign body with a small lithotrite, but it was so friable that I could not remove it completely. I then did a prostatectomy, and at the same time rid him of his foreign body. The patient was up in a fortnight's time, and his wound was dry on the sixteenth day. He now passes water with the courage and success of a boy.

The results in the cases that recovered have been, in the overwhelming majority, gratifying in the extreme. In most the patients can lie all night without being disturbed. A few report that they rise once in the night, and of these some say that this is due more to force of habit than any uncontrollable desire. In a few cases I have not been able to quite get rid of a certain amount of cystitis. Like other infections elsewhere in the body, infections of the bladder are hard to eradicate completely, notwithstanding careful irrigation carried on long after the wounds in the bladder have healed up. Two of the prostates removed, though apparently benign, proved on section to be malignant, and the patients died some months after from recurrence. In one case the tumour fungated through the abdominal wound after the latter had been soundly healed.

In one case a permanent suprapubic fistula remained. The operation was performed in the early days of prostatectomy before the exact anatomy of the procedure had been worked out. I must have removed a portion of the pelvic fascia in addition to the prostate. If violent efforts are necessary to remove the obstruction the surgeon may feel sure he is in the wrong layer and should desist lest damage be done to the neck of the bladder. The prostate must be enucleated, not torn out.

In two cases incontinence resulted after the operation. In one this was due to a drainage opening in the perineum, which was kept open for a long time. The compressor urethrae was, no doubt, damaged by the incision and the prolonged use of the drainage tube, which was rendered necessary by the absence of any attempt at healing of the suprapubic wound. Due respect should be paid to the integrity of at least a portion of the compressor. The anterior portion should be left to act as a sphincter in case the sphincter vesicae does not resume its functions. In the second case, the prostate was of the hard fibrous type. In my attempts to remove this I must have gone beyond the limits of the prostate. The first complication was a stricture, which I divided, with the result that the patient now has incontinence. In future I do not propose to make any attempt to remove such a prostate. It is beyond the art of surgery to remove completely a hard fibrous prostate with impunity. Prostatectomy, as recommended by Pardoe, or the use of the prostatic punch of Young, may prove to be of service in these cases.

The most serious complications that I have had to deal with have been as follows:

Hæmorrhage.—This has usually been primary, occurring during the first forty-eight hours. It is always present to

a certain extent, and it requires some judgement to determine when it has passed safe limits and when interference is necessary. In some cases it is due to wounding of a vessel in the bladder wall when opening into it, and in some to tearing of the mucous membrane during the removal of the prostate. I use no instrument to tear through the mucous membrane over the prostate, but with the tip of the index finger rupture the internal meatus in an upward direction. The proper layer is soon felt. At the junction of the prostate with the base of the bladder posteriorly, separation ought to be carefully carried out, else a long strip of mucous membrane is liable to be torn away with the prostate, giving rise to hæmorrhage. In most cases the bleeding comes from the plexus of veins around the prostate. In a few cases I have found it necessary to pack the cavity from which the prostate had been removed with a narrow sterilized bandage. This arrests the hæmorrhage and is easily removed in a few days. I have tried a plug of gauze tied on to the end of a catheter and pulled through the urethra without success. I had one case of secondary hæmorrhage of an alarming character on the seventh day after operation. This was due to separation of sloughs and was at first very hard to arrest. The narrow bandage packing was ultimately successful. Raising the foot of the bed on chairs has proved of value in some of the slighter cases. It cannot, of course, be continued for long in the case of old people.

Shock.—In most of my cases a fair amount of shock has been present. I have noticed it most when strenuous efforts are being made to enucleate the gland. This complication can, however, be reduced to a minimum by proper preparation of the patient and rapidity of operation. I have my patient's bladder washed out and all preparations, including those of the surgeon and his assistant, completed before the anaesthetic is given. If possible, I secure the services of an anaesthetist skilled in the administration of ethyl chloride as a general anaesthetic. I have completed the removal of the prostate in sixty-seven seconds from the beginning of the skin incision until the prostate was delivered. A few additional moments are spent in rapidly washing out the bladder and suturing the wound. A large drainage tube is left in the bladder. The patient is got back to bed as soon as possible and warmth applied. Salines by rectum should be administered until the shock has disappeared, which it generally does in a few hours. If it continues, subcutaneous infusion is resorted to. I do not use strychnine. I believe lives are sometimes lost by slow and too deliberate operating. The patients are often old and worn out, and the less they are handled the better. The least that can be done must be done with as much rapidity as is consistent with safety.

Hypostatic congestion of the lungs has more than once caused me considerable anxiety. The patient with the very large prostate, referred to above, developed it after a few days, but ultimately recovered. Change of posture and the use of the usual well-known remedies are indicated.

Sepsis is one of the most troublesome and dangerous complications I have had to deal with. If the bladder is septic I have it washed out before operation for some days, and in a few cases I have drained suprapubically as a preliminary measure. The drainage provided by the suprapubic wound is, however, not ideal. In one or two cases after operation I have tried, as an additional safeguard, perineal puncture, as suggested by Lynn Thomas, with satisfactory results. I would advise, however, that the drainage tube in the perineal wound be not kept in too long. I wash out the bladder every day while the patient is in the home or hospital, or until the urine is quite clear. While the suprapubic wound is still open this is done by inserting the nozzle of the syringe into the external meatus and forcing the fluid through the urethra into the bladder. Débris from the cavity vacated by the prostate is thus stirred up from below, and thorough cleansing is more certain thus to be obtained. I have no experience of vaccines in these cases, but I am very willing to give them a trial, and should expect benefit from them.

Epididymitis and epididymo-orchitis have given me a good deal of trouble. The torn ends of the ejaculatory ducts are liable to be infected, while the raw surface left after removal of the prostate remains unhealed. Every effort must be made to keep this surface as aseptic as pos-

sible in the hope of preventing this complication. It is often accompanied by a milk-white discharge from the meatus. It may be unilateral or bilateral, and is attended with a good deal of pain and constitutional disturbance. During the treatment of this condition the testicles ought to be supported on a broad strip of strapping from thigh to thigh placed as near the fork as possible. Glycerine and belladonna will relieve the pain, due care being exercised to prevent absorption of the belladonna.

Suprapubic fistula is an occasional complication. If this shows any tendency to persist I tie in a catheter, if I am satisfied that all sloughs have separated and the interior of the bladder is free from foreign matter. I have been in no hurry to remove the suprapubic drainage tube. It acts as an exit for phosphatic deposit and tags of mucous membrane, which might otherwise form nuclei for calculi. I have only had one case of permanent fistula. Touching the edges of the fistula with nitric acid or the actual cautery has proved successful in some, while in others I have been obliged to curette once, and occasionally twice, under a local or general anaesthetic. I have also faith in the occasional passage of a full-sized dilator. In one case I found that the cavity left after the removal of the prostate was maintained as a separate cavity, communicating by a small opening with the bladder. Radial incisions in the diaphragm threw the two cavities into one and cured the fistula.

Phosphatic deposit on the suprapubic wound and in the bladder is most annoying, and I have tried almost everything suggested to prevent it. I am at present trying the application of a few drops of acetic acid to the wound and dropped into the bladder through the drainage tube. I have not sufficient evidence to warrant me in recommending this procedure, but it can do no harm, and seems to me to be a likely remedy. In addition an attempt may be made, by suitable diet and excess of fluid, to prevent the deposition of salts.

Stone in the Bladder.—I have not had a case in which I have had to operate for a stone of any size. In one case the patient had attacks of pain and retention shortly after his wound was healed. With the cystoscope I detected a small calculus, which I crushed with a small lithotrite, without an anaesthetic. His symptoms immediately disappeared. In another case I picked out through the urethroscope a small stone which had blocked the urethra. Attention to the details I have given above will go far to prevent this complication.

Uræmia occurring immediately after operation generally ends fatally. In a more chronic form it may appear in the weeks or months following. The outlook is not good, but the patients may be kept going for a while by diuretics and aperients. One of my patients succumbed on the third day from this complication.

Stricture of the urethra ought not, I think, to occur with proper methods of operating and the choice of suitable cases. It is liable to occur after attempts to remove hard, fibrous prostates. As I have stated, it was present in one of my earlier cases.

Incontinence of urine occurs in some cases for a short time after the operation. In a very small proportion it persists. I have had two cases of permanent incontinence. From the experience I have had in these two cases I believe it can be avoided by keeping to the proper layer in removing the gland and in paying due respect to the compressor urethrae muscle.

Abscess in the kidney region occurred in one of my cases, as I have mentioned. Probably the patient had pyelonephritis. He began to have rigors about a fortnight after the operation, and, although I opened the abscess, he never rallied, but sank a few days later, and six weeks from the time of his operation.

Hæmatæmesis occurred in one of my cases. It only lasted a few days, however, and the patient left the hospital apparently quite well. He was a worn-out old man of 80. I hear that he died some months later, but I do not know the cause.

Ventral Hernia.—I have had at least two cases in which the scar stretched to an uncomfortable extent. This must be a sequela in a certain number of cases, especially if the bladder is septic at the time of operation. It is wise, having regard to the possibility of this complication, not to make the wound in the abdominal wall too large, and to bring the cut margins of the sheath of the rectus together

with deep sutures. A suitable bandage is all that is necessary in the way of treatment.

Mental symptoms of a mild type have been present in several of my patients. One old man used to weep like a child without any apparent reason. My nurses say that a prostate patient is always a little "queer," and many of them are very difficult to deal with. I have not met with an acute outbreak requiring restraint.

Notwithstanding the low mortality in this series of cases I cannot say that I look lightly upon the operation of prostatectomy. Many are the pitfalls before the patient can be pronounced free from danger, and the medical attendant must give the closest attention to the after-treatment if he is to bring the case to a successful issue.

The patient, from his point of view, usually indicates to his medical attendant when his sufferings have reached the limit of endurance, and it is for the surgeon to determine whether the case is suitable for operation or not. In the future, I believe, cases will be subjected to operation earlier, before permanent damage is done to the urinary organs, with a corresponding diminution in the mortality.

SOME PROBLEMS CONNECTED WITH RHEUMATOID ARTHRITIS.

By F. G. THOMSON, M.A. CANTAB., M.D.,
M.R.C.P. LOND.,

PHYSICIAN TO THE ROYAL MINERAL WATER HOSPITAL, BATH.

THOUGH we are now able to distinguish rheumatoid arthritis from other forms of arthritis, and definite criteria have been established upon which to base a reasonably sound diagnosis, little corresponding advance has been made with reference to the pathogeny of the disease, and in consequence our methods of treatment are still almost entirely empirical. Attempts have been made towards a rational form of treatment—first, by the administration of intestinal antiseptics, on the assumption that the disease is a result of intestinal toxæmia; and secondly, by vaccine-therapy, on the assumption that the disease is a general infection. Neither of these assumptions is proved, and our present somewhat blindly directed methods of treatment are anything but uniformly successful in cutting short the disease, and it only too frequently happens that the victims of this relentless disorder get steadily worse. The swollen and tender joints become progressively more ugly, the wasted and distorted limbs more burdensome and useless. The false hopes engendered by remission are promptly quenched by the inevitable relapse. In no case, however slight, can we look upon the disease as otherwise than serious, and it is incumbent on all who see much of the disorder to consider carefully the bearings of such knowledge as we now possess relative to the intrinsic nature of the disease, and to see in what direction further investigations might profitably be undertaken to establish an accurate and complete pathological basis.

Rheumatoid arthritis may be defined as a disease, characterized by the occurrence of more or less symmetrical, spindle shaped, inflammatory swellings of the peri-articular structures, affecting first the smaller joints of the hands and feet, and accompanied by wasting, cramps, and contractures of muscles. The more severe cases are marked by moderate fever, anaemia, and occasional swelling of lymphatic glands and spleen, and most cases show more or less well marked sensory abnormalities and vasomotor changes. The disease tends to last for many years, with occasional intermissions of varying duration. Nearly every joint in the body may be ultimately affected, and the later stages may be complicated by osteophytic outgrowths resembling the condition found in osteoarthritis. The intensity of the disease varies within wide limits, and the clinical picture may be correspondingly diverse. The fact that various local foci of infection may be associated with the disorder has given rise to the suggestion that the cases presenting the above-mentioned characteristics do not constitute one disease. The tendency in some quarters is to limit the term "rheumatoid arthritis" to the more acute type occurring in young women, more particularly after childbirth, the less severe and less typical cases being considered in a different category under

the term "infective arthritis." The proof that the associated infective foci are the direct cause of the disorder is insufficient, and clinically one is able to trace a complete series of cases, from the severe type mentioned above to those in which the characteristic joint lesions, themselves slight, constitute almost the only evidence of the disease. It would appear more correct in the present state of our knowledge to confine the term "infective arthritis" to those conditions such as pneumonic, tuberculous, pyogenic, and gonococcal infections, in which there is indubitable proof of the microbial origin of the joint lesions. The term "rheumatoid arthritis" indicates by common consent a certain combination of clinical phenomena, and, as regards doubtful etiological factors, is entirely non-committal. On the other hand, the term "infective arthritis," as applied to conditions conforming more or less closely to the rheumatoid type, implies knowledge which we can hardly claim and conveys no indication of clinical features.

The more closely we become acquainted with this condition, the more patent does it become that we are dealing, not with a localized condition of arthritis, but with a general disorder by which the whole system is profoundly affected. The anaemia, wasting, glandular enlargements, vasomotor symptoms, cramps, and trophic disorders, all point the same way, though in the slighter cases these symptoms are less prominent and apt to be overlooked.

Apart from the joint lesions, one of the most noticeable and constant phenomena in true rheumatoid arthritis is a remarkable condition of vasomotor instability of the extremities.

No one who is frequently brought into contact with the disease can fail to notice the constancy of these associated vasomotor changes, from which patients suffer great discomfort and considerable pain. A condition in which the extremities look blue, congested, and puffy, giving rise to a tense, swollen sensation, alternates with a form of spasmodic ischaemia, in which the fingers are cold, pallid, waxy, and numb. The intensity of these vascular changes varies within considerable limits, but may be so great as to suggest the presence of Raynaud's disease. In illustration of this I may be allowed to quote the case of a well-known member of our own profession with typical rheumatoid lesions of both hands, who at the commencement of his illness, before joint lesions became manifest, diagnosed his own condition as Raynaud's disease.

The vasomotor abnormalities may exist in greater or lesser degree for long periods before other symptoms of rheumatoid arthritis supervene. Patients will frequently state that they have been subject to "bad circulation" or "dead fingers" for many years before the onset of joint lesions. One middle-aged patient stated that for something like thirty years there had been such a severe tendency for the fingers to become "numbed and dead" that ordinary housework was almost impossible, and it is not uncommon for patients to give a history of five or more years during which they have noticed similar symptoms.

A study of the histories of a considerable number of cases suggests that the tendency to marked vasomotor instability is an index of some personal idiosyncrasy predisposing to the disease, rather than a direct result of the exciting cause.

Associated with the vasomotor changes are the muscular cramps, which are very characteristic of the disease, and occur with great frequency. They do not necessarily occur in the muscles directly connected with the affected joints, and may occur entirely in the legs when the hands and arms are the site of the more severe articular lesions. In such a case I have known walking to be entirely prevented owing to the pain occasioned by violent cramps in the calves directly the patient attempted to get about. The coexistence, in both rheumatoid arthritis and Raynaud's disease, of spasmodic ischaemia of the extremities and cramp of the limbs, suggests that the latter is due in both conditions to spasms of the arteries supplying the muscles, with resultant accumulation of metabolic end products.

The early incidence of rheumatoid arthritis on the nervous system is indicated by the marked increase of reflexes, early wasting, and definite sensory disorders, which together go to make up a large part of the clinical

picture presented by the disease. The late Dr. W. M. Ord was the earliest to suggest that the disease was primarily a nervous disorder, and though the exact significance of the nervous symptoms has not been determined, further researches in this direction may possibly throw light on the essential nature of the disease.

The well-marked increase of deep reflexes is a notable feature in the early stages of the disease, and Dr. R. J. Llewellyn, who has made a careful study of the superficial reflexes, states that these also may be definitely increased. Muscular wasting may ensue with considerable rapidity, and even precede any marked lesions of the joints. In addition to the general wasting associated with the disease, the extensor muscles of the affected joints seem to be specially picked out. As the shoulder-joint is frequently affected next in order to the joints of the hands and wrist, it not uncommonly happens that the early wasting of the deltoids, together with the smaller muscles of the hands, is somewhat suggestive of the early stages of progressive muscular atrophy.

Sensory changes, as numbness, formication, and sensations of pins and needles, are constant and early phenomena. The exact distribution of sensory changes and of the pain associated with the disease is a matter of considerable interest. Llewellyn finds the sensory changes to correspond with segmental areas, and points to certain abnormalities of superficial and deep reflexes as bearing out the suggestion. I must admit that I have been unable to demonstrate in my own cases any clearly defined segmental distribution. On the whole, the distribution of sensory changes has seemed to me to follow that of peripheral nerve branches rather than of spinal segments, but in this connexion we must remember the possibility, suggested by Dr. James MacKenzie, that intrinsic lesions of the joints may themselves give rise to referred pains of segmental distribution.

The whole subject of the motor and sensory phenomena associated with rheumatoid arthritis is one of much interest, and affords a large field for further investigation. Unfortunately the few recorded *post-mortem* examinations throw little if any light on the question, and as, in the nature of things, we are likely to get little help from this source in eliciting the character of the earlier stages of the disease, accurate clinical observation becomes doubly necessary.

The above mentioned nervous and vasomotor phenomena, together with the anaemia, debility, and symmetrical joint lesions, point to the conclusion that rheumatoid arthritis is essentially a widespread systematic intoxication, and the question remains whether it is a toxæmia from without due to bacterial invasion, or a disorder from within due to qualitative or quantitative changes disturbing the balance of the various internal secretions.

From the time when Drs. Bannatyne and Wohlmann first demonstrated organisms in the synovial fluid till the present, numerous investigations have been carried out, both in this country and abroad, with a view to the isolation of a specific organism, either from the joints or blood. Many observers have failed to demonstrate organisms at all, while in the cases where they have been found there is no uniformity of results. Instances of improvement following a course of vaccine-therapy have been recorded, but their number is not sufficiently great to enable us to say whether the administration of vaccine, generally speaking, is likely to prove more efficacious than other methods of treatment. Though there is a good deal of clinical evidence, and a certain amount of experimental evidence to support it, the hypothesis of the bacterial origin of the disease must still be considered *sub judice*.

Efforts have been made to correlate the disorder with the presence of different local foci of infection, and pyorrhœa alveolaris, rhinitis, otorrhœa, sinusitis, endometritis, and inflammatory conditions of the gastrointestinal tract have been severally considered responsible for the condition. Here, again, the evidence is inconclusive. The very multiplicity of the affections named, and the variety of organisms responsible for them, suggest that whatever influence they may have as predisposing factors, we must look elsewhere for the determining cause. Further, such conditions as pyorrhœa, uterine discharges, and septic conditions generally are so extremely common that if they were direct causes of

rheumatoid arthritis we should expect the latter to be far more frequent than it is.

In a large proportion of cases of rheumatoid arthritis there is no demonstrable site of infection. In these the supporters of the chronic infective theory are forced to postulate some cryptic source of infection in the gastrointestinal tract, and we cannot dismiss the possibility that chronic intestinal toxæmia may stand in a more direct relationship to the disease. Patients frequently complain of chronic dyspeptic symptoms as an antecedent to the joint troubles. Strangeways states that 39 per cent. give a history of antecedent gastric disorders, but unfortunately the cases from which the statistics are derived included forms of arthritis other than rheumatoid. In my own cases symptoms of gastric ulcer, latent or otherwise, have occurred sufficiently often to be very suggestive of some association between the two diseases, but the number of cases has not been great enough to render statistics on the point of any value. The removal of decayed teeth and treatment of pyorrhœa alveolaris are frequently followed by striking improvement in rheumatoid symptoms, but this is probably to be explained by the marked improvement in general health and vitality which results from the removal of digestive disorders. Intestinal antiseptics certainly have an influence for good in the disease, and, as far as my experience goes, small repeated doses of grey powder seem to have done more good in the treatment of the more acute types than any other remedy, though salol, β -naphthol, and other antiseptic drugs no doubt possess similar properties in varying degrees.

Thus the theory of gastro-intestinal toxæmia is sufficiently plausible, and borne out to a certain extent by therapeutic tests, but further investigations are required as to any bacterial or chemical features of the gastro-intestinal tract, peculiar to the disease, before we can unreservedly accept it.

Whatever views we may hold as to the infective origin of rheumatoid arthritis, there can be no doubt but that the personal element is an important factor in the genesis of the disease. The fact that about 80 per cent. of the cases occur in women, nearly all between puberty and the menopause, is in itself suggestive. Again, many of the sufferers come of a distinctly arthritic stock. Garrod quotes over 40 per cent. as having a family history of gout or "rheumatism," and it is no uncommon thing to find two or more members of a family suffering from the disease. I have notes of one case in which no less than seven members of one family, in two generations, suffered from the same, or at least a similar, disease at the same time—namely, father, mother, three sisters, and two female first cousins.

Consider, again, the age and sex relationship of rheumatoid arthritis to gout. Whereas nearly 90 per cent. of cases of rheumatoid arthritis occurring in women fall between the age of 15 and 45, arthritic gout in the female sex is extremely uncommon between these ages. Thus it would appear that there is some powerful agency at work in women during the reproductive age which is as conducive to rheumatoid arthritis as it is antagonistic to gout.

On the other hand, the vast majority of cases of Graves's disease correspond in sex and age limits to those of rheumatoid arthritis, and the general relationship of the two diseases suggests the existence of some important factor common to both. Numerous cases have been recorded by McAlister, Llewellyn, Sprigg, and others in which definite Graves's disease and rheumatoid arthritis have existed simultaneously in the same patient, and symptoms of hyperthyroidism, in the form of tremor, soft rapid pulse, moist skin, and tendency to pigmentation, are amongst the most constant features in the more severe cases of rheumatoid arthritis.

Whether the profound constitutional changes found in both diseases are due to microbial infection is at present uncertain, but this question does not affect the conviction to which we are by circumstances forced, that in both rheumatoid arthritis and Graves's disease there exists a strong personal predisposing factor, which is enormously enhanced in the female sex, especially during the period of reproductive activity. In both diseases there appears to be some deep-seated metabolic error, involving important changes in internal secretions, and the personal factor predisposing to either may consist in a congenital or

required instability of the normal relationships which govern secretory activities.

However this may be, there is a strong family resemblance between Raynaud's disease, rheumatoid arthritis, and exophthalmic goitre. Whether there is any etiological or pathogenic factor common to those diseases remains to be seen. At the present time the pathology of all three is equally secure, and the nature of any relationship between them is entirely conjectural.

Whatever its relationship to other diseases, rheumatoid arthritis presents in itself many points of interest and many features of obscurity. I have attempted to indicate briefly certain problems in connexion with it which require to be elucidated before we can claim to have a sound knowledge of its pathology. On the clinical side a wide field of investigation is afforded in the systematic and careful consideration of family history and individual peculiarities in so far as they indicate a personal factor predisposing to the disease, together with precise investigations as to the nature and significance of the so-called accessory symptoms as they affect the nervous and vascular systems respectively. On the pathological side we require to know what relationship, if any, exists between the various foci of infection which frequently precede the disease and the subsequent phenomena, and more especially the importance of gastric and intestinal toxæmia as an etiological factor. It is possible that expert bacteriological examination of the flora of the gastro-intestinal tract in a series of cases might throw considerable light on this aspect of the question, and such investigations are urgently required.

Systematic chemical and bacteriological examination of the urine, to determine not only the presence or absence of disease of the urinary tract, but more particularly the standard of renal efficiency and the presence of any peculiar features of excretory activity, are also required to throw further light on any metabolic peculiarities incidental to the disease.

THE OCCURRENCE OF ACUTE PNEUMONIA DURING TREATMENT WITH ARSENIC.*

BY

F. PARKES WEBER, M.D., F.R.C.P.,

PHYSICIAN TO THE GERMAN HOSPITAL, LONDON.

In a few cases I have observed the sudden occurrence of pneumonia in children whilst they were undergoing arsenical therapy on account of lymphadenoma or some other disease, and it has appeared to me that the association was no chance one, but that the pneumonia was in some way dependent on the taking of arsenic, as is arsenical herpes zoster. Two of the patients likewise had attacks of arsenical herpes zoster. The rapid recovery from the lung disease was another striking feature.

CASE I.

Sophie T., aged 15, under my care at the German Hospital in 1902 for lymphadenoma, was a thin anaemic girl. The lymphatic glands on the right side of the neck and the spleen were greatly enlarged. Enlarged cervical glands had been present as early as 1898. In June, 1902, whilst under arsenical treatment, she had a short acute attack of pneumonia at the base of the left lung, accompanied by very little fever. It may be noted that about a year previously (1901) whilst taking arsenic she had had a mild attack of herpes zoster (doubtless arsenical herpes zoster) on the left side of the chest, though in regard to her general condition the arsenic seemed to have done her good. The herpes zoster apparently caused her no pain or inconvenience.

She died in December, 1902, and the necropsy showed the presence of considerable (partly miliary) tuberculosis in addition to old lymphadenoma. The spleen was enlarged to about five times the normal size and contained whitish masses. Microscopically the spleen, and the liver also, were found to contain minute tubercles. A hard, fibrous mass situated at the back of the upper part of the abdomen and displacing the stomach and liver forwards, had microscopically the appearance of chronic hard lymphadenoma.

CASE II.

A boy, Roger S., aged 8 years, suffered from typical Hodgkin's disease (lymphadenoma), which involved the cervical lymphatic glands and the spleen. In 1902 he was under the care of my colleague Dr. Karl Fürth, who has kindly allowed me to refer to the case. The disease, which was supposed to have com-

menced about three years earlier, was apparently diminishing under arsenical treatment, when in December, 1902, he developed signs of pneumonia (dullness and bronchial breathing at the base of the left lung) accompanied by only slight fever. The arsenic was discontinued. The boy had likewise typical herpes zoster on the right side of the chest and a generalized eruption of minute vesicles on the trunk, possibly due to arsenic. This was followed by a good deal of desquamation, especially on the palms of the hands (? arsenical).

The boy seemed fairly well when he left the hospital in January, 1903. But he did not live long.

CASE III.

A boy, Freddy J., aged 7½ years, was admitted under my care in June, 1905, for chorea minor. The case had a special interest of its own, inasmuch as the patient was left-handed and the right half of his head was distinctly bigger than the left half. The choreic trouble, which was specially marked in the left upper extremity, was temporarily associated with loss of speech ("choreic aphasia"). Auscultation of the heart showed a slight mitral systolic murmur, when he left the hospital in September, 1905.

In the following year he was readmitted for slight chorea, and whilst under arsenical treatment, on March 6th, 1906, he developed pneumonia of the lower part of the left lung (impairment of resonance and crepitation) with considerable fever. There was no fever after March 13th, but crepitation could be heard over the affected lung for some days more. The pneumonia seemed to be of a mild type. There was very little cough and no pain.

CASE IV.

A little girl, Anna G., aged 4 years, when being treated, during 1910, with liquor arsenicalis for a lichen-like affection, developed acute pneumonia (with dullness and bronchial breathing) at the base of both lungs. There was considerable fever, but the pneumonic signs cleared up very well. There was for a time in this case a diffuse cutaneous erythema, which may have been of arsenical origin, and was followed by slight general desquamation and brownish pigmentation.

CASE V.

A girl, Theresa E., aged 14 years, who was undergoing radium treatment and was taking arsenic and iron for an acute and malignant type of Hodgkin's disease (lymphadenoma). A lymphatic glandular swelling had been first noticed on the left side of the neck in January, 1912, and, after operative removal of this in May, 1912, a fresh glandular tumour had rapidly formed on the same side of the neck. Radium treatment was tried in August, and was followed by great diminution of the swelling in the neck, but soon afterwards a striking enlargement of the spleen, and probably of intra-abdominal lymphatic glands also, occurred. She was losing ground in spite of treatment by arsenic and iron and the radium therapy, when, on December 5th, 1912, I saw her with Dr. Smulian for acute lobar pneumonia of the lower part of the left lung (dullness, bronchial breathing, and some crepitation) with moderate fever. The respirations were 46 a minute, and the pulse 120. The pneumonia had apparently commenced with general convulsions three days previously, and it seemed (considering the patient's bad general condition) to have come as a "terminal" infection. However, on the next day the patient was already recovering from the pneumonia, and in a few days she was able to leave her room and go out for drives. The lymphadenomatous disease nevertheless rapidly progressed, and she soon died.

In the foregoing cases the patients were all young, and the recovery from the pneumonia was excellent, even when the general condition, as in the last case, was extremely bad. There was little in the way of distressing cough or pain. It seems to me that arsenic may possibly predispose some persons to an attack of (? pneumococcal) pneumonia, just as it is acknowledged to predispose some individuals to an attack of herpes zoster, which is perhaps, like pneumonia, a disease of infectious (microbic) origin. On the other hand, my cases are too few in number to draw any certain conclusions from, and I do not know that any similar cases have been described in the literature on the effects of arsenic, or in that on pneumonia. It must not, however, be forgotten that it is only comparatively recently that herpes zoster has been acknowledged to be in some cases a consequence of the ingestion of arsenic, as a medicine or otherwise—as, for instance, as a contamination of beer in the English epidemic of arsenical poisoning in 1900.

I think it highly probable that cases of pneumonia similar to those which I have recorded will soon be observed by others amongst children and young persons undergoing arsenical treatment. If other cases should be found to confirm my suggestions, I would be tempted to think that the arsenic, whilst predisposing towards pneumonia, must also exert a favourable effect on the reaction of the body towards the disease—that is to say, that when pneumococcal pneumonia occurs in patients who are being treated with arsenic the pneumococcal infection is quickly

* A paper read at the Medical Section of the Royal Society of Medicine on January 28th.

and successfully resisted. Perhaps later on some arsenical drug like salvarsan or neo-salvarsan will be found to have a beneficial effect in pneumococcal pneumonia or other pneumococcal infections, and it might be worth while to undertake experiments with mice or rabbits in this connexion—that is to say, one might try the effect of arsenical preparations, in regard to experimental pneumococcal pneumonia, in those animals.

THREE CASES IN MIDWIFERY PRACTICE.

BY

JOHN REID, B.A., M.D., B.Ch., B.A.O.,

LATE SENIOR HOUSE-SURGEON, SOUTH INFIRMARY, CORK.

THE following unusual midwifery experiences occurred in my practice within four weeks, from the middle of March to the middle of April, 1912, and I think that as the material results are so good, and as one child born with asphyxia pallida recovered, it is worth while to publish the cases.

CASE I.—*Rupture of Uterus with Extrusion of Intestines.*

This case I saw with my colleague Dr. Meade, of Ballymore. The patient, who had had two difficult instrumental labours and two miscarriages, had been in bed for a couple of days, and for the last twenty-four hours was passing matter from the vagina. She had also some abdominal pain. As she was but six months pregnant she did not suspect labour. Getting out of bed one morning at 10 o'clock to pass urine, the baby was expelled into the vessel. She got back into bed. On Dr. Meade's arrival he found three coils of intestines hanging out of the vagina, as well as the cord. Having disinfected his hands and arm and the intestine, he returned the gut and at the same time turned out the placenta, which had been retained in the uterus. At this time the patient was collapsed and was given hypodermic injections of strychnine. I saw her next afternoon, when she was vomiting severely and had well marked peritonitis. The pulse and temperature were high, and the tenderness over the abdomen extreme. The prognosis was most grave. On the third day a small piece of placenta was expelled. On the fifth day, when I saw her again, her condition was easier. After five days she began to improve, and in three weeks was well on the road to recovery.

Her magnificent recovery was due to her own splendid constitution and the care taken of her by Dr. Meade, who had so carefully put back the intestines, and had adopted a semi-Fowler position, as well as gentle douching twice daily. She had hypodermic injections of strychnine twice a day, quinine and digitalis in pills thrice daily, and magnesium sulphate every third day. With the exception of the most gentle douching, no examination or manipulation of the genital passage was attempted, as we considered perfect rest of the parts gave her the best chance. What the condition was which allowed the intestines to protrude is difficult to tell. Probably she had an abscess in the posterior wall of the womb, low down, or else some collection of pus in Douglas's pouch, and the labour pains driving down the head of the child broke the walls of the sac, and so the intestines protruded. Of course, the child (which was under six months) died shortly after birth.

CASE II.—*Myelocle and Meningo-encephalocele.*

This was a case of breech presentation, seen with Dr. Hennessy of Bandon. Chloroform was administered and the breech was extracted in the usual manner with extreme difficulty, owing to contracted pelvis. The arms were next extracted, but it was wellnigh impossible to remove the head. We noticed on the centre of the back a myelocle, and it was our intention to cut across the neck with a scalpel and introduce a catheter into the cranium, as we considered it might be a case of hydrocephalus. Whilst considering the advisability of doing this, and yet wishing, if possible, to extract a living child (as the only other one was stillborn), the head came away with a strong pull, and to our surprise showed an enormous ruptured meningo-encephalocele. Here was an example of both a myelocle and a meningo-encephalocele. The uterus was thoroughly douched out with hot creolin solution, and the woman recovered in the usual time without any abnormality of temperature or pulse. I have arranged with her if she becomes pregnant again to have Caesarean section performed.

CASE III.—*Asphyxia Pallida.*

A primipara was seen by me after she had been in labour for thirty-six hours. I found membranes ruptured, head presentation and prolapse of cord. I found afterwards a marginal insertion of an ordinary length of cord, and also that there was a history of curettage and wearing of a pessary for retroflexion. Her condition of sterility that had lasted for some years, so

that there was probably some laxity of uterine muscle. The cord was pulsating and the fetal heart fairly strong. As the membranes were ruptured I considered the best chance for the child was rapid delivery, having warned the father that the child would undoubtedly be dead. With considerable difficulty I extracted by the aid of axis traction forceps, a male child, of normal size, in a condition of absolute asphyxia pallida. It was white and flaccid, and showed no attempt at respiration. I cleared the mouth of mucus, rubbed it with brandy, and tried artificial respiration by Schultze's method, and plunged it into hot and cold water. Finding these methods useless, I sterilized a plated oval female catheter, slightly curved, having five holes on either side, and hooking my left forefinger round the epiglottis, I gently passed the catheter into the child's trachea, and inflated the lungs, ten or twelve times a minute as near as I could judge. After fifteen minutes I could see the child's heart beating, and there was an occasional gasp; then the gasps became more frequent, and after three-quarters of an hour it was breathing well and quietly, but exceedingly weak in its cry. He is now a fine healthy boy, to the great joy of his father and mother.

In Holt's *Diseases of Infancy* (p. 71) it is stated that inflation of the lungs is not usually of much general value, but is sometimes successful, and he recommends a soft catheter or the laryngeal tube of Ribemont. I venture to think, however, that a sterilized metal catheter such as I have described, if inserted gently, will meet the conditions.

Some months previous to this case I used similar treatment in another case of asphyxia pallida, but without success. I could see the heart beating vigorously, and the child would give some gasps, then the heart got weaker, and finally, after keeping the heart going with the help of my assistant for an hour and a half, it gradually weakened, the gasps ceased, and death ensued.

As the cases of these two children seemed to me to be interesting from a physiological point of view, I wrote to Professor Halliburton (to whom my sincerest thanks are due) as to why one child died and the other recovered. Since increasing venosity stimulates the respiratory centre we had here an excess of CO₂; why, then, did my expired air, containing a large amount of CO₂, produce a stimulation of the respiratory centre? Professor Halliburton's reply is as follows:

Your cases of asphyxia pallida are very interesting. I imagine that in your second case the child was practically dead from deprivation of oxygen before you began the blowing in of air. The respiratory centre is very sensitive, and I would imagine that the few gasps you got were due to the oxygen supplied by your own expired air, and not to the CO₂ in your expired air. The child would already, owing to lack of oxygen, be loaded with CO₂, and beyond a certain stage this gas is a poison. The pallor would be due to stoppage of the circulation and constricted blood vessels; hence no blueness. But I suspect the blood was very venous nevertheless, and I cannot therefore think that any acapnia was present. In the first case the recovery due to oxygen supply was accomplished because the child to start with was only say 75 per cent. and not 99 per cent. dead.

The explanation given by Professor Halliburton is a great help, and it is a great incentive to know the reason why one is doing a certain action, and shows that by keeping up the treatment for a considerable time valuable infant lives might be saved. No stillborn child should ever be condemned to its grave without this method being effectually carried out, for assuredly success will many times follow.

THE report presented to the annual meeting of the Royal Bath Hospital and Rawson Convalescent Home, Harrogate, on January 30th, announced the resignation of Dr. Charles Gibson, who for twenty-one years had been an honorary medical officer to the hospital, and during that period had rendered it incalculable services. In moving the adoption of the report Major Dent, the chairman, observed among other things that it would be seen that very few subscriptions had been withdrawn owing to the National Insurance Act, and he hoped in connexion with institutions like that there would be no falling off. Whatever happened in other institutions the Insurance Act did not affect an institution like theirs, and it was essential that charitably disposed people and workpeople should continue liberally to support it. Certain alterations were made in the rules, and Dr. Hobson and Dr. Gibson were appointed honorary consulting physicians, Dr. Hinsley Walker and Dr. Johns were appointed honorary medical officers, and Dr. G. E. Kerr Pringle and Dr. David Brown were added to the honorary medical staff.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

LARGE BROAD LIGAMENT CYST WITH OVARIAN DERMOID ON THE OPPOSITE SIDE.

A woman aged 35, married thirteen years, was sent to see me by Dr. Ford, of Forest Gate. She had never been pregnant. She had menstruated regularly—on the last occasion three weeks before I saw her; during the previous six months the loss had been rather more than usual, and she had complained of a feeling of fullness about the abdomen, with pain occasionally in the cardiac region. The abdomen, which was markedly enlarged, was occupied by a swelling which was located more especially in the left abdomen, and extended from the pelvis to the level of the lowest rib. Fluctuation was easily elicited. The tumour was ovoid in shape. The cervix uteri was very high, almost on a level with the upper border of the pubic bone. The body of the uterus could not be clearly defined. The vaginal roof anteriorly and to the left of the cervix was slightly depressed by a portion of the abdominal swelling. Through the right fornix was felt a small firm swelling, which was the right ovary enlarged to nearly four times its natural size.

The abdominal cyst was tapped and thereafter enucleated from the broad ligament. It contained typical parovarian fluid. There was no trace of the left ovary. The right ovary was also removed. It was of the size of a small Tangerine orange, and was a dermoid cyst containing bone, hair, and sebaceous material.

London, W.C.

JAMES OLIVER, M.D., F.R.S. Edin.

THE ASSOCIATION OF BAD TEETH WITH LEAD POISONING.

ix lead works one comes across many men who are pale and badly nourished, some of them languid and disinclined to work. Occasionally they complain of epigastric pain and irregularity of the bowels. Finding them with a blue line generally surrounding carious teeth, many medical men notify these cases as instances of plumbism.

During the last year I have ordered such men to have the teeth extracted, with the result that all the signs and symptoms disappeared, and instead I found them with a healthy colour on the cheek, their nutrition improved, and their capacity and desire for work everything that could be desired.

It is important to lay stress on the recognition of this connexion. It is important to the men who are prejudiced for other work, to the employers who have to pay compensation, and to the neighbourhood, should the industry be affected financially in consequence of an erroneous diagnosis.

This connexion of carious teeth and plumbism is important, because with such ever-present pyogenic foci pouring poison into the stomach, its mucous membrane becomes inflamed, and thereby offers a greater absorbing surface to the lead, especially if it be converted into lead iodide by the internal administration of calcium or potassium iodide.

Iodides are strictly contraindicated in the treatment of plumbism, and should never be given. The best treatment is by means of calcium permanganate, which cures the gastric inflammation.

The pyogenic infection is vastly more dangerous than the inhalation of lead dust.

Swansea.

G. ARBOUR STEPHENS, M.D.

THE APPLICATION OF TAXIS.

The following plan I find useful: The last case I tried it in was an elderly male with a small, tight femoral hernia. I sit close to the bed, place the patient's knee on the side affected over my corresponding shoulder, and get some one to steady the foot. One hand passes between the thighs, the other is on the outside of the thigh. I then tilt my shoulder up, raising the patient's pelvis, and apply taxis in the usual way. The method is very comfortable for the practitioner.

Glasburgh, S.O.

JAMES G. MACASKIE.

Reports

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

CENTRAL LONDON SICK ASYLUM, HENDON.

SPONTANEOUS FRACTURES; PLATING; NON-UNION; SALVARSAN TREATMENT; SECOND PLATING; RECOVERY.

(By BRIAN METCALFE, M.R.C.S., L.R.C.P., Assistant Medical Officer.)

THE patient in the following case, a man aged 40, was stepping off a stationary tramcar on December 22nd, 1911, when he felt something give way in his right arm. There was no pain, but the arm immediately became powerless. He went straight to a hospital, and was admitted at once. He remained an in-patient for five weeks, the arm being placed on an internal angular splint, which was only removed for the purposes of x-ray examination. At the end of five weeks he was discharged to attend as an out-patient.

State on Examination.

He then entered the Central London Sick Asylum, the arm being still on the splint, and his condition: Fusiform swelling about the lower third of the right humerus. Crepitus easily obtained, the fragments being extremely mobile, movements caused no pain, x-ray examination showed an almost transverse fracture of the lower third of the humerus, no overlapping, no comminution; a good deal of callus was present. The patient gave a definite history of syphilis, for which he had received only spasmodic treatment. There was a healed scar on the corona, and four years previously he had been treated in Hendon Sick Asylum for gummatous periostitis of the left clavicle and left parietal bone; in both situations there were now present soundly healed and depressed adherent scars.

Treatment.

The arm was placed in plaster-of-Paris for six weeks, and iodide and mercury given internally, and at the end of this period there was still no union.

On March 29th, 1912, the fracture was exposed by an incision on the outer side of the arm—a false joint with a thick capsule, and great excess of callus were found. The joint was excised and the fragments united by one plate and four screws placed on the external surface of the bone; an internal angular splint was applied. The wound healed by first intention; the splint was removed at the end of a month; there was still no union. A skiagram showed good apposition, some callus, and the plate holding well.

The patient was now put on thyroid extract, 5 grains twice daily. The iodide was increased to a 100 grains per diem; Bier's bandage was applied for three hours twice a day, there was also daily massage. After two weeks of this treatment the patient took his own discharge, there being still no signs of union.

On May 29th, 1912, he returned to the Hendon Sick Asylum, meanwhile having attended a hospital as an out-patient. During the whole of this time the arm was kept on an internal angular splint, but there was still no union. The screws were firm in the upper fragment, but loose in the lower one. On the right buttock there was a typical syphilitic rupia.

Primary Union after Salvarsan Treatment.

On June 6th, 1912, the patient was given 0.6 gram of salvarsan intravenously, the median basilic vein being deliberately exposed and opened. I have used this method on fifty-eight occasions, and prefer it to attempting to directly plunge a hollow needle into the vein. By June 15th, the rupia having healed, the old incision was reopened, and the former plate and screws removed; another false joint was found to have formed, very little callus was present, the ends of the fragments were excised and two plates inserted, one anteriorly and one externally. The arm was put up on an internal angular splint; primary union took place, and bony union was firm and complete at the end of four weeks.

REMARKS.

I heard from the patient on November 15th, five months after the second plating, saying that his arm was strong and well, and that he had never felt better in his life.

It was intended to give the patient two further doses of salvarsan, but as he felt so well he was averse to receiving another injection. There can be little doubt that this was a case of spontaneous fracture due to a gumma, and I think that it shows the important part that salvarsan took in the ultimate cure of this fracture, as the patient throughout was treated by potassium iodide in increasing doses with no effect. I am indebted to Mr. Hopkins, F.R.C.S., Medical Superintendent, for permission to publish the above notes.

Sir ARCHIBALD GEIKIE, K.C.B., President, in the Chair.

Resilience of the Arterial Wall.

In a paper on the influence of the resilience of the arterial wall on blood pressure and on the pulse curve, Drs. S. R. WELLS and LEONARD HILL, F.R.S., stated that the form of the pulse curve and the systolic and diastolic pressure (measured by the sphygmomanometer in the case of man) were modified very greatly by the conduction of the pulse along any particular artery. The conduction varied with the resilience of the arterial wall. An artery which was contracted, and therefore more rigid, conducted the systolic crest almost with undiminished amplitude from the heart to the peripheral vessels, and there was in such an artery a wide difference between the systolic and diastolic pressure. In a relaxed, resilient artery, on the other hand, the systolic wave expanded the wall of the artery, and part of its energy was stored up as potential energy in the wall. As this came into play during diastole and the systolic wave reached the peripheral vessels in diminished form, the height of the diastolic wave was approximated to that of the systolic. The arteries were controlled so as to bring about one or other of these conditions at the periphery—a hammer-like pulse with big difference between systole and diastole, or a pulse with small difference and a more uniform mean pressure. The evidence for these conclusions had been drawn both from the investigation of thin-walled rubber tubes (specially made) and of arteries.

Ganglion in the Human Temporal Bone.

Mr. A. A. GRAY reported the occurrence of a ganglion hitherto undescribed in the human temporal bone, below and in front of the stapedius muscle. In the specimen in which it was discovered the ganglion was comparatively large, but it was thought probable that considerable variations in this respect occurred in individuals. As far as present investigations show the ganglion was associated with two nerves—the facial nerve and Arnold's nerve—but it was possible that fibres from other nerves might enter it. It was irregular in shape, finger-like processes projecting from it into channels in the surrounding bone. It contained on the whole a rather large proportion of fibres relative to the number of nerve cells. The majority of the nerve cells were multipolar, but occasional bipolar cells were found.

The Action of Adrenin on Veins.

Messrs. J. A. GUNN and F. B. CHAVASSE reported the results of a research on this subject. They found: (1) That the action of adrenin upon ring preparations of veins remote from the heart was to diminish their calibre as in the case of arteries; the veins, therefore, probably contained veno-constrictor nerve fibres from the thoracic-lumbar sympathetic system. (2) That the action of adrenin on quiescent rings from the superior vena cava near the heart was to cause them to beat rhythmically and powerfully. (3) That (a) the accelerator-augmentor nerve supply of the heart and (b) the rhythmically contractile tissue extended up the superior vena cava for at least 6 to 8 mm. from the veno-auricular junction in the heart of the sheep. (4) That the induction by adrenin of rhythmic contraction in the quiescent superior vena cava seemed, on the whole, in accordance with the myogenic theory of mammalian heart rhythmicity.

Treatment of Trypanosomiasis and Yaws by Antimony.

Captain H. S. RANKEN, R.A.M.C., in a preliminary report on the treatment of human trypanosomiasis and yaws with metallic antimony, stated that intravenous injection of metallic antimony in a fine state of division was a therapeutic measure applicable on a large scale to the treatment of human trypanosomiasis. A considerable number of cases had been so treated, and in a further series combined treatment was employed, salvarsan or atoxyl being given in addition to the antimony. As a routine dose, 1 grain of antimony was given in 4 oz. to

6 oz. of physiological salt solution. In the great majority of cases treatment brought about considerable improvement, as evidenced by disappearance of trypanosomes from the blood and lymphatic glands, improvement in nutrition, mental state, etc. It was not yet possible to determine the ultimate results of treatment. The symptoms following treatment were described, and it was stated that in certain individuals hypersusceptibility existed. Reference was made to the exceedingly rapid trypanocidal action of antimony and to its effect on the leucocytes. The preparation was also used in ten cases of yaws, and all were cured. The usual course of treatment was three or four doses.

Extrusion of Granules by Trypanosomes.

Major W. B. FRY and Captain H. S. RANKEN described some further researches on the extrusion of granules by trypanosomes and on their further development. Two classes of granules were mentioned: (a) Those representing probably stored food material; and (b) those of nuclear origin and character, but the paper dealt with the latter only. The mechanism of extrusion as observed in human and animal varieties was described, and the influence of drugs and other effects discussed. A description of the free granule and its after-development and fate was given. Many of the observations were made on the parasite in the living state, but the paper also contained notes on fixed and stained specimens, and Mr. H. G. PLIMMER, F.R.S., added a note on a new method of blood fixation.

MEDICAL SOCIETY OF LONDON.

Monday, February 10th, 1913.

Sir W. WATSON CHEYNE, President, in the Chair.

Early Operation in Appendicitis.

Mr. EDMUND OWEN opened a discussion on early operation in appendicitis. His remarks are published in full in this issue of the JOURNAL (p. 321).

Mr. W. H. BATTLE did not think that any one with experience of appendicitis in its acute form could deny that operation including removal of the appendix at the commencement of the attack was advisable, and that it constituted the only plan of treatment that could be regarded as certain to yield adequate results in a large series of cases. To advise a patient to submit to operation was the counsel of perfection. If the operation were deferred, the patient lost very much and gained little by his refusal to submit to operation in the first instance. Early operation was not only life-saving, but also the period of illness was shortened, and if done quite early the wound could be closed without drainage, and danger of subsequent hernia was obviated. He said that he was not an advocate for indiscriminate operation. One should always endeavour to diagnose the state of the appendix, but the correct clinical estimation of the case was of greater value. Indiscriminate operation in every case and at any period in an acute attack would be found almost as disastrous as no operation at all.

Mr. C. P. CHILDE said that he was a warm advocate of operation in appendicitis at the earliest available moment, and he considered that any counsel of delay or any attempt to discriminate between cases that should be operated upon and those which might be left to an interval operation was a putting back of the clock in the treatment of the disease. His reasons were based on 700 operations. The more extensive one's acquaintance with appendicitis became, the more one became convinced of the unreliability of any symptoms as guides to the immediate or future safety of the patient. He considered he would be acting with an assumption of knowledge he did not possess if he tendered a patient suffering from appendicitis advice that he might safely await the removal of his appendix until a subsequent date.

Mr. G. GREY TURNER also spoke strongly in favour of early operation. His results of a total of 681 operations bore out his contention. Of these the total mortality was 35, or 5.13 per cent. In 43 cases of acute appendicitis without peritonitis no deaths had occurred. In 130 of acute appendicitis with localized peritonitis only 3, or 2.3 per cent.

Mr. GEO. H. TURNER said that the results of operation for appendicitis at St. George's Hospital had shown considerable improvement during the last four years. This he ascribed to the cases being sent earlier. In his last 100 consecutive cases he had had only 1 death, and had had 62 consecutive cases without a death. He could see no use in waiting. He advised operation at every stage so long as the patient was not moribund. There was practically no risk whatever in the early stage.

Mr. CRAWFORD RENTON regarded the paper as epoch-making. Early operation was the only proper treatment in acute cases. He had always operated at once for many years. The mortality of immediate operation was about 2 per cent.; if deferred, 20 to 40 per cent.

Major HULL, R.A.M.C., said that it would be admitted generally that all early cases should be operated upon before pus formation took place. If this were done the mortality would be practically nil. He regarded those cases due to a pure *Bacillus coli communis* infection as less serious, and as accounting for the majority of the cases where recovery without operation occurred.

Mr. W. H. CLAYTON-GREENE said he had read a paper on the subject ten years ago, and considered that the high mortality was due to delay. His opinion of the value of early operation in limiting the mortality and preventing complications was confirmed by the attitude of many physicians, who had become more surgical even than the surgeons.

Mr. A. H. BURGESS also spoke in favour of early operation.

Mr. EDMUND OWEN briefly replied.

EDINBURGH MEDICO-SURGICAL SOCIETY.

Wednesday, February 5th, 1913.

Mr. J. M. COTTERILL, President, in the Chair.

The Relation of the Radiographer to the Physician and Surgeon.

Dr. A. MCKENDRICK read a communication on this subject. He said that two alternatives offered themselves in a discussion of this question: (1) Where the radiographer merely occupied the position of an *x*-ray photographer; and (2) where he was regarded as a consultant in the same sense as the pathologist and the ophthalmologist. The status of the radiographer in various Continental hospitals was generally that of the latter alternative, and in certain British hospitals only a written report was sent out, the plates being retained, classified, and stored in the *x*-ray department. The question was not new, having been discussed at several Continental congresses, and it was still unsettled. Mr. WALLACE said that a report alone by the radiographer who was not acquainted with the case would often be of little value. Further, it sometimes happened that the best radiograms were produced by men without any medical education. At the same time he was always glad to have the assistance of the radiographer in the interpretation of a plate. Dr. CHALMERS WATSON said that unsatisfactory plates were often due to inadequate instructions given by the physician and surgeon. Mr. STRUTHERS said the primary duty of the radiographer was to take a good plate. If he were to assume the position of a consultant, he would require to be equipped not merely with technical skill, but with a thorough knowledge of the other means of diagnosis. Dr. MCKENDRICK replied.

Joint Tuberculosis.

Mr. JOHN FRASER said that into the anatomy of a joint there entered the articular ends of the opposing bones covered by articular cartilage, in the child usually built up of epiphysis, epiphysal cartilage, and metaphysis. The synovial membrane was composed of a connective tissue lined with flattened cells. A number of blood vessels ramified in its deeper parts, and were specially abundant at the joint reflection, where they formed the circulus vasculosus. According to the attachment of the joint ligaments, the circulus vasculosus lay in relation to the epiphysis or the metaphysis; for instance, in the elbow-joint it lay in relation to the metaphysis, in the knee-joint in relation to the epiphysis. From the circulus vasculosus vessels entered the underlying bone. Perivascular lymphatics accompanied the circulus vasculosus, and also entered the bone. When tubercle attacked a joint,

changes became evident in the synovial membrane, the articular cartilage, the blood vessels, and the neighbouring bones. Mr. FRASER described these changes at full length with the aid of lantern slides. Professor CAMPBELL, in discussion, said that he had often been struck by the determining influence of the position of the circulus vasculosus in the site of tubercle in a joint. The appearance of the endarteritis was very like that in syphilitic vessels. Mr. STILES alluded to the difficulty of the treatment of bone and joint tuberculosis in hospitals owing to lack of space, and defended the use of radical operation. In the apportioning of public funds to the problem of tuberculosis, he made a strong plea for a fair share for surgical tuberculosis. Dr. J. MILLER said that in a recent series of 60 cases of tuberculosis not a single bovine strain had been isolated. Endarteritis of the kind described was also seen in pulmonary tuberculosis, and in the large arteries near tuberculous joints. Mr. DOWDEN spoke of the prevalence of surgical tuberculosis in China and Labrador, where cow's milk was not used. He would be curious to learn the strain of bacillus present in the virulent senile tuberculosis of bones and joints. Dr. MCKENDRICK pointed out the similar *x*-ray appearances of bones in rheumatoid arthritis and tuberculosis. Dr. CHALMERS WATSON alluded to the marked endarterial changes in rheumatoid arthritis—a chronic toxæmia due to the pathological action of bacteria normally resident in man. Dr. C. GUTHRIE spoke of the importance of environment in predisposing to or protecting from tuberculosis. The President pointed out the great need of a convalescent home on a large scale for cases of surgical tuberculosis. Mr. FRASER replied.

LIVERPOOL MEDICAL INSTITUTION.

Thursday, January 30th, 1913.

Dr. LLOYD ROBERTS, Vice-President, in the Chair.

Specimens.

At the fourth pathological meeting of the session the following specimens were shown and described:—Mr. ARTHUR EVANS: *Adenoma of the thyroid*. Mr. KEITH MONSARRAT: (1) *Hydatid cyst of the kidney* which had ruptured into the renal pelvis; (2) *Alveolar cyst*; (3) *Goitre with cystic and myomatous degeneration*—there were in this case some clinical symptoms of myxoedema; (4) *Carcinoma of the pylorus*; (5) *Carcinoma of the colon* (two cases); (6) *Chondrosarcoma of the breast*, which was described as probably peritheliomatous in nature. Mr. THELWALL THOMAS: (1) *Carcinoma of the caecum*; (2) *Oesophageal pouch*; (3) *Epithelioma of the scrotum*; (4) *Chondroma of the nasal septum*; (5) *Epithelioma of the tongue*; (6) *Epithelioma of the forearm*. Dr. NATHAN RAW: (1) *Secondary sarcoma of the dura mater*; the primary growth was in the choroid of the eye; (2) Two uteri with *Carcinoma of the cervix* which had been removed after Caesarean section. Mr. THOMAS, Dr. NATHAN RAW, Dr. R. E. HARCOURT, and Dr. WILLETT took part in the discussion.

Fulminating Pneumonia.

Professor ERNEST GLYNN read a note on fulminating pneumonia. He gave notes of 15 cases with 4 deaths from a public institution; 2 died in seven hours, 2 in thirty hours. All the cases occurred in children. In the most rapid cases there was no lung consolidation; pneumococci were demonstrated by inoculating mice, and by microscopical sections. Photomicrographs illustrating the lesions in the lungs and kidneys were shown, the latter being due to the virulence of the toxæmia. Professor BEATTIE, Dr. RUNDLE, and Dr. STALLYBRASS discussed the note, and Professor GLYNN replied.

Some Studies in Anaphylaxis.

Dr. MURRAY BLIGH read a paper on this subject, based on experimental work carried out with Dr. Blair Bell. He drew a comparison between anaphylaxis and serum sickness; and reference was made to heredity, to passive anaphylaxis, and to anaphylaxis *in vitro*. On the principle of the reaction of passive anaphylaxis, an attempt was made to devise a method of determining whether a given individual were sensitive already which would be applicable to the diagnosis of cancer and other diseases. The inquiry was commenced by sensitizing a group of animals, according to orthodox methods, with the object

of observing the development of the symptoms and sequelae so graphically described by others. Anaphylaxis was not obtained. Several varieties of antigen, in varying doses, repeated at the end of varying incubation periods, were injected into rabbits and guinea-pigs. Eighty-six consecutive experiments were performed without the development of a symptom that could be attributed to anaphylaxis. The fact of anaphylaxis was not disputed, but the conclusion was drawn that it was a phenomenon more difficult to obtain than to avoid. Dr. WAKELIN BARRATT thought that the author of the paper was well advised in publishing the results obtained; and it was much to be desired that the conditions of the production of experimental anaphylaxis should in all cases be accurately recorded. Dr. GELAIRE said that the phenomena which seemed to be sufficient to explain that anaphylaxis formed an albumin—anti-albumin—reaction were, to his mind, not yet definitely determined. If it were true all anaphylactogens ought to be of an albuminous character, such as animal or vegetable albumin, or the albumin of bacteria, etc. But since they knew that anaphylaxis could be brought about by the combined action of antigen-antibodies-complement, they should bear in mind that antigen and antibodies were not all pure albuminous substances. That they were lipoids was shown in the syphilis reaction, in echinococcus disease, and in the alcoholic extracts of tubercle bacilli, etc. Anaphylaxis could be produced by glycogen, peptone, trypsin, saponin, sodium oleate, etc. As regards the quantity of serum injected, he said that bigger quantities had been used by those who were able to produce anaphylaxis than had been employed by Dr. Bligh and himself. He thought that those observers who had obtained positive results with very small quantities of serum had probably been using for the second injection serum from the same animal as that from which the serum for the first injection had been taken. The freshness of the serum was of importance, as the amount of fibrin ferment varied with the time the serum had been kept. The susceptibility of an animal to anaphylaxis depended both on the species of the animal and the kind of serum used. Pigs, for instance, could not be made anaphylactic with horse serum, and the results with rabbits were not constant. On the other hand, there seemed to be something in the serum which prevented anaphylaxis altogether. Extracts of organs produced anaphylaxis, but on adding fresh serum of the same species anaphylaxis could be prevented. Dr. Gelaire then related some of his own experiments, and explained his conclusions. Since the serum of animals rendered anaphylactic contained much less complement than before the injection, he thought research as to the cause of anaphylaxis should be directed to the investigation of the serum of the injected animal. Dr. T. R. BRADSHAW thanked Dr. Bligh for his interesting paper, which dealt with a subject which appeared to be of great practical importance at a time when serum-therapy was largely employed, and dwelt on certain points in connexion with the subject which were difficult to comprehend.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

Wednesday, February 5th, 1913.

Sir ANDERSON CRITCHETT, President, in the Chair.

Specimens.

MR. G. COATES showed a case of *Congenital mesoblastic strand* adhering to and penetrating the cornea. Mr. A. RUGG GUNN showed a case of *Persistent hyaloid artery* with massive white formation obscuring the optic disc. Mr. A. S. COBBLEDICK showed a case of *Congenital deformity of the inner canthus*. Mr. J. B. LAWFORD exhibited a case of *Disease in the region of the pituitary body*. The patient showed no definite evidence of acromegaly. The PRESIDENT showed a case of *Kerato-iritis* in which he had performed peritomy; the whole of the vascular conjunctiva, which had been very much thickened, had greatly improved.

Resumed Discussion on the Physiology of Intraocular Pressure.

Mr. MARTIN FLACK, in resuming the debate, criticized the scheme submitted to the last meeting by Professor

Starling, as it did not take account of any capillary bed and the resistance due to it; thus the conditions obtaining in the eyeball were not adequately represented. Moreover, to hypotheate for the vessels rubber, and for the fluid, water, did not establish a parallelism with actual conditions. He proceeded to elaborate the argument which Dr. Leonard Hill submitted in his opening, and said that Dr. Hill's work on the circulation of the brain had never yet been proved to be wrong, although it was published a number of years ago. Admittedly the eye was not quite rigid, but it was sufficiently so for physiological purposes. When a skull was trephined, and the rigidity of the skull thereby modified, it did not interfere with the cerebral circulation. In Dr. Hill's and his own view, the tissue fluid was maintained not by any filtration pressure due to the *vis a tergo*, but to the pulsatile expansion and shrinkage of organs, and the expressive action of both intrinsic and extrinsic muscles, as well as by changes in posture, gravity, etc. Mr. THOMSON HENDERSON (Nottingham) declared that his views on the physiology of intraocular pressure were entirely dominated by the splendid work of Dr. Leonard Hill on the intracranial pressure. He (the speaker) maintained that the intraocular pressure was not a question of volume, but that it stood and varied with the intraocular venous pressure. Some of the views disregarded the fact that the vessels were embedded in a loose tissue stroma, which was in open communication with the angle of the anterior chamber. Therefore the ciliary epithelium could not act as a mere passive filtering membrane, because the pressure on both sides of it was the same, and if fluid did escape from the vessels it would make its way direct into the angle of the anterior chamber. He exhibited sections of eyes of different animals, and submitted that the anatomical conditions about the angle of the anterior chamber were such as to absolutely preclude any idea of filtration of aqueous. He had now a collection of 13,000 sections of eyes, mounted serially. Mr. HERBERT PARSONS said he could not understand the antipathy to the filtration idea by Dr. Hill and his colleagues, who seemed to introduce a very difficult method of physico-chemical influence to account for processes which were explicable on simpler grounds. He could not see anything in the present discussion, so far, to cause him to modify, except in questions of terminology, the views he expressed in his work on the pathology of eye conditions. He proceeded to comment on weak points in Dr. Hill's experiments, and to argue that, the walls of the globe not being rigid, unless the animal were enarized in the experiments, there was enormous pressure exerted by the extrinsic muscles. He was the first to show that the increased pressure produced on stimulating the peripheral end of the cervical sympathetic was due to retraction of the unstriated muscle in the orbit. He did not think the consideration of the mode of production of accommodation was germane to the present discussion. Mr. RAYNER BATTEN demonstrated his views on intraocular pressure by a series of ordinary rubber child's balloons. Mr. GREEVES pointed out that Coster found, in his experiments, that there was a definite increase of volume when the intraocular pressure was raised, and he had himself done a similar experiment with fresh pig's eyes. Professor STARLING and Dr. LEONARD HILL then replied in detail on the whole debate, and were heartily thanked by the Section.

SECTION OF ANAESTHETICS.

Friday, February 7th, 1913.

Dr. J. BLUMFELD, President, in the Chair.

Nitrous Oxide in Major Surgery.

Mr. H. M. PAGE noted, at the beginning of this paper, that a revival in recent years of the interest taken in anaesthesia was attributed to Dr. Crile's work on shock. Mr. Page desired to suggest further investigation of this agent on this side of the Atlantic. The difficulties of the administration, if the surgeon was not to be hindered in his work, the strain on the anaesthetist, the embrous apparatus and the expense were pointed out. Against these drawbacks was placed the non-toxicity of nitrous oxide, the few after-effects and the good condition of the patient at the end of the operation, a condition which was observed in a proportionally modified degree, even when ether had been added throughout the administration,

Regulated rebreathing was strongly advocated, as the author found that it facilitated the administration without prejudice to the patient. The work of the physiologists on the subject of the loss of CO_2 and acupnia was mentioned, and especially the recent work of Yandell Henderson, and it was maintained that account must be taken of it and rebreathing carefully used, even if all Henderson's conclusions could not be accepted without reserve. Ninety-four major operations were brought forward, out of which 51 were intraperitoneal. The ages of the patients varied from 5 to 81 years. Out of the 51 intraperitoneal cases, 7 died, but none immediately after the operation, and in all the operation was severe. The special indications for the use of nitrous oxide in major surgery were: (1) Desperate cases from toxæmia or traumatism or hæmorrhage, if spinal anaesthesia be not used; (2) operations on diabetics, where nitrous oxide was preferable to any general anaesthetic and to spinal anaesthesia; (3) certain genito-urinary operations. Mr. Page then turned to the details of this method. A previous injection of a narcotic with atropin was recommended, and, failing this, atropin alone. Induction should always be practised with the addition of ether. Afterwards the addition of ether should be resigned, to attain the required depth of anaesthesia rather than to push the N_2O by increasing pressure. It was stated that a tendency to cessation of respiration without toxicity, possibly due to loss of CO_2 , and in other cases a true toxicity, might be met with. The most important contraindications were advanced degenerations of the heart and vessels, a marked degree of emphysema and dyspnoea or obstruction to the airway. Deaths said to be due to the anaesthetic had been reported. The author's opinion was that these dangers and deaths could be avoided by the unremitting attention of a skilled anaesthetist who has seen his case beforehand and deliberately chosen this method, and that $\text{N}_2\text{O} + \text{O}_2$ with or without the addition of ether, would then give the patient in certain cases an additional chance of recovery. Mr. PAGE then gave a demonstration of Dr. Teter's apparatus, recommending that a bag should be added close to the facepiece, and also showed a simple arrangement he had devised which answered fairly well and was portable. It was stated that all apparatus must allow of the employment of rebreathing. The PRESIDENT considered that Mr. Page had made out a good case for the use of gas and oxygen, and for rebreathing—at least, in very dangerous cases. He had himself in a few instances used gas and oxygen where it was essential to avoid any toxic effects, and his experience agreed with that of Mr. Page. It was difficult to reconcile the avoidance of the asphyxial element with the view that no diminution must be allowed in the CO_2 content of the blood. Mr. BELLAMY GARDNER said that in 1897 he brought forward the use of gas and oxygen for minor operations—namely, those not involving abdominal section—and in the following year Mr. Herbert Paterson used that anaesthetic in an operation lasting an hour and fifty-five minutes. Later he (Mr. Gardner) related his experiences with it for larger operations, exclusive of abdominal sections. It was many times more expensive than the older general anaesthetics, but was particularly indicated for diabetics, in which cases it was the most valuable anaesthetic available. Dr. DES VORUX testified to the rapid recovery of consciousness and the lack of unpleasant after-effects in patients whose condition demanded extreme caution. Mr. H. E. G. BOYLE found that when gas and oxygen was the anaesthetic, and no other narcotic was given beforehand and no ether added to the gas and oxygen, it was difficult to effect relaxation of the abdominal muscles, but it was much easier to effect it with the aid of the narcotic and the ether. He had given this anaesthetic in three diabetic cases, where amputation at or about the knee was performed, and in all with success. In rectal operations it was inadvisable, as it set up spasm and opisthotonos. Dr. C. S. LOOSELY had used Dr. Teter's apparatus in 6 cases, all children, with success, but he had to use a little ether in one instance to keep up the relaxation of the muscles. Mr. ASLETT BALDWIN had the highest opinion of this anaesthesia for major surgery, especially in diabetic and septic subjects. In order to avoid opisthotonos in rectal work, he placed the patient on his side and trussed him up with a jack towel. Mr. A. L. FLEMING (Bristol)

exhibited a simplified apparatus of his own design and manufacture for giving gas and oxygen, which allowed of rebreathing. Mr. PAGE replied.

SECTION FOR THE STUDY OF CHILDREN'S DISEASES.

At the meeting on Friday, January 24th, Mr. A. H. TUBBY, M.B., F.R.C.S., President, in the chair, there was an exhibition of clinical cases and pathological specimens. Among the exhibits were the following:—Miss A. L. KANN (for Mr. D. C. L. Fitzwilliams): (1) A case of (?) *Fibrolipoma* in a boy aged 2 years and 8 months. There were four small swellings on the back of the arm and in the axilla, that in the axilla being as large as an orange, bulging the pectoral muscles forwards. They were not fixed and felt fibrous. (2) A case of *Lymphangioma*, resembling a hernia of the lung, above the right clavicle, of a boy aged 6. It probably continued into the thorax. Dr. R. C. JEWESBURY: *Two similar unusual heart conditions in sisters*. The lesions were probably congenital. Mr. R. C. ELSMIE: Three cases of an unusual form of *Disease of the hip-joints*. Two of these corresponded to Calvé's pseudo-coxalgia. The third was of more doubtful resemblance. By the aid of skiagrams it was shown that the epiphyses of the heads of the femora were a little flattened, their surfaces uneven, and their upper edges proportionately thicker than normal. The necks of the femora were shorter and thicker. Dr. J. WALTER CARR: *Congenital syphilis with enlargement of the liver and spleen* in a girl aged 12. He inquired as to the advisability of using salvarsan in such a case. Also a case of *Hirschsprung's disease* (congenital hypertrophic dilatation of the colon) in a boy aged 9. Dr. C. W. CHAPMAN: A case of *Arterio-sclerosis with absence of radial pulses* in a girl aged 15. The Wassermann reaction was negative. A trace of albumen was found in the urine. Mr. SYDNEY STEPHENSON: *Interstitial keratitis and osteoperiostitis* in the tibiae in a boy aged 6, in whom the Wassermann reaction was positive. Neo-salvarsan had produced considerable improvement.

SECTION OF BALNEOLOGY AND CLIMATOLOGY.

Thursday, January 30th, 1913.

Dr. PERCY G. LEWIS, President, in the Chair.

Fibrositis.

Dr. LEWELLYN (Bath), in opening the discussion, intimated his intention of confining his remarks to muscular fibrositis. He emphasized the importance of gout as an ætiological factor, 28.8 per cent. of all cases in his experience displaying objective stigmata, tophi, etc., whilst only 8 per cent. gave a previous history of acute articular rheumatism. The abrupt onset of acute cases was apparent not real, the causal process having developed insidiously. The muscular effort impeached was not so much the cause of the malady as the occasion of its disappearance. As regarded constitutional symptoms, he laid stress on the frequency of pyrexia even in milder cases, and also considered not uncommon the incidence of endocardial symptoms. Pain was the chief subjective symptom in acute cases, aching and stiffness in chronic types; the objective changes in the former cases were swelling, increased local heat, and, most important of all, increase in muscular tone or hypertonus, as shown by palpation. Hypertonus outlasted subjective symptoms, formed the link between exacerbations or relapses, and was responsible for disorders of movement whether volitional, passive, or synergic, and also for disorders of circulation. The rhythmic movement and relaxation of exercise being replaced by a state of tonic spasm, the circulation through affected muscle was impeded, and venous stasis resulted. This venous stagnation was a strong contributory factor in the production of nodules or infiltrations; in other words, the result of congestive induration.

Professor STOCKMAN (Glasgow), in dealing with the pathology of fibrositis, said that the pathological condition of fibrous tissues varied from an oedematous and rapidly proliferating tissue, showing many fibroblasts and very few leucocytes, to a dense and compact nodule or patch, according to the site of the mischief. A very significant feature distinguishing pathological from normal fibrous tissue was the presence of marked periarteritis and endarteritis in the blood vessels of the affected area, strongly

supporting the idea that the condition was the product of reaction to an irritant conveyed in the blood. The sensitiveness of the subjects of chronic rheumatism to variations of temperature, humidity, etc., was probably due to excessive exudation of lymph from the diseased vessels under such conditions and their imperfect absorption. Some degree of interstitial neuritis was commonly found in the nerves of the affected areas, which explained the very painful nature of the disease.

Mr. KENNETH GOADBY opened the discussion on the bacteriological side, giving a summary of animal experiments in which various bacteria isolated from the mouth, posterior nares, tonsil, faeces, and urine had been tested on animals. Certain of the organisms, *Streptobacillus matae*, *Streptococcus longus*, and *Bacillus macrodentalis*, had been isolated from the urine and faeces of cases suffering from fibrosis. Autogenous vaccines of these organisms had produced first well-defined exacerbation, and, finally, after a continued dosage, amelioration and improvement in the symptoms. Two cases were described in which no organisms were found in the urine until after heavy massage of the affected parts, followed by the application of Bier's bandage. On the following morning organisms were demonstrated in the urine.

Dr. JAMES MACKENZIE drew attention to certain forms of heart disease which occurred associated with muscular rheumatism. Among the various evidences of cardiac disturbances, he was able to demonstrate that heart-block occurred. As the presence of this heart-block implied a limited lesion affecting the auriculo-ventricular bundle, he suggested that, in all probability, the cardiac affection in these cases was due to an invasion of the heart muscle by the same process which Professor Stockman had shown to be present in the skeletal muscles.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

At a meeting on Thursday, February 6th, the PRESIDENT (Dr. Stanley Riseley) in the chair, Mr. ERNEST FINCU, in a paper on *Internal derangements of the knee-joint*, gave statistics of the results of treatment in 59 out of over 100 cases which had been treated in the Royal Infirmary, Sheffield, during the five years 1907-11. After a few preliminary remarks on the anatomy of the joint, illustrated by lantern slides, he considered its mechanism. Theoretically a sudden extension from a flexed or semi-flexed position would cause injury to the internal semilunar cartilage. This was confirmed by a definite history of a sudden extension in 44 of the 59 cases. In 7, however, the patient declared that the joint was fully flexed, and in 8 the position could not be ascertained. He briefly considered the symptoms and signs, pointing out that the diagnosis when the patient came to hospital was usually based on the history of the accident and the subsequent history of the patient as regards locking of the joint, etc. Twenty-five of the cases were miners who had been injured in the pit; twenty of these had the joint injured by a sudden extension movement. The treatment recommended was operative, and by that he meant removal of as much of the cartilage as possible. In 3 cases where the cartilage had simply been stretched down it had to be removed subsequently. In the after-treatment the patient should be allowed to walk as soon as possible with no retentive apparatus on the limb whatever. The cases in which there was any ankylosis had all worn hinge splints subsequent to operation. Of the cases, 56 had injury to the internal cartilage and 3 to the external; 2 cases had both cartilages removed from the same joint. The ages ranged from 11 to 56 years. The average duration in hospital was twenty-two days, the least seven days, and the longest thirty-seven days. The length of time elapsing after the operation before work was resumed was from nine days to five years; 5 had not resumed work, and of these 1 had marked fibrous ankylosis. In the other 4, no satisfactory cause could be found for the alleged incapacity. In 10 cases, nine months or more elapsed before work was resumed. In the remaining 44 cases, the average time was four weeks. In the great majority of the cases creaking was felt in the joint on movement, but in no way interfered with their work. There had been no suppuration. The technique he left for discussion by the members of the society. Mr. FINCU also showed

a specimen of *Osteomyelitis and periostitis of the right tibia* removed by amputation from a youth of 16. The specimen showed an involucrum containing sequestra and cloacae. The supposed cause was a "twist of the ankle," six weeks before admission to the infirmary. Mr. GRAHAM SIMPSON, in a paper on *Stone in the kidney*, made an analysis of 30 operations for calculus, 16 in the kidney, 4 in the ureter; 1 operation was in a case of calculus pyonephrosis, and 9 were operations for calculus pyonephrosis. Albuminuria was present in 24 of the cases, obvious haematuria in 10 only. Skiagraphy was positive in 20 out of 21 cases, and cystoscopy was useful in confirming the site of the lesion in 15 out of 19 cases. Pycelotomy was recommended for removing stones, as there was no haematuria after that operation. No case of urinary fistula occurred in this series. Of the ureterotomies, 2 were done by the extraperitoneal route, 1 by the transvesical route, and 1 by the intraperitoneal route. The latter he regarded as an excellent operation. Nephrectomy was performed nine times, once for a small contracted kidney full of stones, and eight times for pyonephrosis. Only 1 case died. In this man a nephrotomy was done for multiple stones, and the patient died suddenly on the seventh day, apparently of a pulmonary embolism.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held on January 31st, the PRESIDENT (Mr. Freeland Fergus) being in the chair. Mr. A. ERNEST MAYLARD showed several cases of *Cancer of the colon treated by operation* to illustrate abdominal incisions and methods of intestinal anastomosis. The incisions recommended were: (a) For exploration, the seat of obstruction in the colon being uncertain—a mid, sub-umbilical, vertical incision; (b) for caecum and lower ascending colon—an oblique incision in the right iliac region; (c) for hepatic flexure and upper ascending colon—a transverse incision carried outwards from a point situated above and to the right of the umbilicus; (d) for transverse colon—an incision carried across the abdomen 1 to 2 in. above the umbilicus; (e) for splenic flexure and upper descending colon—a transverse incision carried outwards from a point situated above and to the left of the umbilicus; incisions (c) and (e) gave access also to kidney tumours; (f) for lower descending, iliac, and pelvic colon—an oblique incision in the left iliac region. The methods of intestinal anastomosis illustrated were: (1) By lateral approximation, (2) by lateral implantation or side-to-side union, and (3) by invagination—that is, pulling a short length of the proximal segment through a longitudinal opening in the wall of the distal. The method to be adopted in any case was determined by the amount of free gut available after removal of the involved segment. Where this was limited, the first, where less limited, the second or preferably the third method was recommended. This last lessened the tendency to leakage in the event of distension of the bowel, and diminished the grave risk of infection at the mesenteric attachment. To prevent distension after operation it was advised that the sphincter ani be paralysed and a rubber tube of large calibre inserted, encircled with iodoform gauze soaked in glycerine. Through this tube gas could escape freely, and any discharges which might result from the irritative effects of the bowel wound. Dr. CRAWFORD RENTON read a short paper on *Obstruction of the bowels*. He referred to the various causes of obstruction, and recommended the sigmoidoscope as an aid to the diagnosis of tumours in the rectum and sigmoid. In very acute obstruction Paul's or Moynihan's tube was advised, to drain the bowel previous to a radical operation. The adoption of this procedure had greatly reduced the mortality. Where caecostomy had to be done, the method recommended by Kader for the stomach had been found useful. For paralysis of the bowel, eserine salicylate and pituitary gland were strongly recommended. In the last 33 cases on which Dr. Renton had operated on there were but 3 deaths, which was encouraging; and if the operations were carried out early in every case the mortality ought to be less. Dr. WILLIAM WATSON read a paper on *Adulteration of foodstuffs and its influence on digestion*. The 1901 report of the Local Government Board upon the use of

preservatives and colouring matters in the preservation and colouring of food showed that the substances most commonly used were boracic acid, borax, salicylic acid, formalin, and sulphites, while a large number of other substances were in less common use. One or other of these were found in 39 per cent. of all samples of food examined, including samples of milk, cream, butter, margarine, sausage, bacon, brawn, potted meat, potted fish, meat extracts, meat juices, and temperance drinks. All these substances were germicides, all were gastrointestinal irritants, and all had a more or less inhibitory action on the digestive ferments.

ASSOCIATION OF REGISTERED MEDICAL WOMEN.

A CLINICAL meeting was held on February 4th, the PRESIDENT (Dr. Constance Long) in the chair. Dr. FLORENCE STONEY showed a woman, aged 59, suffering from *Scirrhus carcinoma of the left breast*. When first seen, seventeen months ago, the case was considered inoperable. X-ray treatment had been administered about once a fortnight since then. The case had remained stationary for fifteen months, except that a large ulcerated area had rapidly healed over. During the last two months several new nodules had appeared, and the patient had lost weight. The PRESIDENT showed a woman who had for twenty years suffered from *Morphoea of both legs*. A firm, slightly depressed vascular patch, about 6 in. long, was seen on each shin, and other symmetrical patches were present on the thighs. Dr. AGNES SAVILL said that the condition was rare in showing a telangiectatic condition of atrophy after twenty years. In most cases of morphoea fibrous tissue gradually developed, cutting off the superficial blood supply, and leaving the typical white lardaceous areas inlaid in the skin. Dr. OCTAVIA LEWIN showed a case of *Tertiary syphilitic ulceration of the right knee*, which had responded in a marvellous way to two injections of salvarsan given a year previously at intervals of fourteen days. Other antisyphilitic remedies had been tried without effect for seventeen years, and during this time the knee had been riddled with deep sloughing ulcers; four months after the injections of salvarsan it had entirely healed. Dr. L. GARRETT-ANDERSON showed: (1) A case of *Raynaud's disease* which was improving under treatment by massage, calcium lactate, and thyroid extract; (2) a woman having a *Swelling in the groin*, probably due to venous enlargement, though simulating a femoral hernia.

THE ninety-fourth anniversary dinner of the Hunterian Society took place on Tuesday, February 4th, at de Keyser's Royal Hotel. The President, Mr. A. H. Tubby, F.R.C.S., who was in the chair, gave the loyal toasts, and Dr. Hyslop then entertained his audience with a witty speech in proposing prosperity to the Hunterian Society. In his reply, Mr. Tubby traced its foundation back to 1819, and recalled a long list of illustrious presidents, including Bright, Lavington, and Sir Thomas Curwen. In speaking of the Hunterian lecturers, he mentioned Dr. Frederick Taylor, who had dealt with sleepiness, and Professor A. Keith, who had discoursed on the anatomical and pathological characteristics of Napoleon's remains, and cited a discussion which had taken place on anaesthesia. Before concluding the President made reference to the fact that the society had recently been turned out of its old home, the London Institute, and was now temporarily receiving the hospitality of St. Bartholomew's Hospital. He feared that it might turn out that in the future its home would be in the West End, but he preferred a City address, as he considered this advantageous to the society. The toast of the "Guests and Sister Societies" was ably proposed by Dr. W. Langdon Brown, who twitted the previous speaker for claiming that the society was the second oldest of the learned societies. He mentioned that the Abernethian Society had a prior claim. Sir W. Watson Cheyne, Bart., replied for the Medical Society of London, and Sir Francis Champneys, Bart., for the Royal Society of Medicine. Dr. Latham, who also replied, referred to the work of the Astor Committee and foreshadowed great things from the grant for medical research. The toast, "The Orator and Officers," was given by Dr. W. M. Ettles and responded to by Dr. Goodall. Dr. F. J. Smith gave the health of the President, and Mr. Tubby replied briefly.

Reviews.

ACHONDROPLASIA.

IN the title of his book—*Achondroplasia, its Nature and its Cause: A Study of the Stunting of Growth in Embryonic Cell Groups caused by Amnion-pressure in the Different Stages of the Skeleton*,¹ Dr. MURK JANSEN, Lecturer on Orthopaedic Surgery in the University of Leyden, explains succinctly enough the purposes which he has set before him. The monograph is divided into two parts: the first, which studies the nature of achondroplasia, is chiefly clinical, and the second, which discusses the cause of achondroplasia, and concludes that it lies within the province of teratology.

In the first part the author furnishes us with a minute description and accurate measurements of the abnormalities met with in the several degrees of achondroplasia dwarfism, and he demonstrates with the utmost clearness that the amount of retardation of growth in the various skeletal structures varies directly, not with their distance from the head or centre of the body, not with the time of their ossification, not with the time of their change into cartilage, but accurately with the time of their primary formation as sclero-blastema. Influences prejudicial to development acting upon the primitive cell groups at this early period are sufficient to retard permanently the growth of the structures, and this retardation is most marked in those parts of the skeleton which are latest formed and most immature at the time of injury.

Secondly, the author is able to demonstrate equally clearly that with achondroplasia are constantly found certain other deformities not characterized by the stunting of growth, and these he describes under the heading of "Mechanical Malformations." Among these are a marked shortening of the basis cranii from before backwards, compensatory enlargement of the skull from side to side, depression of the bridge of the nose, backward displacement of the hard palate and tilting upwards of its hinder end, arcuate kyphosis of the spine, and bending forward of the sacrum and coccyx between the legs. The author endeavours—and we think successfully—to show that these mechanical malformations which, inasmuch as they are much less conspicuous than the phenomena of dwarfism, have for the most part hitherto passed unnoticed, are occasioned by the unfolding of the embryo, and by an exaggeration of the head and neck curves of the embryo as it lies within the uterus. He concludes that the period of excessive infolding characteristic of achondroplasia coincides with the scleroblastema stage of the skeleton, and that it is limited on the one hand by the "physiological curving" of the third, and on the other by the "physiological stretching" of the sixth week of embryonic life. The excessive infolding is in turn the result of excessive amnion pressure. In the last part of his book he discusses the relation of other occasional and less characteristic symptoms of achondroplasia to excessive amnion pressure and excessive infolding of the embryo. Among such occasional symptoms are hare-lip, micrognathia, agnathia, myxoedema, hydrocephalus, gas bubbles in internal organs, subcutaneous fatty masses, and excess of sexual appetite. This last symptom, according to the author, finds explanation in the disturbance in the development of the pituitary body, which undoubtedly exists in the severer cases.

We confess that we are not entirely satisfied with the evidence that exaggeration of sexual function is common or usual in achondroplasia. The references to the literature quoted are explicable if we remember that a normal sexual activity and a normal development of the sexual organs is likely to excite remark when contrasted with the apparent immaturity of the rest of the body. Be that as it may, we believe that the views expressed in this work will profoundly influence our conception of the nature and cause, not only of achondroplasia, but of many other developmental abnormalities. We have nothing but admiration for the remarkable powers of

¹ *Achondroplasia, its Nature and its Cause: A Study of the Stunting of Growth in Embryonic Cell Groups caused by Amnion-pressure in the Different Stages of the Development of the Skeleton* (encephaly, achondroplasia, kakomelia). By Dr. Murk Jansen, Lecturer on Orthopaedic Surgery, University of Leyden, Holland. Leyden: E. J. Brill, Ltd. London: Baillière, Tindall, and Cox. 1912. (Demy 4to. pp. 98, figs. 50.)

observation, reasoning, and imagination of which the author shows himself possessed. His work may well be the starting point of much fruitful investigation in the domain of teratology and congenital abnormality.

PUERPERAL INFECTION.

DR. HAMM'S monograph on puerperal infection² is an interesting summary of the present position of the various scientific questions that group themselves under this title, and loses none of its interest from the fact that it purports to give the finishing stroke to the doctrine of sapraemia. The author, who has himself worked through most of the relative investigations in the laboratory, adopts a classification based on that of Aschoff for the possibilities of infection, and then passes to the detailed discussion of the evidence relating to individual micro-organisms. This discussion occupies almost half of the whole number of pages, and is followed by considerations of puerperal predisposition to infection and of virulence, of which not haemolytic power but rapidity of growth and presence in pure culture are the best criteria. He then passes to more clinical questions in the consideration of the forms of puerperal fever. In the course of this he indicates that there is no essential difference in the various lymphangitic types, save in the rapidity of spread, and states that bacterial multiplication in the blood itself is merely a premortal phenomenon. This section concludes with the statement that since in cases of rise of temperature on the evening of delivery he always found numerous micro-organisms in the vaginal secretion, often in pure culture, these cases must be looked upon as the expression of an endogenous infection of a slight kind.

On the therapeutic side we find a strengthening of various recognized positions, such as the sparing, but not always conservative, treatment of abortions, even when haemolytic organisms are present, the reinforcement of uterine contraction by ergot, the leaving of retained membranes which are not removed immediately on delivery, and the douching of the vagina with hydrogen peroxide. The uterine douche may be used once when it can remove matter that would serve as pabulum for organismal multiplication. Dr. Hamm is sceptical of the efficacy of the various methods of bacterial therapy that so far have been employed.

OPERATIVE SURGERY.

THE new edition of BINNIE'S *Manual of Operative Surgery*³ is published in one volume instead of two. This, as the author points out in the preface, is a reversion to the original form of the book. The work is a complete departure from the average type—the old-fashioned type—of textbook on operative surgery, in which predominance was given to amputations, excisions, and ligation of vessels. These for the most part were nothing more or less than surgical exercises, and were seldom or never required to be performed on the living subject. The manual of operative surgery of to-day must contain descriptions of all the newest operative procedures, and a diligent search in this work has found no omissions. Indeed, it is possible that a severer discretion might have been exercised with advantage, and reference to some operations not in the least likely to stand the test of even a very short time might have been profitably omitted. The author has preserved the balance of the various sections in a satisfactory way, and the regions have each a due proportion of space. There is no waste of words in describing the different steps of operations, but rather is there a tendency for descriptions to lose in lucidity what they gain in brevity. The method adopted is to describe step 1, step 2, and so on, and under each step different modes of performing it are detailed. References to the original sources are given in every case. A notable feature is the large number of illustrations; these are rather unequal, but the inequality is explained by the fact that almost all are reproductions

of the originals which range through the whole gamut, from the simple sketch illustrating Lister's operation for old-standing ununited fracture of patella with explanatory notes in his own handwriting to the elaborately detailed fine lines of the Mayo stomach pictures. The proof reading seems to have been hurriedly done; we find blunders on pages 314, 516, 539, 853, amongst others. The merits of the work are undoubtedly great, and its already well-recognized position will be more firmly established than before. Surgeons will find it a thoroughly cosmopolitan book, in which the whole range of the very newest of modern surgery as well as of surgery of remoter date is concentrated.

The fourth edition of MR. H. J. WARING'S *Manual of Operative Surgery*⁴ has followed quickly upon its predecessor. The whole work has been revised and the high standard has been thoroughly maintained. Descriptions of some new operations, for example, those connected with blood vessel surgery, have been introduced and those of some old ones omitted. Such a constant regenerating process is necessary. Operations on the limbs are much fewer than even a few years ago, and those on the abdomen, head, and thorax are much increased in number. Some more operations might well have been omitted from Mr. Waring's list. Many of the operations for ligation of arteries are merely dissecting-room exercises seldom or never performed on the living subject. Similarly, some of the amputations might have been cut out. The employment of skiagraphs of the hand and foot in illustrating the lines of incision in certain amputations is to be heartily commended; the relation of the incision in the skin to the line of section through the bone is made strikingly clear. In the preface the author says that the question of anatomical terminology has been carefully considered and that he has adopted the international terminology throughout. This is certainly a little confusing, but the student has at hand in the beginning of the volume a glossary of this terminology. In spite of this it is sometimes difficult to find the new equivalent of certain terms in the old terminology. Changes of this sort are not popular at first, but any change which makes for the unification of scientific language and description ought to be accepted as graciously as possible. No alteration in the arrangement of the work has been made. After two very complete introductory chapters on general surgical technique brought thoroughly up to date the student is plunged at once into the intricacies of gastric surgery. We remember that in a former edition Mr. Waring explained this apparent departure from a gradual leading on from simple operations to more and more difficult ones. After all, the book is intended to reach a wide circle of readers, and the student must turn to the index to find what he wants. This manual is a safe guide in operative work, as absolutely sound in its teaching, and one well fitted for every-day use by the practitioner. It is hardly necessary to add that as one of the Oxford Medical Publications the publishers' part of the work is well done. The illustrations are apt and not too numerous. We have discovered so far two clerical errors: on p. 167, fifth line from bottom of page, and on p. 361, where the word "facial" has been maltreated.

The temptation to write a textbook on operative surgery seems difficult to resist. Probably many of them have in a manner grown very much as Topsy "grewed." The teacher begins with a few loose leaves of notes for the use of his pupils, then these are printed and extended, then the students ask if they cannot buy these notes, and so very soon a book is launched into the world. Perhaps Professor VICTOR SCHMIEDEN'S book⁵ did not grow up in

² *Die puerperale Wundinfektion*. Von Dr. Albert Hamm, Oberarzt an der Universitäts-Frauenklinik in Strassburg, i.E. Berlin: Julius Springer, 1912. (Roy. 8vo, pp. 167. Mk. 6.)

³ *Manual of Operative Surgery*. By John Fairbairn Binnie, A.M., C.M. Aberd., Surgeon to the General Hospital, Kansas City, Mo., Fellow of the American Surgical Association. Fifth edition, revised and enlarged. London: H. K. Lewis, 1912. (Roy. 8vo, pp. 1163; figs. 1365. 30s. net.)

⁴ *Manual of Operative Surgery*. By H. J. Waring, M.S., M.B., B.Sc. Lond., F.R.C.S., Surgeon to and Joint Lecturer in Surgery at St. Bartholomew's Hospital, Consulting Surgeon to the Metropolitan Hospital. Fourth edition. London: Henry Frowde, and Hodder and Stoughton, 1912. (Cr. 8vo, pp. 828, figs. 541. 12s. 6d. net.)

⁵ *Der chirurgische Operationskursus*. Ein Handbuch für Aerzte und Studierende. Von Professor Dr. Victor Schmieden, Privatdozent der Chirurgie an der Universität, Berlin; Assistent der Kgl. chirurgischen Universitätsklinik. Zweite, erweiterte und verbesserte Auflage. Mit 435 Abbildungen im Text und einem Vorwort von Professor Dr. A. Bier. Leipzig: Johann Ambrosius Barth, 1912. (Royal 8vo, pp. 480. Mk. 14.50.) And *The Course of Operative Surgery*. By Professor Dr. Victor Schmieden. Translated and edited by Arthur Turnbull, M.B. Glasg., M.A., B.Sc., Demonstrator of Anatomy in the University of Glasgow. London: Baillière, Tindall, and Cox, 1912. (Roy. 8vo, pp. 365, figs. 435. 12s. 6d.)

this way, though its appeal appears to be more or less local and limited. It is local in so far as it is the practice of Professor Bier's clinic which has been closely followed, and it is limited in that the book is avowedly concerned more with operations on the dead subject than on the living. But in spite of these limitations the volume will be found very useful. It is convenient in size; the descriptions of operations are concise without loss of clearness; the numerous illustrations are of a very high standard of artistic merit, and yet they are anatomically and surgically accurate. The practitioner who seeks for guidance will find the principles of the surgical art well set forth; for details he must go elsewhere. The student will find the book excellent and readable, and he will be relieved to see that the text is not overburdened with names of operators and suggestors of operations, and that simple methods have been everywhere preferred to complicated ones. There are some points to which attention should be drawn. In the description of the mastoid operation we find no mention of the dental burr, an instrument which makes the exposure of the sigmoid sinus and the mastoid cells a much safer and easier business than the employment of chisels throughout. The operation is by no means clearly described. The author says that "Syme's amputation is not often employed in practice," and prefers Pirogoff's, but we believe that Syme's is the commoner operation, in this country at least. No description is given of nephrectomy by the abdominal route. Simultaneously with the second German edition appears the first edition in English. The translation is by Dr. ARTHUR TURNBULL of the Anatomy Department, Glasgow University. Dr. Turnbull adheres absolutely to the text, adding only a few notes here and there, and a name or two on some illustrations. The English of the translation is not always unimpeachable; for example, on page 256 we find "very grave risk of the transverse colon going gangrenous," and throughout the translation there is a too manifest tendency to adhere to German idiom and phraseology. The translator perhaps flatters himself and the author when he expresses the belief that the book will become the "student's handbook in every college where English is the medium of surgical instruction." We are patriotic enough to hope that quite as good books are written by English authors for English-speaking students. We observe that the proof reader has passed at least two errors: on page 181, second line from foot of page, and on page 203 in the descriptive lettering of the illustration.

Professor PELS-LEUSDEN'S work on *Surgical Operations*⁶ is on the whole a good average book. In the preface he disclaims any attempt to range over the whole field of operative surgery, but his effort to be brief without omitting anything important has not been very successful, for the book has 726 pages, of large size. We do not think that anything important has been omitted, but we do think that there are things in it which might well have been omitted, and others which might have been done a great deal better. We cannot think that any good purpose is served by the description of Momburg's method of constriction to control the abdominal aorta, and the omission of other methods much less dangerous. And we venture to think that the translator errs when he says in a footnote that Momburg's method has "gained an honourable position in obstetrical and surgical practice." As to the things which might have been done better we take the description of suprapubic prostatectomy. Freyer's method is supposed to be adopted; but the description differs widely and in many details from the Freyer operation as we understand it. In the chapter on nephrectomy we find the two routes sufficiently well described, with, perhaps, too sanguine an estimate of the ease of the transperitoneal method. The author takes the tuberculous kidney as his type, and it is difficult to accept the opinion expressed that it does not greatly matter although some portions of diseased renal tissue are left behind, as permanent cure results. The most likely thing to happen is the persistence of a perma-

nent and troublesome sinus—and that is not cure. The author recommends that the thickened ureter should be followed down as far as possible, ligated, and stitched to the lower extremity of the external wound, where it may later receive proper irrigation treatment. The practice in this country is to sterilize the cut end of the ureter and drop it back into the wound, where, as experience shows, it is harmless. In the chapter on bone and suture of bone there is no reference to Lane's plates; indeed, there is a notable absence throughout the volume of reference to the work of other than German and French surgeons. The chief merit of Professor Pels-Leusden's book, indeed, consists in this—that it is representative of German surgery. The translation is by Dr. FAXTON E. GARDNER, but we cannot conscientiously congratulate him on the result.

NEUROLOGICAL SURGERY.

PROFESSOR KRAUSE'S monograph on the surgery of the brain and spinal cord,⁷ the translation of which by Professor HAUBOLD of New York is now completed in three handsome volumes, is an elaborately illustrated and completely documented work. But it is more than that: it is a storehouse of information simply and carefully recorded by a surgeon of almost unrivalled experience in this field; it is a work of reference to which every other surgeon will certainly be indebted. In our preliminary notice of the first volume we praised the coloured plates, but did them less than justice; a fuller acquaintance with the work of the portrait painter Max Landsberg convinces us that the pictures do indeed illustrate the technical and pathological conditions disclosed at actual operations; certainly they form a valuable addition to the instruction in the text. The first volume is largely concerned with general principles and technique. Krause employs an osteoplastic method exclusively on the skull; he uses no electrical instruments, but relies on burrs and Dablgren forceps, avoiding even Gigli's saws. He pays great attention to preliminary and permanent haemostasis. The two-stage method, except for abscess, is his choice, with an average interval of six days. The precise directions given for dealing with leptomenigitis, cysts, tumours, cortical excisions, abscesses, as regards bone, dura, drainage, dressings, and other details, are valuable. His methods of approach to the Gasserian ganglion and pituitary body are already well known. It is interesting to find that he does not agree with Cushing as to the best site and method of decompression. In the closure of large defects he favours an osteoplastic method, but employs also free transplantation of bone. For topography he relies upon Krönlein, finding Kocher's method inaccurate. His experiences of temporary and permanent drainage of the ventricles are not very satisfactory. It may be noted that he does not use morphine as a preliminary to anaesthesia in brain operations; neither does he wear gloves when exploring the cranial contents; there is no doubt that gloves do eliminate the fine shades of tactile sensation which may be essential for delimiting some brain tumours. It is, however, when we reach the second and third volumes that we realize the wealth of the author's clinical experience, and the assiduity with which the full benefit of every individual observation has been extracted. It is only by reading *in extenso* the clinical histories incorporated in the text that the brief introductory paragraphs on each section of the subject, and each branch of it, are wholly appreciated. This involves, of course, great expenditure of time, but the time is well spent: and cumbersome though the method is, it is probably unavoidable where there are such enormous differences even between analogous cases, as there often are with cerebral and spinal disorders. More than two hundred pages are devoted to "Epilepsy," including Jacksonian; to those the result of infantile palsy, birth injuries, tumours, intoxications, reflex irritation, and to those without anatomical lesion; genuine general epilepsy; traumatic and reflex epilepsy. Some of his results are very remarkable; many are disappointing; and this applies both to cases in which a definite lesion is discovered and to those in which cortical excisions were made at the initiating centre.

⁶ *Surgical Operations: A Handbook for Students and Practitioners*. By Professor Friedrich Pels-Leusden, Chief Surgeon to the University Surgical Clinic and Chief of the University Polyclinic in the Royal Charity Hospital of Berlin. Only authorized English translation, by Faxton E. Gardner, M.D., New York. London: Robman, Limited, 1912. (Sup. roy. 8vo, pp. 756; figs. 663. 30s. net.)

⁷ *Surgery of the Brain and Spinal Cord*. By Professor Fedor Krause. Translated by Professor H. A. Haubold, M.D. Three volumes. Numerous coloured plates and figures in text. London: A. K. Lewis, 1910-12. (Imp. 8vo, pp. 1201. 30s. net each volume.)

When he comes to the consideration of neoplasms, Krause's regional differentiation of focal symptomatology is of great importance. No better indication of its value could, perhaps, be offered than the written diagnoses attached to the cases when sent to the author for operation by his colleague, Oppenheim; they are models of precision. In Volume III the question of prognosis is discussed; it is, of course, melancholy, but far less so than it used to be. The mortality in different regions varies from 25 to 66 per cent.; the cures are, however, in many cases permanent and practically complete. Of 81 neoplasms only 9 were solitary tubercle; the gliomata numbered 21, sarcomata 15, and fibrosarcomata 11. Of 24 patients with tumours of the cerebello-pontine angle only 4 were cured. Intracranial suppuration, wounds, and injuries are dealt with a little briefly by comparison. The spinal cord is treated with just the same thoroughness as the brain, both as to diagnosis, prognosis, and operative technique; the case-histories and pictures should afford a parallel for almost any problem a surgeon may have in hand. In the face of a pathetic appeal in his preface it would be unfair to criticize the translator; but it is difficult to excuse a carelessness that renders "Vorderbein," in an important passage, by "forebone."

Dr. L. N. Denslow has obtained such encouraging results by the surgical treatment of tabes dorsalis that he has laid them before the medical profession in a small book.⁸ He finds in every male case of this disease, without exception, an abnormal condition of the urethra; and that by suitable treatment of this condition many of the signs and symptoms may be cured, alleviated, or held in check. Syphilis, he holds, is not enough to cause locomotor ataxy; the most prominent additional factor in the male is urethral irritation, and the preponderance of male over female cases may be accounted for by the greater extent of the urethral surface in men. Dr. Denslow first examines his patients most carefully with the urethroscope or the Otis urethrometer, to find erosions, granulations, or strictures. Care must be taken not to irritate a hypersensitive urethra; the lesions, when found, are given the appropriate local treatment. At the same time care must be taken to avoid constipation (which is the rule in tabes) and gastric disturbances. He believes that urethral irritation, using the term in a very wide sense, is the cause of all sorts of disturbances of health in many cases, instancing *inter alia* epilepsy, melancholia, partial paralysis, syncope, general alopecia, acne, functional eye troubles, anaemia, cystitis, and uraemia. Dr. Denslow carries out his local treatment for long periods, usually three months, in one case quoted for seven. His book may be commended to the attention of specialists in diseases of the genito-urinary system and to neurologists.

SYPHILIS.

As the author states in the preface of the second edition of *Syphilology and Venereal Disease*,⁹ great changes have lately taken place in our outlook on this whole subject. Mr. MARSHALL published the first edition of this book in 1906, and he was able to include therein some mention of Schaudinn's great discovery of the *Spirochaeta pallida*, which has since been so fully confirmed and amplified; but the Wassermann reaction had not then been invented, nor had diamidoarsenobenzol been synthesized. There is, however, yet another change which marks a still greater advance, slowly affecting the whole of syphilology, and that is the increasing recognition of the importance of venereal disease as an influence on public health. The recognition of this factor is now illustrated (at the expense of the medical profession) by the provision which is made in the Insurance Act that the treatment of venereal disease should form part of the medical benefit provided by that measure. But it is undoubtedly a great sign of progress that the public authorities should realize the importance of early and efficient treatment of venereal disease, and discard their

old policy of merely ignoring its existence, and Mr. Marshall might have given more attention to this aspect of his subject. He has an interesting chapter on syphilis in relation to life assurance, and the book would have been increased in value by the addition of one on venereal disease in relation to public health. Important work has been done on this subject in Australia and Denmark within recent years. On the clinical side the book is strong. Primary syphilis, secondary syphilis, tertiary syphilis, quaternary or parasymphilis are all fully dealt with—as fully as is possible within the limits of a comparatively small book, and gonorrhoea and its scarcely less important complications also receive their due meed of attention. Discussion of the modern developments of syphilology is deferred to the last chapters of the volume. Mr. Marshall holds that the chief use of the Wassermann reaction is in the diagnosis of nervous affections. Whether others agree with such a limitation of its utility or not, and most observers, we fancy, would testify to the information they have derived from it in many other obscure cases, there can be no doubt that he is right when he says that clinical evidence should never be supplanted by laboratory tests. As regards the treatment of syphilis with salvarsan Mr. Marshall is well known to hold very conservative views, but in his chapter on the subject he gives a very fair summary of the case for and against the use of that remedy—in fact, the conclusions at which he arrives are far more favourable to salvarsan than one would expect, after reading the sarcastic comments on the subject which he has frequently published in letters to the medical press. In conclusion, it may be said that the book forms a very useful guide to the study of venereal disease. Its value is enhanced by the inclusion of a large number of references at the end of each chapter, but it might with advantage have been more fully illustrated.

Dr. MARCHILDEN'S book on the *Wassermann Reaction*¹⁰ is another addition to the many works dealing with this subject, and, like most of its kind, attaches rather undue importance to the diagnostic and therapeutic values of the reaction. Without in any way wishing to belittle the value of the work done by laboratory workers, it would almost seem necessary to remind some of them that syphilis was not infrequently diagnosed and successfully treated prior to Wassermann's discovery. The technical part of the book is clear and concise, but as regards the interpretation of results we find several contradictory statements. For instance, on page 73 the author states that many eruptions can be readily distinguished from syphilis by the Wassermann reaction, while on the same page he says that a positive reaction only means that the patient is syphilitic, not that the lesion is necessarily syphilitic. Again, on page 92 he says that he has never obtained a complete negative reaction after potassium iodide alone, while on page 95 he remarks that the reaction may entirely disappear under this drug. Another apparent contradiction concerns the nature of the antigen; for, after stating that the value of the antigen does not depend on the quantity of spirochaetes contained in the tissue, he says that the ideal antigen would be a pure culture of the *S. pallida*. Again, the author's conclusion that in some early cases of chancre after prompt energetic treatment the reaction "remains negative throughout life" is somewhat premature, considering that the reaction was only discovered in 1906.

A PUBLIC MEDICAL SERVICE PHARMACOPOEIA.

THE advanced condition of the organization of the Leicester Public Medical Service is shown by the fact that the board of management has now published a pharmacopoeia for use in the district in the work of all branches of the service. It contains some eighty formulæ; in some cases these are similar in essentials to official formulæ and can be used in place of them, as in the case of compound decoction of aloes, in which the expensive saffron is omitted and ginger takes the place of compound tincture of cardamom. The greater number of the formulæ, however, are for mixtures, pills, lotions, gargles, etc., frequently in use, but for which no formulæ

⁸ *A Surgical Treatment of Locomotor Ataxia*. By L. N. Denslow, M.D. London: Baillière, Tindall, and Cox, 1912. (Cr. 8vo, pp. 128, 3s. 6d. net.)

⁹ *Syphilology and Venereal Disease*. By C. F. Marshall, M.D., M.Sc., F.R.C.S. Second edition. London: Baillière, Tindall and Cox, 1912. (Cr. 8vo, pp. 572; 5 plates. 10s. 6d.)

¹⁰ *The Wassermann Reaction*. By T. W. Marchildon. London: Henry Kimpton, 1912. (Cr. 8vo, pp. 114, with 11 illustrations and coloured frontispiece. 6s. 6d. net.)

are included in the *British Pharmacopoeia*. The prescriptions are excellent and the compounds are inexpensive; it is, of course, important, for the purposes for which this pharmacopoeia is compiled, that money should not be wasted on useless ingredients or on expensive articles when cheaper ones are equally efficient; thus the use of "sweet oil" in place of olive oil is authorized, and another note states that "non-alcoholic tinctures may be used in the preparation of these formulæ where pharmacological action will not be impaired." By arrangement with the chemists of the district, medicines prepared in accordance with this pharmacopoeia are kept ready for use, as well as the ordinary medicines of the *British Pharmacopoeia*; and these formulæ will also be recognized for insured persons, except where preparations not in the tariff or the *British Pharmacopoeia* are included. In these cases equivalents will be substituted in accordance with a list issued by the Chemists' Association, the titles of the formulæ remaining the same. Formulæ are given both in imperial and metric weights and measures. The book is thin, of convenient dimensions for the pocket, and interleaved with plain pages, and it would not be surprising to find it adopted in other districts as well as that in which it has been produced. The office of the Leicester Public Medical Service is at East Bond Street, Leicester.

NOTES ON BOOKS.

A VAST number of writers have taken advantage of the crusade against tuberculosis to express their views as to prophylaxis and treatment. For the most part they merely repeat an oft-told tale. The writer of this little book, a practitioner of forty-seven years' standing—*Notes on the Treatment of Tuberculosis*¹—being convinced of the virtues of a certain prescription containing some little used drugs, is anxious that others should benefit by his experience. As a strong believer in the need for calcium salts as a protective, especially in childhood, and in the value of cod-liver oil, he sets forth his opinions with much argumentative skill, backed by quotation from writers of varying degree of authority; but the arguments all lead up to the prescription and the calcium salts at last. A compact little book, well printed and set up, containing many sound observations and much good advice within a limited range.

The eleventh number of the Clinical Series of the *Archives of the Middlesex Hospital* includes a paper by Sir Pearce Gould on some unusual cases of mammary growths; a review of one hundred cases of chorea treated by chloroform, by Dr. Essex Wynter; some notes on thrombosis, by Mr. Somerville Hastings; a paper on the significance of rheumatic rashes, by Dr. E. A. Cockayne; an interesting report on an unusual case of carcinoma of the pelvic colon, by Mr. Alfred E. Johnson and Mr. Lakin. Mr. Alfred E. Johnson contributes an interesting short note on the substitution of the application of tincture of iodine for dressings. After reading Mr. Reginald Alcock's paper on iodine as the sole dressing for operation wounds, in the BRITISH MEDICAL JOURNAL of February 3rd, 1912. Mr. Johnson used tincture of iodine and discarded dressings in cases where the wound was closely sutured. In this way he treated over fifty cases of operation, including 12 operations for the radical cure of hernia, 12 for appendicitis, 4 coeliotomies, 2 nephropexies, 2 for undescended testis, and 6 for removal of superficial tumours. In a few cases where dressings were considered necessary at first—for example, in amputation of the breast until the drainage tube was removed, and in excision of varicose veins to support the limb for forty-eight hours—they were given up as soon as possible, and iodine solution applied. The results, he states, were most gratifying; the comfort of the patients was increased, and the wounds healed even better than with dressings; in no case did the slightest inflammatory reaction occur. This number of the *Archives* contains also a communication on methods in mental therapeutics, by Mr. H. Campbell Thomson; a report by Dr. Comyns Berkeley on two cases of chorion-epithelioma; a note by Mr. Sampson Handley on two fatal cases in which acute appendicitis lighted up an old tuberculous lesion; and a case of rupture of the vagina during coitus, by Dr. Victor Bonney.

¹ *Notes on the Treatment of Tuberculosis*. By John Laird, L.R.C.S. and P.L. Bristol: John Wright and Sons, Limited. London: Simpkin, Marshall, and Co. 1912. (Cr. 8vo, pp. 85. 2s. 6d. net.)

THE PARLIAMENTARY COMMITTEE ON PROPRIETARY REMEDIES.

WITH the end of the Parliamentary Session the authority of the Select Committee appointed to inquire into the sale and advertisement of proprietary medicines lapses, but at the meeting of the Committee on February 6th the Chairman (Sir Henry Norman) announced that as the investigations had not been concluded a report would be presented to the House of Commons recommending that the Committee be reconstituted next Session.

WOODWARD'S GRIPE WATER.

The first witness called was Mr. William Woodward, managing director of Woodward Limited, of Nottingham, proprietors of Woodward's Gripe Water. The witness stated that the preparation was based on the prescription of a family physician; in Nottingham it was recommended by members of the medical profession, and two of them, to his knowledge, purchased considerable quantities for dispensing. He complained that the formula published in *Secret Remedies* with regard to the preparation was inaccurate, seriously incomplete, and misleading. One active ingredient of considerable medicinal value was omitted. Dealing with the general question, the witness expressed strong objections to the publication of formulæ. He claimed that the prime cost of the ingredients of proprietary medicines bore a larger proportion to the sale price than in the cost of ingredients of most medicines dispensed by doctors.

In reply to Dr. Chapple, the witness agreed that it might be a good thing if the exaggeration that prevailed in advertisements of proprietary medicines could be suppressed, but he did not think legislation was necessary to that end.

STEEDMAN'S SOOTHING POWDERS.

Mr. J. A. South, manager of the firm of Steedman and Co., 272, Walworth Road, S.E., manufacturers of Steedman's Soothing Powders and other preparations, said that the soothing powder had been on the market since 1820. The medicines sold by the firm were compounded by a pharmaceutical chemist, and the formulas were known only to the firm and to Mr. Hake, who would appear.

The Chairman called the attention of the witness to a statement on the label of the packets of soothing powders to the effect that "to prevent substitution His Majesty's Honourable Commissioners of Excise had ordered the name of John Steedman to be printed on the Government stamp."

The witness replied that this statement had been withdrawn.

Mr. Lawson: It rather implies that the Government is at your back?

The Chairman: It does not imply it; it states that to be the case.

The witness was questioned with regard to a pamphlet issued by his firm, bearing on its title-page the words—"Hints to Mothers on the Treatment of their Children. By M.D. of London." He said that the services of the doctor in writing this pamphlet were obtained through an agent. He did not know the name of the writer, as it was made a special condition that this should not be revealed.

The Chairman: You must realize that that is a very unsatisfactory statement from our point of view. Here is an advertisement of a proprietary medicine written by a man with the highest medical qualification in the world. Did he write the parts relating to Steedman's Powders?

The Witness: If not, they were submitted to him.

Have you his authority for saying that everything was submitted to him, and he approves of it?—Certainly.

Pressed to give the Committee the name of the doctor either publicly or privately, the witness retorted that Dr. Cox said if he knew of a medical man doing such a thing as this he would report his conduct as infamous in a professional respect. After that, how could he give the name to the Committee?

The Chairman: Then it amounts to this: that the medical man desires to have his name suppressed because he knew he was committing an act contrary to the etiquette of his profession.

In reply to further questions, the witness said the

medical man who wrote the pamphlet had no interest in the business. He could not say definitely whether he received payment; an agent made the arrangements.

Mr. Cawley: You are sure he was paid?

The Witness: I think it is very probable.

The Chairman: It is in our power to require you to produce the correspondence. The public interest, if the Committee so decided, would override your promise. It is a serious matter that an advertisement of a proprietary medicine should be circulated in the name of a medical man with a very high qualification. We should like to have asked him his views as to the therapeutic effect of the medicine.

Dr. Chapple pointed out that "M.D. of London" was not the orthodox way of describing a medical graduate of London University. A doctor reading "M.D. of London" would conclude that the person so described was not a holder of the London University degree, but perhaps resided in the metropolitan area.

The witness promised the Chairman that he would endeavour to obtain permission to disclose the doctor's name, either publicly or privately. As he expressed a desire to refer the Committee to Mr. Hako as to the therapeutic value of Steedman's Soothing Powders, no further questions were addressed to him.

Mr. Henry Wilson Hake, the next witness, said he was a member of the Institute of Chemistry, a Fellow of the Chemical Society, and lecturer on chemistry and toxicology at Westminster Hospital. He held the degree of Ph.D. of Giessen University.

The Chairman: You appear here in connexion with the manufacturers of Steedman's powders?

The Witness: I should not like to put it in that way; I come here to correct an erroneous statement in *Secret Remedies*. Continuing, the witness said the analysis given in that book was incomplete, and gave an entirely erroneous impression as to the composition of the powders.

The Chairman: You will naturally expect that we shall wish to recall Mr. Harrison and submit the preparation to the arbitration of the Government analyst?

The witness said he entirely agreed with that course being taken. As to the analysis in *Secret Remedies*, he said that one of the ingredients which had been entirely overlooked was discoverable by chemical analysis, and was an important constituent having a useful therapeutic effect. It was a simple and commonly prescribed drug. One of the drugs used contained a very minute preparation of an alkaloid; this was so minute as to be probably undetectable in a single powder. The statement in *Secret Remedies* as to the percentage of ash had no definite meaning, as the ash would be a mere product of the incineration of any vegetable matter present. The therapeutic effect of the formula given in *Secret Remedies* and the actual prescription used by the makers would be entirely different. He had carefully analysed a packet of twenty-four powders, and found that their composition agreed with the formula disclosed to him by the company. He also analysed the powders in 1904 and 1909 with practically identical results.

The Chairman: Does it surprise you that an analyst of presumably high standing should make a public statement regarding the contents of a medicine which gives an entirely erroneous impression?—It not only surprises me, but I think it is a very regrettable matter.

Is the analysis in this case difficult from an analyst's point of view?—It ought not to be difficult to a chemist who had a knowledge of drugs and was accustomed to handling them. I do not wish to say anything against Mr. Harrison, but I think if he had possibly taken a little more trouble, or consulted a brother chemist who possibly might know a little more in that particular direction, I think he would have made a better analysis.

Mr. Harrison made a great number of analyses?—Far too many, I imagine. These things take a very long time if one has no information as to the formulae.

But there is no special difficulty about this particular analysis?—The ordinary analytical chemist might find great difficulty in these matters.

Dr. Chapple: Why?

The Witness: Because it deals with chemicals not in the ordinary ken of the analytical chemist.

The Chairman next invited the witness to deal with the therapeutic effect of the powders, and particularly with

the effect of calomel upon young children. The witness replied that he could quote some medical opinions; he was not a medical man but a chemist.

The Chairman: That places the Committee in a difficulty. Mr. South referred us to you on this point, so we refrained from asking him any questions.

In reply to Dr. Chapple, the witness said the analysis in *Secret Remedies* only omitted one ingredient; it was accurate in all other respects.

THE ASSOCIATION OF PUBLIC VACCINATORS OF ENGLAND AND WALES.

ANNUAL MEETING.

THE annual meeting of the Association of Public Vaccinators of England and Wales was held at the Hotel Cecil, London, on January 31st. The chair was occupied at the commencement by Dr. A. H. MARTIN (Evesham), the retiring President. The annual report and financial statement were approved and adopted. The TREASURER reported a satisfactory balance on the year's working. Drs. Major Greenwood (London), Sharman (London), Bateson (Bradford), and Rose Smith (Liverpool) were elected to fill four vacancies on the Council. Dr. Arthur Maude (Westonham) was elected President for the present year. The retiring President was heartily thanked for his services during the past year.

The PRESIDENT gave an interesting address based on a recent report by Professor Kirchner, issued by the German Government. Dr. Maude suggested that our Government would do well to issue a translation of the report. Interesting extracts were then read from a volume of biographical essays recently published in America. The eulogy of Jenner was the most warmly expressed of all.

Annual Dinner.

In the evening the annual dinner was held at the Hotel Cecil. In the absence of Dr. W. T. Williams (Manchester), Dr. HOLMES (Liverpool) proposed "The Guests," and Sir JAMES CRICHTON-BROWNE, who replied, said he came to that dinner with mingled feelings of pleasure and pain. It was a pleasure to meet a large body of professional brethren who were engaged in an eminently useful public work, and who were diligently and efficiently safeguarding the national health. It was a pain to reflect that those services were not more justly appreciated and fully utilized. The number of conscientious objectors who proved to the satisfaction of one stipendiary magistrate or two magistrates in petty sessions—a discrete or a confluent authority—that they believed that vaccination would be prejudicial to the health of their offspring was increasing largely, and it seemed to him to be just another illustration of the spirit of lawlessness and defiance of authority that was abroad and of the apathy of the public on questions vitally affecting its welfare. It was difficult in these days for the still small voice of scientific wisdom to make itself heard, but any turbulent and noisy coterie was allowed to influence the course of legislation. Sir James next paid a tribute to Dr. Monckton Copeman's scientific work in connexion with vaccination, and made an amusing reference to the possibility of a militant agitation against vaccination. As a patriotic Scotsman he sometimes thought that Jenner's investigations and experiments might have been stimulated by conversations he had with John Hunter, that illustrious surgeon and anatomist, and that thus Scotland had had a finger in the pie. As in the case of many other great and beneficent inventions and discoveries, vaccination was anticipated in popular belief before it assumed a scientific shape.

Surgeon-General G. J. H. EVATT, C.B., with whose name also the toast was coupled, expressed his pleasure at being associated with an organization of medical men charged with the important public duty of applying a scientific preventive remedy to the population against a very dreadful disease of which he had seen so many terrible examples in his experience among unvaccinated people in India. Medical men knew the truth about these things, and it was their duty to educate the people.

The PRESIDENT (Dr. Maude) gave the toast of "The Association of Public Vaccinators of England and Wales." He contrasted the state of affairs in Germany with

England. In the former the Government issued concise and convincing literature to the public on vaccination. The association had for several years been doing a valuable educational work. It owed this largely to one man (Dr. Drury), who had been doing almost more than they could conceive it possible for one man to do. In this country the Government gave no help. The association was doing useful work, and must keep on doing it because the red terror was going to arrive. The President concluded with an appeal for increased membership of the association.

Dr. A. E. COPE, who responded, referred to the work of the Organizing Secretary (Mr. Charles Greenwood), and that of Dr. Drury, who seemed to him to be an instance of multiple personality. With Dr. Maude as President the association should have a bright and useful year.

A programme of songs and duets was provided, which contributed to a most enjoyable evening.

ONE HUNDRED YEARS AGO.

THE FASTING WOMAN OF TUTBURY.

In February, 1813, the medical profession was beginning to unmask the imposture of the fasting woman of Tutbury, and our brethren of those days were reading Dr. Henderson's "Observations on the Case of Ann Moore" in the *Medical and Physical Journal*.¹ Ann Moore, by reason of her resolution and cunning and on account of the notoriety she attained to, has made her way into the pages of the *Dictionary of National Biography*;² and in the same work³ is to be found a short account of the life of Dr. Alexander Henderson, who was instrumental in breaking up the fraud. The former gets 120 pages in the *Dictionary* and the latter 29!

Ann Moore was born at Rosliston in Derbyshire in 1761, and was the daughter of a day labourer named Pegg. She was a good-looking girl; she was married to a farm servant named James Moore when she was 27 years old, and was afterwards deserted by him. She had a large family; but, falling into poverty, she went to Tutbury in 1800 to try to find honest employment. At Tutbury, near Burton-on-Trent, made notable by its castle, which had served as one of the prisons of Mary Queen of Scots, Ann Moore spent the next thirteen or fourteen years of her life. She soon began to attract local attention by her long fasts, and in the years 1806-7 she was said to have lost all desire for food. It is noteworthy that she was then 45 years of age, and had, therefore, arrived at the climacteric. A steadily increasing stream of visitors came to see her and went away wondering; pamphlets began to be written about her; it was suggested that her appearance might possibly presage the coming of a famine, and finally a "watching" took place in 1808 and lasted for sixteen days. At the end Ann emerged triumphantly, having actually improved in health and spirits under the test; at least so it was given out. The crowds of visitors increased, and their sympathy must have been of a substantial nature, for in 1812 Mrs. Moore deposited £400 in the funds. In the summer of that year, however, Dr. Alexander Henderson, an Aberdonian (hard-headed we may imagine), a graduate of Edinburgh University (of 1803), and physician to the Westminster General Dispensary, paid a surprise visit to the "fasting woman of Tutbury."

He, with two friends, were in Staffordshire on other business, and it seemed a good opportunity to inquire into the story of the fasting woman. "We lost no time," wrote Dr. Henderson, "in proceeding to the dwelling of Ann Moore, whom we found sitting up in bed. . . . She did not seem in the least discomposed by our abrupt entrance, though, on reaching the house, some bustle was heard in the upper story, as if preparations had been making for our reception." Dr. Henderson noticed that Ann was rather thin, that her abdomen was not contracted, that the beating of the abdominal aorta was not more easily felt than usual, that the pulse was 94 (firm and regular), that the skin was moist, that there was no deficiency of saliva in the mouth, that her voice was

strong, and that she could move her arms and fingers with considerable force. He also smelt an offensive urinous odour. Mrs. Moore told them that she had tasted no solid food for upwards of five years, and no drink for nearly four years, that she had passed no urine for three years and no faeces for five, that she had not slept nor laid down in bed for more than three years, that she took snuff, that she had fits, that she could not open her mouth, and that she had lost the power of the fingers of her left hand. We can imagine that Dr. Henderson pricked up his ears when he heard her state that she had passed no urine for three years, and that he made a mental note when he observed her move one of the fingers of her left hand.

In the article which Dr. Henderson contributed to the *Medical and Physical Journal* (loc. cit.) on his return to London, he enumerated fourteen circumstances which in his opinion invalidated Mrs. Moore's assertions. It would be wearisome to enumerate them all, but to some reference may be made. He pointed out the natural and healthy appearance of her face; the strength of her pulse, muscles, and voice; the moisture of her mouth, nostrils, eyes, and skin; and the entireness of her intellectual faculties. "If," he wrote, "the functions of the stomach were entirely suspended, it is not likely that the saliva would continue to be regularly supplied." He touched next upon her "notorious immoral character," upon the obvious interest which she and her attendants had in supporting the deception, and especially upon the imperfect manner in which she had been watched (of this there could be no question), along with her dread of a repetition of the watching, and indeed of all experiments whatever. There could be no doubt that she was passing urine; her statements varied and contradicted each other, and her actions were not consistent with her statements. Dr. Henderson gave instances of these inconsistencies. He believed that he had collected "a sufficient body of evidence to prove that there were no solid grounds for supposing that the order of Nature was subverted in the person of Ann Moore." He wrote his report at Golden Square, the date being November 25th, 1812, and Dr. Samuel Fothergill, one of the editors of the *Medical and Physical Journal*, published it in February, 1813.

This was the beginning of the end; a second watching was insisted upon and was begun on April 21st; only ministers of the Church of England, medical men, and magistrates were allowed to take part in the watching; for seven days Ann Moore took no food, but on the ninth day she was so weak as to be in danger of death, and a few hours later she made confession of the fraud that she had practised, admitting that she had received food in liquid form from her daughter when she kissed her night and morning. The Rev. Leigh Richmond, Rector of Turvey, in Bedfordshire, one of the watchers, wrote a full account of these occurrences, and this was published in the same medical journal in June of the same year (1813).

It should be added, to give Dr. Henderson full credit for his share in detecting the fraud, that he had published a little book on the matter before the second watching took place, and that in it he pointed out the parallel which existed between the case of Ann Moore and that of Anna Maria Kinker, the notorious fasting woman of Osnabrück. Indeed, this was an age of fasting folks, for Chambers, in his entertaining *Book of Days*,⁴ tells of Mary Waighton, of Wigginton (also in Staffordshire); of the French girl, Christina Michelot; of Ann Walsh, of Harrogate; of the fasting boy of Chateauroux; of Katherine M'Leod (Pennant's fasting woman of Ross-shire), and of the Swabian woman, Monica Mutcheteria; all these persons had lived in the second half of the eighteenth century.

This note on the fasting woman of 100 years ago may fitly close with the editorial comment in the *Medical and Physical Journal* for May, 1813:

Our readers are now in possession of the facts which the industry and ingenuity of Dr. Henderson have enabled him to acquire upon a very curious subject. The public appears to take considerable interest in it; for, though honest John Bull is a very credulous animal, he is very angry when he discovers that a deception has been practised upon him.

Nova et Vetera.

A CLERICAL PIONEER OF VACCINATION.

THE following unpublished letter of Edward Jenner, the discoverer of vaccination, to the Rev. William Finch of St. Helens, Lancashire, and some account of the experiments of the latter, may be of interest to your readers.

Sir,

Knowing that you have carried the vaccine inoculation to a considerable extent, I take the liberty to request the favor of you to give me the result of your practice. As it is probable that the subject may shortly undergo public discussion I wish to be prepared with Testimonies of the efficacy of the Cowpox as a preventive of the Smallpox from the most respectable authorities. I am no stranger to that mass of evidence you were so good as to publish in favor of the new practice in the *Medical and Physical Journal*; but on the present occasion written testimonies will have a greater weight.

I by no means wish you to go into detail; it will be sufficient if you will kindly state the numbers you have inoculated and then adduce your proofs that the Inoculation protects the Constitution from the contagion of the Smallpox. If you please you may add too your opinion of the utility of the discovery.

I remain Sir,

With great respect

Your obedt. humble servt.

E. JENNER.

London
Bond Street
136

Feb. 7th 1802.

P.S. Pray accept my thanks for the obliging manner in which you were good enough to mention my name in the *Medical Journal*.

The letter is addressed to "The Rev. W. Finch, Minister of St. Helens"; it bears several postmarks, having been mis-sent to St. Helens, Isle of Wight, and St. Helens (? Church), London. The London postmaster made the note "Try Lankeshire." There was 11s. 8d. postage to pay on it. It is now in the possession of Mrs. James Hesketh, late of Bolton, a great-niece of the Rev. W. Finch.

This clergyman, great-great-uncle of the present writer, was born at Wigan in 1753, and was educated at the Wigan Grammar School. He was chief usher of the school in 1775 when he received the living of St. Helens, which he held until his death in 1815. The living of St. Helens was a perpetual curacy, the great tithes going to King's College, Cambridge, and the small to the Vicar of Prescott, who, however, had no control over the parish, the appointment being in trustees. The title "Minister" arose from the incumbent in 1662 not having complied with the Act of Uniformity, and continued in use until 1868, when perpetual curacies were abolished, and all incumbents not rectors were made vicars.

The "mass of evidence" alluded to in the letter was published in the *Medical and Physical Journal*, which was continued after 1815 as the *London Medical and Physical Journal*.

The Rev. William Finch wrote under date of March 11th, 1800:

On the 17th of November last I inoculated a child of 8 months old with a lancet, armed the eighth day preceding with vaccine matter, and sent me by the Rev. R. Holt, Rector of Fimmere, Oxfordshire.

The identity of this child is shown by the following extract from the St. Helens Parish Church register kindly made for me by the Rev. Albert Baines, M.A., the present vicar:

1799. Daniel, son of David Scarborough, Clogger, of St. Helens, Born 4th March; Baptised 31st March. This child on the 17th November following was the first in these parts that was inoculated with Vaccine Matter, By me, W. Finch, Minr.

The article in the journal goes on to describe a normal case of vaccinia. Other children were inoculated from the first child and others from them, the total reaching 714. Three cases varying from the normal are described.

On February 25th and 26th he inoculated with variolous matter twenty children whom he had inoculated with vaccine matter in November and the beginning of December. To use his own words, "The result of the experiment is that they have all entirely resisted the infection." He then goes on to say: "Only two produced, each, on the place of insertion, a small P.O. K, if such it can be denominated, of about quarter of an inch in diameter."

The paper concludes as follows:

Such are the nature, process and effects of inoculation here with vaccine matter; and this may serve as an additional evidence to the testimony already given of its efficacious properties if you think it worthy of a place in your very useful and instructive journal. Upon contemplating its astonishing powers, I could not help falling into this reflection—If the observation of the naturalist be true "Wherever a poisonous plant grows its antidote is found," why may not the same observation hold good in this respect also? If it could be proved that the human constitution imbibes that virulent malady the small-pox from the milk or animal diet which the lowering herd furnishes, by parity of reasoning, then in the same quarter its counteracting principle subsists. Nature is uniform in all her laws. Everything she generates has its opposite. There is no evil without its corrective and here she produces an effectual remedy for that malignancy. It surely cannot be too highly prized. To show the discoverer of it every praise, every gratitude is due. The joy and delight it diffuses through every family here is inexpressible, and it may not be unbecoming to subjoin, it gives me the liveliest satisfaction and pleasure to hear the people exclaim—"Blessings on the head of him that first wrought such happiness for us!"

I am, Gentlemen,

Your most obedient humble servant,

W. FINCH,

Minister of St. Helens.

March 11th, 1800.

HERBERT PECK, M.D., D.P.H., etc.,
Barrister-at-Law.

Chesterfield

LITERARY NOTES.

THE annual report of the Library Committee of the College of Physicians of Philadelphia contains a short disquisition on the proper disposal of pamphlets and reprints—a serious difficulty for every medical librarian, and a source of no little perplexity to many private individuals who have been taught by experience that a very common consequence of "making a clearance" is the discovery a few days later that one of the dusty, dog-eared rejected has suddenly become for the moment worth its weight in gold. Formerly the College arranged its unbound pamphlets and reprints by classes on shelves like books. This, as was to be expected, proved an unsatisfactory arrangement. Now the pamphlets and reprints are arranged by subjects; the proper subject-heading is written on each, and the set then arranged alphabetically under the authors' names. When a sufficient number of pamphlets on one subject has accumulated they are bound in a volume, and the subject-title of the volume is entered in the general catalogue of the library. Each separate pamphlet or reprint is not entered in the catalogue, but the inquirer looks up his subject in the general catalogue, gets the volume or volumes of reprints and pamphlets on it, and then finds a collection of original articles arranged in the alphabetical order of authors' names, and all belonging more or less to the same period. Each volume should be dated on the back, and there should be bound in as a fly-leaf a list of its contents; these two points are not mentioned in the report from which we quote, but no doubt they have received attention. It may be added that the library of the College has an important collection of early printed books and manuscripts; it has a special fund for the purchase of such rarities, but it has also many individual benefactors, among whom, last year, Dr. George E. de Schweinitz seems to have been the most generous.

It is to Frascatorius, the philosopher-physician of Italy who lived in the sixteenth century, that we are indebted for the word "syphilis." He gave the title, "Syphilis,"¹ to a poem, which has been described by Osler as the most successful medical poem ever written. He does not appear to have assigned any reason for originating this word, and its etymology has been a matter of much speculation. By some authorities the Greek σφίλιος—swine lover—has been accepted as the origin; others, again, argue that its derivation is from σφάλλος—maimed or impotent. But, however this may be, the fact remains that the poet-physician of the sixteenth century described the disease so accurately in all its essentials that his account of it remained unsurpassed until well into the nineteenth century. Briefly, the poem of Frascatorius tells of Syphilis, a shepherd who kept watch over the flocks

¹ See a paper by A. T. Downing, M.D., in the *Boston Medical and Surgical Journal*.

of King Alcithous. Becoming incensed at a drought so extreme that the cattle perished for want of water, Syphilis blasphemed the Sun God, who, enraged, darted forth infection on earth, air, and stream, the unfortunate shepherd being himself the first victim of the disease.

Syphilis ostendit turpes per corpus aehores:
Insomnes primus noctes, convulsaque membra.
Sensit, et a primo traxit cognomina merbus.

There is no description of the disease either in Hippocrates or Galen, and it was in 1494 that Europe was first startled by a great epidemic. It was not, however, until the lifetime of Frascatorius that men emerged from ignorance to a knowledge of the disease. There were many speculations at the time as to the origin of the malady. Some insisted that it was brought from America by the soldiers of Columbus; but Frascatorius did not share this view, on the ground that the spread of the disease was too rapid. It was traced by others to the French and Spanish campaign in Northern Italy in 1494. The army of Charles contained many mercenaries, and indulged in scenes of the wildest debauchery as it passed through Northern Italy; after the retreat and disbandment of the army the various units—Spanish, German, Swiss, and French—are presumed to have scattered, carrying with them to their respective countries the devastating contagion. Matters got so bad in Paris, indeed, that a decree was passed in 1496 requiring all infected persons to leave the city within twenty-four hours. This was, however, by no means the first appearance of the disease in the civilized world, for Celsus, living in the first century before Christ, speaks of certain affections of the genitals, including ulcers on the glans penis, and Aretacus, three centuries later, refers to a disease which destroys the uvula to the bones of the palate. From the evidence of Martial we cannot but believe that the ancestors of the present day spirochaete were well developed in imperial Rome. Horace, too, pointed out to the Romans of his day that the age was prolific in sins, which polluted even their offspring. During the first year or two of the fifteenth-century epidemic the disease was practically untreated by the physicians of the time, and quacks and charlatans had the field to themselves. When at last the profession began to pay attention to the disease, the use of mercury, originally introduced in therapeutics by the Arabs, began. Frascatorius, after setting out rules as to diet, says in the poem already referred to:

The greater part, and with success more sure
By mercury perform the happy cure;
A wondrous virtue in that mineral lies.

Lard was used as a vehicle mixed with larch gum and turpentine, and with this preparation the whole body was smeared with the exception of the head and breast. The patient was then sweated profusely under thick bed clothing; this was repeated for ten days. Mercury soon fell into disuse, however, and in turn infusion of guaiacum wood, sarsaparilla, and saffras became the popular remedy. In 1538, however, mercurial inunction came back into favour, and the drug was administered internally in the form of the red precipitate. In 1821 tincture of iodine was first used locally in specific ulcers of the throat with good results, and to Dr. Wallace of Dublin belongs the honour of first using potassium iodide in syphilis. The mercurial treatment of syphilis by inunction is at the present day much as it was in the time of Frascatorius, and indeed, until Schaudinn demonstrated the *Spirochæta pallida*, and Wassermann the reaction bearing his name, and finally, until Ehrlich gave salvarsan to the world, we have been content, for three hundred years, to follow in the footsteps of the old poet-physician of Italy whose inspiration first gave this disease the name it bears.

We have received a note from Mr. C. Strickland, M.A., travelling medical entomologist to the Royal Society, respecting the word employed in our notice of Professor Minchin's *Introduction to the Study of the Protozoa*, in the *JOURNAL* for December 7th, p. 1612. He agrees that the use of the adjective "chromatinic" for "chromatic" is to be commended, and that Professor Minchin's substitution of "chromatinic" was well advised. Mr. Strickland is of opinion that "chromatic" is an absurd derivative from "chromatin," and he employed the newer and more correct word himself in his paper on *Hæpzetomonas buccifæ* in

Parasitology, 1911. "Chromatic," as we know, is an English word well accepted in general literature. In Murray's *New English Dictionary* it is defined as (1) "of, or belonging to colour or colours; consisting of or produced by colour (chiefly a scientific technical term)"; (2) "a term used in music." It is clear, therefore, that giving the word a third application is highly inadvisable; the more so as in the *Standard English Dictionary* "chromatic" is already recognized as a scientific technical term. Therefore its use in science in a quite different sense to that usually understood is to be avoided as liable to cause confusion.

A catalogue of second-hand books issued by Henry Sotheran and Co., 140, Strand, and 43, Piccadilly, contains a number of books from the remaining portion of the library of the late Lord Lister. There are nearly 4,000 volumes, and the books on medicine, Quakerism, Scotland, and theology are classified under those headings. The first two entries have a special personal interest; the one is a copy of Æschylus inscribed "Joseph Lister, 17.10.1845," and the other is a copy of the fourteenth edition of *Evenings at Home* in four volumes inscribed on the fly-leaf of the first, second, and fourth volumes, "Joseph Lister from his Papa. 17th of 4th Mo. 1833," when the child was six years old. The boy's progress may be traced in other entries, as in the inscription in Lindley's *School Botany*, "Joseph Lister, 4th month, 1844," and in Hutton's *Recreations in Mathematics and Natural Philosophy*, inscribed "Prize Copy 'to Mr. Joseph Lister, of Upton, Essex, from University College, London, as First Prize in the Experimental Class of Natural Philosophy.'" Some of the volumes in the list, it may be noted, were originally in the library of Professor Syme, Lord Lister's father-in-law.

SCIENCE NOTES.

The physiological functions of the ductless glands have been ascertained by the administration of their extracts on normal animals, by the results that follow on their removal, and by the train of morbid symptoms that ensue when they are the seat of gross lesions. But very little is known of the changes that ensue secondarily in them in diseased conditions of the body. The suprarenal gland and adrenalin, its chief but probably not its only secretion, have been most fully studied. Ribadeau-Dumas and Harvier have found various striking changes in the suprarenals in diphtheria, typhoid fever, pneumonia, and scarlatina. The changes were albuminoid and fatty degeneration, with oedema or with hæmorrhage, in both cases leading to necrosis, and are probably to be attributed to the intoxication. In view of the adrenal insufficiency brought about by these diseases, we are led to conclude that the life of the individual is thereby compromised, and various observers consider that a rational treatment of fevers ought to include the administration of extract of the whole suprarenal and not of adrenalin alone. But observations on pathological conditions of the suprarenal should not too hastily determine the therapeutic procedure, for probably no organ, investigated *post mortem*, shows more frequent departures from what would be considered a typically normal condition. Even in Addison's disease, which is often associated with tuberculosis of the adrenals, not infrequently the glands are found in a condition that may seem identical with that of adrenals from other totally dissimilar diseases; and, on the other hand, gross lesions of these glands may exist without, so far as is known, any concomitant symptoms of a striking nature. We do, however, know the potency of adrenalin, and ophthalmologists can be forgiven for the administration of the extract over a wide variety of diseases, and perhaps credited with cures or ameliorations of diseased conditions less tractable to other medicaments. In a large number of cases of Addison's disease suprarenal extract is without effect, in others the clinical facts of decrease of asthenia and increase of arterial tension are noticeable, but such cases are rare. It has been used with apparently good effect occasionally in intractable vomiting of pregnancy and in osteomalacia, but the repeated administration necessary is not without grave danger, and greater success has been claimed for pituitary extract, which has very little toxic action, and which can be injected in larger doses repeatedly for a much longer time.

British Medical Journal.

SATURDAY, FEBRUARY 15TH, 1913.

THE METROPOLITAN WATER BOARD AS A HEALTH AUTHORITY.

ON March 15th the King, accompanied by the Queen, is to open the new reservoir built for the Metropolitan Water Board at Chingford. The ceremony of cutting the first sod—the public commencement of the work—was performed nearly five years ago. Now the reservoir is nearly completed. When finished, it will have cost about £550,000, will be capable of containing three thousand million gallons, and the area covered by the water will be 416 acres. After storage for a sufficient period, the water will pass along a canal one and a quarter mile long to the filter beds at Lee Bridge, and will ultimately be distributed to 1,600,000 people as a good, wholesome, drinkable water.

The Londoner, accustomed to take everything in the complex whole of which he is a unit for granted, may have been tempted to ask why Their Majesties should be willing at a trying time of the year to undertake a somewhat tedious and dreary journey in order to open one more reservoir. Doubtless it is because the King rightly looks upon the completion of this large work as of vast importance to the health of the metropolis and the well-being of the people. This side—the health side—of the Water Board's work is the one which should be emphasized in connexion with the opening of this great undertaking.

For some time after the formation of the Metropolitan Water Board the main idea and controlling influence of its policy was the commercial aspect of so great an enterprise. The buying out of the eight water companies by the Board at the huge cost of £47,000,000, the great yearly income of £3,000,000, the gigantic task of supplying to each one of over seven million souls 34 gallons of water a day, distributing it in 6,300 miles of pipes over an area of 620 square miles, so impressed many interested in the work of the Board that the commercial idea was the only one they would entertain. Slowly, it may be, but surely, the health-idea has penetrated to the heart of the Board's work and to the minds of the people of London, so that both are now prepared to say, with Sir John Simon, "water is the power of life and death."

Evidence of the truth of this saying is unfortunately plentiful in the history of the metropolis, for if we look at the effect of two water-borne diseases, cholera and typhoid, we can see the ravages they used to make in London's population. In the various cholera epidemics—1832, 1849, 1854—the deaths from this disease were 31.4, 61.8, 42.9 per 10,000 people. Fortunately the lesson of such events has been taken to heart, and through the care of municipal authorities in safeguarding our water supply, aided by the alertness of the various port authorities, this country is kept cholera free. But enteric fever is still with us, and the outbreaks of this disease in

Maidstone, Lincoln, and Swanage, confirm the finding of the Royal Commission on Rivers Pollution that "the admixture of even a small quantity of these infected discharges with a large volume of drinking water is sufficient for the propagation of those diseases amongst persons using the water," a conclusion supported by scientific experience throughout the world. London's record in this connexion is extremely interesting and instructive, for if we take the annual mortality from enteric fever per million persons living in London over a considerable period we find that in 1838-40 it was 1,339, in 1841-50 it was 979, and in 1861-70 it was 904. In 1871-80 it fell to 244, in 1891-1900 to 136, and in 1903 to 81. In 1904, when the water supply was transferred from the companies to the Water Board, the enteric fever rate was 63 per million, and by 1910 it had still further declined to 43 per million. It is not easy to estimate the commercial value of the difference in the mortality from enteric fever of 1,339 per million in 1840 compared with 43 per million in 1910; but if the difference be taken as, in round numbers, 1,300 per million, then by the last census population of 4,500,000 we get a saving of life of 5,850. Now, what is the money value of a life? Dr. Farr answered this question in the thirty-ninth annual report of the Registrar-General (1876). He calculated that an agricultural labourer at the age of 25 was worth £627, and that, taking the whole population, the value per head was £150. Since 1876 money has become cheaper and wages have gone up; but even at the low price of £150 per person London saves £877,500, which if it could be turned into hard cash and presented to the Water Board would be a godsend to the few "commercial members" of the Board who view with alarm the necessity of making a deficiency rate. This life-saving health-idea should also lead those who have to pay the rates imposed by the Water Board, which are here and there somewhat heavy, to look with a more kindly eye and speak with a less bitter tongue of the successful but costly undertakings made for their benefit.

London is not singular in making a huge expenditure to secure this necessary of life—a pure potable water supply. Manchester, Glasgow, Liverpool, and Birmingham have gone to Thirlmere or Loch Katrine, or to the mountains of Wales, and gigantic works are in progress to bring the superfluous waters of the moorlands of Derbyshire into the homes of the workers in the Midlands. But the problem has been more difficult for London. For whereas Liverpool or Birmingham could buy up a valley and convert it into a lake or a chain of lakes, having to take heed only that the pure water of the moorlands shall not be polluted by the scattered habitations of man and then to carry it across country, London has to start with sources of supply in thickly settled valleys where initial contamination cannot be prevented.

Undoubtedly the work necessary to supply the consumers in the Metropolitan Water Board's area with a plentiful supply of good water is a costly undertaking, for the reason mentioned. Over 74 per cent. of the water supplied comes from contaminated sources; 60 per cent. comes from the Thames and 24½ per cent. from the Lee; and before it is safe to drink the water of these rivers it must undergo a costly process of purification.

The first step in the process of supplying London is to buy the water from the Thames and Lee Conservancies at an annual cost of £50,000. Then comes the erection of pumping stations and engines and of reservoirs for storage, active and passive—that

is to say, for quantity and quality. Next comes the making of filters, service reservoirs, and all the consequential expenditure for distribution connected with them. The total capital expenditure on these works since the Board became the water authority down to March, 1912, has been nearly three millions sterling. If we take the works completed since the Water Board took over the undertaking and compare them with the companies' figures, we find that the storage reservoirs for unfiltered water was under the companies 4,007 million gallons, and those added by the Water Board 5,758 million gallons, making a total storage of 9,835 million gallons, with all the other connected works in proportion. Moreover, a recent Act of Parliament gives the Board power to construct reservoirs at a cost of £4,100,000. Thus the Water Board has in the past done the necessary work for the supply of good water to its customers, and there is no indication that it will fail in its duty in the future.

To check the engineers in carrying out their duty in respect of the purifying process the Board has a water examination department, and an excellent staff in a well equipped laboratory takes samples from filters and wells, hydrants and taps, filtered and unfiltered sources, and subjects these samples to a drastic examination, chemical and bacteriological, day in, day out. During the year ending March 31st, 1912, nearly 15,000 samples of water were so examined. In this laboratory research work also is carried on and many valuable reports have been issued, such as those on the vitality of the typhoid bacillus; on the effect of storage on the bacterial content, and on the softening, purification, and sterilization of water. These reports have been found exceedingly useful not only to London, but to water authorities everywhere. So it comes about that the policy of the Water Board, the money of the ratepayers, and the devoted services of the officers, all conspire to carry out the great central notion that the health of the consumer is the thing that pays in a water supply.

THE ALLEGED DANGER OF THERAPEUTIC PROGRESS.

THE racial aspect of medical progress, a subject which was forcibly discussed by Sir James Barr in his presidential address at the annual meeting of the British Medical Association at Liverpool, is not escaping the attention of transatlantic thinkers. In a contribution to *American Medicine*¹ Mr. Lawrence Irwell invites his readers to accept the conclusion that therapeutic discoveries are not necessarily the unmixed blessing which at first sight they might appear. He argues that it is by the elimination effected by fatal diseases that the strength of a community is maintained; and that whenever a malady, hitherto almost invariably fatal, is added to the list of curable ailments there arises a new danger of national deterioration. Individuals who owe their survival and chance of bringing children into the world, not to their own inherent soundness, but to medical knowledge and skill, are, he contends, racially parasitic individuals, and are the source of this danger. He gives as a familiar instance the saving of life effected by the modern operation for the removal of adenoid growths; many of the individuals thus enabled to survive no doubt become useful citizens, but what percentage of them, he asks, are

desirable parents from the point of view of national physique? On the other hand, he refers to the fact that certain forms of constitutional stamina, in particular that which confers the power of resisting infective disease, are favoured by the herded conditions of civilized life. In matters of health, and in most others, things are not always what they seem; a pale and sickly clerk, on exposure to infection, may reveal an unsuspected power of resistance, while a splendid savage, belonging to a tribe which has never been submitted to the selecting power of the microbe in question, will almost inevitably succumb. Mr. Irwell believes that Jews, although liable to tuberculous infection, have by selection achieved a considerable immunity in respect of its fatal effects. "It is correct," he thinks, "to say that tubercular Jews usually continue to live, and death is, as a rule, due to some other cause." In cities where the coloured population predominates, the much greater mortality of tuberculosis among the coloured than the white members infected is in all probability due to the fact that the white man, having been for a much longer time subjected to urban conditions, has undergone selection by the tubercle bacillus. The same is true of the other great scourges of civilization—small-pox, alcohol, plague, and the venereal diseases—each of which, when introduced to a community affording virgin soil for its ravages displays a very high destructive power. Mr. Irwell, therefore, would seem to be numbered among the followers of Dr. Archdall Reid, and he goes on to maintain that, while the tendency is for the susceptibility of civilized communities to infective diseases and to alcoholism to decline, there are other forms of disease which appear to be steadily increasing. In the United States chronic nephritis and circulatory diseases in general are becoming distinctly more prevalent, a fact which Mr. Irwell attributes in part to excessive meat eating.

In estimating the validity of the assertion that therapeutic progress, in common with other improvements of the environment, constitutes a real danger to national stamina, the verdict will obviously depend in the main on the relative importance of the factors of nature and nurture. The late Sir Francis Galton arrived at the conclusion that the importance of the former altogether overweighed that of the latter. The impression produced on his mind, after a review of the available evidence, was "one of some wonder whether nurture can do anything at all beyond giving instruction and professional training."² But it should be observed that in Galton's investigations the differences of environment considered were by no means of an extreme kind. Dr. Neave has recently advanced evidence with regard to the physique of school children in different areas of Manchester tending to a contrary conclusion.³

That any amelioration of the environment favours the survival of weaklings is a self-evident proposition, but Weismann's contention that, natural selection being in abeyance, their defects will be generalized by panmixia, is open to question, for the paramountcy of natural selection as a condition of forward evolution is at the present moment one of the most controverted points of evolutionary doctrine. Natural selection is, after all, a negative principle; it is to the positive aspect of the problem that the main interest has now shifted—namely, to the conditions that determine favourable variations and the possibility of bringing these under prescient control.

¹ Disease as a Factor in the Evolution of the Human Family. By Lawrence Irwell, M.A., B.C.L., *American Medicine*, December, 1912.

Inquiries into Human Faculty.

THE ANTARCTIC DISASTER.

OF the four who were with Captain Scott at the South Pole on January 18th, 1912, Dr. E. A. Wilson was one, and he perished with his leader from exposure and want during a blizzard about March 29th, when the party was only eleven miles from a well-stocked dépôt, and had accomplished the longer part and, as far as the surface conditions went, the worst part of the return journey. There, short of food and of fuel, they were held by a prolonged blizzard, and died together in their tent. One of their party, Captain Oates, who had broken down in health, had disappeared into the storm some ten days earlier. The fifth member of the party, Petty Officer Evans of Rhosilly, near Swansea, died on February 17th. He had broken down, and his death was accelerated by concussion of the brain sustained on the Beardmore Glacier. Captain Scott's last note and appeal was written on March 25th, 1912: "We are weak, writing with difficulty." He acknowledged himself beaten by the elements. "We took risks—we knew we took them. Things have come out against us, and therefore we have no cause for complaint, but bow to the will of Providence, determined still to do our best to the last. . . . Had we lived I should have had a tale to tell of the hardihood, endurance, and courage of my companions which would have stirred the heart of every Englishman."

The last words of Captain Scott, and the story of the courage and determination shown by the men he led, have gone to the heart of every man and woman in the British Isles, and his appeal that those who depended on them shall be properly cared for will not go unheeded. The Prime Minister gave expression to the general sentiment when he said in the House of Commons on Tuesday that the last message of Captain Scott was one of the most moving and pathetic utterances in the annals of this country of a brave and enduring man face to face with a tragic and noble end of a career of self-devoting service, and would not fall on deaf ears. The Admiralty has already issued a notification that the circumstances in which Captain Scott and his comrades lost their lives prove the constancy and resolution with which they carried out the duty for which they volunteered, and that consequently the loss of Captain Scott and Petty Officer Evans is to be regarded as if they had been killed in action. The medical profession will likewise desire to do every honour to its member who died with Captain Scott.

Dr. E. A. Wilson, who was the son of Dr. E. T. Wilson, of Cheltenham, took a first class in the Natural Science Tripos, Cambridge, and before graduating M.B. in 1900 went through a medical course at St. George's Hospital, but he was by nature a naturalist. He early gave himself to studies of this kind, and utilized a very considerable artistic talent in depicting natural phenomena. He was a member of Captain Scott's first antarctic expedition in the *Discovery* in 1901, when he acted not only as medical officer but as vertebrate zoologist and artist. After that expedition returned in 1904 he was for some time field observer for the Grouse Commission, and eagerly accepted the post of Head of the Scientific Staff of the National Antarctic Expedition which left England in 1910. We hope to publish a fuller account of his career in a later issue.

The two medical officers of the expedition were Surgeon George M. Levick, R.N., and Surgeon Edward L. Atkinson, R.N. At an early stage two parties were formed, and of one of these—the Northern,

under the command of Lieutenant Campbell—Surgeon Levick was a member. The other party was divided into two when Captain Scott's party of sixteen began the expedition to the South Pole on November 2nd, 1911, and Surgeon Atkinson was left with the remainder—or Western party. Members of the Southern, or polar, party were sent back at various stages in sections, and the final section which pushed on the last 150 miles to the Pole numbered five. They were expected back early in March, and Surgeon Atkinson organized a relief expedition under the leadership of Mr. Cherry Garrard, but was compelled himself to remain in charge of Commander Evans, who was suffering from scurvy. The relief party got to One Ton dépôt on March 3rd, but by the failure of the dogs' food and the bad weather were forced to return on March 10th, eleven days before Scott, Wilson, and Bowers established their last camp eleven miles to the south. Surgeon Atkinson with the only remaining man, Petty Officer Keohane, then made another attempt to relieve the Southern party, but in severe weather with inadequate resources they could do no more than establish another dépôt with provisions for a week. In April Surgeon Atkinson organized another expedition to relieve the Northern party under Lieutenant Campbell; it was stopped by open water, but the Northern party dug themselves into a snow drift, and lived through the winter with the help of a number of seals they were able to kill. A petty officer became seriously ill, but was taken on when the party moved away, after six and a half months, from their winter quarters, and quickly recovered after a food dépôt had fortunately been found. On October 30th, 1912, Surgeon Atkinson, who seems, throughout a most trying experience, to have shown admirable initiative, tenacity, and resource, organized another Southern search party in two sections—one under his own command; the other under that of Mr. Wright. One Ton dépôt was found in good order, and on November 12th Mr. Wright's section of the party came up to the tent containing the bodies of the three brave men—Scott, Wilson, and Bowers—who had died nearly eight months earlier.

The object of the Antarctic Expedition was scientific research, and a scheme had been carefully worked out which included the attainment of the South Pole, although that achievement was never regarded as a chief aim. That the scientific object of their work was uppermost in the minds of the small party that reached the South Pole is proved by the fact that in the tent with the bodies of the three last to survive were found every record of the journey, and geological specimens weighing 35 lb. which they had persevered in dragging with them to the end. These records and specimens are being brought home, and will undoubtedly prove of great scientific value.

It is not possible to form any trustworthy judgment on the causes which led to the catastrophe so near comparative safety. Clearly the immediate cause was the prolongation of the return journey, and this was in part due to unusually severe weather, but in part to the breakdown of one member of the party at an early stage of the return journey, and of another later on. Commander Evans, the second in command of the whole expedition, had suffered seriously from scurvy at an early stage, and it seems probable that the illness of the member of the Northern expedition which must have nearly brought it to disaster was due to the same disease. Such facts lend probability to the opinion expressed by Professor Nansen that the provisions may have been deficient in antiscorbutic properties, and that this

was the reason for the breakdown of two of its members, which seems to have been the determining cause of the destruction of the Polar party.

CLERICAL WORK UNDER MEDICAL BENEFIT.

In every quarter of the country complaints have been made concerning the unnecessary demands made on the time of doctors who have joined panels under the Insurance Act in consequence of the great and unnecessary amount of clerical work entailed upon them. These complaints have had reference especially to the cumbersome day-book, unnecessary in its dimensions and the amount of detail required, to the prescription forms, and to the certificates to be given to insured persons in order that they may claim sickness benefit. The replies of Mr. Masterman in the House of Commons have indicated a recognition of the justice of the complaints received, and on February 6th the Insurance Commissioners in England issued a letter to the secretaries of Local Medical Committees in a large number of counties and county boroughs stating that the Commissioners had given careful consideration to complaints as to the difficulties experienced in filling up the forms of record which practitioners attending insured persons are required to keep, and had come to the conclusion that the information it is necessary to obtain could be recorded in a manner entailing less clerical work. Before coming to any decision, the Commissioners decided to invite to a conference medical practitioners able to express to the Commissioners the views and experience of those actually engaged in the treatment of insured persons. This conference was held on February 11th, and was attended by about ninety representative doctors. The proceedings were conducted in private, but we understand that the medical men present expressed their views freely, that a record was made of all the suggestions, and that it was promised that all the points would receive the careful consideration of the Commission. We understand also that the Commissioners gave a very sympathetic hearing to the representations made, and that the conference separated with the impression that immediate modifications in the forms, so that they shall entail less clerical work, are contemplated.

ATTEMPTED SELF-ABORTION.

The attempt by the woman herself to produce abortion is unfortunately frequent in these days, and some midwives, it is said, go so far as to train their patients, teaching them the perilous art of self-introduction of the bougie. The contingent danger of perforation of the uterine walls is self-evident. Dr. John Douglas, of the Bellevue Hospital, New York, reports an instance in which this complication was followed by remarkable results.¹ A woman, aged 26, was admitted under his care last August on account of a tender, painful mass in the abdominal wall over the outer edge of the right rectus muscle, at the umbilical level. It had been present for a week, and was first ascribed to a fall against a chair. She had borne three children; a year before admission abortion was induced by a midwife, by the introduction of a Lisle thread bougie, which she afterwards gave to the patient to use should she become pregnant again. Ten weeks before admission, the period having been a fortnight overdue, the patient passed the bougie without causing herself much pain, and inserted a cotton tampon into the vagina. This tampon came out some hours later in the lavatory, and she thought that the bougie came away also, but she did not see it, though she remembered seeing the tampon. There was no further "history," beyond the appearance of the tender lump in

the abdominal wall, no faintness, fever, or disten- even abortion, though she was really pregnant. temperature was 99.6°, pulse 104, and the leucocyte count was 14,800, with 78 per cent. of polymuclear cells. Dr. Douglas made an incision through the integuments over the swelling, opening an abscess cavity well walled off by adhesions and apparently just beneath the peritoneum. Two ounces of pus, giving evidence of colon bacillus infection, came away, and a Lisle thread bougie 11½ in. long, which lay curled up in the cavity, was removed. On the second day there was some bleeding from the vagina, and eleven days after the operation abdominal pain and free hæmorrhage set in, a three months fetus coming away one day later. At the end of a week, after the application of the curette, the patient was discharged cured. Dr. Douglas discusses certain puzzling features about his case, which must strike every pathologist, surgeon, obstetrician, and gynaecologist. The point of perforation, and the question whether the peritoneum was perforated or the broad ligament opened up, the bougie entering the subserous connective tissue anterior to the parietal peritoneum, remains unsolved. The whereabouts of a bougie not properly accounted for, and the fact that if still in the patient's body it does not necessarily cause grave uterine hæmorrhage, acute peritonitis, or even abortion, are matters which must not be overlooked.

EPILEPSY.

L. W. WEBER has recently² urged that the clinical definitions of epilepsy should be revised. He objects to the somewhat reckless manner in which persons of various types are dubbed epileptics, and maintains that the evidence in favour of the supposition that Julius Caesar, St. Paul, Mahomet, and Napoleon suffered from epilepsy is so slight that it cannot for one moment be accepted. It is, he says, necessary to form a clear idea of what constitutes epilepsy before we can hope to advance in its treatment. He therefore selects a type and describes it as "true epilepsy." This condition is characterized by the periodic occurrence of convulsive attacks, associated with loss of consciousness, the periodic occurrence of temporary psychic alterations, which he describes as "Dämmerzustände" (the literal translation of this is "twilight conditions"), and lastly, a chronic course which leads gradually to a permanent psychic alteration, taking the form of a peculiar character and a peculiar form of dementia. To bring a case within the definition, the convulsions must be periodic, and must be attended at times at least with unconsciousness. The second point does not justify the diagnosis of epilepsy alone; nor is it always easy to observe the conditions of temporary clouded cerebration. The third point is highly important, and he goes so far as to state that when periodic fits and conditions of clouded cerebration have continued for five to ten years, and are due to a true epilepsy, the epileptic character and the peculiar dementia will certainly be found. Should these psychological changes not appear the diagnosis is not justifiable. He points out that true epilepsy always begins early in life. It is most frequent from the 6th to the 20th years of life; less frequently it begins earlier, and only rarely does it first manifest itself after 20. An affection associated with fits which begins after thirty years is not true epilepsy. He discusses the etiology at some length, and traces some cases to acquired cerebral disturbances, chronic poisoning, metabolic disturbances, and so forth, and finds that some cases develop on the basis of an inherited predisposition. He emphasizes that epilepsy is never inherited as such, but merely a predisposition. Pathologically chronic diffuse changes in the neuroglia, vessels and fibres are found according to the length of time during which the affection has lasted. In quite fresh

¹ *Amer. Journ. Obstet.*, January, 1913, p. 25.

² *Monat. für Gyn.*, Nos. 51 and 52, 1912.

cases in which death follows as the result of the status epilepticus fine changes may be found. Passing on to other forms, he recognizes a condition of reflex epilepsy which he admits to be a subgroup of true epilepsy. At times these cases can be controlled by the removal of the area which delivers the exciting peripheral stimulus. "Gastro-intestinal epilepsy" is a term which merely indicates the origin of the determining factor of a certain class of true epilepsy. In objecting to the term "hystero-epilepsy," he points out that the combination of epilepsy and hysteria does not justify the fusion of the two conditions. Since the epilepsy is the more serious affection of the two, it is better to classify these combined cases under the epilepsies. Cases in which the usual signs of epilepsy, but without the fits, are present are often termed "psychic epilepsy," but Weber objects to the hazarding of the diagnosis unless the characteristics of the true epilepsy are present. The second large group are called the "symptomatic epilepsies." Here the secondary conditions need not be present; it suffices for the diagnosis that fits occur periodically, and that they are associated with loss of consciousness. This form may occur later in life, and to it belong the traumatic epilepsies, the alcoholic and emotional epilepsies, and the so-called senile or cardio-vascular epilepsies. Jacksonian epilepsy is also a symptomatic epilepsy. He insists that they never lead to the condition which he speaks of as true epilepsy.

THE SURGICAL TREATMENT OF PULMONARY CAVITIES.

G. BAER states that the chances of spontaneous recovery in the case of large cavities of the lung are bad, for the patient runs a great risk from haemorrhage, mixed infection, retention of pus, and secondary aspiration pneumonia.¹ While considering artificial pneumothorax the ideal method of treating these cavities, he points out that it not infrequently fails because the cavity was not compressed by the air in the pleural cavity. In a number of cases the upper third of a lung was converted into a sac firmly adherent to the chest wall. Resection of ribs in these cases could not lead to a satisfactory result, and the opening of the cavity would only be useful when a free flow of the contents did not take place through the respiratory passages. Schlange got good results by separating the wall of the cavity from the thoracic wall and plugging the extrapleural cavity with gauze. By experiment on animals Baer found that it was possible to separate the wall from the lung without difficulty. He then applied the method in the case of a man who was under observation in the Schweizerhof Sanatorium in Davos with a large cavity in the left lung. The cavity gave rise to considerable trouble and did not show any tendency to heal. The chest wall was opened by means of a rib flap, and the costal pleura was separated without difficulty. The cavity thus produced was plugged with iodoform gauze. At first it secreted an increased quantity of muco-purulent material. After a week the gauze was changed, some difficulty being experienced in removing the packing on account of adhesions. Up to this time tubercle bacilli were found in the sputum, but subsequently no further bacilli were found. An attempt was made at a later date to make the cavity collapse better by tighter packing of the extrapleural space. This led to a small patch of necrosis, and the lung cavity was therefore opened with the thermo-cautery. The general condition of the patient continuously improved, and Baer proposes to fill the cavity with a paraffin melting at 42° C., as soon as possible. He gives various details in regard to the extrapleural separation and compression, and makes a number of suggestions in regard to the filling of the pulmonary cavity with a mixture of paraffin, bismuth carbonate, and iodoform

(iodochloroxyquinoline). He is of opinion that the method will prove valuable in a number of cases of cavity in the lung.

CANCER OF THE COLON.

THE large intestine is much more commonly the site of a malignant new growth than is the small intestine, and the warning signs and symptoms are often so obscure that until the patient is actually *in extremis* from acute intestinal obstruction a diagnosis of the condition is attended with great difficulty. As Mr. Cunning points out in the lecture published elsewhere in this issue, the condition of complete obstruction is unfortunately far too frequently the stage at which the surgeon is compelled to operate, and the high mortality attending operations which attempt a complete removal of the growth causing the obstruction is considerably lessened if, in such a condition, temporary measures for the relief of the obstruction be adopted and the major operation deferred to a more advantageous occasion. Mr. Cuning even goes so far as to say that beyond quickly relieving the obstruction no examination should be made in these acute cases for the site, nature, and extent of the obstructing lesion, and he lays stress on the friability of the bowel and the great danger of peritonitis. The symptoms that should excite suspicion in earlier stages are, it must be confessed, not sufficiently marked to enable a diagnosis to be made without exploratory laparotomy—for example, what may have been considered a case of chronic appendicitis may prove to be cancer of the caecum, and vice versa. The occurrence of diarrhoea, not yielding to ordinary medicinal treatment, especially if combined with the passage of blood and mucus, and the onset of colicky pains after hot foods or drinks, are symptoms suspicious of chronic obstruction. At a later stage, as the constriction of the growth increases, constipation becomes more marked, and the most important sign of visible peristalsis, due to obstruction, should be sufficient to determine laparotomy. It has to be borne in mind that wherever there is an ulcerated surface there is almost necessarily a localized peritonitis. The treatment of malignant stricture of the colon depends on the condition of the bowel as found at the time of operation. It must be a temporary relief followed by complete operation if the condition is acute. If the growth be removable, then a large portion of intestine (paying due regard to the arterial supply) together with the lymphatic area, should be resected in one piece. And if the growth be beyond radical extirpation, then a short-circuiting of intestine will render the patient's life free from sudden danger and give a more tranquil ending.

COCAINE SNUFFERS.

IN the issue of the BRITISH MEDICAL JOURNAL for January 25th mention was made by our Paris correspondent of a recent meeting of the French Society of Mental Medicine, at which a discussion arose on the alarming increase of the cocaine habit amongst a certain class of Parisian. Vice is almost as contagious as disease, and the spread of cocaine mania in the underworld of Montmartre has assumed such proportions during the last few years as to give rise to considerable anxiety on the part of the medical authorities of Paris. The investigations made by M. Marcel Briand, chief physician to the Paris Clinical Asylum, and M. Vinchon, in the Montmartrois cafés and night haunts, have yielded some curious particulars as to this form of narcomania, and prove, amongst other things, that one of the most common ways of taking cocaine is through the nose, as a snuff. *La Semaine Médicale* has given an interesting account of a meeting of the Clinical Society of Paris, to which MM. Briand and Vinchon brought four cocaine maniacs as living illustrations of the evils produced. All four patients were women from the same

part of Montmartre, and the symptoms were almost exactly similar in each case. Disturbance of general sensibility was the predominating symptom; there was more or less complete cutaneous anaesthesia, the numbness of the extremities producing a certain amount of clumsiness and want of co-ordination. In some cases there was marked anaesthesia of the pharynx, producing a sensation as of a foreign body. Hallucinations and illusions were present, but varied very much in character. The perversions of vision and hearing seemed to be rather intense evocations of definite memories which had left strong impressions upon the brain than real hallucinations—a point upon which the patients themselves laid stress. None of the four women showed any convulsive phenomena, but the hands and feet were tremulous, as were the lips, and the speech was jerky and explosive. In the majority of cases the symptoms of physical debility were in no long time followed by intellectual deterioration. There was no systematic delirium, but a succession of short-lived delirious ideas. The cocaine maniac usually became intensely irritable and quarrelsome, and as a rule learnt to indulge in alcohol to excess. The craving for cocaine, though less imperious than for morphine, usually showed itself sooner, and might even become established in a day or two. The will power was almost destroyed, so that the cocaine maniac obeyed automatically the sensations which prompted her to take a pinch. At times the longing took the form of a violent desire to snuff some powder, even though it did not contain the drug. Incessant nasal cocaineism, it was said, sometimes resulted in perforation of the septum. The taking of cocaine as a snuff seems to be of comparatively recent growth. There were cocaine maniacs some thirty years ago, produced it is said by an attempt to treat morphinomania, but nowadays those who take cocaine by hypodermic injection are a very small minority. The extraordinary extension of the vice dates from two or three years ago, when a small number of *demi-mondaines* introduced the fashion of snuffing cocaine into the Montmartre quarter. Léon Daudet, in his novel, *La Lutte*, has shown how rapidly an entire community may be corrupted by the proximity of a handful of morphinomaniacs, and to-day more than 50 per cent. of the *femmes galantes* of Montmartre are said to be slaves of “la coco,” as it is familiarly termed. The ease with which cocaine may be taken in this way has caused it to supplant ether, opium, and all other drugs in the affections of its votaries; and the connivance of the proprietors of night establishments and dancing saloons, in sales by attendants, and in the enterprise of itinerant vendors, has doubtless done much to encourage the fatal fashion. There are certain pharmacies at which the drug is openly sold, but a whole tribe of middlemen has sprung up who buy it in large quantities at one or other of these shops and resell it at night at exorbitant prices. Two of these intermediaries were brought to the same meeting of the Clinical Society by M. P. Beaussart, and seem to have been quite brazen in admitting the nature of their trade and describing their methods. Under the French law a pharmacist who sells cocaine without a prescription and without registering the name of the purchaser may be prosecuted, and one was recently sent to prison for a fortnight and fined several thousand francs. When he came out he resumed his trade and raised his prices so as to pay for his fine. The new poison law of 1908, designed primarily to regulate the sale of opium in France, is little better than a dead letter; so much so that within the last few months the Procurator of the Republic in Paris has called the attention of the police in the Department of the Seine to the fact that in certain quarters of the city it was possible to buy cocaine, opium, or morphine without any difficulty. He urged upon them a stricter exercise of their duty, but the police are handicapped by

the fact that somebody must be found to lodge a complaint before the courts can act, and the victims of the habit are seldom disposed to help to set the law in motion. Thus, though some half-dozen pharmacists who connive at the trade are well known to the police, it is difficult to bring them into court. This is a dilemma very familiar to us in this country, and it will be interesting, and perhaps instructive, to us to see how our logical neighbours solve it. Apparently something will have to be done, as the habit seems to be spreading from the frequenters of the night cafés of Montmartre to those in different quarters patronized by another class.

THE ANTIQUITY OF MAN.

PROFESSOR GEIKIE began the second course of Munro Lectures in the University of Edinburgh on January 28th. The Munro Lectures on Anthropology and Prehistoric Archaeology were endowed by Dr. Robert Munro, who retired from medical practice in 1886 to devote his attention to archaeological and anthropological pursuits. Professor Geikie's lectures, ten in number, are being given on Tuesdays and Thursdays. Their subject is the antiquity of man in Europe. This antiquity, said the lecturer in his opening address, was very great, and, although the geologist could not fix a definite date, it was quite certain that the history of man could not be comprised within a few thousand years. The earliest human relics and remains belonged to the Pleistocene period, and therefore the lectures would deal with this geological epoch. Some of the Pleistocene mammals were extinct, but others were still living; and they could be divided into three groups—a Southern and Temperate, a Tundra or snow-loving, and a Steppe group. Three kinds of climatic conditions had prevailed during the Pleistocene period—a genial and equable kind, an extremely cold kind, and one which found its modern representative in that of the Steppes. These various climatic changes could not have followed each other quickly over a whole continent; yet man lived through them all; it must therefore be concluded that the human race was of great antiquity in Europe. This, of course, was only one of the geological proofs of man's antiquity. Professor Geikie, in his second and third lectures, dealt with the testimony of the caves, and in his fourth with that of the Pleistocene river drifts. It might, he said, be concluded that throughout Central Europe Tundra or arctic conditions had obtained for a long time, and had been followed by a steppo climate, and that paleolithic man had lived in both these periods.

THE VENTILATION OF SLEEPING CARRIAGES.

The all-steel sleeping car is an innovation on American railroads, and has been received with great favour. An exhaustive study of the ventilation of these cars has been made by Dr. Thomas R. Crowder, of Chicago,¹ following up a previous investigation on the standard Pullman sleeping car of wooden construction. From the hygienic point of view, the great advance in these new cars is said to be the abolition of the “deck sashes”—a row of small windows near the roof line on either side of the car—and the substitution of a ventilating system purely on the exhaust principle. In the old type of Pullman the deck sashes formed the only means of ventilation. Later an exhaust system was added in the form of a device known as the Garland ventilator, which removes air by a suction effect dependent on the train motion, and reverses the fresh-air currents in the car from a downward to an upward direction. Thus, instead of air being admitted at the top through special openings and allowed to find its own way out, it is removed at the top by artificial devices, and allowed to find its own way in through the crevices about doors and

¹ *Archives of Internal Medicine*, January, 1913.

windows which act as intakes. This exhaust device was found to increase the active ventilation of the old cars, and to regularize the flow of fresh air, but the existence of the deck sashes militated against the effective working of the system. The crevices of these loosely fitting clerestory windows were so near the outlets of the exhaust ventilators that the air on entrance was short-circuited and drawn out again without playing any part in the renewal of the breathing zone. In the new steel structures, with the deck sashes practically abolished, and the exhaust system made an integral part of the building instead of being an after-thought, there are few or no natural openings in the upper part of the car, and therefore the entering air must come through the crevices around the windows and doors on the lower levels. It is then drawn upwards to the outlets of the exhaust ventilators near the roof. In some formidable tables Dr. Crowder gives figures for the air supply under these conditions. His method is to determine the respiratory contamination of the air of the car, as represented by the amount of CO₂ produced by all its occupants, and with this as an index, to compute the hourly air supply. A large number of samples of air, taken from the aisles of 36 cars, showed an average carbon-dioxide content of 5.78 parts in 10,000. The average number of occupants was 16.2, and the average hourly air supply per car was estimated at 54,600 cub. ft. With the older type of car, equipped with the same ventilating device, but retaining the deck-sash construction, the air supply was 40,600 cub. ft., and with cars depending solely upon deck-sash ventilation, 28,300 cub. ft. The average hourly air supply per occupied berth (computed as the number of cubic feet which must be supplied to one person each hour in order to maintain the CO₂ at the average proportion found) was 2,170 in the case of the lower berths and 2,000 in the case of the upper. These figures, again, are considerably higher than those obtained with the older type of car, but the difference is not so marked as in the ventilation of the aisles. Although he makes these careful determinations of the quantitative air supply, Dr. Crowder proves himself a man after Dr. Leonard Hill's own heart by saying that the quantity of air is not a measure of the ventilation efficiency, and that the important principle in ventilation is to attend to the physical qualities of the air—namely, its temperature, humidity, and movement. The chemical purity of the air is of minor importance, and ventilation should be regarded as a process to be carried out in the interest of the heat economy of the body. The exhaust system is beneficial, because it furnishes a ready exit and a continuous upward movement and outflow of the air forced in by the wind, thus renewing constantly and equably the lower levels of the car. The air supply is always sufficient to prevent monotony, and the jets of incoming air are individually of such small volume and have such irregular and diffuse movement in the stiller body of air within that the system lacks nothing from the standpoint of comfort, and comfort in this case is a fair hygienic index. Comfort and air purity have little or nothing in common, but comfort has a direct reference to air temperature and motion. The judgement at which the sensory nerves arrive is fundamentally correct. The air is really bad or good just as they indicate, but it is bad or good in the physical and not in the chemical sense.

THE BIRTH OF THE ATOM.

We referred last week briefly to a meeting of the Chemical Society held on February 6th. On the day following the reading of the papers by Sir William Ramsay, Professor Norman Collie, and Mr. H. Patterson, the *Morning Post* published a full account of the meeting. Despite the revolutionary character of the statements made, and of the views more or less tentatively put forward, the Chemical Society received them with enthusiasm, and

Professor Arthur Smithells, who was in the chair, described them as possessing greater dramatic interest than any read hitherto in the history of the society, and in its name returned thanks to the authors for their momentous communication. In view of the controversy aroused, it may be well, pending the full publication of the papers, to summarize briefly the essential experiments. If a vacuum tube is taken and sufficient hydrogen admitted to conduct an electric discharge, helium makes its appearance after sparking has been in progress for some time. If this vacuum tube be surrounded by another containing a little oxygen, both neon and helium are found in the space between the two tubes, the formation of neon being apparently conditional on the presence of oxygen. The authors appear to contemplate three possible explanations: (1) the transmutation of one or more of the elements in the glass or electrodes into helium or neon; (2) the transmutation of hydrogen into helium and neon as a result of the electric discharge to which the hydrogen has been subjected; and (3) the conversion direct of the energy of the electric discharge into helium and neon. Of these hypotheses it is only necessary to say that the authors drew attention to the relations expressed by such an equation as helium (4) plus oxygen (16) = neon (20). Some preliminary discussions of the experiments by Sir J. J. Thomson, Professor Soddy, and Sir Oliver Lodge have been published, and the line of criticism is that the gases may be liberated from the glass and the electrodes in which they have been occluded. Professor Thomson goes further, and has stated that he had found the formation of the gases to stop after a similar experiment had been running for a few days, and for it to be resumed temporarily if the electrodes were charged. For the present the matter must rest there. The subject is one on which the opinion of any but experts is of little value. It may be stated, however, that the readers of the papers are maintaining their opinion in the face of the criticisms, and claim that the publication of their papers will show that they have eliminated the causes of possible error to which attention has been drawn.

THE NEGLECT OF VACCINATION.

WHEN the Royal Commissioners on Vaccination recommended such modification in the Vaccination Acts as would enable parents who had "conscientious" objection to vaccination to obtain exemption for their children, it was not supposed or contemplated that neglect of vaccination on an extensive scale would be the result. The Act of 1898 gave effect to the recommendation and imposed a certain amount of trouble and a small expenditure on those who sought exemption. That Act also instituted domiciliary vaccination and replaced arm-to-arm vaccination by the use of glycerinated calf lymph. These advantages resulted in a great increase of vaccination. The number of those who objected to vaccination was steadily decreasing throughout the country. Unfortunately some magistrates showed little discretion in dealing with applications for exemption. Their praiseworthy zeal for vaccination led them into misguided action. This gave occasion for an agitation by the anti-vaccinators who greatly disliked the Exemption Clause. The amending Act of 1907 reduced the Exemption Clause of 1893 to a farce, the exception being rendered obtainable by a simple "declaration" involving a minimum of trouble and no cost. The effects of this are now reflected in the vaccination returns, which show a large and increasing neglect of vaccination in the country, and the antivaccinators are rejoicing in the measure of their emancipation, and craving for total repeal. Many authorities do not disguise their anxiety; medical officers of health all over the country are issuing warning notes in their annual reports. Those who face the situation with equanimity may find themselves in a fool's paradise. In the matter of

vaccination, the country which gave to the world this boon is now the laughing-stock of other nations. In other countries the Governments advocate general vaccination as well as enforce it. In this country it may be said the Government does neither of these things. The public vaccinator performs his State duties under conditions of unexampled discouragement, except when small-pox is prevalent; then he is the idol of the district, with even his enemies at his feet. Subsequent results have demonstrated beyond all possible shadow of doubt that the Act of 1907 is responsible for the increasing neglect of vaccination. It is equally true that the wholesale manner in which exemptions are being issued, regardless altogether of any question of conscience, is to a large extent due to the indifference of the Government. The President of the Local Government Board has openly avowed his opposition to vaccination—a fact which must prejudice his attitude as the head of the department entrusted with the administration of vaccination. The Government, however, cannot dispense with vaccination as a first line of defence during the prevalence of small-pox. If the public were more definitely impressed with the fact that the Government knows vaccination to be indispensable at such times more confidence in vaccination would be fostered among the people, and with the risks practically eliminated many would realize the desirability of being wise in time who are now merely indifferent. The question of compulsion may be one of politics—even party politics—but the question of educating the masses in all that appertains to public health and preventive medicine is not a matter of politics, but a real duty devolving upon the State. After seven years of deliberation and the accumulation of an enormous mass of conclusive evidence the Royal Commissioners, with absolute unanimity, agreed that it was the duty of the State to provide vaccination for the people. The State has continued to “provide” vaccination, but has failed to recognize that its duty does not end there. In the face of unscrupulous opposition and the dissemination of misleading and often untruthful literature, no attempt has been made to justify the State or to defend the medical men who are employed by the State from the scurrilous attacks made upon them in the press and on public platforms. This is a poor recognition of services rendered, and is a matter which undoubtedly demands more serious consideration.

MEDICAL MISSIONARY CONFERENCE IN PEKING.

The *Peking Daily News* for January 17th and 18th, 1913, gives a very interesting account of the triennial China Medical Missionary Conference, held on this occasion in Peking itself. More than a hundred doctors, of whom twenty were women, attended. The delegates came for the first time to the place of meeting by railroad; they consisted not only of British and American physicians, but also of some of other nationalities, and the sessions were held in the Union Medical College. In the absence of the President (Dr. Philip Conslund, who is at present in Edinburgh owing to ill health), Dr. Logan of Hunan presided over the meetings. Chinese medical men and educational leaders in the new Government visited the Conference, and the President and some of the officials of the China Medical Association also attended and sought for co-operation with the Medical Missionary Association in the advancement of medical knowledge in China. In many respects the Conference was not unlike an annual meeting of the British Medical Association at home. Papers were read, which the *Peking Daily News* says were “of a very high order”; the gates of the West Park were thrown open, and the palace where Kwang Hsu was detained by the Empress Dowager in 1893 was visited by the delegates; visits were also paid to the Temple of Heaven, to the Temple of Agriculture, and to the Confucian Temple, the Hall of the Classics, and the Lamasary;

receptions were given by the American Minister and Mrs. Calhoun, and by the Minister of Foreign Affairs and Mrs. Lu; but the crowning event was the reception given by the President of the China Republic on January 15th, when, as already announced, he received an address from the Medical Missionary Conference, and made in simple Mandarin the reply a translation of which was published in the *JOURNAL* on January 25th (p. 189). The most important matter discussed at the Conference was medical education. There was a strong feeling that the missionary societies should not increase either the number of medical schools or the number of hospitals in China until those already in existence were fully manned and equipped; that the medical curriculum should be a five years one, and that the entrance requirements should be at least the completion of the middle school work as laid down in the Government curriculum. The *Peking Daily News*, in a leading article, said: “The doctors all seem to feel that at a not very distant date the Chinese will be able to care for their own medical schools and for the physical welfare of the people. The present object is to so establish the work being done in these lines by the missionary societies, that when the time comes for the completely turning over to the Chinese of this work, the spirit of Christ as well as that of scientific medicine may be deeply embedded in the hearts of the medical profession of the future China.”

THE LONDON HOSPITAL QUINQUENNIAL APPEAL.

THIS year the London Hospital is issuing its quinquennial appeal to the British public for funds wherewith to carry on its enormous task among the East End poor. In making this appeal, Mr. Sydney Holland is asking for £100,000, in addition to the £110,000 required annually to keep up the institution. That this will be no easy matter, even for the “Prince of Beggars,” in this, the first year of national insurance, is fully recognized. There are many who claim that Mr. Lloyd George’s Act will relieve the hospitals very considerably of their financial burden by abolishing a large number of the out-patients. Though this may prove to be true to a certain extent, it seems already fairly clear that the relief will not be anything like as great as some have assumed. The out-patient staff still continue to see and treat a host of patients who are sent up to them by doctors for consultative advice, whilst the bulk of the women and all the children remain, as heretofore, uninsured. Mr. Holland reckons, from the statistics collected in the six months which elapsed between the passage of the Act and the application of the medical benefits therein provided, that out of 233,500 out-patients treated annually at the London Hospital only some 58,000 will be referred to the panel doctors. This may mean a decrease in expenditure of about £6,000—a mere teacup in the ocean of the total expenditure. The effect of the Act on the number of in-patients is practically nil. The London is the largest general hospital in the country, and, unlike one or two of its more fortunate brethren, has no permanent endowment fund to fall back upon. It is therefore bound from time to time to make a supplementary appeal to the charitable public for funds over and above the annual expenditure. If the public realized the manifold activities of an institution like the London Hospital, they would willingly put their hands in their pockets and quickly collect the sum necessary to defray all expenses and maintain the institution in a state of the highest efficiency. Some 700 persons daily apply to the hospital for treatment. The wards contain some 900 beds, which are occupied annually by 16,827 patients. The number of persons treated as out-patients has already been quoted. Of these 38,870 last year attended the various special departments, and the National Insurance scheme does not profess to provide special treatment. The true magnitude of the figures given is more vividly portrayed when we

realize that during the year over 10,000 patients attended one special department alone, that set apart for diseases of the throat, nose, and ear. The general public ought more fully to realize that the great hospitals have a far wider scope than simply treating the sick. They have an even higher duty to perform in investigating obscure points connected with disease; whilst last, but by no means least, it is their function to educate the coming generation of doctors. If the hospitals are to be starved because the new tax is resented by employers, then the public will suffer a threefold wrong; they will lack that attention which hitherto was accorded them by the hospitals and which can be obtained nowhere else, but an even greater misfortune will be the necessarily inferior standard of medical training which the Insurance Act may encourage unless scientific and clinical research can be continued and extended. If only the public will understand that the wonderful combination of departments directed by highly trained specialists, such as the bacteriological, chemical, x-ray, Finsen light, massage, and baths, can only exist together in institutions like the London Hospital, then we feel sure that Mr. Sydney Holland's appeal will not fall upon deaf ears.

THE COMMITTEE ON TUBERCULOSIS.

THE Departmental Committee on Tuberculosis appointed a year ago under the chairmanship of Mr. Waldorf Astor, M.P., to consider the general policy in respect of the problem of tuberculosis in the United Kingdom in its preventive, curative, and other aspects, has recently held a number of meetings. The Committee, it will be remembered, issued an interim report last May, which dealt mainly with administrative questions. Its final report, which, it is understood, will be issued at an early date, will, it may be assumed, deal among other matters with the organization of the research contemplated by the National Insurance Act, Section 16 (2). That subsection provided that a contribution of 1d. in respect of each insured person should be made to the sanatorium fund out of money provided by Parliament, and authorized the Insurance Commissioners to retain the whole or any part of the sum for the purpose of research. The Committee will in all probability recommend that the researches to be immediately undertaken shall have reference to tuberculosis, but it must be borne in mind that sanatorium benefit may be extended to other diseases, and the provision as to research would then apply to these other diseases. The importance, therefore, of putting the system on a good footing extends beyond the question of tuberculosis alone.

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow on February 3rd, Sir William Macewen, M.D., LL.D., F.R.S., D.Sc.Oxon., Professor of Surgery in the University of Glasgow, was, on the motion of the President and Council, unanimously elected an Honorary Fellow of the Faculty.

MR. G. JAMESON JOHNSTON, F.R.C.S.I., Professor of Surgery in the Royal College of Surgeons in Ireland, has been elected president of the Universal Esperanto Medical Association, in succession to the late Professor Dor of Lyons.

A COURSE of post-graduate lectures on recent views as to diseases of the liver, pancreas, and spleen will be given in the clinic of Professor Gilbert at the Hôtel-Dieu, in Paris. It will commence on March 17th and terminate on April 1st. Two sessions will be held on each week-day with an interval of three days at Easter. The fee for the course is 100 francs. Further particulars can be obtained on application to M. Deval, Chef de Laboratoire, Hôtel-Dieu, Paris. In September there will be another course on the clinical application of laboratory methods to diagnosis.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Royal Commission on University Education in London.—In reply to Sir Philip Magnus, the Home Secretary stated, on February 6th, that the Royal Commission on University Education in London had nearly completed its final report, but it was not possible to say when it would be published.

Medical Referees and the Panel.—Mr. Masterman, in replying to Mr. Bird, on February 10th, stated that medical referees under the Workmen's Compensation Act were not debarred from going on the panels under the Insurance Act.

Tuberculosis Dispensaries in Ireland.—Mr. Birrell informed Captain O'Neill, on February 11th, that tuberculosis dispensaries had been established by the Dublin Corporation in Dublin and by the Down County Council at Banbridge and Newtownards, and negotiations for the acquisition of sites were pending in a number of other counties. Part I of the Tuberculosis Prevention (Ireland) Act, 1908, which dealt with compulsory notification of tuberculosis, had been adopted by twenty-two urban and twenty-eight rural sanitary authorities.

Vaccination.—Mr. Thomas asked the President of the Local Government Board, on February 11th, whether he was aware that in Derby, Leicester, and other towns for many years past less than 10 per cent. of the children born had been vaccinated; that the inhabitants had not suffered in any special degree from small-pox in consequence of this neglect of vaccination, but that concurrently with decreased vaccination both the general death-rate and the infantile mortality had materially declined; and whether he was now prepared to recommend the Government to bring in a bill for the repeal of the penal clauses of the Vaccination Acts.—Mr. Burns said he was aware that there had been a considerable increase in the number of exemptions from vaccination and that there had not been any corresponding increase in small-pox, but he could not undertake to recommend legislation of the kind suggested at the present time.

Inflammable Fabrics.—A Fabric (Misdescription) Bill was introduced on February 4th by Mr. T. C. Taylor. The object of the bill is to prohibit the sale of flannelette or any other textile fabric described as being non-inflammable or safe, unless it conforms to such standard of non-inflammability as may be prescribed by regulations to be made by the Secretary of State. The bill is supported by Dr. Addison, Mr. Boland, Colonel Brocklehurst, Sir Frederick Cawley, Sir Henry Craik, Mr. Ferens, Mr. Hills, Mr. Joynson-Hicks, Sir John McCallum, and Mr. Albert Smith.

Nurses' Registration Bill.—When questioned on February 5th with regard to the prospects of the Nurses' Registration Bill next session, the Prime Minister said he could make no promise for next session, but the claims of the Bill would be considered.

Trade Effluent and Sewage Disposal.—Mr. Burns said, on February 5th, that the recommendations of the Royal Commission relating to the disposal of trade effluents were receiving his attention, but he could not say when it would be possible to introduce legislation on the subject.

England and Wales.

FROM OUR SPECIAL CORRESPONDENT.

LONDON.

ELECTION TO THE LONDON INSURANCE COMMITTEE.

The following address to the medical practitioners in the London Insurance area has been issued by Mr. E. B. Turner and Dr. Evan Jones:

"Having been requested by a large number of practitioners to stand for election as representatives of the medical profession on the London Insurance Committee, we have consented to do so, and ask for your votes and support for the following reasons. We hold:

"1. That the two practitioners elected by the profession to serve on the Insurance Committee for the London area should be entirely independent of the control of that Committee.

"2. That the interests of the very large number of men who have declined to serve under the Insurance Act and Regulations should be safeguarded, as far as possible, on that Committee by the directly-elected representatives.

"The six other medical men nominated and appointed by the Commissioners and the County Council respectively will amply suffice to voice the wishes of those gentlemen who are now serving on the panels, but it is extremely unlikely that they will give any very active support to those who have declined to work under the Act.

"If elected, we shall consider that we represent the whole of the profession in London, and shall do our utmost to further the interest of every member of that profession, whether he be working under the Insurance Act or not.

"EVAN JONES.

"E. B. TURNER."

THE TREATMENT OF TUBERCULOSIS.

In reply to a letter from the Local Government Board, suggesting that the London County Council should prepare a complete scheme for dealing with tuberculosis in London,¹ the Public Health Committee reported to the Council on February 11th in favour of accepting the suggestion, and outlining the general principles upon which it considered provision for treatment of tuberculosis should be made.

Temporary Arrangements.

The Committee pointed out that, although communications had been addressed by the Local Government Board to county councils throughout the country as early as May, 1912, no indication was given until December as to what authority was to be responsible for dealing with the disease in London. The Council, therefore, was in no way responsible for the delay that had occurred. As soon as the Council was approached it decided to make temporary arrangements with the Metropolitan Asylums Board for the provision of a limited amount of accommodation. Authority to provide this was received on December 11th, 1912, and, although various alterations to buildings had been necessary, patients were received on February 10th, 1913.

It was difficult to estimate accurately the number of cases within the county of London, because the disease in all its forms had only just become compulsorily notifiable. There were, however, 33,444 cases of phthisis notified during 1912; of these, 12,366 were Poor Law cases, 12,214 were hospital cases, 500 were school cases, and the remainder (8,304) were notified by general practitioners. The medical officer estimated that there were in London 50,000 persons suffering from tuberculosis, and of these about 20,000 were insured persons. As regards school children, with the extension of medical reinspection and the increasing facilities for diagnosis likely to obtain in the near future it was probable that many more cases of early tuberculosis would be detected each year than had hitherto been the case. The existing provision was in the hands of the various public authorities and of the voluntary agencies comprising the general and special hospitals, the tuberculosis dispensaries, and various philanthropic and religious bodies.

The Value of Existing Methods.

It was obvious that if the best results were to be obtained the work of these authorities and institutions must be co-ordinated. For instance, under the existing arrangements the provision of dispensaries was being dealt with by the borough councils. Although it was not suggested that this arrangement was undesirable, it was essential that there should be uniformity. Moreover, it was very important that the part played by the hospitals, general and special, should not be displaced by any newer dispensary provision. It was equally important that the valuable work of the practitioner should be assimilated in the new arrangements to be made. The dispensaries, if established as separate institutions, should fill up the gaps in the hospital provision. It would be a great misfortune if the hospitals, with their highly experienced staffs, elaborate equipment, and special organization, were not utilized. No new institutions with their limited staff and resources could possibly provide the skill and experience available in the large general and special hospitals. The hospitals had to a great extent evolved the forms of medical treatment now accepted as the best, and the progress of medicine was bound up with their keeping in intimate touch with the patients they had hitherto extensively treated. To conserve the work of these great institutions rather than replace it should be a definite aim in any reorganization of the measures for dealing with tuberculosis now undertaken.

If it was considered desirable to co-ordinate the dispensary arrangements throughout London, uniform agreements should be made between the County Council and the borough councils, and the co-operation of the general practitioner in cases not suitable for dispensary treatment should be secured to the fullest extent possible.

Central Control of the Organization.

The committee pointed out that any measures for the prevention of infection from tuberculosis could not be confined logically to one class. The treatment of the disease could not be regarded as other than a matter of public health administration, and the County Council, in its position of central public health authority, was best fitted to organize the arrangements, as it was important that there should be no departure in London from the well-founded principle of having one central health authority for the administration and co-ordination of all matters relating to public health. In this connexion the committee indicated the important functions already exercised by the Council in regard to tuberculosis. In its function of education authority, also, it had, to quote the Departmental Committee on Tuberculosis, "the opportunity of playing a very important and indeed essential part in the detection, prevention, and treatment of tuberculosis."

Conferences with Hospitals, etc.

The Committee recommended the Council to cause a detailed scheme for the treatment of tuberculosis to be prepared. It would be undesirable at this stage to enter into details, because so many authorities and institutions were concerned; but it was important that the action which the Council was to take with regard to the general situation should be decided as soon as possible. The local authorities, hospitals, and all concerned in the provision of treatment for tuberculous persons in London were experiencing considerable difficulty in deciding what arrangements they were to make for the future because of the absence of any co-ordinating scheme. The question of finance was, of course, of paramount importance as bearing upon the scope of any scheme which might be prepared, and the ideal public health measure must be subordinated to the practical.

Major Levita, the Chairman of the Public Health Committee, moved the adoption of the following recommendation attached to the report:

That it be referred to the Public Health Committee to prepare forthwith and submit to the Council a scheme for dealing with tuberculosis throughout the administrative county of London; that the Local Government Board be informed of the action taken; and that, for the purpose of preparing a scheme, the Committee be authorized to confer with the

¹ BRITISH MEDICAL JOURNAL, December 21st, 1912, p. 1727.

sanitary authorities, the Insurance Committee for London, and such other authorities, institutions, or persons as the Committee may deem necessary.

The recommendation of the Committee was adopted without debate.

THE RELATIVE INFECTIVITY OF LEPROSY.

It was reported to the Metropolitan Asylums Board on February 8th that the Greenwich Borough Council, having made leprosy a notifiable disease in that borough, had asked the Asylums Board to provide hospital accommodation for the treatment of cases. The medical officer to the Board, Dr. H. E. Cuff, reporting on the suggestion, said the Greenwich Council assumed that there was a risk of the spread of infection. In this country, at any rate, the risk could hardly be said to exist. Though the Local Government Board had knowledge of quite a number of lepers, there was only one instance on record (in Ireland) of a previously healthy person developing the disease in these islands. In that case the grossest carelessness and indifference were shown, for the man who became infected had been in the habit of sleeping in the same bed with his brother, who was a leper, and when the latter died the survivor wore his clothes. There was no doubt that leprosy was contagious, but in a low degree, and that prolonged and intimate contact was necessary to permit of the spread of infection. It was known that a man might have the disease and live for years with his wife without giving it to her. In the public mind the idea that leprosy was dangerously infectious was maintained by accounts of the deaths from leprosy which occurred from time to time in the ranks of those who tended the sufferers from the disease. No account was taken of the very much larger number that escaped infection. For example, one sisterhood had had charge of a leper colony for fifty years, and during that time no sister had contracted the disease. Lepers who could be maintained in their own homes could safely be left there, and those who were living under grossly unhygienic conditions could be treated in the London hospitals or infirmaries without any risk to the other inmates. To take sufferers away from their friends and permanently place them in institutions would be an act of cruelty, for the disease was incurable, and the only medical and surgical treatment required was of a general character.

The Board decided to inform the Greenwich Council that it could not endorse the view that special hospital accommodation was necessary for cases of leprosy.

THE APPOINTMENT OF A RESEARCH BACTERIOLOGIST.

At the same meeting a letter was received from the Local Government Board stating, with reference to the proposal to appoint a research bacteriologist (*BRITISH MEDICAL JOURNAL*, December 7th, 1912, p. 1640) that it was of opinion that the officer should be designated pathologist, that his appointment should be annual in the first instance, and that the holder should not, at any rate in the beginning, be required to devote the whole of his time to the duties. Subject to these conditions the Board approved the appointment.

BIRMINGHAM.

PRESENTATION TO SIR THOMAS CHAVASSE, F.R.C.S.

A presentation was made to Sir Thomas Chavasse at the General Hospital, Birmingham, on January 30th, on the occasion of his retirement from the office of honorary surgeon to the hospital, a post which he had held for over thirty years. The presentation took place in the board room of the hospital, the Lord Mayor of Birmingham (Lieutenant-Colonel E. Martineau, V.D.) presiding over a large company.

Sir Thomas Chavasse, owing to a recent accident in the hunting field, was unable to be present, but his son, Dr. Arthur Chavasse, accepted the presentation on his behalf.

A three-quarter length portrait in oils of Sir Thomas Chavasse, which had been executed by Mr. A. T. Nowell, was presented to the hospital to be hung in the board room. The portrait represents Sir Thomas wearing the gown of a Fellow of the Royal College of Surgeons, and is a most excellent likeness. A smaller portrait by the same

artist was presented to Lady Chavasse, who in a most graceful speech said she was exceeding proud of the gift, which she regarded as a proof of the way her husband's work within those walls had been appreciated.

Mr. Gilbert Barling, senior surgeon to the hospital, asked the Lord Mayor to present an illuminated address saying that Sir Thomas had set a fine example of devotion in the way he attended to his hospital work. He was the first surgeon at the hospital who had been inspired by the principles of the late Lord Lister.

Sir Thomas Chavasse became assistant surgeon to the General Hospital, Birmingham, in 1877, and was elected to the full staff in 1881, so that he had been honorary surgeon for over thirty years. During that time his devotion to the hospital had been most marked, and it was chiefly through his influence that the new hospital had been built at the time it was. He had inspired that great benefactress to Birmingham, Miss Ryland, a near relative of Lady Chavasse, to bequeath £25,000 to the hospital. Sir Thomas Chavasse took the greatest interest in the building of the new hospital, and was also able to obtain other large donations towards its rebuilding, and had himself given £1,250 for the endowment of a bed.

Sir Thomas Chavasse has held many important medical posts in Birmingham, for he is ex-President of the Birmingham Branch of the British Medical Association, the Midland Medical Society, the Birmingham Medical Benevolent Society, the Queen's College Medical Society, and the Birmingham Medical Institute.

MANCHESTER AND DISTRICT.

THE MANCHESTER ROYAL INFIRMARY.

IN the annual report of the Board of Management of the Manchester Royal Infirmary for the year 1911 some fear was expressed as to the possible effects of the National Insurance Act on voluntary hospitals, and the report for 1912 stated that to a certain extent the fears had been justified. The work of obtaining new subscriptions had been seriously interfered with, and a few old subscriptions have been discontinued. Though there has been during the past year a slight increase in the annual subscriptions, it is said that there is little doubt that the hospital would have gained a very substantial increase in its subscription list if the Insurance Act had not been passed. The board has had to contend with a widespread belief among the public that hospital treatment is included in the benefits under the Act which insured persons had a special right to claim. On the other hand, a statement has been made that the infirmary would refuse treatment to insured persons, and undoubtedly this had a damaging effect on the subscription list, several letters having appeared in the press distinctly threatening to withhold subscriptions and contributions to the hospital funds if insured persons were refused treatment. To meet this the Board of Management some time ago issued a public statement to the effect that prompt treatment of emergency and accident cases, whether major or minor, would be continued by the infirmary without regard to whether the patient were insured or uninsured; that poor persons, whether insured or not, would receive in-patient treatment on the same conditions as hitherto, and that special treatment for serious diseases of the eye, ear, nose, and throat, diseases of women, and every ailment needing x-ray, electricity, and massage treatment would also be continued as before. The only difference will be that insured persons applying for treatment at the out-patient department will be examined by one of the staff and will receive any necessary immediate treatment, but if it is considered that they are only suffering from some minor medical or surgical ailment, which can be properly treated by their own insurance doctor, they will be referred to him for subsequent treatment.

In the report for 1911 attention was drawn to the original appeal to the public for at least £12,000 additional annual subscriptions, which it was thought would be necessary after removal to the new infirmary if the institution was to pay its way. The response to that appeal had only been £3,783, and the increase during 1912 has been a further £241, making a total increase in annual subscriptions since the removal of just over £4,000 a year. This still leaves £8,000 a year to be provided, and, in

addition, a central branch for accidents in the centre of the city is necessary, which will require a sum of about £25,000 for building and equipment. The board asks that it should be enabled to inform Their Majesties the King and Queen, when they visit Manchester in July, that, as a memento of their visit, Manchester has built, free from debt, a central branch in the centre of the city for the treatment of accidents and out-patients.

WALES.

WORKMEN AND THEIR DOCTORS.

It is a curious but well-recognized fact that workmen who have had to fight most strenuously for freedom in connexion with their own working conditions are often the hardest taskmasters when they come to deal with persons who are working for them. Fresh confirmation of this anomaly has been brought to our notice by a dispute which is now in progress in the Eastern Valleys of Monmouthshire. Up to the coming into force of the Insurance Act the doctors in the Valley were paid by the workmen on a poundage system, that is to say, each workman paid 3d. per £1 of wages for medical attendance on himself and his dependants. As the wages average about 30s. a week, the yearly amount paid to the doctor for family medical attendance averaged 19s. 6d. When the Insurance Act came into force local doctors went on the panel and agreed to accept the insurance rate for the workers with the reduced poundage rate of 2d. for attendance on the dependants. This arrangement, it is estimated, would bring in the same yearly amount per family as before. The agreement involved the introduction of a system of free choice of doctor which had not hitherto obtained. It might naturally be thought that an agreement of this kind, involving no extra payment and giving to the workman a privilege he had not previously enjoyed, would have been accepted as a very satisfactory arrangement, but the workmen's leaders evidently thought there was a chance of getting a control over the profession which they had hitherto not had, and they proposed that the payment to the doctors should be made by the colliery and works owners through a committee of workmen, and also that the poundage rate should now include free attendance on all midwifery cases. As regards the latter we sincerely trust the doctors will not submit to a demand which is, we believe, unfair, and we hope unprecedented. In every medical contract arrangement within our knowledge the attendance on midwifery cases has been an extra, and we certainly do not think that the payment of 19s. 6d. a family per annum is likely to produce such a handsome remuneration for the doctor that he can afford to give freely what has hitherto been looked upon as an extra.

The other demand of the workmen seems to us to be of doubtful legality, while its unreasonableness is not at all doubtful. The payments received by the doctors from the works office are not payments in advance, but are in respect of work which has already been done, and it is extremely doubtful whether the owners of the works could pay the money except to the doctors who have earned it. They certainly could not do so without the consent of the doctors. But it is obvious that the desire to get the money into the hands of the committee is inspired by the wish to get control over the doctor, and probably also by a hope that some of the money may be retained for other purposes besides paying the doctors. But what more control do the workmen want now that they have got free choice of doctor? If they are not satisfied with the attendance they get they will change their doctor, and there the matter would end. The doctor who is unsatisfactory will be punished by loss of practice. The workmen should remember that the only control even a duke has over his doctor is the right of changing him if not satisfied, and such control is found to be perfectly sufficient and satisfactory in private practice. We believe that after calm consideration the workmen will recognize this, and the fact that they have not done so up to the present is no doubt due to the novelty of the situation. It would be unfortunate if the doctors in the Eastern Valleys, members of a profession the value of whose work largely depends upon the individuality which is put into it, should at one blow come under the control of two sets of committees, first the Local Insurance Committee for

the purpose of the panel, and, secondly, a committee of workmen for the purposes of the dependants of the workmen. And the misfortune would be at least as great for the public in the Valleys as for the doctors. The right type of doctor simply will not submit to this pettifoggery and unnecessary interference, and insistence on it will lead to a lowering of the type of practitioner who will accept service in the Valleys. We trust that the doctors of the Eastern Valleys will resist this unreasonable demand to the utmost, and we know that in doing so they will have the support of the Welsh Divisions and Branches of the Association which have so often proved themselves equal to similar emergencies. We would draw attention to the fact that the workmen are advertising for doctors in this district, and we trust that no member of the profession will be so foolish in his own personal interest and so lacking in *esprit de corps* as to apply for such an appointment—at any rate, before seeking the fullest information as to local conditions.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE ROYAL FACULTY OF PHYSICIANS AND SURGEONS AND THE HOUSING QUESTION.

THE Town Council of Glasgow, at its meeting on February 6th, received a deputation from the Royal Faculty of Physicians and Surgeons on the subject of the housing problem and the treatment of consumptives on their return from sanatoriums. Dr. Adam, the President, said that the Faculty had existed for over 300 years, and one of its charter rights was that of watching the interest of the poor. It had been very much concerned lately regarding the question of tuberculosis, the question of better housing, and the question of clearing out slum properties. The deputation came in no carping spirit, but to try to support the corporation in the effort it was making to deal with a very difficult subject, and, if possible, to get those properties swept away at any cost, for he was sure, whatever the cost, it would repay them a hundredfold. Professor Glaister then said he had been charged to lay before the town council the two following resolutions passed by the Faculty:

1. That the Faculty have learned with satisfaction of the action already taken by the Corporation of Glasgow in closing houses and tenements in the slums of Glasgow, which are the breeding places of consumption, and, while appreciating the difficulties in achieving rapidly the end in view, would urge the Corporation to prosecute the same with vigour, in the best interests of the citizens of Glasgow; and also to provide for the housing of the displaced families.

They all knew that owing to the absence or deficiency of building regulations in the past the housing conditions of Glasgow gradually evolved themselves through different centuries, with the result that they had conditions existing in the city which were not consonant with the public health requirements of to-day. These conditions had been bequeathed to them, and they must be gradually removed before they brought the city up to the conditions they all desired.

2. The Faculty are also of opinion that the Corporation of Glasgow should provide suitable hospital accommodation for the more advanced and incurable cases of consumption, these probably being the most active sources of infection.

They knew from their medical experience that tuberculosis was spread among members of families by the imperfect housing conditions in which they lived. They therefore thought that when cases were so far advanced as to be incurable a home should be provided by the Corporation for the sufferers, with such provisions for the visitation of friends as the Corporation might arrange.

Dr. Duncan submitted the third recommendation, which was as follows:

3. That in view of the rapidly accumulating experience regarding the disheartening results which follow the return of sanatorium patients to their own surroundings when these are unsuitable, the Faculty would suggest that the Corporation should provide houses structurally adapted for the home treatment of consumption.

Those who had experience of sanatoriums knew that a large number of patients were sent out who seemed to have the disease arrested—they did not speak nowadays about cured—and if they were able to carry on for some time the treatment they had received from the sanatorium a very considerable number of them would no doubt become well.

Dr. Knox then thanked the council for receiving the deputation, and the council decided to discuss the resolutions at the next meeting of the Corporation.

MEDICINE AND LITERATURE.

On January 31st Dr. J. W. Ballantyne gave an address on Medicine and Literature to the members of the Edinburgh Women Students' Medical Society. He spoke of the medical men who after graduation, and in some instances after a few years of practice, had passed over from medicine into literature, and he cited Campion, Samuel Smiles, Goldsmith, James Hutchison Stirling, and Sir Arthur Conan Doyle. He spoke also of the men who had continued to practise medicine and had yet been ornaments to literature, naming Sir Thomas Browne and quoting from his works, and referring to Oliver Wendell Holmes, to Dr. John Brown, to Mark Akenside, and to some others who were still alive. Allusion was made likewise to the literary men who had been as it were "stickit" doctors, who had got so far as the dissecting room but no further; Southey and Herder, "the Coleridge of Germany," were touched upon. There were also doctors who had written on their own subject of medicine in works which were classics in literature as well as medical textbooks; and the instance of Trousseau's *Clinical Medicine* was cited. So far Dr. Ballantyne had dealt only with one side of the subject, the literary aspects of medicine; but he then turned to another—the medical aspects of literature—and referred to the use of medical figures of speech in general literature; he gave instances of their appropriate employment from Shakespeare's Richard II and Hamlet, and of their scarcely so fitting use by some of the old divines, such as Sibbes. He spoke also of books which might be reckoned as medical which were nevertheless written by non-medical authors, instancing Wellesley's *Primilive Physic*; the *Anatomy of Melancholy*, by Robert Burton, "by profession a divine, by inclination a physician"; and Defoe's *Journal of the Plague Year*. Finally, he gave quotations illustrating the way in which some literary men, such as Henley, had written or sung of their doctors.

SCOTTISH MINERS AND MEDICAL ATTENDANCE.

A further meeting of the executive of the Scottish Miners' Federation (see SUPPLEMENT, February 1st, p. 118) was held in Glasgow on February 4th, when the Secretary stated that no further communication had been received from the Secretary of the Colliery and Public Works Surgeons' Association, and that the executive were disposed to assume that the medical men in the mining districts had accepted the agreement arrived at between the doctors, the men's representatives and the coal-owners at the recent conference held in Glasgow. We are not in possession of full information with regard to the present position, but it would appear that the assumption is incorrect with regard to certain districts at least. At a recent meeting of miners in collieries at Newbattle and Arniston, in Midlothian, it was stated that medical men who had hitherto attended them and their families had refused to accept the arrangement suggested, and a committee was appointed to advertise, as we understand, for whole-time medical officers. The remarks made above under the heading of Wales appear to apply, *mutatis mutandis*, to the position in Midlothian, and any practitioner who may be approached with the object of accepting the appointment in Midlothian is advised in the first place to apply to Mr. J. Burne Mackie, Secretary of the Midlothian Medical Practitioners' Association, 25, George Street, Edinburgh.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

PAYMENT FOR MEDICAL CERTIFICATES.

THE Conjoint Committee of the British and Irish Medical Associations at a recent meeting passed a resolution to the

effect that a minimum charge of 2s. 6d. should be made for every medical certificate of sickness given to an insured person, and, as stated last week, the Standing Committee of the Dublin Clinical Hospitals passed a similar resolution, provided it was found on inquiry that the patient was not liable for the fee. The Insurance Commissioners were asked if the fee for these certificates would be paid by the societies or the insured persons. They replied that it was optional with the societies whether they required a medical certificate or not. It therefore appeared that if a society decided to demand a medical certificate it must pay for it. Further, a special grant of £50,000 has now been allocated to Ireland for the purpose of paying for medical certificates, etc. The societies, however, are at present trying to obtain these certificates without paying for them, by telling the insured persons that if a fee is demanded it is a matter between the patient and doctor and does not concern them. Some insured persons are proceeding against the societies for the recovery of their sick benefit money which has been refused owing to the absence of a medical certificate of sickness. The societies probably all realize that in the end they will have to make arrangements for paying for any medical certificates they may require, and are only holding out at present in the hopes that the medical profession will reduce their charge to 1s. per certificate. As this is the only point on which the medical profession has now any claim on the friendly societies it behoves it to remain firm. It was suggested at the last meeting of the South Dublin Guardians that if the doctors persisted in this line of conduct the guardians could strike back by throwing out proposals to increase their salaries. Last week the Chairman of the Carrick-on-Suir Board of Guardians stated that he voted against granting the increases of the dispensary doctors' salaries because of the doctors' action in refusing to give Insurance Act certificates to poor people in the district. Many of the societies are dispensing with medical certificates and relying on lay inspectors, and already the Dublin hospitals are troubled by visitors calling at all hours to inquire for and see patients who are in the wards.

MATERNITY BENEFIT AND DISPENSARY TICKETS.

Last week a deputation from the Conjoint Committee of the Irish Medical Association and British Medical Association, consisting of Professor White, Dr. O'Connor (Celibridge), Dr. Walshe (Kilkenny), and Dr. Kidd (Enniskillen), waited on the Local Government Board to discuss the position of dispensary medical officers in regard to the treatment of patients receiving maternity benefit, and also with respect to other points arising under the Tuberculosis Act. The Board was asked whether persons receiving maternity benefit—that is, a sum of money for the special purpose of paying doctor and nurse in a case of confinement—were to be considered as poor persons within the meaning of the Act, and if the guardians were therefore justified in giving a red ticket for attendance for the purpose of confinement only. The deputation pointed out that if a red ticket was given the dispensary doctor must attend, and that therefore the patient had no free choice of doctor. Sir Henry Robinson, in reply, said that a doctor must attend on a red ticket, without receiving payment, until the ticket was cancelled. The question of whether the guardians should issue a red ticket for a person in receipt of maternity benefit must be left to be decided according to the special circumstances of each individual case. In view of the provisional regulations made by the Welsh Commissioners as to the fees of medical practitioners summoned under the rules made under the Midwifery Act, laying down that 15s. for the doctor during attendance for labour, and 5s. subsequently, should be paid and recovered from maternity benefit, and also, in view of the many applications for advice from boards of guardians throughout the country, Sir Henry said they had prepared a circular, which had been held over pending the interview. He then read the circular, and asked for the opinion of the deputation. Drs. O'Connor and Kidd and Professor White expressed the opinion that it met the case fairly and reasonably, but Dr. Walshe thought it left the matter very much as it was at present, as it would still be discretionary with the guardians to give tickets where maternity benefit was given.

Obituary.

WILLIAM CARTER, M.D., F.R.C.P.LOND.,

CONSULTING PHYSICIAN TO THE ROYAL SOUTHERN HOSPITAL,
LIVERPOOL.

It is with great regret that we have to record the death of Dr. William Carter, which took place, in his 77th year, at Liverpool, on February 2nd, after a brief illness. For forty years during his residence in Liverpool he figured prominently in the life of the city. He was born in Newbury (Berks) in 1836, the son of Dr. Thomas Carter, who practised in that town. He came of an old Berkshire family, many generations of which had resided at Kingsclere, and on the walls of the old church there the tablets in memory of the family date back to the early part of the eighteenth century. Dr. Carter was educated at the Newbury Grammar School, and afterwards at Charing

Cross and St. Thomas's Hospitals; his academic career was most distinguished, for he carried off, in addition to many other honours, two gold and several silver medals during the course of his studies. He obtained high degrees in medicine, and was also a graduate in law (LL.B., 1866) and science (B.Sc., 1864). Amongst other distinctions he was an ex-President of the Liverpool Medical Institution, Liverpool Literary and Philosophical Society; honorary member of the Société Française d'Hygiène; member of the Irish Medical Schools' and Graduates' Association; Professor of Materia Medica, Liverpool University; Honorary Physician to the Liverpool Royal Southern Hospital; Consulting Physician, Eye and Ear Infirmary; Professor of Botany, Zoology, and Physiology, Queen's College; Lecturer on Botany in the Liverpool Royal Infirmary School of Medicine, and on Chemistry and Natural Philosophy in Liverpool College; Honorary Medical Officer, North Dispensary; Lecturer on Science, Liverpool School of Science, and on Materia Medica and Botany, Liverpool School of Pharmacy; Assistant Demonstrator of Anatomy, Charing Cross Hospital; and President of the Liverpool Microscopical Society. He was a Crown Representative on the Council of the University of Wales. He took the degree of M.B.Lond. in 1864, and at first commenced practice in Dublin, but removed to Liverpool in 1867. He rapidly took a prominent place in the medical life of the city. His pen was facile and his contributions to medical literature numerous, dating back to 1868. He was always of a modest and retiring disposition and shrunk from any action or circumstance which might have been interpreted as holding possibilities of self-aggrandisement; but, in spite of this, his ability and conscientious work soon placed him in the forefront of his profession and commanded the confidence and esteem of his patients and professional brethren. His conscientious adherence to what he considered true principles and settled convictions of what was right and just, both in individual work and

movements for the welfare of the people, made him an indomitable worker and combatant in many reforms.

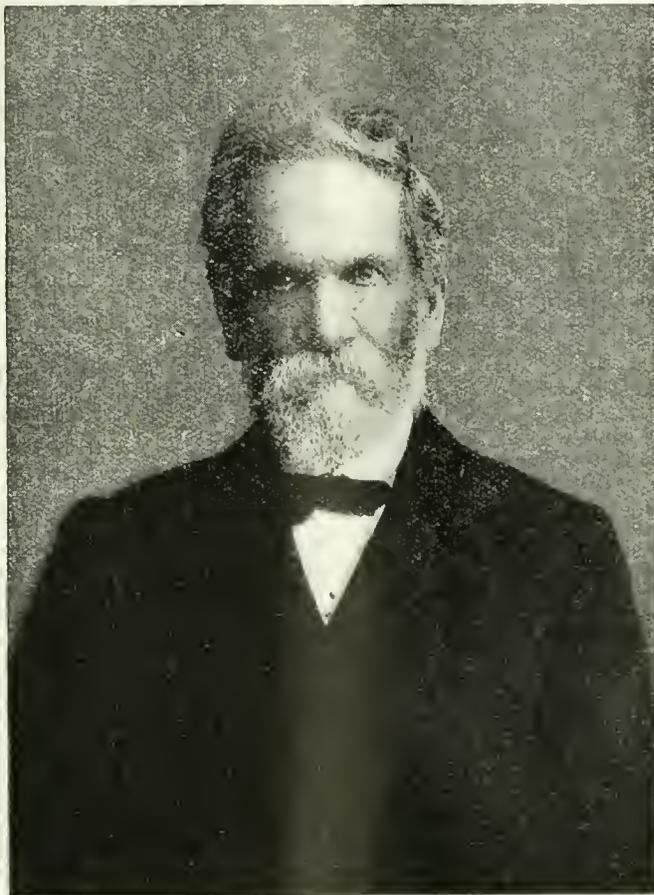

His academic work in Liverpool dated back to the very beginnings of the old Liverpool Medical School, from which sprang the University College, and, finally, the Liverpool University. He was an able instructor in materia medica and therapeutics, and in both subjects was deemed a master. For over thirty-six years Dr. Carter was a physician to the old Southern, afterwards the Royal Southern, Hospital, Liverpool. At the age of 60, when he offered to resign, the committee thought so highly of him and his work that his resignation was unanimously declined, and he remained loyally serving the hospital until the close of his professional career. Shortly after settling in Liverpool Dr. Carter succeeded the late Dr. Nevins as a lecturer on chemistry in the old Liverpool College, Shaw Street. Many of his students became his firm friends in later life, and among the most notable of these were Mr. Justice Pickford and Mr. Austin Taylor, formerly the members for East Toxteth Division. In the School of Science his teaching and enthusiasm gave rise to many personal friendships. One of the working-men students was a Scotsman named George Gordon, who afterwards became curator of the Fitzwilliam Museum, Cambridge, and subsequently assisted Lord Rayleigh in research work. A few years ago Mr. Gordon died, and on his deathbed expressed the desire that all his books and scientific instruments should go to his instructor as a token of his appreciation of the kindness he had received.

In his position as medical officer to the West Derby Union Dr. Carter gained much knowledge that was of service to him in his work as a social reformer. He took great interest in measures of sanitary improvement, and was frequently consulted by the Corporation on sanitary questions. He strove earnestly in the social purity crusade for the cause of social righteousness. The temperance

cause had in him an ardent and powerful advocate. He was deeply interested in the higher education of women, and was a strong supporter of the registration of midwives and lived to see that embodied in the Midwives Act.

In conjunction with the late Dr. Nevins, Francis Newman, Mrs. Josephine Butler, Dr. Ginsberg, and the Hon. James Stuart, he opposed the Contagious Diseases Act which was in due course repealed in 1886. Dr. Carter also took a notable part in the establishment of the National Association for the Repeal of the Compulsory Notification Act. He was connected with the inauguration of the Liverpool School of Tropical Medicine, and devoted much time and energy to its successful development. He also held the office of Chairman of the Cancer Research Committee, the generous founder of the research fund selecting him as the medium of his benevolence.

As an instance of his firm adherence to principle, it may be said that, when the late King of the Belgians desired to confer upon him an important decoration in

DR. WILLIAM CARTER.

Medington's, Ltd., Liverpool

connexion with the School of Tropical Medicine, Dr. Carter refused, owing to the King's attitude to the Congo question, Dr. Carter having been an early member of the Congo Reform Association. His possession of the Mary Kingsley Medal in connexion with the School of Tropical Medicine was, however, a distinction of which he was very proud.

Dr. Carter took the chair at the inaugural meeting of the Liverpool Royal Country Hospital in November, 1898, and was an early and strong supporter of that institution. He continued to act as chairman until the hospital was founded, and remained on the committee until his decease.

Dr. Carter's charitable works were more numerous than known; he always felt great sympathy with the poor, and its expression, though practical and real, was carried out without ostentation.

In 1863, while in Dublin, Dr. Carter married Miss Sarah B. J. Humphrys (second daughter of the late Dr. George Humphrys, of Harecourt Street, Dublin), who predeceased him by several years. The surviving members of the family are Mrs. Macalister (wife of Dr. C. Macalister of Liverpool) and Miss Carter.

In the early part of 1908 Dr. Carter gave up his professional practice, and went to live in retirement at Deganwy, North Wales; but he often visited Liverpool in connexion with his magisterial duties or the various charitable institutions in which he retained a warm and sympathetic interest.

Prior to private cremation, on February 6th, a service was held at Canning Street Presbyterian Church, and the esteem in which he had been held was expressed in the large attendance of professional colleagues, medical practitioners in the city, representatives of city institutions, educational and social, and a large number of citizens from all parts and in all stations in the city.

Mr. ROBERT JONES sends us the following appreciation of the work and character of his late colleague: Few men have won the admiration, love, and respect that the late Dr. Carter inspired in Liverpool during his long and honoured life in that city. His death on Sunday, February 2nd, at the age of 76, will come as a shock to many, for his name had become so intimately associated with all that was best in civic life that great numbers of people who never met him personally had learnt to regard him with affection and trust. Throughout his long life he laboured unceasingly in the cause of suffering humanity, and that not only in his profession but in many phases of social progress. He was active in combating disease and also in encouraging research work, in pressing the claims of sanitation, and in fighting the battles of all those who could not help themselves. He was above all a fighter; one could see that in his strong face, his deep-set steady eyes, his indomitable personality. And yet no man ever accused him of unfairness in argument. He was a fighter but the soul of chivalry. Time and again Dr. Carter would moderate whatever seemed afterwards even a shade over-emphatic, for he was unswervingly scrupulous in small things as in great. There are many who have been touched by the pain he appeared to suffer when he feared he had adopted too resolute an attitude. There are men to-day who treasure letters written to soften words that had caused no rancour, to defend with gentle apology an expression that from his lips could have offended no reasonable person.

He carried in his words, his bearing, his life, all the great sincerity of a prophet of righteousness. He was a puritan, a reformer, and a progressive; but he was a puritan without a breath of cant, a reformer with noble ideals, and a progressive lacking crudeness of conception. Reason ruled his life and steered his ship clear of all the rocks that await so many earnest men. He took a leading part in the social purity crusade, but no man, however spiteful, ever whispered that he was narrow-minded. An ardent advocate of temperance and himself a lifelong abstainer, he nevertheless prescribed alcohol in his professional capacity where he deemed it necessary. Oppression and injustice roused him to a white heat, but he was as simple-minded and gentle as a child. No cause need come abegging in vain to him. From the dumb appeal of animals in the Liverpool Abattoir to the unuttered claims

of unborn infants (which resulted in the registration of midwives) his sympathy was flung wide.

It would seem unnecessary to add that such qualities as his were built strictly upon a rock of principle, and it is interesting to remember that when the late King of the Belgians expressed his wish to decorate Dr. Carter for his services to the School of Tropical Medicine (which he was the means of founding) he refused with indignation, for he was, as any one who knew him might have guessed, a staunch supporter of the Congo Reform Association.

As an instance of the puritan in Dr. Carter, it may be mentioned that it was said that he had never entered a theatre, and, as far as his inclinations were concerned, he never had. The following little incident will serve to show the warm kindness of his disposition: He was called to a theatre in Liverpool one evening to attend an actress who was taken suddenly ill. Having treated her, Dr. Carter prepared to leave. She begged him to stay, however, and not only to do so, but to sit through the performance in a position where his presence would give her confidence. Rather than disappoint her and cause inconvenience to the audience, he took a seat before the stage, and so began and ended his connexion with the theatre.

His modesty, perhaps, impressed strangers most of all, and it is stated that as senior magistrate on the rota of those whose turn was to sit on the Bench he could never be induced to take the chair at the police-court, and on all occasions, despite his many public appearances, he was never one to "catch the speaker's eye."

In his professional and private life he made many friends and was intimate with distinguished men in all ranks of society. He attended Mr. Gladstone in his last illness, and was a friend of Francis Newman. He was often judged to be austere and grave, but he possessed an inexhaustible fund of kindly humour. He was full of interesting recollections of men and events, which delighted his friends. Liverpool has lost in Dr. Carter one of the sweetest and best of men.

HENRY EALES, M.R.C.S.ENG.,

SENIOR SURGEON BIRMINGHAM AND MIDLAND EYE HOSPITAL.

We regret to hear of the death of Mr. Henry Eales, Senior Surgeon to the Birmingham and Midland Eye Hospital, which occurred, after a short illness, on February 8th. The son of the Vicar of Yealmpton in Devonshire, Mr. Eales was born at Newton Abbot in 1852, and began his medical career, as was customary in those days, by being apprenticed to the village doctor. During his apprenticeship there was a local epidemic of scarlet fever, and having to examine the urine of many patients for albuminuria, out of curiosity he examined his own, and found that it contained a large amount of albumen; as he had not had fever it is probable that it was merely the albuminuria of adolescence; but little was known on this subject at that time, and so serious was the view taken of his condition, that for about a year he was not allowed to continue his medical work. Ultimately, as his general health remained good, he was permitted to proceed, and entered as a student at University College, where he gained two silver medals in anatomy and one in materia medica. He took the Membership of the Royal College of Surgeons in 1873, and was shortly afterwards appointed House Surgeon to the Birmingham Eye Hospital. At the termination of this appointment he became demonstrator of anatomy and medical tutor at Queen's College, but a vacancy occurring on the staff of the Eye Hospital in 1878 he was elected one of its honorary surgeons.

For several years before his death he was senior surgeon to the hospital, and was also ophthalmic surgeon to the Guest Hospital, Dudley; to the Hammerwich Hospital, Cannock; to the Balsall Heath Dispensary, to the Edgbaston Royal Deaf and Dumb Institution, and medical referee for ophthalmic cases under the Workmen's Compensation Act. At the annual meeting of the British Medical Association in Birmingham in 1911 he presided over the Section of Ophthalmology; he held office as vice-president of the Ophthalmological Society, as chairman of the Pathological Section of the Birmingham Branch of the British Medical Association, as president of the Midland Medical Society, and treasurer of the Birmingham

and Midland Counties Ophthalmological Society. He delivered the Middlemore Lecture for 1897. At one time he contributed a good many papers to the medical journals, including a Report on the State of the Retina in a Hundred Cases of Granular Kidney (*Birmingham Medical Review*, 1889), Unilateral Retinitis Albuminaria and Toxic Amblyopia (*Trans. Ophth. Soc.*). He was particularly skilful in the use of the ophthalmoscope, his opinion of the appearances in doubtful cases being of the utmost value.

Mr. Eales had built up a large consulting practice, and his death will come as a painful surprise to a wide circle of practitioners and patients who relied upon his skill. The albuminuria which had shown itself during his apprenticeship entirely disappeared by the time he came to Birmingham, but he suffered at one time severely from migraine, which had become less frequent during recent years. Last Christmas most of his family were ill with influenza, but he appeared to escape. Soon afterwards he developed a slight attack of phlebitis in the calf of the left leg. This seemed to get better, but the pain and swelling returned about ten days ago, so that he was obliged to stay in bed. On February 5th he had an attack of vomiting with syncope, and this was followed by a rise of temperature in the evening; but these symptoms were gradually improving, and on the morning of the day he died he looked and expressed himself as feeling decidedly better. A few hours later he died in another attack of syncope.

He leaves a widow, two sons, and two daughters. The elder son is senior curate at Kenilworth, while the younger is the resident surgical officer at the Eye Hospital, and will probably follow his father's footsteps in his profession.

Mr. Eales was a man of singularly amiable character, and his death makes a gap which to his elder colleagues can never be filled. They were sincerely attached to him for his unfailing kindness of disposition, his high character, thorough loyalty, and devotion to his work.

LEONARD NOON, B.C.CANTAB., F.R.C.S.

THE all too small band of active research workers in bacteriology has suffered a severe loss by the death of Mr. Leonard Noon at the early age of 35. Mr. Noon's early training at Charterhouse was followed by a highly distinguished career at the University of Cambridge, which he entered in 1896. In 1898 he gained first-class honours in the Natural Science Tripos, in 1899 a major scholarship in Advanced Physiology at Trinity College, and in 1900 first-class honours in the Natural Science Tripos, Part II. He then entered St. Bartholomew's Hospital, gaining an open scholarship in Anatomy and Physiology. He subsequently held the posts of house-surgeon and ophthalmic house-surgeon in that hospital. He obtained the degree of B.C.Cantab. in 1903, the diplomas of M.R.C.S., L.R.C.P. in 1903, and that of F.R.C.S. in June, 1905. In September of that year he was appointed to a research scholarship at the Serum Department of the Lister Institute, Elstree, where Professor G. Dean was then Bacteriologist-in-Charge. During his tenure of this scholarship Mr. Noon carried out an important piece of research on the laws governing the neutralization of tetanus toxin by brain tissue. Later he was John Lucas Walker Student in Pathology at the University of Cambridge, and at the close of his tenure of this studentship became an assistant in the Inoculation Department of St. Mary's Hospital under Sir Almoth Wright. Here he remained till early in 1911, when owing to continued ill health he had to give up laboratory work entirely. His recent decease, therefore, did not come as a surprise to those who knew, but was none the less keenly felt by colleagues who had enjoyed his friendship in the past and who admired his enthusiasm for research and the critical insight which he always brought to bear on problems under investigation.

The following is a list of Mr. Noon's chief scientific publications: On the Occurrence of Toxic Compounds of Tetanus Toxin and Antitoxin, Tetanus Toxin and Brain Emulsions (*Journ. of Hyg.*, vol. vii, p. 101); Observations on the Evolution of Immunity in Disease (*Journ. of Hyg.*, vol. ix, p. 181); Histological Notes on the Origin of Rodent Ulcer (*Journ. of Path. and Bact.*, vol. xii, p. 5); Prophylactic Inoculation against Hay Fever (*Lancet*, 1911, vol. i,

p. 1572); The Accuracy of Opsonic Estimations (*Lancet*, 1908, vol. i, p. 1203, with A. Fleming).

DR. WILLIAM LATHAM, one of the leading citizens of Ashton-in-Makerfield, Lancashire, died rather suddenly on January 28th, at the age of 51. He was a native of Ashton, and was apprenticed to Messrs. Fisher and Barnish, of Wigan, attending at the same time as a student the curriculum at the Liverpool Medical School. Subsequently he studied at Dublin University, and obtained the diploma of L.R.C.P.I. in 1876 and of M.R.C.S. Eng. in 1878; then, after holding resident appointments in the Liverpool Royal Infirmary, he set up in practice in his native town. He was a member of the British Medical Association, and took an active part in local affairs. He was for a time a member of the old local board, and was afterwards one of the district council representatives on the Ashton and District Education Committee; he took part also in the management of several local institutions. Mr. Latham was made a justice of the peace about four years ago. He was a keen sportsman, and greatly respected in his native town. Two years ago he retired from active practice, owing to failing health, in favour of his son, Mr. William Ewart Latham.

Universities and Colleges.

UNIVERSITY OF LONDON.

MEETING OF THE SENATE.

A MEETING of the Senate was held on January 22nd, under the chairmanship of the Vice-Chancellor, Dr. Herringham.

Resignation from Senate.

Dr. Thomas Buzzard has resigned his membership of the Senate as a co-opted member representing King's College.

Benefactions to University College.

The anonymous donor who a year ago presented £30,000 towards the erection of a new building at University College for architecture, sculpture, and applied statistics, including the Eugenic Laboratory, has now undertaken to bear under certain conditions almost the whole cost of the erection of the buildings in question, in the hope that at an early date it may be possible to complete the Gower Street frontage of the College.

D.Sc. Degree in Statistics.

The degree of D.Sc. in statistics was conferred on Dr. David Heron of University College, who had presented a thesis entitled "A Second Study of Extreme Alcoholism in Adults with Special Reference to the Home Office Inebriate Reformatory Data," and in addition several other contributions to the advancement of science.

Semon Lectures in Laryngology.

At the conclusion of the second Semon lecture given by Dr. McBride on January 24th, Sir Felix Semon, at the invitation of the chairman, Dr. Watson-Williams, Lecturer on Laryngology at the University of Bristol, formally presented to the lecturer the Semon memorial medal, and gave a short address expressing his gratification at the inauguration of the lectures.

Brown Animal Sanatory Institution.

Mr. F. W. Twort, M.R.C.S., L.R.C.P., superintendent of the institution, on February 6th completed his course of five lectures on the comparative study of tuberculosis and Johne's disease.

A LODGE meeting of medical Freemasons who are attending the International Medical Congress in London will be held on Monday, August 11th next, in the Grand Temple at Freemasons' Hall, Great Queen Street, W.C. The lodge will be opened at 5 p.m. and closed at 6 p.m. by the Most Worshipful the Pro Grand Master the Right Honourable Lord Amphil, G.C.S.I., G.C.I.E., and a reception will be held at 4 p.m. in the Connaught Rooms, adjacent to Freemasons' Hall. It is hoped that all Colonial and foreign brethren who wish to be present will communicate with the Grand Secretary of their own jurisdiction as soon as possible in order that suitable arrangements may be made. Brethren in the British Isles should communicate with the Honorary Secretary of the Committee of Representatives of the Medical Lodges in London, Dr. R. J. Probyn-Williams, F.G.D., 13, Welbeck Street, Cavendish Square. Without doubt the medical members of the craft will give a most fraternally hearty reception to their brethren from the distant parts of the Empire and from foreign lands. It is doubtful if Freemasonry was ever since its ancient foundation so flourishing amongst doctors as it is at the present day.

Correspondence.

THE REPORT OF THE COMMITTEE ON FRACTURES.

SIR,—That the Committee on Treatment of Simple Fractures should have found that the results yielded by operation are somewhat better than those accruing from non-operative methods, can hardly be a matter for surprise. How could it conceivably be otherwise? Nevertheless, when we have arrived thus far, we shall find upon reflection that we have been brought no nearer to a final answer to the questions involved in the treatment of fractures. The real crux of the position is embodied in Section X of the Committee's conclusions, which reads as follows:

It is necessary to insist that the operative treatment of fractures requires special skill and experience, and such facilities and surroundings as will ensure asepsis. It is, therefore, not a method to be undertaken except by those who have constant practice and experience in such surgical procedures.

In other words the general practitioner who has *not* "constant practice and experience in such surgical procedures" (but who has probably more fractures to treat than those who have) must adopt non-operative methods. But where and how is he to learn to do this, if in his hospital studentship he has been accustomed to see fractures operated on whenever a little difficulty is presented?

One great fact that emerges quite clearly from the whole discussion is that in the past the teaching in our schools has been inadequate and inefficient in respect of the treatment of fractures; but the present trend towards frequent operation must surely eventuate in such teaching becoming still more inadequate and inefficient in the immediate future. Put in another way, we find that we have been giving practitioners too little teaching in the past, so we propose to remedy this by giving them practically none at all in the future.

The skilful non-operative management of a fracture is a much more difficult and interesting surgical procedure than a skilfully performed operation upon it; it makes higher demands upon the surgeon's thoughtfulness and resource, upon his knowledge of physiological principles and his powers of clinical observation.

I cannot help wishing that Mr. Arbuthnot Lane had employed his great surgical ability in elaborating improved non-operative methods, which would have been of immeasurable value to multitudes of general practitioners and their patients. I am quite convinced that he would have obtained results very nearly as perfect as those yielded by his beautifully executed operations, and of infinitely greater value to scientific surgery and to the community.

My students understand why I refrain from adopting the easy course of operating upon fractures, except in rare instances. On the other hand, when a broken leg comes into the ward they receive quite as much and as careful teaching over it, and they learn quite as many valuable surgical principles and methods from it, as from a major abdominal operation. Personally, I have experienced great interest and learnt much that I deem of great value through habitually setting to work with my students over every case of fracture in the endeavour to devise some simple and effective plan of treatment that will be of value to them when they go out into practice; and this, if I may be absolved from arrogance, is in my opinion just what a hospital surgeon and teacher ought to do.

Briefly, it seems to me quite clear that, unless hospital surgeons and teachers are prepared to advocate that open operation on recent fractures shall be undertaken by all and sundry under all sorts of conditions, they must let it be seen that they themselves regard non-operative methods as of paramount value and importance; that they shrink from resorting to open operation in any but quite exceptional and rare instances; and that they frankly acknowledge that the necessity for treating a fracture by open operation carries with it in some measure, greater or less, an adverse reflection upon their own skill. Unless they do this, how can the general practitioner who goes forth from our medical schools be properly trained in

this the most important branch of surgical work he will be called upon to undertake? Obviously he cannot.—I am, etc.,

R. HAMILTON RUSSELL,
Senior Surgeon to the Alfred Hospital.

Melbourne, Jan. 8th.

THE "CONTROLLED" THERAPEUTIC USE OF NEW TUBERCULIN.

SIR,—The article on "The Controlled Therapeutic Use of New Tuberculin," by Dr. Rigg, is an apt illustration of the danger of rushing to conclusions on very flimsy and wretchedly controlled observations.

An actuary who has no medical knowledge is hardly the person to suggest a practicable plan of controlling the therapeutic use of tuberculin, or to select and appraise the criteria for estimating improvement or the reverse, unless at least he has some knowledge of pulmonary tuberculosis and the different methods of applying tuberculin effectively. If the tuberculin is not used in a proper way in order to secure the best results, it hardly matters what the criteria are or what the controls. The general condition, as judged by the state of nutrition, including difficult analyses of the urine (Mitulescu's work), the character of the pulse, the tongue, digestion, and the temperature, and even the energy of the patient when he is up and about, cannot be jauntily relegated to a secondary place because Dr. Rigg deems it too fallacious. Even the state of the blood before and after treatment is not subjective but objective evidence (Arneith's work and the evidence of other clinicians show this clearly). Variations in weight may also help, provided the patient is not placed under unusual conditions. I admit that if these patients were kept in hospital for observation a new and disturbing factor was at once introduced, the effect of which would vary in individual cases. Further, the changes in the character of the sputum properly analysed is another criterion which helps greatly in measuring the degree of improvement, and the suggestion that "the extrusion of plegerm is so obviously under the control of the patient, and temporary absence of tubercle bacilli in the sputum of patients suffering from active pulmonary tuberculosis is not infrequent," is a gratuitous concession to want of care in the control of the observations.

Having, then, decided to set aside—perhaps at the behest of the actuary—the most obvious means of measuring the effect of subsequent treatment, Dr. Rigg, under the patronage of Dr. Batty Shaw, tells us that the only criterion is "alteration of the physical signs, and of these the greatest attention was paid to rales."

I cannot imagine a more untrustworthy way of judging the effects of treatment than by one or two chance observations upon, and descriptions of, rales in different parts of the lung. Rales are sounds varying infinitely in character at different times of the day, in different conditions of atmosphere, with the condition of rest, or otherwise, and also with conditions, not only in the large lungs, but sometimes outside them, but especially with the state of the bronchial tubes. Rales, too, are themselves modified very greatly by cough, breathing, and the condition of the tissue through which the sounds are conducted, and vary also with the distance of the tubes or tube in which the sound is produced from the surface point of observation. The degree of accuracy in the description of such rales depends largely upon the experience of the examiner and his personal, often inborn, aptitude for distinguishing the ever-changing variations that literally defy exact analysis and description. I admit that a man with a very fine musical ear, highly trained in observing these fine, almost elusive, differences, might be able to set down in technical language the character of the sounds he hears in different sections of a diseased lung, but I doubt whether even such an examiner could properly describe the minute details of these sounds with any approach to accuracy in any reasonable time. Accordingly, there is an uncontrolled personal equation in the proper valuation of these subjective impressions upon the ear which would render them far less trustworthy as criteria than the condition of pulse, of blood, of weight, of urine, of temperature, and of sputum, in which the personal equation of the observer is eliminated. Dr. Rigg eliminates the subjective impressions of the observed for the subjective impressions of the observer, and at the same

time he introduces as criteria subjective impressions which almost defy exact description. Without a doubt changes in the amount, character, and contents of the sputum would be a far safer guide in determining the improvement, or otherwise, of the lung under the influence of treatment than the criterion set up by Dr. Rigg.

The memory of râles, visualized by means of diagrams, cannot be trusted when compared with the auditory impressions upon the observer after an interval of three months. Such a comparison and description to be of any value must first be practised for a long time before it can be trusted as an art. Isolated impressions of this kind without such careful and close study would vitiate the results. The mere extension of the râles might be of trifling importance compared with changes in the râles indicating increased intensity of the process. Seeing, then, that râles undergo such extraordinary changes that might easily elude any but the most highly trained and acutely sensitive musical ear, one wonders that any one should suggest such a treacherous and elusive method of estimating changes in the lungs as an index of improvement or otherwise. It would be interesting to know how long these investigations upon the physical signs occupied, and whether Dr. Rigg has the ear to recognize and the skill to describe accurately his own auditory impressions.

But these objections to the selection of the criteria pale into insignificance when we come to consider the method of selecting the cases for treatment. The cases "presented all grades of involvement of the lungs, from very slight to extensive (one apex to five lobes,)" etc., and although the skilled physician is able with tolerable accuracy, not by means of râles but by means of physical signs generally, to classify tuberculous disease of the lungs in at least three recognized groups, this usual grouping of cases was ignored and the patients were chosen by lot. Was this also the idea of the actuary? I hardly think the actuary would have so decided if he had known that cases of lung disease can be classified more or less accurately into stages. This would have, at any rate, diminished the influence of pure chance. As it is, Heaven only knows what luck determined in this process of selection, because, when there was such a variety of forms of disease, how could the drawing of lots possibly bring it about that two similar series of cases were selected? I do not think that much attention will be paid to work of this sort, even though an actuary has had a hand in it; but we need not bother our heads about either the actuary or the methods of choice, because the method of treatment is unlike any method of using tuberculin in the treatment of tuberculosis of the lungs which has claimed success.

The largest dose used is described as 0.7 mg. of tuberculin T.R. What this means I do not know. T.R. is a liquid preparation, and strictly cannot be measured in milligrams. If 1 mg. means $\frac{1}{100}$ c.c.m. of T.R., then 0.7 mg. is less than $\frac{1}{100}$ c.c.m. of T.R. Those authorities whose opinions are most valued in this special method of treatment would expect no useful effect from such a dose as a maximum. If 0.7 mg. means 0.7 mg. of dead tubercle bacilli, I must tell Dr. Rigg that this is a very inaccurate and misleading method of describing dosage, because there is no proper ratio between the weight of dead tubercle bacilli to the bulk of the liquid preparation T.R. Thus, I should expect no appreciable effect from such a method of administration, nor any appreciable improvement in the patient, but I would not in any case dream of relying upon physical signs, especially râles, noted once, and again in three months' time, for assessing the value of tuberculin treatment.

I have already laid down in my book a reasonable plan for determining the efficacy of various methods of treating pulmonary tuberculosis: (1) A series of cases in various stages should be grouped. (2) No other method of treatment but the one under consideration should be adopted. (3) The results in all cases should be published, and, most important of all, an opinion should be formed of the relative merits of the rival systems, not in three months' time, by physical signs, but in three years' time, by all the recognized methods of estimating the effects of treatment.

The medical authorities at Brompton Hospital attempted to deal with pulmonary tuberculosis, its nature, its diagnosis, and its treatment in a course of lectures occupying

a week. This was pretentious enough, but it would need a genius with superhuman powers to arrive at approximate accuracy concerning the value of tuberculin when all the recognized criteria are calmly set aside and a new criterion is introduced, full of pitfalls even for those best versed, not only in detecting and describing physical signs, but also in deducing therefrom the mixed and variable underlying conditions of tissue and environment upon which the physical signs depend.—I am, etc.,

W. CAMAC WILKINSON, M.D., F.R.C.P.

London, W., Feb. 6th.

THE SUPPORTS OF THE UTERUS.

SIR,—With all due respect to Dr. Fothergill, many of us who have studied anatomy, gynaecology, and obstetrics cannot feel so confident about the true supports of the pelvic viscera. Dr. Moritz may have "conclusively shown" that the so-called ligaments of Mackenrodt are perivascular tissue surrounding the vessels supplying the uterus and not separate ligaments, and very likely he is correct, yet others may be of a different opinion, and "show conclusively" that the ligaments should be interpreted in some other way. Let us turn to a subject apparently far less subtle—the musculature of the pelvic floor, a most important matter in respect to prolapses. The levator ani muscle has been known for centuries, and so has the coccygeus, yet eminent living anatomists like Peter Thompson and Paramore are apparently not agreed as to the precise interpretation, subdivisions, and functions of these structures, which need no aid from the microscope, and require little more, it would seem at first sight, than careful dissection and inspection of preparations in museums. Indeed, I had in mind the views of these authorities (as summed up in a leader in the *JOURNAL*, vol. ii, 1910, p. 392) when I stated in the course of my criticisms on Liepmann's fine *Atlas der Operations-Anatomie* that there remains much uncertainty about the supports of the uterus.—I am, etc.,

London, Feb. 8th.

THE REVIEWER.

* * * In Dr. Fothergill's letter there was a misprint. The title of Dr. Moritz's paper was, "On the nature of the so-called ligaments of Mackenrodt," and not as printed.

THE CONSTITUTION OF THE ASSOCIATION.

Local Medical Committees and the Divisions.

SIR,—Unless we are prepared to rise to the occasion, our Association, which has come rather badly out of the recent crisis, will never recover the proud position it has hitherto held. Eventually we must give up our present constitution, and, no matter at what cost, transform ourselves into a strong trades union. This, however, cannot be effected immediately, and for the next six months, at all events we must make use of the organization we possess to protect ourselves against our two natural enemies—the Insurance Committees and the Approved Societies.

In the early stages of the fight we were told that the Local Medical Committees would be kept in touch with each other by the Branch Councils, who in turn would be co-ordinated by the Central Council.

So far is this from being the case, that in most instances even the committees in adjoining areas are not in touch, and instead of an ordered campaign, we find each unit fighting its own battle without support from its neighbours. This is largely due to the present constitution of the Divisions, and it must be altered before the provisional three months have expired. In peace or in war the true unit now is the local insurance area, and the Council should exercise their power under Article 13 to "determine, recognize, and declare by resolution" the reformation of the Divisions on the above plan. There is no doubt that if we do not carry this into effect somebody else will do it for us. Local Medical Committees, consisting of members and non-members, are, or shortly will be, constituted everywhere, and self-interest alone will force them to combine; surely it is wiser to recognize this in time, and to place our organization at their disposal. But for goodness sake do it at once—to-morrow it will be too late.—I am, etc.,

LACHLAN FRASER, M.D., M.S.

President of the North of England Branch.

North Shields, Feb. 10th.

Medical News.

SIR WILLIAM COLLINS will lecture on an ambulance service for London, at the Polyclinic, 22, Chenies Street, Gower Street, on Monday, February 17th, at 5.15 p.m.

At a meeting of the Royal Microscopical Society on Wednesday evening next, at 8 p.m., Dr. E. J. Spitta will make a report upon the lenses of the late Joseph Jackson Lister, father of Lord Lister.

WE are asked to state, for the information especially of medical men sending patients from a distance, that out-patients are now seen at the National Hospital for the Paralysed and Epileptic, Queen Square, W.C., on Monday, Tuesday, Thursday, and Friday in each week.

THE annual meeting of the After-Care Association will be held at the rooms of the Medical Society of London on February 25th, at 2.45 p.m., when Dr. Hubert Bond will open a discussion on after-care in cases of mental disorder and the desirability of extending its scope.

DR. E. H. STARLING, Professor of Physiology in University College, London, has been elected a member of the Athenaeum Club under the rule which permits the committee annually to elect three persons "of distinguished eminence in science, literature, the arts, or for public service."

At a meeting of the Zoological Society of London on February 4th, Sir John Rose Bradford in the chair, Mr. H. G. Plummer, F.R.S., Pathologist to the Society, presented his annual report on the deaths which had occurred in the gardens during the past year. An examination had been made of the blood of every animal that had died, with the result that parasites had been discovered in 140 cases, and in 80 of these for the first time.

THE next quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland will be held, at the invitation of Dr. Rotherham, at the Darenth Industrial Colony, Dartford, Kent, on Thursday, February 20th. In the morning the members will inspect the colony, which comprises female and male workshops and wards for adult imbeciles, workshops and wards for the feeble-minded section, and a training school and wards for imbeciles under 16 years of age. In the afternoon, at a meeting under the chairmanship of the president, Dr. J. G. Soutar, papers will be read by Dr. J. Beveridge Spence on assistant medical officers in asylums, and by Dr. A. O. Spensley on the system of industrial training at the Darenth Colony.

A SOCIETY for the advancement of clinical study, recently organized in New York City, maintains a bureau to furnish information to resident and visiting physicians regarding the clinical facilities of the hospitals and laboratories of the greater city. It has installed a bulletin board at the Academy of Medicine, in charge of a special clerk, who will answer telephone inquiries. The bulletin board will consist of two sections. On one will be posted month by month the regular clinics, medical and surgical, and also laboratory demonstrations held at stated hours; on the other announcements of daily operations and demonstrations of cases, which, as far as possible, will be announced on the preceding day.

THE Home Secretary is about to appoint two additional inspectors under the Cruelty to Animals Act, 1876. The appointment will be for one year in the first instance, and afterwards probably for five years. The initial salary will be £500, together with the travelling allowances usual in the Civil Service; and if the appointment is continued will rise by annual increments of £20 to £600. The duties of the inspectors will be to pay frequent visits to all premises within their respective districts which are registered under the Act, in order to see that the provisions of the law and the conditions imposed by the Secretary of State are fully obeyed, and to carry out any other duties of inspecting, reporting, and advising with which they may be entrusted by the Secretary of State. They will be required to give their whole time to these duties. For the purposes of inspection England and Wales will be divided into two districts. The inspector for the Southern District will reside in London, and will also act as assistant to Dr. Thane, the Chief Inspector. The inspector for the Northern District will reside at a convenient centre within his district. The inspectors may as circumstances require be transferred from one district to the other or to Scotland. Candidates for these posts, who should be registered medical practitioners, should apply to the Private Secretary, Home Office, London, and their applications should be accompanied by any testimonials and evidence of their qualifications which they desire to submit.

Letters, Notes, and Answers.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

ANSWERS.

THE TITLE OF DOCTOR.

F. J. N.—Appended to the by-laws of the Royal College of Physicians of Ireland is the following resolution of the College:

That, in the opinion of the President and Fellows, a Fellow, Member, or Licentiate of this College may by courtesy and usage call himself "Doctor," but he has no right to use the letters "M.D.," or call himself "Doctor of Medicine," unless he holds that degree from a university.

LETTERS, NOTES, ETC.

PROVERBIAL MEDICINE.

DR. WM. BRAMWELL (Liverpool) writes: I was greatly interested in the article on the above subject, but disappointed that so little was said about diet as mentioned in Homer. The following quotation, though not a proverb, is a wonderful touch of Nature, and would be a sweet morsel for a temperance lecturer. It is Hector's rebuke to his mother because she offered him wine when he made that short visit to his home in order to induce his mother Paris to return to the valley—

Μῆ μοι οἶνον ὄρεε μελίφρονα, πότνια μήτηρ,
Μῆ μ' ἀπογοιῶσης, μενεός δ' ἀλκίης τε λάθουμαι.
(*Il.*, vi, 264.)

(Do not raise wine, that cheers the heart, to me, revered mother, lest this unnerve me, and I forget my might and my vigour.)

This reminds me of a very amusing incident in the life of the late J. B. Gough, the great temperance advocate, who, when lecturing at one of the universities, was confronted by a stalwart young athlete who went on to the platform armed with that passage in I Tim. v. 23, where St. Paul bids Timothy to take a little wine for his stomach's sake. Gough took a long look at him amid the roars of the undergraduates, and then said: "Gentlemen, look at this young man! Look at him! Look at his muscles! Look at his biceps! He has the strength to fell an ox, and yet he says he wants a little wine for his stomach's sake!" Needless to say, the incident ended in the complete triumph of the lecturer.

TREATMENT OF CHRONIC BRONCHITIS AND EMPHYSEMA.

DR. T. REUELL ATKINSON (Chadwell Heath) writes: Noticing a letter in the JOURNAL for February 1st from Dr. Read, giving his experience of the benefit he has received from the use of heroin and menthol pastilles, may I say that for several winters in succession I have had a winter cough which I dub "bronchial catarrh"? We all know how common this form of catarrh is in our climate and how difficult it is to cure. It comes on in the late autumn, and has generally lasted with me far on into the following spring. I have tried all sorts of remedies, including heroin, menthol, terpin, etc., but with very little relief. This season, when it once more returned, it occurred to me to try the inhaler made by Squire and recommended for consumptives. On it I used drops containing carbolic acid, creosote, tr. iodi, sp. etheris, and sp. chlorof. For two or three successive nights I wore it in bed, and also wore it at home during the daytime before and after my rounds. It cured the cough in a very few days, and I have had no return of it this winter. Of course the weather has been exceptionally mild, and this mildness may account for the disappearance of the cough in Dr. Read's case and in my own. But I have had the cough in other mild winters, and I incline to the belief that the inhalation cured it. The treatment seems sensible. I shall certainly try it another year if the cough returns. Patients, however, to whom I have suggested this line of treatment, have said they would prefer the cough.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|-----|
| Eight lines and under | ... | ... | ... |
| Each additional line | ... | ... | ... |
| A whole column | ... | ... | ... |
| A page | ... | ... | ... |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restante* letters addressed either in initials or numbers.

The Hunterian Oration

ON
HUNTER AND LISTER,

AND ON

THE MUSEUM OF THE ROYAL COLLEGE OF
SURGEONS OF ENGLAND.

DELIVERED BEFORE THE COLLEGE ON FEBRUARY 14TH,
1913,

BY SIR RICKMAN J. GODLEE, BART., M.S.LOND.,
F.R.C.S.ENG., HON. M.D.DUB.,
PRESIDENT OF THE COLLEGE, BTO.

GENTLEMEN,—The picture which on these occasions hangs over the head of the orator was, as is well known, painted under peculiar circumstances. John Hunter was urged to sit to Reynolds by his friends, and principally by Sharp the engraver, who, with strange prescience, foresaw that his engraving of the portrait would prove to be his *chef d'oeuvre*. But Hunter objected; he thought it almost as great a waste of time as he did only four years later, "when he fairly wished Sir Joshua and his friends at the devil when called on to take part in the funeral of this eminent artist and delightful author." Besides, he would not allow them to pay for it, and he had always more than enough use for his own money. At last, however, when he was 60 years old, he yielded. It is easy to imagine him—and with much sympathy—fuming and fidgeting in that great armchair, with the description of his specimens (on which he set great value, but which was burnt after his death by Sir Everard Home) at his side. Time after time the master tried to catch his likeness, but without success, and he was almost giving up in despair, when suddenly on Hunter's face came this rapt expression, as, with his mind fixed on other things, he ceased to be worried with his surroundings. Quick as thought the canvas was turned upside down, and between the original legs appeared this face, which even in the present cracked and faded condition of the picture has been the admiration of succeeding generations. We have been blamed for having allowed it to become so ruined, but possibly the way in which it was painted may partly account for the disaster.

Look at the picture! I have gazed at it, in season and out of season, for half a lifetime trying to guess what was the thought that calmed and possessed his restless mind. And now, at last, I seem to know. For one thought occurs again and again in all his writings, and speaks to-day from his museum to him who grasps the idea of its arrangement: *What is Life?* That mystery which baffled the intellect of the ancients and which still, *pace* Professor Schäfer, is awaiting solution. What is Life? And then I recall his strange formula, which haunts the memory like a sort of wild refrain, "*Body, Blood, and Motion!*" When the motion of the blood stops the blood dies; and then the body dies, some parts of it sooner, some later; but it dies, although there is no difference in its constitution perceptible to the senses. Truly as he observes, "mere composition of matter does not give life; for the dead body has all the composition it ever had. *Life is a property we do not understand; we can only see the necessary leading steps towards it.*"

We all admire the picture. But what would we not give to see for a moment the failures which still exist under the paint at the lower part of it? That would be a likeness of the real man such as we can only gather from hearsay.

LONDON IN THE TIME OF HUNTER.

If he were to slip out of his frame into our midst it would give us a shock to see, instead of that inspired philosopher, a sturdy, thick-set man in a brown, eighteenth century full-skirted coat and breeches, a bull neck, an underlump jaw, thin white hair that had once been red, and such an eager manner and such a sparkling eye! He could not have stepped into this theatre, for the place where our College stands was occupied by residences, except one part in the rear, where there was an old theatre giving on Portugal Street. But I can imagine

him crossing the open treeless square, with a pond in the middle, and making his way by Queen Street and Long Acre or the Strand to his house in Leicester Fields. He would hardly have ventured on a cross-cut through St. Giles's, for even in my young days it was a questionable district for respectable pedestrians. I think of the people he might have met; Dr. Johnson, blinking as he groped his way towards the Cock Tavern in Fleet Street; Fanny Burney, the novelist, bowing from her sedan chair to Edmund Burke or Wyndham; "Sir Roger" in his coach and four; Mrs. Siddons or Garrick stepping towards Drury Lane; the refined Percival Pott, his greatest rival, or Warren Hastings with his anxious face. And one might wonder that he is scarcely mentioned in the writings of Mrs. Montagu or Madame Piozzi, and that he does not seem to have mixed much with the distinguished intellectual circle whose names are still to us household words, if one did not think of the enormous amount of work which Hunter crowded into the forty-five years after he left Scotland at the age of 20, with no great reputation for diligence or application. I see the strange dress of the common people, and hear the noisy rumble of the huge wagons, and the "eries of London"—that little London of 500,000 or 600,000 inhabitants, which in 1740 did not extend beyond Old Street, Queen Square, and Portman Square on the north, "Tyburn Tree" and Westminster on the west, Mile End on the east, and was connected by two bridges only with the small borough of Southwark, enclosed by the upward loop of the river. It was like a great isolated country town, and from this square ten minutes' walk led to green fields and farms and streams and primroses and footpads. At Leicester Square his great yellow coach, which had crossed the drawbridge at the back of his house leading into Castle Street, would be waiting for him, and his coachman would drive off with his two bay stallions to his country house at Earl's Court. If Leicester Square was at all in the state I first remember it, it must have been a waste indeed. He would go down Coventry Street, looking much as it does now (though Regent Street did not exist), and along Piccadilly, then occupied only by the mansions of the great. Passing St. George's Hospital he would turn to the left down Bell Lane, now the Brompton Road, through fields with hedges and trees, till he reached his destination at Earl's Court, two miles from London.

Pictures of the house show it as a plain stuccoed villa, evidently built in stages, standing in grounds of moderate dimensions. It looks uninteresting, but we know that there were caves and dens of the earth, in which wild beasts were kept and from which they sometimes escaped; and coppers in which the skeleton of a giant could, if need arose, be quickly freed of its flesh. Other strange animals roamed about the park, and a stuffed crocodile hung, like a presiding saint, over the front door. Within were carried out all sorts of investigations; for it was to Earl's Court that he retired whenever he was able—too far from London for casual interrupters, but not far enough to miss calls of great importance or urgent necessity. There, no doubt, many of the preparations were made, if not mounted, which found their way into the Museum at Leicester Square.

HUNTER'S MUSEUM.

There is an engraving of No. 23 at the south-east corner of Leicester Square, and we can picture the front parlour and the study, and afternoon bedroom, and the print room, and the sedan chair standing in the hall. He bought the lease of this house and of one at the back in Castle Street, and between them he erected a building at a cost of over £3,000. On the ground floor were the great parlour for weekly meetings of his medical friends and a theatre for his lectures. Above it was the museum, lighted from the top, 52 ft. long and 28 ft. wide, with a gallery all round. The house in Castle Street was used for the different branches of human and comparative anatomy, for his printing press and publishing departments, and contained a sitting room for his students.

Let us try to think what this museum was like and why it was formed, for it seems strange for a busy surgeon to devote a large part of his house and a very large part of his life and nearly all his fortune to the formation of an enormous anatomical museum. One could not imagine

such a collection now in Harley Street or Cavendish Square.

In the first place, it must be borne in mind that Hunter was a man of phenomenal industry, whose mind was interested in everything to do with nature; to him the pursuit of natural history amounted to a passion—a passion that many of us can sympathize with, “for Nature never did betray the heart that loved her.” But it must also be remembered that he possessed in an almost exaggerated degree the mania for collecting, which is also a vice not quite unknown amongst my audience, who sit on Chippendale or Empire chairs, speculating on the works of the Old Masters. Another vice he had which is shared by too many of our profession. He only thought of money as a means for gratifying his ruling passion, and so he crowded his house with works of art, and his museum not only with specimens which illustrated his novel views of physiology, but with others interesting only from their rarity or beauty. He thought no more of spending £500 for the skeleton of the Irish giant, or buying a picture by Zuccarelli, or Hogarth’s prints, than is now thought of paying a thumping sum for a sixteenth century bronze; and though he took the keenest interest in his patients’ diseases, he looked at the “damned guinea” only as the means for enriching his collection; and so it is no wonder that he left little to his heirs besides this incomparable Museum.

But it must not be thought that this was a mere *omnium gatherum* of everything that came in his way—very far from that. It only needs to examine the specimens now in the Museum, all religiously distinguished by their two black figures, to appreciate that either he never put up anything except the best—which is not likely—or that, like a true collector, he eliminated all except the best; for they are nearly all of superlative excellence, and illustrate in a striking way the particular object for which they have been preserved—that is, the physiological or pathological process, not the mere isolated anatomical fact.

It is almost inconceivable when looking through Hunter’s posthumous papers that out of this apparent chaos such a definite plan could emerge as the groundwork of the Museum. One is lost amongst such subjects as the sociability of man and animals, the rising of animals, air in the bowels, the mind, fossils, or parts whose uses are not known. No one can attempt to summarize such a vast variety of material, but we may gather from Cliff’s catalogues, which were copied from Hunter’s manuscript and from Owen’s careful appreciation of them, the system on which the original museum was arranged. That, however, would be going over well-trodden ground, and I will therefore, though the prospect may seem dull enough, try to explain to what extent the arrangement of our present museum follows or departs from the plan of the master.

In an advancing science like ours too slavish a worship of the past could only lead to stagnation, and therefore some modifications have been made, although it has been the wise custom of the succeeding conservators to think twice or three times before such innovations were introduced.

If Hunter were really here to-day and asked how we had occupied our stewardship, in the first place I should be dreadfully alarmed, as being in the presence of a man endowed with many of the attributes I most admire without possessing, such as intense diligence, absolute exactitude, the power of abstraction and unlimited patience, and at the same time in that of a remorseless critic of the absence of those qualities in others. However, after invoking the support of our conservator and the two curators, who would admirably defend me, I should invite him to walk through our Museum. But first I should tell him that his collection waited in its original abode till 1800, when it was taken over by the College, and that during that time it was carefully watched over, kept clean, and dusted by his trusty assistant Cliff.

THE CONSERVATORS OF THE MUSEUM.

Cliff, it may be observed, was born in great poverty and was sent up from Devonshire by Hunter’s sister, and was engaged by him on February 14th, 1792, a year and a half before his death, without fee, to write and make drawings and dissect and take part in the charge of the museum. Poor faithful Cliff! He got 7s. a week for seven years

from Matthew Baillie and Home, and kept patiently dusting and cataloguing. At last, when the Government gave £15,000 for the collection, and subsequently £12,500 in addition, and the College gave £21,000 for the building of the first museum, he was made the first conservator. He held this post till 1842, when he retired on account of ill health, with a pension of £400 a year.

And here I should slip in the piece of information that the College has spent not less than £500,000 upon its construction and maintenance up to this time.

Cliff saw the incorporation of several other museums, such as those of Blizard, Astley Cooper, Heavyside, Brookes, Liston, Langstaff, South, Howship, and other famous surgeons. He had not brains enough to enlarge it himself, but he was sincerely devoted to the memory of his master—I had almost said he was an abject worshipper—and with the assistance of his son he got it into order for display and development by the more distinguished men who followed him.

The first of these was Richard Owen, a man of a different type, whose very aspect suggested cerebral hypertrophy. He was appointed assistant conservator in 1827, and full conservator in 1842. So he worked long with Cliff, married his daughter, and was thoroughly imbued with his father-in-law’s hero worship. He became a comparative anatomist and palaeontologist, and added many of those weird forms which now occupy the floor, glyptodonts and megatheriums, and the giant elk, and fossils by the gross. But his great work was the publication of the memorable descriptive and illustrated catalogue of the physiological series of comparative anatomy, to which department he made important additions. Owen’s was a stressful reign; for he could ill brook control, and the Museum committees were frequent and stormy. And so, great man though he was, he left, without a vote of thanks or regret, to take charge of the Natural History Department of the British Museum in Bloomsbury in 1856.

Then came Quckett, of the Quckett Club fame, who had been student dissector at the College and assistant curator since 1842. He was essentially a microscopist, one might say a born microscopist, for his father was one before him, and at the age of 16 he gave lectures on microscopical subjects, illustrated by a microscope he had made for himself out of a roasting jack, a parabol, and a few pieces of iron he had purchased at a neighbouring marine store. He added little to the Museum except a valuable microscopical collection, but he drew up a catalogue of the fossil organic remains of plants. He was, as his portrait indicates, a jovial man. He retired on account of ill health, and when he died at Pangbourne in 1861 he left a penniless and, alas, unpensioned widow.

And he was followed by Flower, a strong organizer and a born manager of men, whose graceful figure and handsome face many of us can remember. Under his peaceful rule dissensions ceased. He was, to begin with, assistant surgeon at the Middlesex Hospital, and served as surgeon in the Crimean war. He was appointed conservator in 1861 and stayed until 1884, when he succeeded Owen in charge of Waterhouse’s terra-cotta palace at South Kensington. He developed into a pure comparative anatomist and specialized in bones, and especially human bones. He amplified and enlarged Hunter’s osteological collection, and has left in it a memorial to his industry and skill to which I shall refer later.

A word of explanation with regard to the natural history collection must here be introduced.

There were no natural history museums in London before Hunter’s time. But the British Museum in its earlier days began to make such a collection. In 1809 they wanted to get rid of these specimens, and sold them to us for £180, but in 1814 they found they had made a mistake, and so we sold them back again, but by good fortune retained the Evelyn plates of vessels and nerves, made in 1642 by a professor in Padua under Evelyn’s direction, and given by him to the Royal Society, and by them to the British Museum. Dr. Keith has had them properly mounted, and they now have a prominent place allotted to them.

Hunter had a good many stuffed animals, but after obtaining a Royal Warrant, which is required before any of his specimens can be disposed of, they were sold or otherwise got rid of in 1829, 1834, 1843, and 1876;

including, alas! those collected by Captain Cook. It must be remembered that at one time we used to fit out exploring expeditions such as those of Captain Everard Hoone, Banks, Beechey, Franklin, Russ, Parry, and Darwin, with bottles and apparatus, and have now in our possession many of the specimens which they brought home.

When Flower left in 1884 he was succeeded by the amiable, retiring, laborious Stewart. Being a man of artistic temperament, he was attracted by such subjects as mimicry, symbiosis, and protective colouring. He was at first a teacher of physiology at St. Thomas's Hospital, but after his appointment here worked as a comparative anatomist. He extended Owen's rearrangement of the Physiological Series, which was not quite on Hunter's lines, as they both took rather the mechanical view as opposed to the physiological. A consummate draughtsman and a clear exponent, he made many discoveries which he was too indolent (may I say?) to publish, but they remain on the stands as silent but eloquent witnesses of his work.

And now I should tell Mr. Hunter that the mantle has fallen upon a thoroughbred compatriot of his own, and should feel confident that between them there would be illustrated the *action of the principle of universal sympathy*, except, perhaps, that there might be some incongruity between the northern accent of the one and that which used to be current in the neighbourhood of Long Calderwood. It would be necessary to add that under Dr. Keith's guidance, with the able assistance of the curators, Mr. Shattock and Mr. Byrne, we are trying our best to keep Hunter's spirit in view in all the changes which have been lately made and are still in prospect, and that "Body, Blood, and Motion," is our motto, and that to illustrate the processes of life is our leading idea.

These are the conservators, but it would be wrong not to mention some of the illustrious workers who, without holding that office, devoted much time and labour—often a labour of love—to the Museum. Pre eminent amongst them is Sir James Paget, who examined and elucidated so thoroughly, and wrote so much of the descriptive part of the catalogue; and besides his there are the names of Stanley, of Goodhart, and Doran and Eve, and men like Elliot Smith, who have added complete chapters to its story.

GROWTH OF THE MUSEUM.

Some idea of the way in which the Museum has grown may be gathered by remembering that no part of the original building remains. The room which was first erected in 1800 and completed in 1813, just a century ago, partly on the site of houses belonging to the College, partly on that of the old theatre in Portugal Street, occupied a position in the middle of the three existing galleries, and this was large enough to contain all the 13,682 of Hunter's specimens, including some which, as I said, have disappeared, as is shown by a very indifferent sketch, apparently of Clift's, in which the head of a giraffe, no doubt the one which in 1834 went with the other stuffed animals to the British Museum, appears looking out of the museum through the gallery into the Cabinet Room, whatever that may have been.

The Museum is now more than three times the original size, and contains 64,766 mounted specimens, and there are besides still unexplored stores to which constant additions are being made.

Some people may wonder why we try to keep adding to our invested funds. I say nothing about the uncertainty of riches, though that is perhaps more obvious now than when the phrase was coined. But I should like to point out that the Museum will continue to grow, and that we may some day wish to enlarge it, which would involve three things: Diminution in income from rents, loss of interest on capital expended, and increase in expenditure for upkeep.

The Museum now consists of three long rooms, two of which are parallel with one another, and the third at right angles to those, both the first and the third being divided into two parts. Roughly speaking, the last contains the Physiological Series, while the two others are devoted to Anatomy and Pathology; but there are other rooms to which reference will be made, and scattered throughout are curiosities which have to find places where they can. Here a huge skeleton of a whale floats, like Mahomet's

coffin, in mid air, and elsewhere are such unlikely objects as the clothes of a man stripped off by lightning, leaving him intact, or the initials—perhaps of two lovers—found on splitting a beech tree, healed over and buried beneath many annual rings.

A TOUR OF THE MUSEUM.

But it is really time to proceed with the proposed formidable inspection, and I would suppose that we begin by conducting Hunter through the door opening out of the Conservator's office into the smaller part of the eastern room, in the cases round the walls of which is the commencement of the series of comparative osteology.

He would gaze with astonishment at the group of vast fossil skeletons, and might possibly ask us what they had to do with his Museum—a question which might at first seem hard to answer. But the great black statue of Owen in the corner would remind us that in 1855 he gave some lectures in this theatre on Hunter's published and posthumous papers on fossils, and that he showed by many quotations that Hunter began to hold almost modern ideas about geology and palaeontology as early as 1761, when he was serving with the army in Portugal. The story of Noah's deluge had not satisfied Leonardo da Vinci and Fracastoro in the fifteenth century, but it still hampered the thoughts of scientific men of the eighteenth century. It was therefore remarkable that Hunter was able to emancipate himself so completely and, to quote from Owen, to recognize "first, the effects of running water as in valleys and river courses; secondly, the deposition of the matters so transported to the sea, noting the different distances to which such transported matters would be spread over the sea bottom, according to their size and other physical characteristics; thirdly, the erosive action of the sea on coasts, as moved by tides, currents, and winds; fourthly, the power and mode of operation of a retiring sea on a rising land; fifthly, igneous expansive force and volcanic eruptions; and sixthly, deposits through animal or organic agency."

This includes almost every agency of geological dynamics recognized at the present day, except that of ice, and was arrived at "by supposing from the state of the earth as it is now what must have taken place formerly." From this standpoint Hunter seemed to have an inkling of the origin of species and the gradual evolution of life, and was able to contemplate in some measure the antiquity of man. Thus, it is fitting that (presided over by Owen) these horrid monsters should guard the portals of our Museum, and that Hunter's 2,773 fossils should be lodged, with his invertebrate specimens, in a special place of honour.

So we should turn to the left and tell him that the crowd of vertebrate skeletons in the next room, among which he would recognize many of his own favourite preparations, should really be in the cases along the walls, only unfortunately they are too large. These cases contain the continuation of the comparative osteology series. In passing we should point out Flower's magnificent preparations illustrating the evolution of the individual mammalian bones. On our way up to the galleries it would be explained that leading out of them are the new rooms added last year, containing a collection of surgical instruments, the embryo of a medico-legal collection, his own invertebrate collection, and the fossils to which I have just referred. And then in the galleries he would find his own physiological series amplified and enlarged. We should show them with confidence, tempered by the fear that he might impatiently resent certain modifications of order and arrangement, though he could not fail to recognize that the *idea* had been grasped. We should point out that the physiological series still illustrates processes rather than isolated facts, and is, therefore, drawn from the whole range of comparative anatomy. Thus, taking as an example the heading "Kidney," he would find specimens from 133 animals other than man, no less than 71 out of the total 144 being his own; and that the same thing is carried out under the other headings.

In order to grasp the plan on which the whole museum is arranged it would then be best to visit the ground floor of the eastern rooms. Beginning with the cases on the walls, we should find illustrations of normal (and, it must be owned, some abnormal) varieties of humanity, amongst

which Byrne, the Irish giant, would be a familiar object. There are skeletons of dwarfs, of average men and women, and of geniuses and of criminals; and then we should start on the splendid collection of skulls illustrating ancient and modern types and examples of those of all the races under the sun, present and extinct. This fills up both sections of the room and a considerable part of the middle room.

The floor of the eastern rooms is devoted to specimens illustrating human anatomy. First, the collection of disarticulated bones in progressive series, showing their development from early fetal life to maturity; and then dissections, which are said to be unequalled, mostly made by the skilful hands of Mr. Pearson, who has been prosector here for fifty-six years.

The Pathological Section.

And now there would be left only the pathological section, to which it would be my duty and my pleasure to especially invite the attention of my guest, as I now do that of my audience.

Hunter's catalogue of this part of his collection was left in considerable confusion, but it is clear that his idea was to divide it into two main groups, one illustrating processes of general pathology, the other the various morbid processes affecting particular organs. This has long been before the minds of those who have had charge of the Museum. But it is only during the last year that the Council has made arrangements for a full display of specimens illustrating general pathology.

The floor space of the central room has been cleared in a way it is needless to describe, and if it were only possible to find a better home for the suspended skeleton of the whale, uninterrupted daylight would illuminate groups of glass and gun-metal stands so arranged that they can be observed from all sides, labelled and supplied with handy card catalogues, and following one another group by group in the following order:

- | | |
|---|-------------------------|
| 1. Hypertrophy. | 5. Degeneration. |
| 2. Aplasia. | 6. Necrosis. |
| 3. Hypoplasia. | 7. Repair and grafting. |
| 4. Atrophy. | 8. Inflammation. |
| 9. Infective diseases: | |
| <i>Bacterial:</i> Glanders, Acute Endocarditis, Diphtheria, | |
| <i>Tubercle, Leprosy, Actinomycosis.</i> | |
| <i>Protozoal:</i> Syphilis, Tropical Diseases, etc. | |
| 10. Cysts. | |
| 11. Tumours. | |
| 12. Foreign bodies. | |

I have placed upon the table a few Hunterian specimens in order to show that it has not only been possible but highly advantageous to use them for this purpose. You will observe what remarkably fine preparations they are.

- | | | |
|---|-----------------|---------------------|
| 1. A ringed stem to illustrate | ... | Hypertrophy. |
| 2. An edentulous jaw to illustrate | ... | Atrophy. |
| 3. Atheroma of the aorta to illustrate | ... | Degeneration. |
| 4. Experimental necrosis on the metatarsal bone of an ass to illustrate | ... | Necrosis. |
| 5. A hare-lip cured | } to illustrate | Repair. |
| 6. A fractured clavicle | | Grafting. |
| 7. A cock's spur implanted in the comb to illustrate | ... | Inflammation. |
| 8. Myositis ossificans | } to illustrate | Inflammation. |
| 9. Necrosis of skull following a scalp wound | | Inflammation. |
| 10. Tubercle in the lung of an ox | } to illustrate | Infective diseases. |
| 11. Specific necrosis of the skull | | Infective diseases. |
| 12. Gas cysts in a hog's gut to illustrate | ... | Cysts. |
| 13. Secondary sarcoma of rib to illustrate | ... | Tumours. |
| 14. Gunshot injury of humerus of swan to illustrate | ... | Foreign bodies. |

It would have been impossible in Hunter's time to make so complete a list as this because the great group of infective diseases would have been simple and unanalysed. If he had possessed a knowledge of bacteriology it would have saved him a vast amount of fruitless speculation, or at all events speculation which now seems to be disappointingly beside the mark. I think he would have lingered long over this department, for I hope it has been made clear that what has just been said is intended to be the kernel of my address: that this exhibition of illustrations of general pathology though a new departure, is Hunter's idea, and that it is not only new but good and,

as far as I know, unique. I would, therefore, urge my hearers to visit and study it and judge for themselves of its utility and interest and of the skill of those who have brought it together.

The tour of the Museum would be completed by visiting the galleries of the central and eastern blocks, where the specimens are arranged according to the organs affected. In ascending to them it would be pointed out that a staircase descends to the basement in which is housed our unequalled odontological collection, where amongst the specimens which came to us from the Odontological Society are Hunter's own classical preparations.

And now I should bid my guest adieu, feeling, if not saying, that while in his writings there may be some things hard to be understood, here in our Museum is recorded in unmistakable language the record of thoughts and ideas that it is impossible to misapprehend.

SUGGESTED ANATOMICAL AND PATHOLOGICAL INSTITUTE.

Thus, in an imperfect way, I have tried to show what the Royal College of Surgeons has done, and hinted at the certainty that some day the Museum will have to be enlarged. Now let me put before you a vision of the future. Ought not this great city to have an Anatomical and Pathological Institute? Our university has again, by collision, passed into the nebulous state, and we know not in what form, nor, indeed, in what orbit or orbits it may finally revolve. It may be anticipated with confidence that it will emerge as a life-supporting globe or double star with a more equable temperature than at the present moment. Money is to be had for proper asking, and a site is generally obtainable when it is required. Can you not see such a noble institute close at hand, forming a part of a really living university, and also in close connexion with our College, attracting workers from all over the world, to utilize the vast material the Museum contains? It would strengthen the feeble bonds which at present unite us to the university, and supply a long-felt want of the medical faculty. It would offer opportunities for original research in human and comparative anatomy and in pathology; and in its theatre lectures on advanced subjects would be delivered *urbi et orbi*.

RECENTLY DECEASED MEMBERS OF THE COUNCIL.

The terms of the bequest under which these orations are given instruct the speaker that "such oration should be expressive of the merits in Comparative Anatomy, Physiology, and Surgery, not only of John Hunter, but also of all such persons, as should be from time to time deceased, whose labours have contributed to the improvement or extension of Surgical Science."

This would be an impossible task, for the whole world is apparently included in the purview; but according to custom, and by inclination, I must say a few words about two friends and colleagues on the Council whose vacant places we must deplore.

Clinton Thomas Dent, an all-round original and successful surgeon at Hunter's own hospital, was Vice-President at the time of his unexpected death last summer. He had no specialism in medicine, and he will rather be remembered by his numerous friends for his many-sided character, multifarious attainments, and sterling worth than for striking additions to surgical practice or literature, and yet his contributions to them were neither few nor unimportant.

Sir Henry Trentliam Butlin, my immediate predecessor, on the other hand, was well known as a surgical pathologist, whose chief labours were devoted to the treatment of, and the elucidation of the cause of, cancer, a subject to which it may be said he devoted his last breath. Those who can recall this day four years ago, when his oration was delivered in perfect English and without a note, will agree that he was a finished orator. We on the Council knew him as an admirable man of business, who wisely conducted the affairs of this College, as a man of the highest integrity, a pleasant companion, and a faithful friend.

COMPARISON OF LISTER AND HUNTER.

But beyond and above all the other leaders, or men in the ranks, who have passed away during the last two years, is Lister, who by common consent is the greatest—that is, the most thoughtful and original—surgeon since Hunter's time, one who more than any of his predecessors

was influential in revolutionizing both the science and the art of surgery. It is not the occasion to enter upon a survey of Lister's work, but it may be interesting to consider the influence that Hunter had upon him, and briefly to compare the two men.

The first time I heard the name of John Hunter was in my youth during one of Lister's vacations, which he often spent at his father's house. The subject he was describing is forgotten, but the name impressed itself upon my young memory, and many a time in after-years have we, who were closely associated with him, heard this name recalled with reverence and admiration. Occupying a prominent place in his study was Sharp's engraving, bequeathed to him by Mr. Syne, and now my treasured possession, as is also the edition of Palmer's *Life*, which is marked in many places. These passages show that Lister was studying this book at the time he was making his early observations on coagulation of the blood. Indeed, a precise date may be fixed by a pencil note to the account of "a gentleman with violent inflammation in one of his eyes and whose blood was extremely sily, though the coagulum was very loose." The note is, "No excess of fibrin in this buffed blood apparently. J. L. /58." Other remarks are opposite references to inflammatory fever; the principles of bleeding, and especially their possible dependence upon continuous sympathy; and local diseases cured by sympathy, as by the application of an irritating medicine applied to some other part which this diseased part sympathizes with. There are several in the lecture on aneurysm; indeed, there are exclamations marks opposite some references to hydrostatics. And similar annotations are met with in the lecture on fistula and elsewhere.

It might be wondered what were the points of attraction between men in many ways so different. Certainly Lister possessed none of Hunter's mania for collecting. He had, indeed, what he called his museum, one or two bread-pans containing specimens, no doubt of great value, and familiar to the succeeding generations of attenders at his lectures. But his shelves and cupboards were filled with more transitory things—flasks and test tubes, and the materials for experiment. Lister bought no costly works of art, and was content with early or late Victorian furniture; and though he often adopted Hunter's generous but confusing method of leaving the amount of the fee to the patient's decision, he did not spend the proceeds in the same reckless way.

The points in Hunter's methods which Lister seemed most to admire and adopt were, first, that he appears to have taken nothing for granted. No matter how revered the teacher, how sacred the tradition, Hunter and Lister both asked themselves whether the evidence was sufficient to support the theory or warrant the treatment. Perhaps they would not have liked to be called sceptics, but in scientific matters they were, and it is the only safe position for a scientific man to adopt, though it may not indicate the path of worldly wisdom to the practitioner.

Illustrations might be given in Hunter's operation for aneurysm, or his observations on fistula in ano, or in Lister's amputation of the thigh, his excision of the wrist, or his methods of treatment of varicose veins or hydrocele. But there is no need to multiply examples. The whole story of Lister's discoveries and of the modifications in ordinary surgical practice which he introduced testifies to the truth of this assertion.

But, secondly, the most striking resemblance between them is their habit of referring everything to experiment. Their lives were occupied in testing by means of experiment every problem that presented itself. They were, indeed, both of them, ideal inductive philosophers.

It seems in some quarters to be considered that an inductive philosopher is debarred from framing for himself hypotheses, but this I conceive is not the case. Did not Bacon himself say, "Vaga experimentia mera palpato est"? Such an idea would seem to imply that the followers of that great thinker experiment at large, and only accept the results of those promiscuous excursions. The difference, however, between them and the deductive philosophers is that the latter found their creed on deduction from unverified postulates, whereas the former require proof of the correctness of the premisses before they complete the syllogism. No great Baconian can get on without

hypotheses, but he is ready to reject those that are not supported by his experiments. Are not Pasteur and Darwin proofs of the truth of this statement?

There is an interesting appreciation of Hunter's character in Buckle's *History of Civilization in England*. Buckle is almost labouring the point that the trend of thought in Scotland in the eighteenth century was deductive and that in England inductive, and is arguing that Hunter was a sort of hybrid.

When John Hunter arrived in London, in 1748, Newton had been dead more than twenty years, and the English people, absorbed in practical pursuits, and now beginning, for the first time, to enter into political life, had become more averse than ever to inquiries which aimed at truth without regard to utility, and had accustomed themselves to value science chiefly for the sake of the direct and tangible benefit which they might hope to derive from it.

That Hunter must have been influenced by these circumstances will be obvious to whoever considers how impossible it is for any single mind to escape from the pressure of contemporary opinion. But, inasmuch as all his early associations had inclined him in another direction, we perceive that, during his long residence in England, he was acted on by two conflicting forces. The country of his birth made him deductive; the country of his adoption made him inductive. As a Scotchman, he preferred reasoning from general principles to particular facts; as an inhabitant of England, he became inured to the opposite plan of reasoning from particular facts to general principles.

It is rash to differ from so great an authority, but, as a matter of fact, did Hunter really get his mind down on methods of reasoning and such abstruse questions during his idle youth at Long Calderwood, when he cared much more for country sports than for books, or whilst helping his convivial brother-in-law, Buchanan, in his carpenter's or wheelwright's shop? Did he even acquire from his surroundings or by inheritance any method of ratiocination? I think not. And if Scottish influence had anything to do with the formation of his mind it must have come from his brother William. But, in reading much of his writings and in trying to assimilate the spirit in which the Museum was planned, I feel that Buckle has overstated his case, and that Hunter was essentially an inductive philosopher.

And so was Lister. His whole life was made up of experiments. Any time that could be freed from practice or unavoidable public and private duties was spent in his study, investigating for himself such subjects as the coagulability of the blood, the growth of micro-organisms, the properties of antiseptic substances, blood pressure, and so forth, and it is interesting to notice how he called in aid for the solution of his special problems a well-grounded knowledge of botany, zoology, chemistry, and physics, subjects of which it is becoming too much the habit nowadays to minimize the importance.

But there are fundamental differences between them, of which the most important (to speak with all respect) is that Hunter's work is the more diffuse. He seems to fly from one subject to another, as if he were unable to resist the temptation to investigate everything that came in his way. It is as though what has been referred to above as the spirit of the collector inspired his more serious work, and so he has left a record of an almost incredible number of problems either completely or partially elucidated.

Lister, on the other hand, did not yield to this temptation if he felt it. Starting on the narrow path upon which Providence had placed him, he followed it till it broadened and straightened out into the great highway that led him to his goal. Not that he denied himself the pleasure of occasional explorations of tempting by-paths, but what he gained from these excursions was always utilized to corroborate and support him upon his journey. And thus it comes about that Lister's fame rests chiefly upon the one great achievement of his life, whilst the lesser and more subsidiary ones are by many forgotten or ascribed to others; whereas it is difficult to mention one or even a few of Hunter's labours which stand out in glaring predominance above the rest.

Of less importance, but equally striking, are the differences between them in temperament, culture, and manners. Hunter was imperfectly grounded in general education, a small reader, abrupt, not to say rough, in his conversation, which was flavoured with a full share of the impetuous vocabulary of the eighteenth century. Though generous, he was impatient; though on the whole a good

friend, he was somewhat inconstant; and his mind was so fully occupied with his work that more solemn subjects had no chance of consideration.

Lister's mind was well stocked with classical and other learning, and his library was lined with carefully studied books. He was gentle and courteous, and though full of humour he could not abide even those relics of coarseness which survived in "polite conversation" in the nineteenth century. He was always ready to make allowance for the incompetence of those who did their best; he made no enemies, and his position as regards more serious matters was a very different one from that of his great predecessor.

Both, however, were fond of argument, and neither in the course of it could easily brook opposition. Verily it is a matter of thankfulness that they lived at different epochs. It is well that Lister was able to contemplate Hunter's many great qualities and his few obvious defects through the modifying mists of the intervening years.

CLOSING REMARKS.

I have spent the last year in an atmosphere premeated by the spirit of John Hunter; I have had the privilege of passing the best years of my life in the closest intimacy with Lister, and I often ask myself in what way a genius surpasses the average man. After a day passed in the company of such a one, and after meditating on any particular thing that he did, the ordinary man might fancy that there was nothing in it he could not have done equally well himself; and yet the life's performance is so different! The individual touches of the brush might conceivably be made by anyone, but only the artist can produce the picture. That, of course, depends upon the master mind which co-ordinates the details, making them minister to the result. We cannot attain to that, and it is the consciousness of this superiority of the great that makes the position of ambitious mediocrity so painful. But though we cannot reach to the height of Lister or of Hunter we may make our lives more useful by imitating their extreme diligence, their accuracy, and their habit of finishing whatever they were engaged upon before turning to the next matter; by not shirking the long days of labour and nights devoid of ease, or spending too much of our time on pleasures and indulgences.

The problem of life to Hunter was the still unsolved riddle of its meaning and of its origin. Lister was content with the belief that at the present day there is no spontaneous generation. Had he doubted the truth of this doctrine he might possibly have had misgivings as to the truth of the gospel that he preached. Fortunately he did not doubt, for he was a man of firm convictions.

But after all, whether chemical changes are now and always converting dead inorganic substances into living protoplasm is, for practical men, no more important than the more abstruse question as to whether matter is composed of atoms or vibrations. Life for us has another meaning; whilst the blood is moving in our bodies, as John Hunter said, we have life, and the problem for us, taking him for an example, is not simply to keep alive, but to live well.

Nicht dass man lebe, sondern wie,
Ist Mannes würd'ges Streben;
So lang mir Leben Gott verlich,
Will ich's lebendig leben.

THE De Dion Bouton (1912) Company will send in response to applications addressed to 10, Great Marlborough Street, London, a pamphlet giving "owners' opinions" of their 14, 15, 18, 24, 25, 26, and 30-h.p. cars.

VEDDER, in an interesting article on the etiology of beriberi (*The Philippine Journal of Tropical Medicine*, vol. vii, Sec. B, No. 4, 1912), states that the administration of large amounts of alcohol has not produced neuritis in fowls. Fowls develop polyneuritis when fed on a diet containing a sufficiency of all the alimentary principles, providing no one of the ingredients of this diet contains the neuritis-preventing substance. This neuritis-preventing substance is not volatile, but is destroyed by heat. It is not an inorganic salt, and probably not an alkaloid. Since it has been shown that this substance is not a fat, protein, inorganic salt, or alkaloid, it seems probable that it is an organic base, as claimed by Funk, but Vedder so far has been unable to confirm this.

ACHES AND PAINS CONNECTED WITH THE EYE AND NOSE.*

By CECIL E. SHAW, M.A., M.D., M.Ch.,
LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN QUEEN'S
UNIVERSITY, BELFAST.

In a society accustomed to listen to deeply scientific papers, some apology seems necessary for bringing forward such a commonplace subject as aches and pains. My excuse is that after twenty-five years of work at the eye, it is more profitable to give the result of experience, and leave original scientific theories to younger men. Besides, commonplace though my subject is, it is one of great importance, for such pains not only call aloud for relief, but in many cases their exact location and character may give us valuable help in diagnosis.

I do not know of any natural classification of pains, so shall first consider the more acute pains, and then the chronic aches, and especially headache.

1. *Pain in the eye itself*, increased by every movement and accompanied by redness and watering, is often due to a foreign body in the eye, even though the patient is not aware of having got such. The commonest place of lodgement is under the upper lid, which must be everted to see it, or on the cornea. If the particle is a small piece of grit in the cornea it may not be visible except by focussing a strong beam of light from a lamp or candle sideways on the eye with a lens.

2. *Sharp neuralgic pain*, coming on every night for weeks or months and hindering sleep, is not uncommon. It is not only in the eye, but around it, and shoots over the top of the head and down the side of the nose, and may affect one or both eyes. Such pain points to chronic iritis, and is important to recognize if vision is to be saved. It is often mistaken for neuralgia, but in the latter there are the typical tender points, while in iritis there is generally to be seen, on careful inspection, a slight pink blush in the sclerotic round the cornea—that is, ciliary injection, which points to deep-seated disease of the eye. In many cases the eye is tender on pressure over the closed lids. The pupil is fixed, and often partly blocked with lymph, and vision is more or less affected. Such cases often occur in apparently healthy young adults as the result of syphilitic infection.

3. *Acute Iritis*.—A somewhat similar, but often more severe pain, coming on with marked signs of irritation—injection, photophobia, and lacrymation—and a dull muddy look in the iris, with contracted pupil and little or no loss of vision, indicates acute iritis, commonest in young adults. It is easily mistaken for simple catarrhal conjunctivitis, in which there may be similar signs of irritation, but the diagnosis is made by observing that the pain is worse in iritis, and is not confined to the eyeball, and also in iritis the pupil is sluggish or immovable. Further, in conjunctivitis there soon appears a sticky secretion, which is absent in iritis.

4. *Acute Glaucoma*.—The same acute pain and irritation, coming on suddenly in a person over 50, with dilated pupil and great loss of vision, indicates acute glaucoma. In this case the pain is proportionate to the vascular disturbance, and may be agonizing and accompanied by vomiting. The loss of vision is far greater than in iritis; in very acute cases even perception of light may be lost in a few hours. The condition is not, properly speaking, an inflammatory one, but is congestive like strangulated hernia, and unless quickly relieved it leads to permanent loss of sight.

5. *Gout in the eye* is not common, but it is well to remember that it may occur, and be very alarming. It comes on suddenly at night with great pain in the eyeball, which is acutely congested and irritable; but the pupil is clear and moves freely, and vision is not affected. The pain may pass off in a few hours and the other symptoms soon go, but the attack may soon return, or may be succeeded by typical gout in the toe.

6. *Sphenoidal Sinusitis*.—A very severe bursting pain, generally described as in the middle of the head, but sometimes shooting up to the ears, with marked constitutional symptoms, is caused by suppuration in the sphenoidal sinus, and less severe but still marked neuralgic pains

* Read before the Ulster Branch of the British Medical Association.

arise from acute conditions in the other sinuses—probably accidental blocking of discharge in a chronic inflammation of the sinus, as they are often relieved by painting or spraying with adrenalin. Suspicion should be directed to the nasal sinuses by the fact that there is commonly a history of severe influenza recently, or of long-standing nasal trouble, with crusts of dried pus in the nostrils, and perhaps an offensive smell. Pus from the sphenoidal sinus finds its way into the pharynx and not into the nostrils, but it is seldom that one sinus alone is affected, and there is pretty sure to be suppuration in some of the other sinuses—ethmoidal, frontal or maxillary—discharging into the nostrils. Acute symptoms are, however, comparatively rare in these cases, and chronic headache, to be discussed presently, is far more frequent.

7. *Malignant Disease.*—Constant or frequently recurring pains, rather vaguely localized about the back of the nose and shooting up into one or both ears, especially if occurring in an elderly person, call for careful examination, as they may be due to malignant disease. In some such cases pain is an early and prominent symptom, but on the other hand it may be entirely absent. I have seen a case of carcinoma in the posterior wall of the naso-pharynx, spreading its roots, apparently, in the bodies of the cervical vertebrae, and running to a fatal termination, quite painless from first to last.

Headache.

Coming now to some forms of headache, there are two due to nasal disease which often escape detection for long periods.

8. Hypertrophy or cystic enlargement of the middle turbinated bones is, I believe, a fairly frequent cause of headache in young adults. This hypertrophy is different from the hypertrophy of the inferior turbinateds seen in children and young people associated with adenoids. The headache may be a dull frontal one, with a feeling of weight or tension about the bridge of the nose, and sometimes a little redness of the skin there also. It comes on in the afternoon, and is made worse by heat and damp. I have more than once heard from country patients sad complaints of their inability to enjoy the social attractions of a "swarry" owing to the headache brought on by the atmosphere of the hot and crowded room. In such cases, if one paints the inferior turbinated bones with a little cocaine and adrenalin to cause the mucous membrane to shrink, one will see the middle turbinated bones, large, rounded, and smooth, pressing against the septum.

9. Chronic suppuration in the accessory sinuses is, as mentioned above, a frequent cause of headache. In some at least of these cases the headache is not due to the direct local influence of the diseased tissue, but to the circulation of toxins in the blood. My reason for this belief is that in cases of chronic sinus disease which have run on for years without treatment, one sees that the skin is a very unhealthy colour—a dirty yellow. After a few weeks of treatment, during which the pus has been washed away instead of being swallowed, the change may be most striking; the skin becomes clear and rosy, and at the same time the headache disappears. Sinus disease most frequently arises from influenza, except in the maxillary sinus, where it often arises from the teeth. If the maxillary, frontal, or anterior ethmoidal sinuses are affected, the pus will appear in the nostrils, which will be filled with dirty yellow crusts very hard to get rid of; if the posterior ethmoidal or sphenoidal sinuses are affected the pus will drain into the naso-pharynx, where it is seen in sticky yellow strings or dry flakes.

10. The severe and continuous headache which is caused by tumours, gummata, etc., in the brain has no direct connexion with the eyes, except that the occurrence of such severe headache calls for careful examination of the optic discs. If the sharp outline of either disc is blurred and its vessels overfull, it is probably due to a beginning papillitis, and is strong evidence that the headache is due to a new growth. Papillitis occurs in about 90 per cent. of brain tumours, both it and the headache being due to increased intracranial pressure.

11. The last ache which I wish to notice is the headache arising from errors of refraction, especially from astigmatism; and this, in my experience, is far the commonest cause of headache. In 1,000 consecutive eye cases in my private practice, I find that 45 per cent. came on account

of some inflammation, degeneration, or injury of the eye, while 55 per cent. came on account of errors of refraction, 40 per cent. astigmatism, 10 per cent. hypermetropia or presbyopia, and 5 per cent. myopia. This may seem a high percentage of astigmatism, but it is to be remembered that where the error is a simple spherical one it is often passably corrected by glasses picked up at an optician's, whereas astigmatism calls more loudly for thorough examination and treatment.

Astigmatism.

Almost every case of astigmatism suffers from headache, not generally very severe—and, indeed, it has been said that the more severe a headache is the less likely it is to be due to the eyes. But headache due to eyestrain is very constant and wearing, often coming on at the same hour daily for months without intermission, except perhaps on Sundays and holidays, when the strain is less; and such intermissions should always direct attention to the eyes. In other cases headache only comes on when something has affected the general health to some degree. As Dr. Berry of Edinburgh says, overexertion of the eyes when the nervous system is below par is far the commonest cause of ocular headache.

It is to be noted that it is specially the low and not the high degrees of astigmatism which give rise to headache; this is probably owing to an involuntary but very tiring effort of the ciliary muscle to correct the slight astigmatism by irregular contraction. Such low degrees of astigmatism are compatible with fairly good sight, so often pass undetected when vision is only roughly tested. One sign may be noted as hinting at astigmatism, and that is that the patient reads several of the smaller lines of test type incorrectly. With hypermetropia or myopia it is common to see a patient read down to a certain line, say $\frac{1}{2}$, correctly, then stick. But with a slight degree of astigmatism he may read $\frac{1}{2}$, $\frac{5}{8}$, and $\frac{3}{4}$ all incorrectly, making mistakes in every line. If asked about his sight he says it is excellent, and is quite surprised to find that it can be improved. Some years ago one of our champion golfers came to me saying that he thought he needed glasses for office work. He had slight astigmatism, but said that he had splendid sight for distance, and was very sceptical when told that glasses would help him even out of doors. However, he agreed to try them, and shortly afterwards told me that he could follow the flight of a golf-ball as he had never done in his life before.

Not every astigmatic person needs to wear glasses constantly, and often they are only necessary for reading, writing, and other near work. But where headache is troublesome it may be necessary to wear the glasses all the time; and this brings me to a point I wish specially to emphasize, which is that the correction of errors of refraction is not a mere mechanical affair, and should not be entrusted to the optician. The patient's age, occupation and state of health, and the difference between the two eyes, if any, have all to be considered. Last month, for instance, I saw a girl who is at a boarding-school in a country town in Ulster. Her sight was poor and she needed glasses, but on inquiry I found that she was working nine and a half hours daily, and that on very Spartan fare! It was necessary not only to attend to her eyes, but also to open her mother's eyes to a sense of the situation.

If time permitted I might discuss many other aches and pains, but I have discussed only the more frequent and important, in the hope that these notes will give a basis of discussion to the experienced, and possibly may be of some help to the beginner.

THE net personalty of the estate of the late Dr. C. Theodore Williams has been sworn at £118,798.

THE firm of E. Leitz (18, Bloomsbury Square, London) have recently issued a guide to photomicrography primarily prepared for users of apparatus made by the firm, but discussing also general principles. Among the subjects dealt with are the selection of a place for setting up the apparatus, the mode of photographing solid objects, and the method of obtaining stereoscopic photographs. Photographic details are well discussed, as are also the preparation of lantern slides and cinematograph pictures. The firm has also issued a pamphlet giving directions for the use of the large metallurgic microscope with camera for the study of metals.

TUMOURS OF THE ORBIT: A PLEA FOR OPERATION.

By SIR WILLIAM COLLINS, M.S., M.D., B.Sc.LOND.,
F.R.C.S.ENG.,

SENIOR SURGEON TO THE ROYAL EYE HOSPITAL, LONDON.

THE orbit is territory upon which the ophthalmologist and the general surgeon meet. Growths in that region may be held to fall within the sphere of activity of both, and are sometimes renounced by the one in favour of the other. Their pathology and classification are not thoroughly elucidated, and their treatment is often, I think, not too satisfactory. I am not alluding to simple tumours such as exostoses or dermoid cysts, which are not infrequent in this region, but to vascular and malignant growths, which, though relatively rare, are not so uncommon as some writers would have us believe; nor, in my experience, is the outlook, if treated by operation, so gloomy as the statistics vouchsafed by some authorities would seem to imply.

To illustrate my meaning I will cite the following cases on which I have operated, several of whom had been previously advised that the risks of the operation itself were so great or the liability to early recurrence so considerable that surgical intervention was discouraged, or even strongly discountenanced.

CASE I.

Mrs. B., aged 65, admitted to a private ward in the Royal Eye Hospital on September 26th, 1910. There is a small hard nodular swelling about as big as a filbert to be felt at the orbital margin of the left malar bone. It is firmly planted and feels as if it were continuous with further growth which the finger detects on firm pressure between the bone and the globe. The swelling was first noticed six months ago, and of late has been increasing in size. The eye is displaced upwards and inwards and there is diplopia, most marked when looking down and to the left. There is no pain. Breathing through each naris is normal, but the left antrum appears to be more opaque than the right on transillumination. The finger detects no swelling in the naso-pharynx and the maxilla does not seem distended or enlarged. Vision, right eye $\frac{3}{6}$, left eye $\frac{5}{6}$ +1.75 D. Fundi normal except that the left optic disc is somewhat redder than the right. Pupils equal and react normally. There is some ulceration of the septum nasi on either side, but there has been no epistaxis. There is a systolic aortic bruit, and there is evidence of osteo-arthritis in the interphalangeal joints. Urine: Specific gravity 1018, acid, no albumen or sugar. Operation had been disavised. On September 28th, in the presence of her medical attendant (Dr. Salt), the patient was placed under chloroform, and Sir William Collins made an incision through the lower eyelid exposing the tumour, which had the appearance of a periosteal sarcoma. The eye was excised, the growth freely removed by the elevator, scissors and forceps; and all the soft contents of the orbit were carefully cut away. The orbital plate of the superior maxillary bone and the orbital surface of the malar, whence the growth sprouted, were scraped clean. Zinc chloride and opium paste spread on strips of lint was then packed lightly into the orbit in apposition to the bony surfaces but not so as to come into contact with the eyelids, which were spared. The incision in the lower eyelid was sutured. The skin was smeared with eucalyptus vaseline. The patient bore the operation well, and convalescence was uninterrupted. The $ZnCl_2$ strips were removed on the evening of the second day leaving a desiccated bony surface all round. The patient left the hospital on October 10th.

P.S.—I had satisfactory reports of the patient during 1911 from Dr. Salt, and in June, 1912, I saw her. The orbit is perfectly healthy and there is not the slightest evidence of any recurrence. Some of the ethmoid cells are exposed at the upper and inner part of the orbit, but they give no trouble.

In June, 1912, I again saw this patient. She was in excellent health and perfectly free from any recurrence.

CASE II.

Mary M., aged 32, married, one child 3 months old. Father and mother alive and well, and four brothers and one sister also in good health. Patient has old hip disease, left, and wears a high boot. No history of phthisis.

Seven years ago she was a patient at the London Hospital for a tumour on the outer part of the right upper eyelid, which was removed. There has, however, always been some swelling in the same spot.

On July 27th, 1907, she was admitted into the London Temperance hospital under Sir William Collins with an irregular, prominent, tense, elastic, well defined, painless swelling at the upper and outer margin of the right orbit, as large as a walnut. It is firmly fixed to the bone, and the skin glides freely over it. The globe moves normally and is not displaced by the swelling. There is some ptosis. The vision of each eye is $\frac{5}{6}$ and J.1.

On July 29th, 1907, under $CHCl_3$, Sir William Collins cut down in lacrymal region, and with elevator prized out the tumour,

which was cystic in places. It healed quickly, and the patient went out on August 10th. Microscopically there was lacrymal glandular tissue, but in parts there was the appearance of sarcoma.

On December 29th, 1908, the patient was readmitted with a small tumour in the site of the old scar, which had appeared two months ago; it is painful on touch. The patient volunteered the statement that when she peels onions the left eye waters but the right does not, though it becomes red and smart.

The swelling complained of is of the size of a pea, and appears to grow from the periosteum just interior to the right external angular process.

On January 7th, 1909, under $CHCl_3$, Sir William Collins dissected out the small growth. A section showed it to be sarcomatous.

The patient was readmitted on November 15th, 1910. There is now a good deal of exophthalmos of the right eye, which has come on during the last two months, and the vision of the eye has rapidly failed. Sir William Collins advised enucleation of the eye and growth, which he did under $CHCl_3$ on November 17th. The growth was freely cut away as it extended widely, and, after removal of the soft structures in the orbit, the cavity was lightly packed with zinc chloride and opium paste on strips of lint.

The next day there was some epistaxis, but otherwise convalescence was rapid, and the patient was discharged on December 10th. The pathologist reported: "The growth appears to be round-celled sarcoma."

On June 30th, 1912, some pain in the orbit was complained of, and there was some swelling. The patient was readmitted, and under $CHCl_3$ Sir William Collins removed all the cicatricial soft tissues in the orbit. Portions of the frontal and maxillary bones were cut away, and $ZnCl_2$ reapplied.

The patient was seen in November, 1912. She had gained in weight and was free from any local or other recurrence.

CASE III.

Mrs. W., aged 42, had for fourteen years had some proptosis of the right eye. This had commenced after the birth of the second of her three children. Prominent tortuous veins made their appearance at the inner canthus; the eye became more and more prominent until, when seen in 1905, it had become most unsightly and repulsive. The right globe was projected out almost on to the cheek, and a huge plexus of worm-like veins clustered around the inner canthus. She had sought advice, but one ophthalmic surgeon had told her it was too dangerous to operate on. The eyelids could not close—a bruit could be heard with the stethoscope over the orbital swelling. The vision was reduced to J.20 in the right eye; the fundus shows some enlargement of the veins of the optic disc. She had a large varix in the right thigh, and had suffered from haemorrhoids. Sir William Collins, under chloroform, tied the right common carotid in November, 1905, but this produced no marked effect on the swelling or proptosis. In December, 1905, Sir William, under chloroform, slit the outer canthus, excised the eyeball, and, separating the mass with his finger from the bony walls of the orbit, clamped and tied the vessels far back, and cut away the venous bunch with very little haemorrhage. The orbit was lightly packed with iodoform gauze, and healing was rapid and uninterrupted.

The growth proved to be a venous cavernous angioma, and contained some phleboliths.

The patient was seen this year (1912), and is quite well.

CASE IV.

A man aged 48 was seen by Sir William Collins at the Royal Eye Hospital in March, 1893, with a swelling, of three months' duration, below and to the inner side of the left globe, elastic to the touch, and displacing the eyeball up and out. There was increasing epiphora. Vision was not much affected, $\frac{3}{6}$ and J.1 with +2.50 D. No history of syphilis. Under A.C.E. mixture Sir William excised the eye, and with the elevator prized away the growth and periosteum from the orbital walls. All soft tissues were cleared away, and zinc chloride and opium paste applied. Portions of the bones came away as sequestra. The growth was a round-celled sarcoma. Convalescence was uninterrupted. The patient attended as an out-patient for some long while afterwards, and showed no evidence of recurrence.

CASE V.

A man, aged 42, was a patient at the London Temperance Hospital, sent up by Dr. Lightfoot of Newcastle, with a history of "polypi" in the left nostril, and of a small growth having been removed from the left orbit, which was reported to be sarcomatous. The left naris was blocked, and the finger encountered growth in the naso-pharynx; the left eye was diverted, apparently by some swelling at the inner part of the orbit. No enlarged glands could be felt. Under $CHCl_3$ Sir William Collins divided the upper lip, opened up the nose, removed the greater part of the left maxilla, and cleared out the orbit. No soft parts were left between the roof of the orbit and the hard palate, nor between the septum nasi and the left malar bone. The ethmoid and sphenoid sinuses were scraped out, and zinc chloride and opium paste was applied to suspicious places. Convalescence was uninterrupted, and, when complete, the right Eustachian tube could be seen on looking through the left orbital cavity. He was readmitted some months later for removal of infected glands and for touching infected spots. A silver plate and a glass eye attached to spectacle frames covered up the gap left remarkably well. The growth was a rich spindle-celled sarcoma, both in the orbital

tumour and in the cervical glands. Ten months after the first operation he was reported to be well, gaining in weight, and without local or other recurrence. The following year, however, there was further return in the glands, and the patient died from exhaustion.

HAEMATOMA OF THE LEFT ORBIT TREATED BY MODIFIED KRÖNLEIN'S OPERATION.

BY

J. M. COTTERILL, M.B.,

EX-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF EDINBURGH; CONSULTING SURGEON TO THE ROYAL INFIRMARY, EDINBURGH;

AND

GEORGE MACKAY, M.D., F.R.C.S.E.,

OPHTHALMIC SURGEON, ROYAL INFIRMARY, EDINBURGH.

ABOUT four years ago A. M., now aged 38, a blacksmith, was fitting a shoe to the left forefoot of a horse when the animal, suddenly turning its head, struck him with it on the left temple. He felt somewhat dazed at the time, and experienced a sensation of fullness about the left brow and side of the head, but as there was no discoloration nor external bruise and his sight was unaffected, he thought little about it. Some months later he began to notice that when he stooped forward at his work, or bent down to tie a shoelace, his left eye tended to come forward. It returned to its proper position on raising his head again. He did not take any advice about it until he found that the condition was becoming more pronounced, especially when he turned his head to the left while bending. In that attitude his sight became dim. He at length consulted Dr. Tod of Leith, who examined his eye, but could find no obvious explanation for his complaint.

On January 2nd, 1909, he went of his own accord to the Royal Infirmary and was seen by Dr. J. V. Paterson, who also was at a loss to discover anything at fault until the patient had assumed a stooping attitude for a few minutes. The patient's statement that his left eye protruded so long as his head was low was then confirmed. Nothing was suggested as regards treatment at that time, and he returned to work.

In May, 1912, the patient got his left foot crushed by a horse stepping on it, and was off work for five weeks. When able to be about again he noted that his eye was becoming worse.

On the evening of June 19th he spent fully two hours reading the Insurance Act, and had no discomfort when he retired to bed. But on waking on the following morning he found that his left eye and lids were protruded, and that he could not move this eye in any direction. There was partial ptosis of the left upper lid and severe pain going from the left orbit to the back of his head. Dr. Tod advised him to go to the Royal Infirmary. When he came to the eye wards on June 22nd the ptosis, protrusion, and fixation were marked, but there was no definite tumour, solid or cystic, nor any nodulation to be felt in the orbit. There was no pulsation nor thrill detectable, nor could any bruit be heard over the eye or temporal region. He had almost full vision. There was nothing abnormal to be seen in the fundus. Examination of the nose, pharynx, and accessory sinuses was negative. Yet it was evident that there must be some mass about the apex of the orbit pushing the contents directly forward and interfering with the proper innervation of the ocular muscles. As it was obviously desirable to explore the condition of the orbit as far back as possible without in the first instance opening into the fascial sheath, the case appeared to Dr. George MacLay to be one well suited for Krönlein's operation. Mr. Cotterill now saw him in consultation, and concurred in the above opinion. The patient was therefore transferred to the general surgical wards on July 1st, and operated upon the same day.

Operation.

A horseshoe-shaped incision was made at the outer side of the orbit, with its base directed upwards and outwards, the lower limb of the incision being carried backwards along the zygoma. The periosteal capsule of the orbit was detached and pushed inwards with the eye. The orbital margin of the frontal, the malar bone, and the

zygoma were divided with a fine saw and chisel, and the bone thrown upwards and outwards with the skin flap. No new growth was palpable, but just inside the periosteum at the back of the orbital cavity a mass was felt which proved to be a haematoma. About a table-spoonful of recent clot was carefully removed by scoop and finger; and as nothing more could be felt except some thickening due to the wall of the haematoma, the wound was closed with horsehair stitches, and a collodion dressing applied.

After-History.

Two days later the proptosis was much less obvious, and by July 10th the wound was completely healed, and the eye apparently normal.

On July 24th the patient was discharged, and his only complaint was of slight diplopia on looking to the left.

Examined on December 12th, 1912, he reported himself fit and well. The vision of each eye was equal to 5. There was no protrusion in any direction. The movements of the left eye appeared to be perfectly performed, but he stated that he had slight diplopia on looking to his extreme left, and that he had occasionally slight pain and sensations of stretching about the left temple. He admitted, however, that these were quite trivial, and that he was practically cured.

THE INFLUENCE OF SEPTIC INFECTION IN THE CAUSATION OF EYE DISEASE.

By B. T. LANG, F.R.C.S.,

CHIEF CLINICAL ASSISTANT, ROYAL LONDON OPHTHALMIC HOSPITAL.

It is known that inflammation is Nature's attempt to repair damage. It follows, therefore, that an inflamed eye must have been damaged, and that the inflammation occurs at or near the seat of the damage.

Suitable treatment of an inflamed eye implies finding the cause of its injury in order to prevent recurrence or continuance of its action. Where damage results from a perforating wound or ulcer the cause is obvious; but in the majority of cases of scleritis, keratitis, iritis, cyclitis, and choroiditis the cause is obscure. Cause there must be, and, since physical damage is excluded, we regard the chemical effects of bacteria or their toxins as that cause. Now bacteria cannot arise within the eye by a process of biogenesis; they or their toxins come from without, brought by the blood stream.

For many years kinship between recent gonorrhoea and iritis, between syphilis, iritis, and choroiditis, and between inherited syphilis and interstitial keratitis has been recognized. So much so that these lesions are known as "gonorrhoeal" iritis, "syphilitic" iritis, and "syphilitic" choroiditis; whereas other forms of iritis are termed "rheumatic," and choroiditis is designated "myopic," "diabetic," or "traumatic," and the like.

Many of these inflammatory lesions are infective and depend for their origin on some septic focus, from which the exciting substance must travel to the seat of the disease by the blood stream. Whether the causative agent is bacterial or toxic is uncertain. On the one hand, attempts to grow organisms from the fluid of the anterior chamber in cases of acute non-suppurative iritis always fail; on the other hand, the anterior chamber is very like a joint cavity, and gonococci can be seen in and cultivated from the joint fluid in cases of acute gonococcal arthritis. Histological demonstration of the bacteria in the inflamed tissues is out of the question, because no eye is ever excised during the onset of the acute stage.

Direct evidence is therefore unobtainable, and the views here expressed are based on the evidence that has been obtained by treating the supposed source of the infection. The eye itself has often been left severely alone, and at the most merely given physiological rest by the use of a mydriatic and bathed with hot water.

Septic foci occur in three situations:

1. Along the respiratory-alimentary tract.
2. Along the genito-urinary tract.
3. On the skin or in a sinus leading from it.

The following cases are illustrative of the infective influence of chronic inflammation. The cases under review, with four exceptions, all occurred in my father's practice, and I am indebted to his notes for these abstracts. They

have all been seen during the last seventeen years, as this view of the septic influence on eye disease did not occur to him until 1895.

I. RESPIRATO-ALIMENTARY TRACT.

Chronically Inflamed Lacrymal Sac.

M. C., female, aged 45, had an inflamed eye with fine grey keratitis punctata and fine vitreous opacities. A chronically inflamed lacrymal sac was the only septic focus that could be found. The sac was removed and the eye rapidly recovered.

No case of intraocular inflammation traced to frontal or sphenoidal sinusitis has come under observation. One case of advanced choroiditis was met with, in which there was considerable ethmoidal disease—only slight improvement followed radical treatment of the nasal condition.

Empyema of the Antrum of Highmore.

Q. N., female, aged 34, suffered from defective vision associated with fine keratitis punctata. She had a chronic empyema of the antrum of Highmore, but as this did not worry her, she refused to have it treated. The keratitis punctata persisted for some months, and she then went abroad and has been lost sight of.

Chronic Suppurative Otitis.

M. L., female, aged 27, had an iritis with grey keratitis punctata and posterior synechiae. She had a chronic suppurative otitis. The ear was treated and the discharge cured, and the eye rapidly recovered.

Chronic Gingivitis and Pyorrhoea Alveolaris.

Chronic gingivitis is the commonest of all causes. It is not necessary for a tooth to be loose or for a socket to emit pus on pressure. Slight marginal inflammation around the necks of a few teeth is all that is required in a susceptible patient. Of the 176 cases under review, buccal sepsis was traced as the cause in 71.

CASE I.

E. C., female, aged 25, came for an opinion in December, 1909. Right eye quite normal; left eye vision = "hand movements." Glaucoma secondary to an iritis of three years before. The patient had pyorrhoea alveolaris.

Eight months later the patient returned on account of dimness of vision of the right eye, noticed a fortnight previously. V. = 8, not improved by glasses. No keratitis punctata.

A fortnight later there were twelve large dots of keratitis punctata. Active treatment of the pyorrhoea was started, and the eye rapidly recovered.

Three months later right eye vision = 8 and Sn. 0.25. No keratitis punctata present. She had completely recovered. She had had many teeth extracted, but had ten left, each surrounded by healthy gum.

Ten months later she returned with a mist in front of the right eye once more. V. = 8 and fine vitreous opacities. Several of the remaining teeth found to be infected. Treatment of teeth started at once. A fortnight later, V. = 5, two dots of keratitis punctata; and another fortnight later all teeth had been extracted.

There was absorption at the root tips and streptococci were cultivated from the roots. V. same, keratitis punctata still present.

Three months later, V. = 7. Remains of keratitis punctata. Vitreous clear. Nine months later, patient quite well. Vision same.

CASE II.

M. Q., female, aged 38, realized in October, 1910, that she had had a mist in front of the left eye for a few weeks.

Right eye V. = 8. Quite normal. Left eye V. = 8. A few dots of keratitis punctata and a patch of superficial choroiditis in the yellow spot region. The treatment of the patient's pyorrhoea began next day.

Ten days later left eye V. = 7 partly. Two dots of keratitis punctata.

A week later left eye V. = 6 partly.

A fortnight later left eye V. = 5 and Sn. 0.5. She could not see the whole of each letter at one time and reading was slow.

Four months later left eye V. = 4 and Sn. 0.25. The patches of choroiditis were very faint.

CASE III.

W. U., female, aged 34, began to have an inflamed right eye in India in September, 1911. The patient's condition was regarded as syphilitic, and she was treated with mercury and potassium iodide; but the eye became worse. Five months later she came to England, when she was seen for the first time. Right eye V. = counts fingers at 1 metre. Eye red, painful and tender. Much episcleritis, keratitis and iritis. No keratitis punctata.

Left eye V. = 8. Quite normal. Many tooth stumps and much pyorrhoea alveolaris.

A month later eleven teeth or stumps had been removed. The eye got worse during the period of extraction, but rapidly improved after. Posterior synechiae had not broken down and the cornea was infiltrated in the centre.

A month later the eye was much better, and a fortnight after it was clear. There was no keratitis punctata. Three months

later right eye V. = 8. There was a large central nebula. The eye was quite quiet and there was no keratitis punctata.

Chronic Tonsillitis.

A chronically inflamed tonsil, particularly if any crypts are blocked with mucus, is a possible focus.

I. L. D., female, aged 43, had an iritis with posterior synechiae, and a chronically inflamed tonsil, which was removed. The iritis rapidly subsided.

A month later the eye was quite quiet.

In none of the cases under review was the cause traced to the naso-pharynx, larynx or trachea.

Lungs.

Tubercle of the eye is, of course, quite common; and in some cases the lungs also are infected. Whether the organisms are inhaled or ingested is unimportant so far as the treatment of the eye is concerned. In no case was the tuberculous focus in such a situation as would allow of the extirpation of the whole disease. Cases occurred of tubercle of the sclera, cornea, iris, ciliary body and choroid. The more recent have been treated with tuberculin injections.

Sepsis along the abdominal portion of the alimentary tract is not often demonstrably the cause of eye disease.

Chronic Gastritis.

Iritis occurred in four cases in which chronic indigestion was the only disorder of any kind that could be discovered.

Typhoid Fever.

In one case choroiditis was noticed after typhoid, which is indeed a recognized cause of choroiditis.

Chronic Appendicitis.

W. T., female, aged 28, in the beginning of November, 1911, noticed that there was a blur in front of the left eye. This gradually became more marked, and a fortnight later she came for an opinion. Right eye V. = 8 quite normal. Left eye V. = less than 8, Sn. 4.5. Large patch of central choroiditis. She was sent to a dentist, who treated a small amount of pyorrhoea. In spite of this the eye got steadily worse, and three weeks later she could not recognize the test type board across the room.

Three weeks later the right eye became similarly affected. V. = 8 slowly, the vision being blurred just below the fixation point.

There were two small patches of choroiditis just above the yellow spot region. Two days later two more patches had appeared and the vision was 8.

Two days later, right eye V. = 7, patches larger. Left eye as before. Surgeon reported that the patient had chronic appendicitis. There was a history of two attacks some few years before.

Four days later appendicectomy was performed. The appendix was thickened and histologically showed signs of chronic inflammation.

A fortnight later the patches in the right eye had coalesced and it looked like the left. Twenty-seven days after the appendicectomy, right eye V. = 8 and Sn. 0.5. Left eye V. = 7, partly and Sn. 0.65. Discs normal. Diffuse pigmentary disturbance in both macular regions. Sclera not exposed.

Eight days later, right eye V. = 8 and Sn. 0.5. Left eye V. = 8 partly and Sn. 0.5. A fortnight later, right eye V. = 8, 8 letters. Left eye V. = 8. Blur, although still present, was less dense and was just over centre of fixation.

Five months later the vision was the same, the blur less pronounced.

This is the only case of choroiditis due to appendicular trouble, but E. F., male, aged 39, had several attacks of iritis; he had had seven attacks of appendicitis, and no other source of sepsis could be found.

There is no corresponding case due to chronic inflammation of a gall bladder.

Sprue.

In one case choroiditis occurred while a patient was suffering from sprue.

Chronic Colitis with Mucus.

This was apparently the cause in two cases, in neither of which could any other septic focus be found.

W. B., widow, aged 52, had severe colitis in June, 1907, which became chronic. Three months later an attack of iritis began in the right eye. A month later, when seen for the first time, there were two posterior synechiae and much keratitis punctata. The former were broken down in forty-eight hours by atropine, but the latter remained in spite of local treatment. Two months later iritis developed in the left eye.

A fortnight later she went abroad for her colitis; she returned four months later, by which time the colitis had subsided, and both eyes were quiet, and there was no keratitis punctata.

Dysentery.

One case of choroiditis occurred while the patient was suffering from dysentery in the tropics.

Chronic Constipation.

In 14 cases constipation was the only cause that could be found.

E. M., female, unmarried, aged 27, had an episcleritis. She was subject to periods of constipation, during which the eyes became red. When her bowels were freely open the eye quieted down. This occurred on several occasions.

II. GENITO-URINARY TRACT.

Bacterial Infection of the Urine.

R. M. M., male, aged 57, noticed at the end of November, 1911, that there was a blur in front of the left eye near the fixation point. V. = $\frac{5}{6}$, partly and slowly. There was a small patch of pigmentary disturbance near the yellow spot.

The patient was edentulous. His false teeth were quite clean. His urine was found to contain a streptococcus and a coliform bacillus in less than 0.001 c.c.m. There was no albumen or pus. Vaccines were prepared and given over a period of three months. The blur gradually disappeared and the vision improved until four months later it was $\frac{5}{6}$. At this date there were no streptococci or coliform bacilli in the urine.

Urethritis.

The male urethra as the result of gonococcal infection is frequently the cause of eye trouble. The urethritis need not be recent. In iritis a definite history of gonorrhoea is sufficient to justify the administration of a gonococcal vaccine. These cases clear up rapidly if the vaccines are given in sufficiently large doses.

No case has come under observation where chronic inflammation of the Fallopian tube was the cause of any eye trouble.

Uterine Polypus.

L. D., aged 59, suffered from a recurrent iritis, with keratitis punctata. After the removal of a uterine polypus she had no further attack.

Utero-vaginal Discharge.

E. S., aged 26, suffered for four years from recurrent attacks of iritis. She had a chronic utero-vaginal infection with a Gram-positive anaerobic organism, which suddenly became acute. She was cured of it, and since that date she has had no return of her eye trouble.

III. THE SKIN OR A SINUS LEADING FROM IT.

Varicose Ulcer.

F. C., female, aged 55, was ill in bed with a varicose ulcer. Iritis with keratitis punctata developed in the left eye. No septic focus other than the ulcer could be found. Left eye, V. = $\frac{5}{6}$. The ulcer healed and the eye rapidly recovered. Two months later; Left eye, V. = $\frac{5}{6}$.

Chronic Purulent Discharge from the Navel.

E. M., female, aged 20, was suffering in May, 1903, from an iritis with posterior synechiae and keratitis punctata. Right eye, V. = $\frac{5}{6}$. The teeth were bad and were put in order. No other source of sepsis could be found. In spite of all treatment both eyes got rapidly worse.

Four months later; Right eye, V. = $\frac{5}{6}$, partly; left eye, V. = $\frac{5}{6}$. A physician found that she was suffering from a purulent discharge from the navel, which the patient admitted had existed for a year. When once this was treated and cured the patient's eyes made a rapid recovery. Three months later; Right eye, V. = $\frac{5}{6}$; left eye, V. = $\frac{5}{6}$, partly. A year later; Right eye, V. = $\frac{5}{6}$, partly; left eye, V. = $\frac{5}{6}$, partly.

It not infrequently happens that two causes are acting at the same time, such as pyorrhoea and tubercle or tubercle and syphilis.

E. G., female, aged 37, was suffering from a cyclitis. Many vitreous opacities were present, and no fundus details could be seen. As her gums were extremely bad, her teeth were extracted, and the vision rapidly rose from "counts fingers at 6 metre" to $\frac{5}{6}$. It was then possible to see the fundus. Diffuse choroiditis was present, and the suggestion of syphilis was borne out by a positive Wassermann reaction. The patient was treated with mercury and given a dose of salvarsan (0.6 gram), but the vision never improved beyond $\frac{5}{6}$.

Patients often suffer from some chronic inflammatory lesion for years without ill effect; then perhaps after some minor ailment which reduces vitality, such as exposure, trauma, or a "cold," the eye will suddenly become inflamed. That such minor ailments are only the exciting, and not the predisposing, cause, is shown by

the fact that the eye remains inflamed long after they have ceased to act, while it recovers rapidly with the cleaning of the septic area. This is particularly noticeable after operations. Patients whose mouths are septic frequently take a long time to recover from such an operation as a cataract extraction. If, however, the septic focus is removed, the eye will often recover rapidly.

A. B., widow, aged 56, had a left extraction with iridectomy. On the fourth day there was a good anterior chamber, the cornea was bright, the pillars of the iris were free, but there was much scleral and circumcorneal injection. Six days later the eye was slightly worse. There was no keratitis punctata. Her teeth were found to be carious, and there was some pyorrhoea for which she was treated. A week later the eye was much better; a fortnight later the eye was white.

Susceptibility to the influence of chronic inflammation may be hereditary.

L. G., male, 54, had iritis. He explained that it was "gouty iritis." His father and his grandfather had had it before him, and he supposed that it must have been the port in the "good old days." He had a very septic mouth, which was put in order. He rapidly recovered from his iritis, and has not had another attack.

It may be worthy of note that the areas of septic inflammation which are found by analysis of these 176 cases to give rise most often to eye troubles are those that are subjected to frequent mechanical disturbance. For example, infection of the gums, which are massaged at each meal, or of the male urethra, which is continually disturbed during micturition, are each more productive of eye trouble than infection of the mucous membrane lining the frontal or any other sinus, or of the cervix uteri.

It may of course be argued that, whereas very many people have very septic mouths, very few have inflamed eyes, and that if there were any real connexion between septic teeth and inflamed eyes many more eyes ought to be inflamed. This seems to me to be an argument of little force, for whereas many men get gonorrhoea, very few get gonorrhoeal arthritis.

I would suggest that senility of itself and myopia of itself do not cause choroiditis. The senile arteritis and the stretching of the choroid in myopia each tend to reduce the resistance of the choroidal tissues. I suggest that these are really cases of septic choroiditis occurring in eyes that are in a weakened state. In support of this contention, I would like to point out how very much less choroiditis one sees in private patients with myopia than in hospital cases, and that senile central choroiditis is most frequently found in patients of the workhouse type.

CONCLUSION.

It is in no way desired to suggest that it is necessary in every case to find out and treat a septic focus to cure the patient. Many cases of iritis and the like recover under the influence of ordinary treatment and the action of drugs, but such cases frequently recur unless the septic focus is treated. In cases of choroiditis I believe it is necessary to treat the cause thoroughly early in the disease in order to obtain any great recovery of vision.

The object of this paper, and of the analysis of cases of which it chiefly consists, is to bring out the relationship of the patient's "general condition" to eye disease. Absolute proof that any one case recovered because one type of treatment was employed is impossible, and if my contention were based upon but two or three cases that had recovered as the result of treating (or removing) the supposed septic cause, I should base no argument upon it. It is the fact that no fewer than 176 cases have been subjected to careful analysis, which emboldens me to maintain the views here expressed. I hold that these eye conditions are often septic in origin and not due to anaemia, idiopathic tendencies, rheumatism, or the gouty diathesis.

THE Optimists (Lennox House, Norfolk Street, Strand, W.C.) are a group of business men whose object is to economize time and money in commerce. But among their list of fourteen specific aims there are two which will appeal to every one—they desire to save time wasted by irrelevance at public meetings and by unproductivity at appointments.

RECURRING TORSION OF THE SPERMATIC CORD: OPERATION.

By J. W. DOWDEN, F.R.C.S. EDIN.,
SURGEON, ROYAL INFIRMARY, EDINBURGH.

IN the BRITISH MEDICAL JOURNAL of April 29th, 1905, there was published a paper by me on the subject of "Recurring torsion of the spermatic cord, with an account of five cases."

The second case detailed was that of a lad, aged 16, who had suffered for four years previously from recurring attacks of pain every two or three months, which affected the left testicle. The onset of these attacks was always sudden. The pain, sickening in character, shot up towards the left kidney and caused prostration. In about a quarter of an hour vomiting occurred, and later, some swelling in the scrotum, followed by gradual cessation of the pain and disappearance of the swelling. These attacks passed off completely in a matter of a couple of days.

Mr. C. W. Cathcart, in whose wards the patient was at that time, most kindly asked me to operate for the condition. At the operation there was found the characteristic appearances associated with recurring torsion—clear fluid in the tunica vaginalis, a testicle and cord hanging free in this, and a broad arrangement of the cord with separation of the vas deferens from the vessels. The parietal tunica vaginalis was removed, and a strip of the visceral investment was separated with difficulty from the free aspect of the testicle. Catgut sutures were inserted to unite the surface of the testicle and the scrotal wall.

Since this operation (some nine years ago now) the patient has had no symptoms whatsoever referable to the left testicle. Some three years ago, however, he began to suffer from similar symptoms on the right side. In fact, so strongly did these symptoms imitate his previous condition on the left side that he applied for treatment in February, 1911, having recognized that his condition was similar in character to that which had affected his left side, and for which he was operated on nine years previously. He knew of no cause which precipitated the attack. It might come on while walking, standing, or lying in bed.

State on Examination.—Nothing definite could be made out in any way, and the history of his symptoms had entirely to be relied on. He was anxious to have an operation done, and this was performed in Mr. Cathcart's ward, and I am again indebted to that surgeon for his kindness in permitting me to carry out the second operation.

Operation.—An oblique incision was made over the right external abdominal ring. The tunica vaginalis was found to be large, and contained about 2 drachms of clear yellowish fluid. The testicle and cord hung free in the tunica vaginalis, but did not show the breadth nor the definite demarcation between the vas deferens and vessels which characterized the condition of the left side. The parietal tunica vaginalis was removed and the testicle fixed by catgut sutures to the scrotum.

The subsequent history was that of complete cure.

REMARKS.

The case is of interest on account of the diagnosed and successful treatment on the left side, now nine years since operation, but it is mainly of importance on account of the onset of symptoms affecting the right side, the recognition of the condition by the patient, and his request for operation. I have seen acute torsion of the spermatic cord in a man of 55 coming on for the first time and attributed to a slight injury.

THE Central Public House Trust Association, 15, Dean's Yard, Westminster, S.W., has issued for the use of motorists, cyclists, and other tourists and travellers a list of hotels and inns under the management of the Public House Trusts and the People's Refreshment House Association. General catering is a special feature of these trust houses, and the managers receive a personal profit from the food and non-alcoholic trade. Excellent bedroom accommodation, it is stated, is to be found in the majority of the houses, but in some of the smaller village inns it is of the cottage type. The list is remarkable, inasmuch as it gives the names of inns in many small places in which the motorist or cyclist might not expect to find a comfortable and well-conducted house. The pamphlet is provided with an index.

SIX CASES OF HYDROCELE IN INFANTS TREATED BY OPERATION.

[WITH SPECIAL PLATE.]

By JAS. H. NICOLL, M.B., C.M. GLASG.,
SURGEON, WESTERN INFIRMARY; EXTRA SURGEON, ROYAL HOSPITAL
FOR SICK CHILDREN, GLASGOW.

IN a paper on the surgery of infancy, read at the Meeting of the British Medical Association in Belfast in August, 1909,¹ and based on an experience of some 9,000 operations up till then performed on children treated as out-patients, I advocated the relegating to the out-patient operating theatre of a much larger number of the cases treated in our children's hospitals, and particularly pleaded that "in children under 2 years of age there are few operations indeed which cannot be as advantageously carried out in the out-patient department as in the wards," with great gain to the hospital's accommodation and efficiency. My views have not been left uncriticized. In particular, operations for hernia were singled out by certain critics as being unsuited for out-patient treatment. As a matter of fact, as our statistics show, operations for hernia in out-patient infants are amongst the safest and most efficient of all our operations. More recently the opinion has been expressed that the operative treatment of hydrocele is unsafe in the out-patient department.

The opinion is as ill-founded as that expressed regarding hernia. My experience has been that the operative treatment of hydrocele in children is as uniformly successful in the out-patient as in the in-patient department.

During November and December I have operated on the following six cases of hydrocele in the out-patient department of the Royal Hospital for Sick Children, Glasgow:

| Name. | Age. | Date of Operation. | Result. |
|-----------------|------------|--------------------|------------------|
| John S. | 2 months. | Nov. 8th, 1912. | Primary healing. |
| John L. | 2 weeks. | Nov. 8th, 1912. | Primary healing. |
| James M. | 5 months. | Nov. 15th, 1912. | Primary healing. |
| John W. | 4 months. | Nov. 22nd, 1912. | Primary healing. |
| John L. | 3 months. | Dec. 3rd, 1912. | Primary healing. |
| Allan W. | 18 months. | Dec. 27th, 1912. | Primary healing. |

All were cases of hydrocele of the ordinary "acquired" type. No local preparation was done till the child was under anaesthetics on the table. The dressing was a small pad of sterile gauze fitted by a strip of adhesive plaster. The children were taken home by their mothers after operation, and brought back in a week for removal of dressing and sutures.

The operation performed in all six is indicated in the drawings made for me by Mr. A. Kirkpatrick Maxwell. A skin incision (1 to 1½ in.) was made just above the groin over the inguinal canal, and the spermatic cord exposed just below the ring. The testicle and hydrocele were pushed up into the wound, and the upper end of the hydrocele sac exposed by a few snips of the scissors (Fig. I). The exposed sac was then emptied by trocar and cannula (Fig. II). The collapsed sac with the testicle was then pulled out of the wound, and the sac dealt with—either by tearing out its internal serous lining, by complete excision, or by bisection and suture of its halves back to back behind the testicle. Replacement of the testicle in the scrotum, and suture of the wound in the groin completed the operation.

(In the comparatively small hydroceles of infancy no drainage is necessary. In operating by this method for large hydroceles in adults, it is advisable to use a drainage tube, reaching from the wound to the bottom of the scrotum, for forty-eight hours.)

¹ BRITISH MEDICAL JOURNAL, vol. ii, p. 753, 1909.

AT the recent examination held by the Sanitary Inspectors' Examination Board for inspectors under the Public Health (London) Act (1891), fifteen candidates passed, all but one of them women.

MR. JAMES H. NICOLL. HYDROCELE IN INFANTS TREATED BY OPERATION.

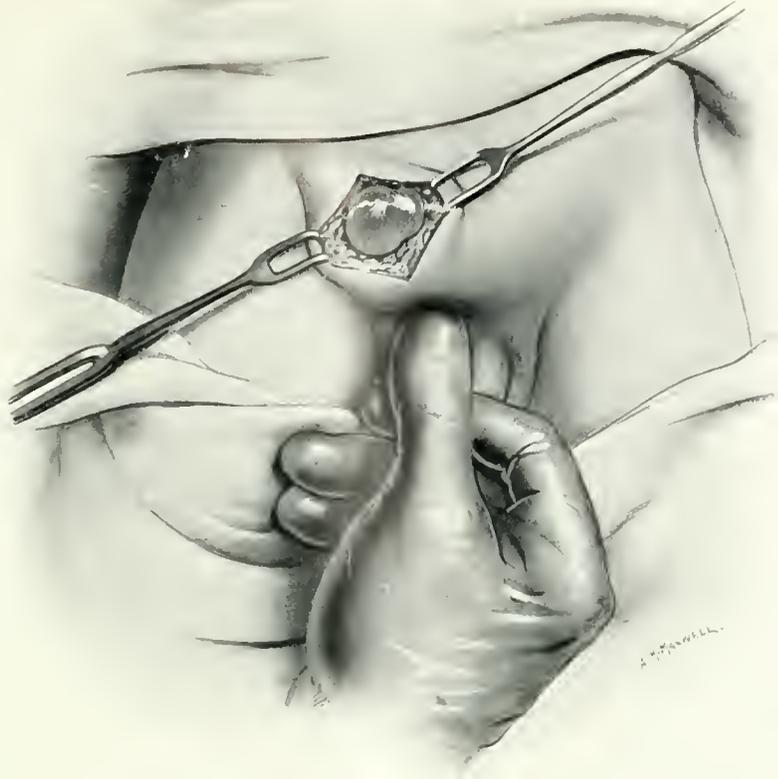

FIG. I.—Upper end of hydrocele sac pushed up to, and exposed in, the wound over the inguinal canal.

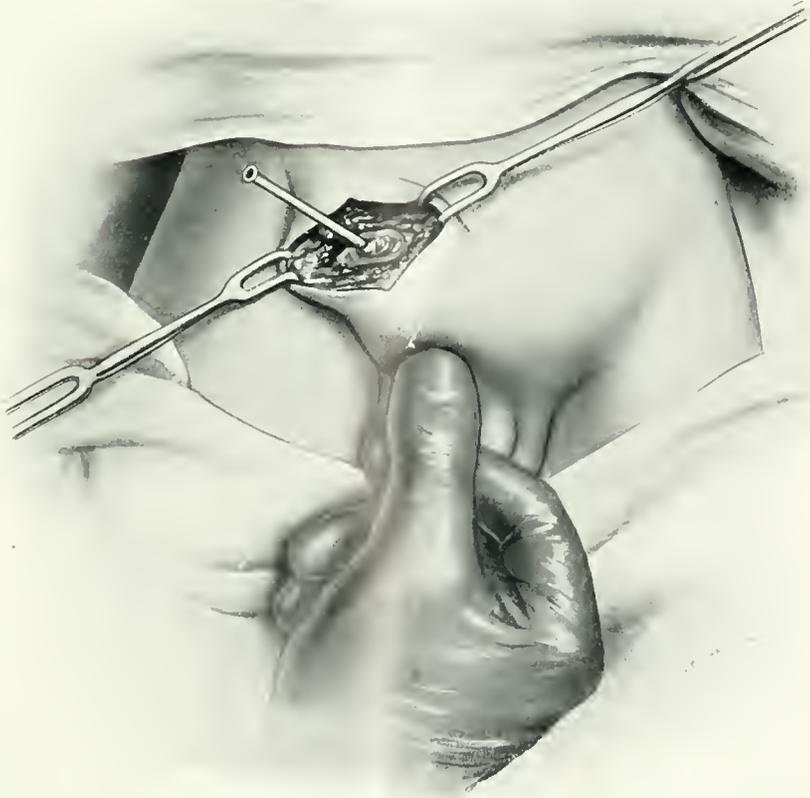

FIG. II.—Sac emptied by cannula through wound above groin.

OCCLUSION OF THE INFERIOR VENA CAVA, AS A RESULT OF INTERNAL TRAUMA (DISSECTING VARIX ?)*

THE CASE OF THE LATE DR. W. RIVERS POLLOCK.

BY

S. G. SHATTOCK, F.R.C.S.

PATHOLOGICAL CREATOR, ROYAL COLLEGE OF SURGEONS, ENGLAND;
JOINT LECTURER ON PATHOLOGY, ST. THOMAS'S HOSPITAL.

THE parts which form the subject of this communication were bequeathed to the Royal College of Surgeons, for dissection, by the late Dr. W. Rivers Pollock, at the time of his death (1909) Obstetric Physician to the Westminster Hospital; and this he did, by reason of the singular, if not unique, clinical history connected with his disease. I may first give the latter, then describe the specimen, and finally make a short comment on the case.

History.

In 1884, Pollock, when about 24 years of age, and in a condition of perfect health, won the 120 yards hurdle race in the Cambridge University sports—16½ seconds.

In the same year he ran successfully for Cambridge against Oxford, performing the same feat in 16 seconds. He held his breath during the whole time.

This record has since been equalled; and was broken in 1907 by K. Powell, of King's College, Cambridge.

Immediately after the race was over he lay on the grass, and within a few seconds complained of pain in the lumbar spinal region. He was put to bed, where he remained for six months.

Oedema of the legs, and to a lesser degree of the abdomen and scrotum, supervened at once, and persisted for the period mentioned. Whilst in bed, the superficial veins began within a few days to dilate, and this dilatation slowly progressed.

During the rest of life the distended veins were supported by the systematic use of carefully adjusted elastic pants reaching as high as the thorax.

Albuminuria appeared directly after the event, and persisted throughout life. Death occurred on October 5th, 1909—twenty-five years later.

Mr. Arthur Evans, who attended the patient during the last six years of his life, informs me that he was subject to attacks of phlebitis and thrombosis in the enlarged saphenous veins, these attacks being readily brought on—for example, by the pressure of a crease in the elastic pants.

On September 25th, 1909, the patient noticed some tenderness and discoloration behind the right internal malleolus: this extended to the dorsum of the foot: on the 29th the temperature was found to be 100° F., and he had a slight rigor. The next day his throat became sore, and on October 1st the signs of well-marked tonsillitis appeared, the lesion on the foot having vanished. The throat became more painful, and the temperature kept up. On October 4th, the right tonsil was freely incised under gas; not more than three or four drops of pus escaped. Death took place on the day following, and was attributed to tonsillitis and septicaemia.

Dr. J. N. Bernstein, who made the autopsy, tells me that, although carried out within six hours after death, there was such a degree of generalized emphysema as to render a satisfactory examination of the viscera impossible.

Description of the Specimen.

The preparation comprises the superior and inferior vena cavae, wanting their cardiac terminations. The right azygos vein is considerably dilated.

Except for its highest part, the whole of the portion of the inferior cava preserved is converted into a flat impervious ribbon, which is most contracted and thinnest for a distance of 6.5 cm. (2½ in.) opposite and below the renal veins. A portion has been cut away from the front of the vessel below the veins last named, showing that its lumen is completely occluded. The common iliac veins and the portions of the external and internal preserved are

likewise flattened and obliterated, though somewhat less reduced in size, owing to the presence of internal adherent coagulum. The tributaries and trunk of the left renal vein are pervious, though, as tested with the probe, the entrance of the latter into the cava is closed. The same is true of the trunk of the right renal. The right spermatic vein, as far as its entrance to the cava, is likewise pervious. From the left side of the lower part of the cava there projects the occluded end of one of the lumbar veins of the same side. The upper divided end of the inferior cava is pervious, though reduced in size.

It was found during the dissection that the hepatic veins were unoccluded.

REMARKS.

Occlusion of the inferior vena cava as a result of infective thrombosis is a well-known condition, and not a few examples of it have been met with, the thrombus extending into the main trunk from some of its tributaries, either from the femoral and iliac veins below—for example, in typhoid infections—or from the hepatic veins above. Occlusions arising from the direct invasion of the wall by new growth, or by the extension of malignant tumours, of the kidney along the renal vein, are likewise well recognized, though rare occurrences in pathological anatomy. Any suggestion of such an infective origin in the case under notice, however, is excluded by the history. It is incredible that an infective disease should have been present in an athlete in such perfect condition as to have accomplished the feats recorded. Contrast it, for example, with the following, which lately came under the care of Dr. C. R. Box at St. Thomas's Hospital.

A man, aged 21, ten weeks before his admission to the hospital, felt out of health, and had a rigor, which he attributed to a bicycle ride. During the next five weeks the rigors recurred on two or three occasions; finally he fainted whilst at work. Swelling of the abdomen followed, and 5 pints of serum were removed. When admitted, on September 6th, 1912, he was suffering from ascites and enlargement of the liver; there was no evidence of nephritis. Paracentesis on September 10th was rapidly followed by reaccumulation; the abdomen was opened, but no cirrhosis or tuberculous disease of the peritonium was found. There was no appreciable oedema of the legs.

Death occurred, with dyspnoea and cyanosis, on September 23rd. He had no rigors whilst in the hospital, but there was slight fever of remittent type; the urine contained a trace of albumen. *Post mortem*, there was an adherent thrombus, with softened centre in the inferior cava behind the liver; the cava below was filled with more recent non-adherent clot, which did not entirely occlude it. The clot did not reach into the iliac veins, but superiorly it extended for a short way into the right auricle. Organizing thrombi were found on microscopic examination in the hepatic veins throughout the liver. The portal vein and its tributaries were normal.

The liver, spleen, and kidneys were congested; the lower lobes of both lungs were the seats of pale infarcts. In Dr. Pollock's case the occlusion of the cava arose under such exceptional circumstances as to indicate some exceptional factor in its etiology. And the hypothesis which I venture to put forward is that in consequence of the extreme distension of the inferior cava, occasioned by the holding of the breath throughout the race, a localized rupture of the intima, or of this and the media, took place, which was followed by the forcible extravasation of blood into the walls of the vein—whilst, that is, the exertion was still in progress; that the lesion, in short, in its initial stage, was the counterpart of a dissecting aneurysm of the aorta. Since by classical usage the word "aneurysm" is confined to arterial dilatation (Galen), whilst swelling of the veins has from the time of Celsus been known as varix, the term "dissecting varix" would be that best suited to meet the condition supposed.

The initial lesion would be like that of a dissecting aneurysm, but the two would soon lose their resemblance. In the case of the aorta, the internal pressure is maintained, and the dissection may proceed to great distances, the blood in most cases finding its way again into the arterial system through a consecutive and

more distant rupture of the intima; and the intramural channel, if death does not ensue, becoming lined with organized coagulum, and converted into an adventitious collateral.

In the case of the vein, on the relief of the abnormal internal pressure, further extravasation into the wall would cease—the normal intracaval pressure would be too low to prolong it. But, as a result of the intramural extravasation, the calibre of the vein would be so reduced, if not actually closed, that secondary thrombosis would take place, which would eventually occlude the channel. All the nucleated cells of the body are capable of furnishing thrombokinasé. And after the partial rupture supposed, the ferment would be furnished by the injured tissues as well as by the leucocytes. From the intramural clot the coagulum would extend, at the site of the rent, into the diminished lumen of the vein, and so bring about its complete occlusion.

The intramural coagulum would subsequently undergo a transformation similar to that occupying the lumen, and in process of time become indistinguishable from the proper coats of the vessel.

The transverse rent of the intima and media that is so readily produced in the aorta or other artery by the application of a tight ligature, or by compressing the vessel transversely in a Spencer Wells's forceps, is not producible by the same violence in the cava or other vein. This difference is to be explained mainly by the direction of the muscle fibre. In the case of the artery the ligature sinks without much resistance into the media by displacing its circular fibres, the externa remaining intact: the intima is ruptured last. This can be shown by tying an aorta upon a test tube.

If the force used is not extreme, it will be found on slitting up the artery and examining the cut edge with a hand lens, after making gentle longitudinal traction, that the externa and intima are intact, whilst the media is cleanly ruptured. In the larger veins, like the cavae and iliaes, the longitudinal disposition of the chief part of the musculature, whether on the inner or outer side of the circular fibres, together with the admixture of white fibrous tissue with the muscle, prevents the ligature from penetrating in the same way. The inner coats of a vein can be ruptured, however, by internal tension.

If a pair of lithotomy forceps is introduced into the common iliac vein, or the cava, and slowly opened out until a rending sensation is felt, it will be found on slitting up the vessel that the inner and middle coats present one or more longitudinal ruptures, the external remaining intact.

This is the lesion that I presume occurred in Pollock's case.

This view will commend itself the more if one endeavours to picture what the condition of the inferior cava would be in the particular circumstances under which the accident occurred.

In the first place it is an old observation (known as Müller's) that if a prolonged inspiratory effort is made with the mouth and nostrils closed, the negative pressure, or *vis a fronte*, so induced within the thorax, results in such a filling of the intrathoracic veins, systemic and pulmonary, and of the two auricles (the lungs being unable to expand and aid in filling the potential space) that the auricles become overdistended, and rendered incapable of efficient contraction; and this to so high a degree that the pulse becomes imperceptible.

The embarrassment of the auricles is due not to excessive internal pressure, but rather to the fact that their musculature is too weak to enable it to cope with the negative pressure acting without; for the ventricles may continue to beat, though, as they are receiving little or no blood, none reaches the systemic arterial system.

The connexion of Müller's name with this observation is, as Dr. Augustus Waller has shown, one of the incongruities encountered from time to time in the history of science. The observation was originally made by Frey, and in recounting Frey's experiment Müller appends a brief footnote, in which he suggests that the cessation of the pulse is due to kinking of the subclavian arteries. The name of Müller has, therefore, in some inexplicable way, become transferred from this, his suggestion, to the actual experiment.

Secondly, in the converse observation (Valsalva's), a prolonged, forcible, expiratory effort, with a closed airway, will likewise stop the pulse by reason of the general compression of the thoracic viscera.

Professor A. Keith¹ has pointed out that the venae cavae, with the innominate, iliac, hepatic, and renal veins, being closed off below by the valves in the common femorals, and above by those in the subclavian and jugulars, constitute a cistern or reservoir, which may be filled from its tributaries, but which can only empty itself through the right auricle.

In Pollock's case, so far as the *vis a tergo* is concerned, it is clear that the influx into the cavae, or the venous cistern, would reach its highest mark, seeing that the active muscular contractions of the limbs and trunk would drive the blood through the peripheral tributaries into the reservoir without its being able to return. Some reflux through the hepatic veins by way of the capillaries of the liver into the main, and valveless trunks of the portal system might occur, though this would be limited by the comparatively short space of time the effort lasted, and by the general compression of the abdominal viscera maintained by the contracted state of the parietes. But the state of things within the thorax is not so easily determinable.

The chest, it is true, was in the expanded position, but dynamically the condition was one of forced expiration, prevented by the closure of the airway; in addition to this there would be the less important positive pressure exerted by the elasticity of the expanded lung itself.

Under these circumstances, although little diminution in the volume of the lungs (only that due to compression of their contained air) could take place, the intrathoracic vessels and the heart would be amenable to the effects of pressure, since the exit of blood forwards by the aorta would be free, and the outlet backwards from the right auricle into the cavae would still remain open. The tricuspid valve, which is never fully competent in the normal condition (as tested after death), would allow, again, of some reflux into the right auricle, and so into the venous cistern.

The point not so easy to determine, then, is whether the expiratory effort with a full chest and closed airway would compress the auricles and intrathoracic veins so as to empty them, as in Valsalva's experiment; or whether these would remain overdistended and embarrassed, as in Müller's. The first view is probably the correct one.

In either case an intrathoracic stasis would result; and as the forcible expulsion of blood from the veins of the limbs and trunk into the cavae preceded, the pressure within the cistern would continue to rise until it led to rending of the internal coat at some spot in its most capacious segment, namely, the inferior cava; and below the entrance of the hepatic veins.

The cava, in fact, behind the liver is supported by the sides of the deep sulcus, or even canal, in which it lies; the second arrangement is well shown in Blandin's fifteenth plate.

This would tend to make the stretch below, the seat of highest distension; and this is where the obliteration has taken place. That the trauma arose below the entrance of the hepatic veins is shown not only by the patency of the latter, found after death, but by the total absence of ascites from the clinical symptoms.

The safety of the auricles under overdistension in general may be, as Professor A. Keith² has suggested, due to the support the pericardium would furnish when its capacity of reserve was overdrawn.

The possibility of such an injury having arisen not from distension, but from mechanical strain acting *ab extra*, may be dismissed. The cava is nowhere tightly fixed to the spine, it is not included between the crura of the diaphragm; and as the diaphragm would be in some position of descent, no longitudinal stress arising from causes external to the vein can be assumed to have taken a part in producing the result.

Lastly, there arises a question whether in Pollock's case there was any predisposition to the occurrence of thrombosis: that is, an exalted coagulability which might occasion thrombosis under conditions that would not otherwise have availed.

This question is raised by the fact that one of the patient's brothers had previously died abroad with oedema of the lower part of the body, which had been attributed to the pressure of a supposed sarcoma upon the inferior vena cava, and that another brother had died from embolism of the pulmonary artery following thrombosis of the femoral vein.

That there may be a familial condition which is the converse of the haemophilic, one of exalted coagulability, is quite credible, but I cannot find that such has as yet been observed in healthy individuals—that is, a constant abnormal rapidity of coagulation in the shed blood as distinguished from the variations which occur under well-recognized conditions in the same individual.

VACCINE-THERAPY IN CHRONIC BRONCHITIS.

BY
H. T. GILLETT, M.D.,
OXFORD.

It seems probable that a large proportion of cases of bronchitis are caused by an invasion of the bronchial mucosa by pathogenic organisms.

Ritchie¹ made a number of *post-mortem* examinations of children who died of acute bronchitis, and showed that the bronchitis was caused by micro-organisms, chiefly the *Diplococcus pneumoniae*, streptococcus, *B. influenzae*, and *M. catarrhalis*. Berkart² believes that some forms of bronchial asthma are due to a specific inflammatory condition of the bronchial mucous membrane caused by microbial influences.

If the micro-organisms are responsible for causing attacks of bronchitis, we should expect that relief and cure would follow the injection of a suitable vaccine in suitable doses. Clinical experience has already borne this out. Lathan³ recorded 5 cases which he successfully treated by vaccines. H. R. Smith⁴ recorded 3 cases treated by vaccines, with favourable results, the duration of these cases before treatment being sixteen years, eight years, and six years respectively. Shivdas⁵ has recorded 39 cases, of which 21 were completely satisfactory.

I have treated bronchitis—both acute and chronic—by this method, but I propose to record here only the first 8 chronic cases in the order in which I attempted to benefit them. I used only autogenous vaccines with one exception. Stock vaccines may be sometimes effective, but a stock vaccine of similar morphology to the causal organism does not necessarily correspond to it in every respect. So that it seems safer to use only autogenous vaccines.

The sputum was collected as far as possible aseptically—boiled water was used for brushing the teeth and rinsing the mouth; a little was also gargled and swallowed. The next phlegm was expectorated into a bottle that had been boiled. Smears of the sputum were made and stained for tubercle bacilli and other micro-organisms. A little of the sputum was then washed and shaken up with sterile saline and one or two loopfuls sown on one or more of the following media: Agar, Pfeiffer's agar, and nasagar. From the growth of fifteen to thirty six hours the vaccine was made up. The dilution with sterile saline was made with a view to avoid the necessity of subculturing, as it has been said that subculturing reduces the efficiency of the vaccine. By this means it is impossible to obtain pure cultures, but it is easy to judge what is the important micro-organism, and to regulate the doses accordingly. The frequent accompanying forms of *M. catarrhalis* can do no harm, and possibly are often requisite to make the treatment successful.

There can be no doubt that a number of Gram-negative organisms are classed together under the term *M. catarrhalis*, and it is difficult at present to know which to exclude and which to include in the vaccine.

CASE I.

Female, aged 75, had suffered with a cough for forty years, with occasional attacks of acute bronchitis. When she began this treatment in November, 1911, she had just recovered from an acute attack. The sputum was nummular; there were no tubercle bacilli, but smears showed that it was full of pneumo-

cocci. By the dilution method I obtained a practically pure growth of pneumococcus. The vaccine was given about once a week in increasing doses, starting at 25 million. After three months' treatment she had lost her cough, had improved in general health, and gained 3 lb. in weight. Treatment was continued for five months altogether. There has been no recurrence of the cough up to the present.

CASE II.

Female, aged 65, had had a bad attack of influenza seventeen years earlier. Ever since that attack she had had a chronic cough, bringing up about 2 oz. of phlegm daily. The vaccine of streptococcus and *Micrococcus catarrhalis* was given in doses of 1 to 20 million, beginning treatment on February 12th, 1912. She was at that time unable to lie down flat at night, but after four injections she was able to do so. The cough and sputum ceased at the end of five weeks, and her appetite and general condition improved. However, in July she began again to bring up a little sputum, but after three injections of a vaccine similar to the previous one the cough completely disappeared, and she has remained free from it since.

CASE III.

Female, aged 35, had had bronchial "asthma" for fifteen months. In March, 1911, she was an in-patient at the Radcliffe Infirmary for two weeks, where she was treated for "bronchial asthma." She sometimes improved a little, but nothing seemed to give her permanent relief. She was able to get about, but was very short of breath and frequently had dyspnoeal attacks, particularly at night. She used to wake regularly at 2 a.m. and had very little sleep. She was cook in a family, and her mistress valued her and was anxious to keep her on if she could be cured. So I suggested we might try a vaccine. I gave the autogenous vaccine of streptococcus at intervals of about a week in increasing doses, beginning with an injection of 15 million on February 27th, 1912. She was soon able to lie down at night and to sleep through until the morning. Treatment was continued for four months. The amount of sputum at the beginning was 8 oz. daily; at the end of treatment it was scarcely half a drachm. She was better in every way; she could go upstairs without shortness of breath. She gained 9 lb. in weight. The cough and dyspnoeal attacks have entirely ceased and there has been no relapse.

CASE IV.

Female, aged 65. Had suffered for eighteen months from bronchitis and dyspnoea. When I saw her first the cough was almost incessant, the breathing was laboured, and she could not lie down in bed. Her nights were very much disturbed. The daily amount of sputum was 1½ oz. The autogenous vaccine of pneumococcus and *Micrococcus catarrhalis* was given in increasing doses at intervals of about a week, beginning on March 26th, 1912, with an injection of 25 million. She soon began to improve, and within four weeks she was able to get downstairs, and was sleeping through the night instead of waking with the cough between 1 and 3 a.m. The expectoration was easier, and the daily amount of phlegm steadily diminished till at the end of nine weeks there was none at all. Treatment lasted three months. Sixteen injections were given altogether.

In this case there was recurrence in November, and she is at present having treatment with a fresh vaccine.

CASE V.

Female, aged 32; five months before I saw her she had an "influenza" attack, with a "cold on the chest," and loss of voice. From that time she had been suffering from repeated colds and coughs. I examined smears of the sputum, and found the predominating organism was *Micrococcus catarrhalis*. In May, 1912, I gave her two injections of a stock vaccine with an interval of five days. The cough was considerably improved, but as she could not stay longer in Oxford the treatment was not continued. I heard recently that her cough is still troublesome.

CASE VI.

Female, aged 42, had been subject for two winters to recurring attacks of bronchitis. She was generally "wheezy" on waking in the morning, and always got very short of breath on exertion. Treatment was commenced on May 9th, 1912, with the vaccine of pneumococcus and *Micrococcus catarrhalis*. She improved rapidly, and after three weeks' treatment she walked about five miles one day; she had not walked so far for several years. At the end of two months she had completely lost her morning wheeziness and cough.

There was some recurrence in November, but it cleared up again after a few injections of the same vaccine.

CASE VII.

Female, aged 45, had a "bronchial cold" for three months, which did not clear up with ordinary drug treatment.

The autogenous pneumococcus vaccine was given first on June 19th, 1912—dose 42 million. After this dose she was conscious of more stiffness on her chest, and there was also more cough, though the phlegm was looser.

The second injection of 84 million was given nine days later; there followed the usual negative phase with more cough and phlegm, but this was soon followed by improvement. She felt much more energetic, and there was hardly any cough.

Ten days later the third injection of 84 million was given. After this the cough completely cleared up.

CASE VIII.

Female, aged 53, had suffered from recurring pharyngitis, laryngitis, and bronchitis. The present attack persisted for over a month in spite of treatment by drugs and inhalations. She complained of difficulty in getting her breath, hoarseness of voice, dryness of throat, and tired feeling. Smears from the sputum showed streptococci; an autogenous vaccine of streptococcus and *Micrococcus catarrhalis* was made up. Treatment by vaccine was begun on June 19th, 1912.

Three injections were given in the course of eleven days—doses of 50 up to 100 million. There was the usual negative phase after each injection, followed by an improvement in the symptoms. The voice was not so husky, the throat was moist, the tightness of the chest was relieved, and there was more energy and feeling of well-being. All the symptoms cleared up after the third injection.

In the foregoing eight cases no drug treatment was given while the vaccines were being administered, except in Case IV, who had an expectorant mixture for a few weeks.

Three of the eight cases recurred. Of these, Cases II and IV soon recovered again after a few injections, and Case IV is at present improving.

The injections were given without opsonic control; this method of control has of late been largely discontinued. The dosage was judged by the effect produced by the first and subsequent injections on the general symptoms as well as by the amount of local reaction at the site of injection. The first injection in each case was well within the recognized dosage. If there followed very little or no negative phase the next dose was often doubled. If the negative phase was marked, the same dose (or a smaller one) was given in about ten days' time. But usually I was able to increase each dose by about one-third to one-half of the former one, and my aim was to try and obtain a reaction during the following twenty-four hours.

It has been recognized that a course of small doses where reactions have not occurred may be ineffective in producing immunity.

CONCLUSIONS.

Where failure occurs in treatment by vaccine-therapy, the question should be considered whether the failure was due to the patient's feeble powers of response, or to the method of preparation and dosage of the vaccine. With this in view one would pay particular attention to the following points:

1. Make sure what micro-organism is the cause of the trouble and whether others are associated with it.

2. Use an autogenous vaccine in preference to heterogenous.

3. Make it up from *fresh* sputum; try different media for its preparation; grow the micro-organism for not more than twenty-four hours if you can get sufficient growth in that time; avoid subculturing as far as possible; sterilize by heating to 60 C. for a quarter of an hour instead of one hour, or in some cases merely by the addition of 0.5 per cent. carbolic.

4. Give doses large enough to produce a reaction but avoid a prolonged negative phase.

Though vaccine-therapy may be said to be still in its infancy, yet it has already achieved a great deal, both in the prevention and cure of various bacterial diseases. And now that serum-therapy can be combined with vaccine-therapy by giving sensitized vaccines, it seems probable that in the future it may accomplish still more, especially in acute cases such as pneumonia and septicaemia, and will eventually largely replace the treatment by drugs in those diseases which are caused by micro-organisms.

Last year the Royal Institute of Public Health held its annual congress in Berlin; this year it is to be held in Paris from May 14th to 18th, in response to an invitation from the Municipal Council. There will be five sections: (a) State Medicine, (b) Bacteriology and Comparative Pathology, (c) Eugenics and Child Study, (d) Naval, Military, and Colonial, (e) Industrial Hygiene. Facilities will also be afforded for visiting the various public health educational institutions in Paris in connexion with the Board of Health, municipality, universities, etc.

SUPRACLAVICULAR ANAESTHETIZATION OF
THE BRACHIAL PLEXUS.

BY

WILLIAM F. NEIL, F.R.C.S. ENG.,

LATE SENIOR HOUSE-SURGEON, GENERAL HOSPITAL, NOTTINGHAM,

AND

FREDERICK CROOKS, M.B., B.CH.,

SENIOR HOUSE-SURGEON, GENERAL HOSPITAL, NOTTINGHAM.

This form of anaesthesia was first brought to notice by Hirschel¹ in 1911, and later in the same year an article was written by Kulenkampff² giving an account of 100 cases. Early in 1912 Borchert³ published the results of 35 cases; since then it has been used extensively on the Continent.⁴ It is convenient, appears to be free from danger, and by its use severe operations on the arm can be performed painlessly and without shock.

The technique of the injection is easy after a little experience. The brachial plexus is injected at a point which roughly corresponds to the middle of the clavicle. Here the plexus lies close under the skin, so that in many cases its position can be defined by pressure over the first rib. It emerges from under the *scaenus anticus* muscle, and lies in loose tissue which is easily infiltrated. The area into which the solution is injected is bounded internally by the subclavian artery, externally by the clavicle, and below by the first rib.

The patient sits with head turned slightly towards the opposite side. The position of the subclavian artery is defined by palpation, and the puncture made just external to the artery. The site of the puncture is usually just internal to the point at which the continuation of the external jugular vein joins the clavicle; but in some cases, in which the artery lies further out than usual, the puncture must be made external to this point. However, the artery is the chief guide to the position of the plexus, and after a little experience we find that it can be used as the sole landmark. A fine needle 4 to 5 cm. long should be slowly inserted in a direction backwards, downwards, and inwards towards the second or third dorsal spine, so as to strike the upper surface of the first rib. As the plexus lies about 1.5 to 3 cm. from the surface just superficial to the first rib, it should be encountered before the first rib is reached. If the plexus is not struck before the first rib is reached it generally means that in order to avoid the artery the needle has been inserted too far out. The needle must be partially withdrawn and altered in direction, usually towards the artery, until the plexus is struck. When the needle reaches the nerve cords paraesthesia is produced in the arm and hand; when the paraesthesia has been definitely obtained the syringe is carefully attached to the needle and 20 c.cm. of a 2 per cent. solution of novocain with adrenalin injected. No solution should be injected until paraesthesia is definitely obtained, and it is important to remember that when the point of the needle is on the first rib it is too deep for the plexus. Apart from the skin puncture the injection is not painful, the paraesthesia in the arm is not severe, and any necessary alteration in the position of the needle is not accompanied by pain. We do not consider it advisable to make a subcutaneous infiltration, as it tends to obscure the landmarks; besides, with the fine needle, very little pain is caused on puncturing the skin, and only one skin puncture should be necessary.

The anaesthesia comes on gradually, and is usually complete in from five to fifteen minutes, but may require as long as thirty minutes to fully develop. The onset is associated with sensations of heaviness and tingling in the arm, and is usually accompanied by paresis. The extent of the paresis is in direct relation to the depth of the anaesthesia. The anaesthesia does not always develop simultaneously over the whole arm, and one part, usually the back of the forearm, may retain slight sensation for a short time after the anaesthesia has become complete over the rest of the arm. The area of anaesthesia extends up the arm to about 2 or 3 fingerbreadths below the acromion process, but usually a small sensitive area is found on the inner side of the arm, corresponding to the distribution of the intercosto-humeral nerve.

The duration of the anaesthesia is usually from one and a half to three hours, depending on the depth of the anaesthesia; we find that at least one and a half hours of anaesthesia can be relied upon.

To obtain satisfactory anaesthesia the following points must be strictly adhered to:

1. Definite paraesthesia in the arm or hand must be obtained before any solution is injected.
2. The injection should consist of 20 c.cm. of a 2 per cent. solution of novocain. If these points are not adhered to the anaesthesia is likely to be light and patchy. Any solution injected near the plexus before paraesthesia is obtained may interfere with obtaining this paraesthesia, and so prevent localization of the plexus.
3. To allow sufficient time for anaesthesia to develop, usually five to fifteen minutes is sufficient, but as long as thirty minutes may be required.

This form of nerve blocking is free from danger, but the following objections have been raised against it:

1. The risk of injuring the subclavian artery. This should be avoided, as the artery can be distinctly felt. It has been proved that puncture of the artery by a fine needle produces no ill effects.⁵
2. The pleura may be injured, and the solution injected into the pleural cavity. This is avoided if the instructions are carried out and the needle inserted until it comes into contact with the first rib, but no deeper.
3. The possibility of paralysis of the nerve trunks of the arm arising as a result of the injection. There is only one case on record.⁶ In this instance there was paresis of the musculo-spiral, median, and ulnar nerves, which lasted a few weeks. We have not met with any cases of paresis, and we consider its occurrence very unlikely.

Care should be taken not to inject the solution into a vein. To prevent this, the plexus should be sought for with the needle alone, when, if a vein is punctured, the blood will flow freely from the needle. Puncture of a vein produces no ill effect beyond a slight swelling in the neck.

As we have found novocain the safest and most satisfactory drug for local and regional anaesthesia we have used no other in our series. We have had no toxic effects in any of our cases from using 20 c.cm. of a 2 per cent. solution. And as will be seen from a study of the cases when a weaker solution was used the anaesthesia was not so complete and was slower in developing.

We use a fine platinum-iridium needle, 6 cm. in length. (These have been made for us by Messrs. Down Bros.) These needles stand sterilization better than, and are not so liable to break as, steel needles of the same calibre.

The cases below are the first forty tried at this hospital, and include all our failures:

| No. of Cases. | Operations. | Remarks. |
|---------------|---|--|
| 2 | Amputation through forearm | One incomplete anaesthesia. |
| 4 | Amputation of fingers | One incomplete anaesthesia. |
| 6 | Reducing impacted Colles's fracture | Two failures. |
| 6 | Setting fractures of forearm | Complete anaesthesia. |
| 11 | Suturing tendons and lacerations of arm | Two failures and one incomplete anaesthesia. |
| 4 | Incising cellulitis of arm | Complete anaesthesia. |
| 1 | Sequestrotomy of humerus | " " |
| 1 | Reducing dislocation of shoulder | " " |
| 1 | Plating radius and ulna | " " |
| 1 | Wiring olecranon | " " |
| 2 | Moving stiff elbow | " " |
| 1 | Scraping necrosed metacarpal | Incomplete anaesthesia; only 20 c.cm. of 1 per cent. was used. |

In 36 of the cases we injected a 2 per cent. solution of novocain, using 20 c.cm. for an adult and about 15 c.cm. for a patient under 16 years. In this series there were three failures (Cases 8, 24, and 32). In the two cases (Nos. 1 and 16) in which we used 1 per cent. solution, the anaesthesia was incomplete. It was also incomplete in Cases 3 and 15, in which we used 20 c.cm. of 1½ per cent. solution.

CASES.

We give a brief account of the most instructive cases:

No. 1 was a girl requiring amputation through forearm. At the first attempt we only obtained patchy anaesthesia, but on a second attempt three days later the anaesthesia was good except that the ulnar nerve was slightly sensitive.

No. 3. In this case anaesthesia was light and patchy, paraesthesia not being definitely obtained before injection was made, the puncture being made too far out in order to avoid the artery. A general anaesthetic had to be given.

No. 4. Sequestrotomy of humerus; the anaesthesia was good, but as the incision extended almost to the acromion process a line of infiltration had to be made to cut off the fibres of the cervical and intercosto-humeral nerves.

No. 8. This man had a marked deformity of the clavicle following a fracture, and owing to the alteration in the relation of the clavicle to the plexus we were unable to strike the latter.

No. 15. In this case we used 1½ per cent. solution. There was anaesthesia of the whole arm, but it was not deep; however, it was sufficient for amputation of contracted fingers.

No. 16. Necrosis of metacarpal; 20 c.cm. of 1 per cent. was injected; anaesthesia of radial side was incomplete.

No. 18. Boy, aged 11. Compound fracture of both bones of forearm; 15 c.cm. of 2 per cent. solution was injected. This was the longest anaesthesia we obtained, being complete eight hours after the injection; in twelve hours sensation was beginning to return.

No. 19. In this case a vein was punctured, but no ill effect resulted beyond a slight swelling in the neck, which only lasted a short time.

No. 22. Male, aged 35. Malunited fracture of radius and ulna. As it was a very difficult fracture to plate, this is the severest test the anaesthesia has been put to by us. The anaesthesia was absolute.

No. 23. Female, aged 50. Dislocation of shoulder. This case is interesting, as it shows the extent of the field of anaesthesia. Before the injection was made the patient was complaining very much of the pain in her shoulder, but about three minutes after the injection she said her arm felt comfortable. On induction by Kocher's method she felt slight pain, which we considered to be intercostal.

No. 24. In this man the plexus was very deep, over 2 in., and we could not get satisfactory paraesthesia; we injected 20 c.cm. and waited thirty minutes, but the anaesthesia was incomplete. This case illustrates the anatomical difficulties likely to arise in some cases and to which the failure must be partially attributed, it also bears out the point that definite paraesthesia must be obtained.

No. 25. Male, aged 38. Wiring fracture of olecranon. The anaesthesia was fairly good, but he was a most unsatisfactory patient; just after the injection was made he had a "hysterical fit." As he was so noisy a whiff of ether had to be given to distract his attention. He said after the operation that he did not feel any pain.

No. 32. Male, aged 28. Reducing Colles's fracture. At first attempt we had difficulty in finding the plexus and anaesthesia was very slight. At a second attempt next day we found that the plexus was much deeper and further out than usual; the anaesthesia was perfect.

No. 35. Boy, aged 16. Colles's fracture. Only 14 c.cm. of 2 per cent. solution were injected. Felt slight pain when the fragments were manipulated.

In our 40 cases we had only four failures—Cases 3, 8, 24, and 32; in the first three of these a general anaesthetic had to be given, in the fourth case complete anaesthesia was obtained at the second attempt. In four other cases the anaesthesia was light or incomplete, but was sufficient to allow of the operation being performed; in these cases a weak solution was used. Thus in 80 per cent. of the cases the anaesthesia was complete, in 10 per cent. it was a failure, and in the other 10 per cent., although the anaesthesia was incomplete, it was sufficient for the operation.

We hope to show in our next series of cases that, with experience, the percentage of failures can be reduced by a considerable margin. However, we admit that a small percentage of failures is bound to arise in consequence of anatomical difficulties that will be met with occasionally.

We are indebted to Dr. Paley, assistant house-surgeon at this hospital, for his valuable suggestions for improvement of the technique, and for kindly permitting us to include in our series the cases done by him, particulars of which he left at our disposal.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

THE TREATMENT OF NEURASTHENIA.

At the present time one finds that neurasthenia is being treated, on the one hand, by purely psychical means, and on the other by purely physical measures, and it does not appear that the advantage of combining the two classes of remedies in the treatment of this condition is sufficiently realized.

I consider that static electricity is best suited for the purpose in view, and it has been my practice for some time to make use of combined psycho-electrical treatment for treating neurasthenia in the following manner:

The patient is seated in a comfortable reclining chair on an insulated platform connected with the machine. He is requested to assume a position of relaxation and comfort, to close the eyes, and to rest quietly without speaking or making any movements throughout the treatment. The electricity is generated in the usual way, and its actual application may be varied according to particular requirements; but as a general rule the metallic tassel is so arranged as to give a mild head-breeze. Under such conditions the most restless patients will become tranquillized and soothed to an extent that is difficult to obtain by simple suggestion alone. The effect of the electricity is remarkably soothing, and patients find that in this method they are able to relax their muscles and to rest more quietly than without it. The mental state obtained is not one of sleep, neither is it, apparently, a hypnotic state. It is a "rest state" which very often corresponds to the hypnoidal state described by Boris Sidis.¹

It is my experience that under such conditions the mental state obtained is one of marked suggestibility, and this fact is made use of either to give direct suggestions oneself or to get the patient to give himself such definite self-suggestions as may be advisable. At the same time there is the physical tonic effect of the electricity, which is notably beneficial in all neurasthenic states. In a word, this combined psycho-electrical method enables me to make use of three great principles of nerve treatment—namely, rest, electrotherapy, and suggestion.

I am of opinion that one of the great advantages of static electricity is that it beneficially affects the sympathetic nervous ganglia, with the result that increased peristalsis of stomach and intestines occurs and auto-intoxication is decreased. Where this last-named factor is plainly hindering recovery it is my custom to supplement the psycho-electrical treatment by abdominal massage with a specially designed vibration machine, whilst at the same time prescribing liquid paraffin in suitable doses.

But experience shows that the best results are not obtained unless one combats the morbid mental state also, and so one finds the direct suggestion an essential part of the treatment.

London, W.

EDWIN L. ASH.

IRON PERCHLORIDE IN RINGWORM OF THE SCALP.

DURING some months at the clinic for minor treatment of school children at Cheltenham I tried various applications for ringworm of the scalp, and found a successful remedy in plain liquor ferri perchloridi fortior (*B.P.*). The results obtained by the free use of this very strong and acid solution of perchloride of iron showed a marked superiority over those obtained with any other application, though several preparations were applied of such strength as to create considerable inflammatory reaction. A distinction must be made between liq. ferri perchlor. and liq. ferri perchlor. fort., as the same results are not obtained with the weaker preparation, which is that commonly prescribed.

The scalp can easily be freed from grease and scurf by the use of motor petrol applied on pledgets of common tow, and the head should have one good wash before the

application of the perchloride of iron is begun. As this is very soluble and easily washed away with water, the head should not afterwards be often washed during the treatment.

The strong perchloride solution should be dabbed on the scalp with a camel-hair brush until the scalp is thoroughly stained with it. As the result upon the skin and hair is quite harmless and benign, an occasional prophylactic dressing can be given to the parts unaffected with ringworm. The patches affected should be treated every second day for three times, afterwards every third day for six times, when the cure will generally be effected although the disease has been very extensive. If the head be not then washed, the iron-stained scurf and epidermis will, in the course of some days, come away from the scalp, leaving a healthy skin beneath.

To obtain such rapid and good results as above indicated requires the attendance of the children at a place where the unfailing application of the remedy can be made. It does not appear to be necessary to prevent children going to school whilst undergoing such active treatment, as the cells of the parasite that have been touched with the iron are not likely to be capable of setting up the complaint in another child. By holding the hair aside, part by part, the very fluent liq. ferri perchlor. fort. can be made to stain the scalp thoroughly without cutting the hair, though, of course, it is well to cut the hair close over the affected patches.

J. H. GARRETT, M.D., D.P.H.

Cheltenham.

Reports

ON

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.

MOBILE EXTERNAL SEMILUNAR CARTILAGE.

(Under the care of Mr. HOWARD DENT, F.R.C.S.)

(Reported by T. D. M. STOUT, F.R.C.S., Resident Surgical Officer.)

THE patient, a young woman aged 22, gave a history of having for two years felt a loose body in the knee which caused a loud clicking sound when the knee was moved. No weakness was noticed in the knee until two weeks before admission, when it felt unstable on going up and down stairs. She had never had any pain, and no synovial fluid or thickening could be detected. On examination the knee was found to move well, and the clicking sound was readily heard and felt. A nodule the size of a cherry-stone was felt between the femur and tibia on the outer side of the knee midway between the patella and fibula. On flexion it disappeared into the joint, on extension it appeared outside joint. There was no tenderness, and the knee was quite stable.

A vertical incision was made over the loose body, and it was found to be the external cartilage compressed antero-posteriorly and only attached at its two extremities, no vestige of coronary ligament being present. The cartilage was removed entire, and perfect recovery took place.

THE Lord Mayor of London, accompanied by the Sheriffs, presided over the seventy-seventh annual meeting of St. Mark's Hospital for Cancer, Fistula, and Other Diseases of the Rectum, City Road, E.C., on February 13th. The report showed that 672 in-patients had been admitted, and 2,031 out-patients had received treatment during 1912, a larger number than previously recorded. The Lord Mayor, who is President of the hospital, said that the hospital admittedly laboured under certain disadvantages in its efforts to secure funds, but that generous help ought to be forthcoming when it was remembered how successfully it dealt with most painful and distressing forms of disease.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

Friday, January 31st, 1913.

Dr. J. O'CARROLL, President, in the Chair.

A Case of Polycythaemia.

DR. O'CARROLL showed a man, aged 57, the subject of this disease. He was a scavenger, of middle height, distinctly stout, and alcoholic. He was admitted into hospital on November 28th very cyanotic, with dyspnoea and slight mental confusion; there had been oedema of the feet for a month, and there was cough and expectoration. Physical examination showed little except that the cyanosis was present over the body, that there was a trace of albumen in the urine, and that there was a moderate effusion in the right pleural cavity. But for his extraordinary assurance that he was quite well, he looked as if he had not an hour to live. About 40 oz. of clear fluid were withdrawn from the right pleura, and he was kept under almost continuous inhalation of oxygen. Next day no very marked alleviation in his appearance or symptoms having occurred, 10 oz. of blood were withdrawn from the basilic vein, and the administration of oxygen was continued. On his fourth day in hospital a blood count showed 7,500,000 red cells per cubic millimetre with haemoglobin 105 per cent. Ten ounces of hypertonic saline solution were injected into the pectoral region, and the oxygen was continued. He was again wandering in mind and unconscious of his surroundings. Two days later he was again bled to the amount of 10 oz., oxygen being continued. Next day a little over 40 oz. of clear fluid were taken from the right pleural cavity. An exploratory puncture of the abdomen gave no result. A blood count on December 5th gave 3,800,000 red and 7,000 white cells, and haemoglobin about normal. No abnormal forms were found. He was quite reasonable and apparently comfortable. On December 7th oxygen was discontinued. Thirty-six hours later a blood count gave about 7,000,000 red cells. Thirty-five ounces were withdrawn from right side of chest. He was again oxygenated for three days, and the red cells fell to 3,500,000. On December 13th 50 oz. were taken from the right pleura. On December 16th a blood count showed 7,450,000 red cells; on the 19th 9,250,000; on the 31st 6,250,000; on January 15th of this year 5,500,000 on January 22nd 6,500,000. One examination of the specific gravity of the blood showed that it was distinctly above normal. On January 16th an x-ray examination by Dr. Watson showed apparent dilatation of the aortic arch appreciable both to right and left of the sternum. There was no abnormality of the pupils, no aphonia, no tracheal tug, no pain, no disparity in the radial pulses, and no sign of undue rigidity of the arteries. He has been up and about for the past month; shows no distress or dyspnoea, but looks as if he were again becoming unduly plethoric. Dr. MOORHEAD said he was struck with the variation in the number of red cells in proportion to want of oxygen. He did not regard polycythaemia as any explanation of the symptoms, but was inclined to look on it only as itself a symptom. Dr. O'KELLY and Dr. CROFTON also spoke.

Early Tabes Dorsalis.

Dr. T. GILMAN MOORHEAD exhibited a typical case of tabes dorsalis occurring in early life. The patient, a girl aged 23, recently came under his care with typical symptoms and signs of that disease. Wassermann's test was fully positive, and became negative after salvarsan had been administered without any improvement in the symptoms. There was some girdle pain since the injection. He invited suggestions as to the advisability of further injections of salvarsan. There was no history of acquired disease or congenital taint. Dr. O'KELLY had not seen any bad results from the repeated use of small doses of salvarsan in locomotor ataxy. Girdle pains frequently followed the administration of salvarsan, possibly because

an inflammatory reaction was set up by the setting free of the spirochaete. Dr. CROFTON referred to a case of keratitis in which spinal symptoms developed after the second dose of salvarsan, but cleared up after the third. He related a severe case of tabes where the symptoms almost disappeared after a course of sulphur baths. The PRESIDENT asked for experience of intervenous injections of mercury. He thought it would be worth trying in cases where there was any doubt about the use of salvarsan. There was no evidence that a large dose of mercury had very much effect on the nerve centres, and it might have a destructive effect on the spirochaete. Dr. MOORHEAD, in replying, said he did not think that repeated doses of salvarsan were of much use, and he had come to the conclusion that doses of 0.1 gram were entirely useless. He noticed that the tendency now with regard to the administration of salvarsan was towards larger doses. He was contemplating a further dose of 0.4 gram for this patient, and she was anxious to have it.

Foot and Mouth Disease in Man—Apthous Fever.

Dr. C. M. O'BRIEN read a paper on this subject. A veterinary inspector, aged 35, was bitten last summer by a sheep on the forefinger of the left hand. He applied an antiseptic dressing to the wounded finger, and continued his daily examinations. Three weeks later an abscess developed, and was opened with every antiseptic precaution. No pus escaped, and the wound refused to heal. Over a month after the finger was bitten, redness and swelling appeared on both hands, accompanied by itching of the parts, with a few small, raised, white swellings like little lumps under the skin, especially in the clefts of the fingers. By night time there was slight itching of the upper part of both feet, with a prickly sensation in both soles, becoming worse on walking. The patient complained of malaise for a day or two previously. He then consulted Dr. O'Brien, who found that he had always enjoyed excellent health excepting for an attack of scarlet fever which he contracted at the age of 10. The fingers and dorsal aspect of both hands were markedly swollen and covered with a dull reddish, raised rash, extending to an inch above both wrists; it caused itching. Vesicles in process of formation were observable here and there over the surface of the rash, especially between the fingers and round the nails. The wound on the injured finger gaped, but no pus issued from it. There was no perceptible involvement of the lymphatic glands. A few vesicles were observable on the fauces, on the inside of the lips, on the gums, and the side of the tongue which was swollen and somewhat tender. Speech, deglutition, and mastication were painful, and the saliva was copious. The temperature never exceeded 100°. There was no evidence of any visceral complication. The next day all the symptoms increased and saliva trickled from the mouth. Ruptured vesicles on the fauces now formed small shallow ulcers, with dark red bases. The patient made an uninterrupted recovery, and resumed professional duty within two months. Dr. O'Brien in his paper dealt very fully with the literature of foot and mouth disease in man from the first recorded case in 1695 down to the present day. Professor METTAM said that the incidence of the disease was much greater on the Continent, especially in Russia and France, than in these islands. In one instance the disease was produced in a calf by inoculation with the pus taken from a vesicle on a boy. In 1880 there was a large outbreak amongst persons in Dover who had consumed the milk of cows suffering from foot and mouth disease, and at the time it was noticed that the incidence of the disease was greater amongst those who had used the cream. Diagnosis of this disease was difficult, as the germ was not known. A 300th part of a cubic centimetre of the pus taken from a vesicle was capable of setting up a lesion in cattle, in which there was little difficulty in diagnosis. Lesions often occurred in the mammary gland, and it was probably in this way that the infection was carried to the milk. In the case just reported the period of incubation seemed long, as in the lower animals it was generally from two to four days. As soon as the vesicles ruptured the temperature went down and the lesions rapidly healed. Within a week or so there was an epithelial covering to the corium, and as soon as this took place infection had passed.

ROYAL SOCIETY OF MEDICINE.

PATHOLOGICAL SECTION.

Tuesday, February 18th, 1913.

Professor R. T. HEWLETT, President, in the Chair.

Differentiation of Streptococci.

Dr. H. W. CROWE read a paper in which he advocated the culture of streptococci on neutral red Dorset egg medium as a means of differentiation. In the case of some streptococci the colonies were yellow, in others red, in others plum-coloured. Their forms also varied, the three most characteristic being like a cottage loaf in miniature, or a clerical hat, or a draughtsman. The last-named form was a character of *Streptococcus pyogenes*, and that of the streptococcus of erysipelas was the same. In rare cases a streptococcus would indent the egg medium. Checking the diagnosis by means of the various sugar fermentations, the groups that were differentiated by the coloration and shape of their colonies corresponded with the groups made by Andrewes and Gordon—streptococci of the mouth, lung, intestine, connective tissue.

Obliterative Cholangitis with Duct Dilatation.

Dr. A. HALL recounted the case of a girl, aged 15, who since the age of 7 years had been subject to intermittent attacks of pain and jaundice, and who ultimately died of toxæmia accompanied with hæmorrhages. After death the ductus communis was found extremely narrow and fibrosed; there was an adventitious duct opening into the gall bladder, apart from the cystic duct. The author was unable to explain the cause of the inflammatory obstruction, which had been followed by marked dilatation of the bile ducts in the hilus of the organ. The recurrent attacks of pain he thought due to intermittent obstruction.

Occlusion of the Inferior Vena Cava as a Result of Internal Trauma.

Mr. S. G. SHATTOCK's communication upon this is given *in extenso* on page 385.

SECTION OF SURGERY.

Tuesday, February 11th, 1913.

G. H. MAKINS, C.B., F.R.C.S., President, in the Chair.

Gastro-enterostomy.

Dr. ARTHUR F. HERTZ read a paper on the cause and treatment of certain unfavourable after-effects of this operation. The opening was sometimes made too large, so that the stomach contents passed at once into the jejunum and distended it. X rays showed that food only remained in the stomach for from a quarter of an hour to an hour instead of for three hours; indeed, the rate of outflow sometimes almost equalled that of the oesophagus. The stomach became small and hypotonic. The distended jejunum gave rise to sensations of fullness and discomfort after meals, which were referred to a lower area than those produced by the original condition. The unchanged food irritated the small intestine, causing diarrhoea. Contrary to what was observed in cases of gastro-jejunal ulcer, it was the quantity, not the quality, of the food that produced the symptoms. If the patient ate slowly, lay down after each meal, and took pancreatic ferment, belladonna, or cocaine half an hour later, the symptoms would not develop. If it were found necessary the stoma should be made smaller. The stoma should be placed at the most dependent part of the stomach, a point sometimes difficult to determine owing to the alteration in the situation of the great curvature of the stomach in the erect and supine positions. If the stoma were placed too high, it was a mechanical impossibility for the stomach to drain through the opening until the food collected and reached its level. The condition was relieved by lying down and by compression of the abdomen. Mr. WARREN LOW said that up till now the sense of fullness and diarrhoea after gastro-enterostomy had been ascribed to a slight recurrence of the original malady. The results obtained in cases of dilated stomachs and duodenal kinks were deplorable. Sir FREDERIC EVE thought that the results of the operation, when performed for duodenal ulcer with a patent pylorus, were

bad. In gastroptosis he had obtained good results by stitching up the gastro-hepatic omentum and attaching the lesser curvature to the diaphragm. Dr. RUSSELL was sure that the results from gastro-enterostomy were on the whole very satisfactory, as so few cases returned for treatment. Mr. SIDNEY BOYD advocated a vertical opening, as most likely to ensure permanent success. The PRESIDENT said that gastro-enterostomy was not a cure for gastric ulcer, and thought that the apparent good results obtained by operation in cases of duodenal ulcer were due to the long relief from symptoms often gained by a month's rest in bed. Dr. HERTZ replied that the percentage of absolute success was small. The hypotonic stomach was the most favourable for this operation, but he did not advise gastro-enterostomy for gastroptosis. He had found that in those cases in which the stomach had been fastened up to the diaphragm recurrence took place in a very short time and the stomach got back to its old position.

Effects of Treatment on Gastric and Duodenal Ulcers.

Mr. EDRED M. CORNER read a paper on this subject. From his own 40 cases and the statistics of other observers he came to the conclusion that it was better to wait, and, if necessary, do a gastro-enterostomy later. In the majority of instances it was not required, though many cases of pyloric and duodenal ulcer were benefited by it. When the opening of a gastro-enterostomy was placed laterally very little of the food could be expected to drain through it. Owing to the friable condition of the tissues it was often difficult to close the opening directly. When this difficulty presented itself he used a portion of omentum to close the opening or packed the ulcer with gauze and drained it. This last method, he believed, would become more popular in the future, as it saved time.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

At a meeting on February 14th, at which the PRESIDENT (Professor E. W. HOPE) was in the chair, Dr. J. W. MASON read a paper on *Duties imposed upon port sanitary authorities*. By the adoption of improved systems of administration based on enlightened principles of sanitary science, great changes in our national system had been brought about. Quarantine was now in oblivion, and the abandonment of its restrictions had been a most powerful stimulant in the cause of sanitation. The medical inspection and examination of the passengers and crews of all vessels arriving from infected or suspected ports, which had replaced quarantine, was of national importance, as only by this means could the importation of infectious and other diseases be prevented. Inquiries were made as to illness, removal to hospital, or death from infectious disease of any member of the crew, and as to the prevalence and mortality amongst rats, especially having regard to the measures to be taken to prevent the spread of the plague. Bills of health were also examined. It would be a great advantage if bills of health were made out in one universal language, such as Esperanto. The confidential lists recently issued by the Local Government Board at periodical intervals setting forth the existence of infectious disease at various foreign ports had proved to be invaluable to the medical officers of health to whom they were sent. A port sanitary authority could require the cleansing and disinfection of any ship or articles in it likely to retain infection. In Hull a ship's crew was often removed to the disinfecting station to undergo bathing and disinfection, their quarters and other parts of the ship meanwhile being disinfected. The clothing and effects of deceased seamen should be disinfected before being handed over to the Board of Trade. A very necessary precaution was the pumping-out of all bilge water and water ballast from an infected or suspected vessel before it entered dock, and samples of the water of all ships should be regularly examined both bacteriologically and chemically. The regulation of the examination of foodstuffs imported from foreign countries was an important duty cast upon port sanitary authorities, although a vast proportion of the food examined was sent inland—a sufficient reason for the payment by the Treasury of the expenditure involved, instead of out of the local rates, as at present is the case. The PRESIDENT agreed.

that it would be a distinct advantage to have bills of health in one language, preferring French to Esperanto. He thought it was not sufficiently realized that the immunity the country had had from small-pox was due in great measure to the care taken by the port sanitary authorities, for the disease did not now often pass the ports as it did formerly. He regretted that agreements which had been come to at international conventions were not more rigidly adhered to, and stated that on occasion our own ships had been subjected to disabilities which were altogether unwarranted. Dr. HERBERT WILLIAMS was of opinion that bills of health should be in French. He thought that the information obtained from British consuls abroad was not of much value, and suggested that the Government should insist upon more efficient information being secured. He referred to the difficulties attending the destruction of rats, whose ingenuity enabled them to overcome almost any obstacles placed in their way in getting ashore. Recently the fumes from ship's funnels had been used for fumigating a rat-infested ship, but unfortunately they did not destroy the fleas. Mr. GEORGE BRIGGS, the Chairman of the Port of London Sanitary Committee, stated that the charges in connexion with the port sanitary authority of London amounting to £12,000 annually, were all paid for out of the private funds of the Corporation, and did not come out of the rates. Mr. HERBERT JONES, Dr. H. K. ROBINSON, and Dr. TUBB THOMAS also took part in the discussion.

UNITED SERVICES MEDICAL SOCIETY.

At a meeting of this society, held at the Royal Army Medical College on Wednesday, February 12th, the President, Fleet Surgeon BASSETT SMITH, C.B., R.N., in the chair, a paper was read on *Regimental and field ambulance training* by Major J. OLDFIELD, R.A.M.C.(T.). Discussing the training of medical officers attached to combatant units in the Territorial Force, Major Oldfield drew a comparison between these officers and the medical officers of field ambulances, pointing out that the former, after completing their first training camp or course of instruction, might remain for years on the strength and yet never do a single duty for the battalion or come into contact with any of its officers or men. Even the maximum of a fortnight every two years in contact with their men and their work could not be considered at all sufficient to enable officers to keep in real touch with their duties. The case of the field ambulance officer was very different. He was obliged to attend camp at least once in three years, and this was emphatically laid down as the minimum. This matter was important, as an efficient camp training was the only real way in which a medical officer could be fitted for active service duties. A regimental medical officer was encouraged not to attend camp more often than once in every two years, whereas the obligation was laid upon the field ambulance officer to attend camp not less than once in three years. No doubt the intention was to lighten the duties of busy practitioners willing to join the Territorial Force by providing a regiment with two medical officers attending training in alternate years; but the event had proved that it was easier to get the same class of busy men to go into camp year after year for the full fortnight in field ambulance than to gain the full complement of regimental officers for camp duty every second year. The mere fact, therefore, of "making it easy" was not an inducement which attracted men to join the Territorial Force. What were the duties that a regimental medical officer was expected to perform? It was often most fallaciously supposed that a regimental doctor's only duties were to attend to the sick of his unit in times of peace and to look after the wounded during battle. The truth, however, was very different. It was intended that he should be the commanding officer's right hand man in all matters affecting the health of the troops or prevention of disease amongst them. He was responsible for the custody and use of medical and surgical stores, and for the training and duties of the R.A.M.C. men attached to the unit. He had to examine recruits in camp, see the sick, and be ready to deal with infectious cases and accidents, according to the routine laid down in regulations. He had

also to familiarize himself with his duties in action and to train the bandmen in bearer drill and first aid. All these duties were very important, and it was hard to imagine how they were to be thoroughly performed by an officer to whom no incentive was held out to put in more than the minimum of training laid down in regulations. Major Oldfield recounted his own experiences of both regimental and field ambulance work, and described the increased efficiency with which he performed regimental duty during a temporary return to it, after having served in a medical unit. He suggested (1) that the one portal of entry into the medical service of the Territorial Force should be the field ambulance. (2) That from the field ambulances officers should volunteer for regimental duty not earlier than the close of their first year's training and fifteen days' camp. (3) That a regimental medical officer should not be debarré from an annual camp, but rather encouraged to attend it. Where there were two medical officers in a battalion one should be attached to a field ambulance for his camp and the other trained with his regiment. (4) That every medical officer should train one year in three with a field ambulance in camp. (5) That the annual training as to drills, riding, etc., should apply to all R.A.M.C.(T.) officers. When they lived at a distance from drill halls, travelling expenses should be allowed. (6) That brevet rank should sometimes be conferred on officers showing zeal and ability, coupled with any special excellence, as an incentive to effort. The following officers took part in the discussion: Colonel HARPER, A.M.S.(T.), Lieutenant-Colonel SALISBURY SHARP, R.A.M.C.(T.), and Major WAGGETT, R.A.M.C.(T.), Lieutenant-Colonel BURCHHELL, Major CUMMINS, Major IRVINE, and Captain GRANT of the R.A.M.C. Major OLDFIELD replied.

LIVERPOOL MEDICAL INSTITUTION.

At a meeting on February 6th, Mr. ROBERT JONES, President, in the chair, Mr. F. A. G. JEANS read a note on *One of the functions of the caecum*. He had removed the caecum in rabbits and found that fluid faeces were passed, instead of the usual hard motions. The practical application deduced was that rectal salines should be large in quantity, as relatively more fluid was absorbed from the right half of the colon than from the left. In bad cases of peritonitis fluid might be injected with advantage directly into the caecum or through the stump of the appendix. Mr. F. T. PAUL did not think the appendix could be used in cases where it had been found gangrenous, but tubes might be inserted directly into the large bowel. Mr. THELWALL THOMAS thought saline injections might be given through a rubber tube fixed in an appendix stump, and would so obviate one of the difficulties of rectal injection, which had the disadvantage of requiring the patient to be propped up. Mr. HUGH SHAW thought the appendix and caecum might, from the relative amount of lymphoid tissue they contained, have a protective function as well as absorptive. Mr. JEANS replied. Dr. STOKES read a note on *Puerperal mortality in Liverpool*. It had for years been lower than the average of England and Wales, in spite of so large a poor population. In 1911 74 per cent. of all births in Liverpool were attended by women, and there was a mortality from sepsis of 0.59 per 1,000 births; whilst 26 per cent. of births were attended by doctors, and the mortality from sepsis was 1.8 per 1,000 births. In the past six years doctors' cases diminished steadily in number, and during that time their sepsis mortality was nearly twice as great as many cases attended by midwives. Liverpool had trained midwives for nearly fifty years, long before the Midwives Act. Dr. STOKES concluded that where midwives were well trained, worked under supervision, and could fall back on skilled help, they did the work on the whole better than a badly paid general medical practitioner who was busy with other cases, often septic in nature. Dr. MUSSEN (assistant medical officer of health for Liverpool) said the satisfactory state of the Liverpool puerperal mortality had been largely due to the Liverpool Ladies' Charity, which had trained midwives, so that while England and Wales had some 20 per cent. of the women trained and certificated, Liverpool had only 20 per cent. untrained. Practically all cases were now attended by women who possessed a

certificate. There had only been one outbreak of puerperal fever in Liverpool in the practice of any one midwife since the Health Department undertook their supervision. Cases occurred usually as single cases, a few in groups of two. Each midwife was interviewed on the notification of a septic case, and her methods inquired into. Dr. HARVEY and others who took part in the discussion reminded the meeting that practically all cases which doctors attended were instrumental. Dr. R. J. M. BUCHANAN read a paper on *Tumours of the spinal cord*, and described with lantern slides four cases where the tumour was psammoma, sarcoma, hydatid, and cancer secondary to carcinoma uteri which had been removed three years previously. Dr. Buchanan appealed for early operation in such cases, and showed how in his own cases the tumour was accurately located and easily removed, with satisfactory results. Mr. DOUGLAS-CRAWFORD described two successful cases, and agreed that operation should be done if only for the relief of root pain. Dr. WARRINGTON said that tumours causing no pain gave rise to difficulty. Mr. THELWALL THOMAS deprecated delay, as improvement could not be expected when the cord had been long compressed. He thought that there was no more danger in exploring the spinal canal than any other cavity of the body. Dr. BUCHANAN replied.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this society was held on February 14th, the PRESIDENT (Dr. Dobson) in the chair. Mr. H. COLLINSON read a paper on the *Importance of early diagnosis and treatment in acute perforating duodenal ulcer*. Mortality in operated cases was directly proportionate to the number of hours which had elapsed between the occurrence of perforation and operation. In 27 cases upon which he had operated during the last three years the mortality was 41 per cent. Of these, 10 were operated on within twelve hours, with a mortality of 10 per cent.; 10 cases operated on in the second twelve hours gave a mortality of 40 per cent.; and in 7 operated on after twenty-four hours had elapsed the mortality rate was 86 per cent. Matters of operative detail were discussed, and it was shown that the performance of an immediate gastro-enterostomy was not necessary for the recovery of the patient, and consequently should be reserved for those cases in which operation was undertaken very soon after perforation had occurred. Dr. WARDROP GRIFFITH brought forward a case of *Disseminated sclerosis*. The first symptom, noticed last October, was squint with diplopia, due to paresis of the abducens nerve, but it had to a great extent passed off. Marked weakness of one arm, and then of the opposite leg, soon came on in succession, but considerably diminished. There was no intention tremor nor staccato speech, but, though there had been great improvement, the diagnosis was confidently affirmed on the great increase of the knee-jerk, on the Babinski phenomenon, on the presence of slight nystagmus on lateral movement, and on incipient atrophy of the optic nerve. Dr. VISING showed a case of *Pressure on the main bronchus of the left lung by a malignant growth*. The patient was a man aged 54, who had suffered with cough and breathlessness for two years, and who twice suffered from haemoptysis. The physical signs were, greatly diminished expansion with reduced air entry over the whole of the left chest. X rays showed no evidence of growth or aneurysm. There were no tubercle bacilli in the sputum. Cases were also shown by Mr. L. R. BRAITHWAITE, Dr. M. J. STEWART, Mr. E. W. BAIN, Mr. J. F. DOBSON, Dr. BRONNER, Mr. ROWDEN, Dr. OLDFIELD, Mr. LAWFOED KNAGGS, Mr. ALEXANDER SHARP, Dr. R. A. VEALE, and Dr. WATSON.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

At the mid-session meeting, the PRESIDENT (Mr. W. G. Laws) in the chair, the mid-session address on *Some remediable defects in children of school age* was delivered by Miss MARY THORNE, M.D., F.R.C.S.I. Medical inspection, carried on in schools for ten years, had shown

that healthy bodies and healthy minds could only come from healthy parents and healthy surroundings. In order to secure attention to the daily functions of the body, there should be sufficient and decent lavatory accommodation in every school, and children should be allowed to leave the class if necessary, for if these functions were neglected, constipation followed by anaemia, indigestion, and dysmenorrhoea inevitably occurred. Fortunately, there was a steady improvement in the lavatory accommodation. All girls should have plenty of active movement in the open air, but not in competitive games, which were harmful for them between the ages of 13 and 16 years. Curiously enough, town children had better playgrounds than village children. The lecturer spoke of posture curves, flat feet, desk accommodation, and the position of the windows in the class-room. The light should always come over the left shoulder. The teeth were too often neglected; all second dentition teeth should be stopped on the first signs of decay. The children should clean their teeth at least every night. The importance of clean heads was being instilled into the parents, because they found that the children were refused by the factory surgeons if their heads were verminous. A very large number of blind and deaf children owed their afflictions to the sins of their parents. Heredity was also the largest factor in the causation of mental deficiency. Thus it became the duty of doctors to impress upon parents, teachers, and clergy, etc., the great importance from a medical point of view of encouraging a moral life. Finally, the lecturer deplored the present system of class teaching as opposed to individual teaching; 5 per cent. of the children left school without being able to read and write sufficiently for any practical purposes. There should be a simpler code of instruction: little should be taught, but that little should be well taught.

THE annual dinner of the West London Medico-Chirurgical Society was held at the Hotel Great Central on February 6th, under the chairmanship of Dr. G. P. Shuter, president of the society. After the loyal toasts had been duly honoured, Mr. Richard Lake proposed "The Imperial Forces," and in the course of his remarks spoke of the necessity for universal service, and referred to the periodical instruction given to medical officers in order to keep them up to date with the latest improvements in their profession. Surgeon-General Sir Launcelet Gubbins, Director-General, A.M.S., in acknowledging the toast, mentioned the important part the Colonies were playing in the defence of the empire. He was glad to say that whenever any officers were required for special duty, either under the Foreign Office, Colonial Office, or the Red Cross Society, the medical service of the army was able to meet the demand. Officers had been sent out with the Red Cross Society to the seat of war; the reports received showed that the Servian medical service was the best of those of the armies engaged. Of the Territorial Force he said that if the remainder of the force was half as efficient as the medical section there would not be much to complain of. The Voluntary Aid Detachments, though started only about three years ago, contained 57,000 members, of whom about two-thirds were women. In proposing the toast of "The West London Medico-Chirurgical Society," the Chairman said that the society now contained over 580 members, 33 of whom were original members. The attendances at the ordinary meetings averaged 44. The next Cavendish lecture was to be delivered in June by Sir Berkeley Moynihan. He was afraid he saw trouble ahead for the society, since, owing to the introduction of the Insurance Act, there would be a division of the members into two classes—those who were on the panel and those who were not, similar to what had occurred in Germany through the German Insurance Act. The toast was responded to by Dr. S. D. Clippingdale, who referred to the foundation of the society in 1882 by Mr. C. R. B. Keetley. As a sign of growing interest in the work of the society he contrasted the first volume of its *Transactions*, which consisted of only 86 pages, with the last volume, which contained 356 pages. Dr. F. S. Palmer gave the toast of "Kindred Societies and Guests," which was acknowledged by Sir Francis H. Champneys, President of the Royal Society of Medicine. Mr. McAdam Eccles proposed the toast of "The Chairman," which was duly acknowledged. The toast of "The Officers of the Society," coupled with the names of Mr. Bishop Harman and Dr. Warren, proposed by the Chairman, and acknowledged by Mr. Harman, brought the function to a close.

Reviews.

COLOUR VISION AND COLOUR BLINDNESS.

Researches in Colour Vision,¹ by Sir WILLIAM DE W. ABNEY, is a large and attractive looking book which, the author states, has been written "to show that the trichromatic theory of colour vision does not yet require a funeral service over its remains." On seeing this statement the reader naturally imagines that proof of the theory will be adduced, and that full answers will be given to the criticisms which have been levelled against it by many workers. Much to our disappointment, however, we have been unable to find an answer to a single one of the objections which have carried conviction to many minds and have led many workers in other countries as well as in this to give it up as untenable, on the ground that it affords no explanation of the defect of hue perception, which is the characteristic of colour blindness. This is not the only remarkable feature in the book. Any one who has followed the controversy which has gone on for years about colour vision must be well aware of the work done by Edridge-Green and others who have followed his teaching to show that the trichromatic theory is untenable; yet in this book his name is never mentioned. Nevertheless, tests now recommended by Sir William Abney would seem to be identical in principle with those which Edridge-Green has for so long been advocating.

It is most interesting to compare the present book with those previously published by Sir William Abney. He seems entirely to have abandoned many of the methods he used to advocate and gradually to have evolved others which are not easy to distinguish from those which his opponent has for the last twenty-five years been struggling to get recognized. Dr. Edridge-Green has always stated that the naming of colours in a test is essential, that coloured lights should be used instead of coloured wools, and that matching alone was a most imperfect method of testing for colour blindness. We believe we are right in stating that all these propositions have been strenuously denied at one time or another by Sir William Abney, yet in the book under review many of the tests advocated depend upon the naming of colours. To the Holmgren test he has added two colours similar to those used in the Edridge-Green classification test, and he states that "after an examination has been made, if the examinee is asked to name some of the colours, the giving of a wrong name to any of them will confirm what has probably been found out by the matches." The significance of the word "probably" is very apparent to any one who has had much experience in testing for colour blindness, but a more thorough change of front could hardly have been made; how this has come about might have been explained. To pass over the reasons for the change can scarcely be considered adequate treatment. The author next describes a test by painting similar to that given by Edridge-Green, in which the examinee is asked to name the faint washes of colour. A test by coloured discs is given which has been shown to fail to detect the colour blind. The spectrum test seems for all practical purposes to be identical with the spectrometer of Edridge-Green; so also is the dot and lantern test. A test by simultaneous contrast is described, and unless the reader recognized it he would be unaware that the test described was used by the same worker long ago. The final test is a quantitative one based on the trichromatic theory. This test has been most severely criticized, as it has been found that many colour blind people tested by it appear to be normal, and many normal people colour blind.

It would certainly have been more generous if Sir William Abney had acknowledged the fact that he had given up much which he had previously advocated in his published works and had wheeled into line with what his chief opponent had advocated years ago.

TUMOURS.

DR. A. E. HERTZLER'S *Treatise on Tumours*² is not a record of the author's experience but merely an attempt

¹ *Researches in Colour Vision and the Trichromatic Theory*. By Sir William de W. Abney, K.C.B., D.Sc., D.C.L., F.R.S. London: Longmans, Green and Co. 1913. (Med. 8vo, pp. 428; plates 5. 2s. net.)
² *A Treatise on Tumours*. By Arthur E. Hertzler, Professor of Surgery in the University of Kansas. London: J. and A. Churchill. 1912. (Imp. 8vo, pp. 736; figs. 538, plates 8. 30s. net.)

to combine an account of the clinical aspect of tumours with a description of routine pathological diagnosis. It is by no means such a complete work as its title might suggest. The results obtained by the work of the experimental oncologists have been by design entirely omitted. There are no details of surgical technique apart from a few diagrams and brief indications as to the methods advised by the author.

The first section is devoted to a sketch on the general biology of tumours, whilst the second deals with the special pathology of tumours. Both give a clear account of the subject, but are rather elementary. The teaching is dogmatic, and therefore might be criticized in detail; but all short and dogmatic expositions of these subjects are open to this objection. Little space is devoted to the relation of tumours to embryological development. It is interesting to find that the author is opposed to the routine removal of small pieces of tumour for pathological diagnosis unless radical operation is to follow immediately, holding such practice to favour dissemination. There is no mention of chloroma or of arsenic cancer of the skin.

The third section of the book is devoted to a regional consideration of tumours. It is very unequal, and there is a great lack of proportion. The chapters dealing with the breast, stomach, intestine, and the ovary are satisfactory. The clinical discussion of intracranial tumours is very weak, as is that of intrathoracic tumours. As an illustration of the lack of proportion may be mentioned the fact that tumours of the thyroid are dismissed in one hundred and twelve lines, whilst tumours of the carotid body receive almost the same amount of letterpress. Again, carcinoma of the vulva is dismissed in five lines, whilst four pages are devoted to the rare condition of esthiomene. Twelve lines of letterpress serve for the discussion of developmental tumours of the back. Splenic tumours seem to have escaped mention.

Generally it may be said that the author's teaching is good; it shows plenty of common sense and an almost complete absence of fads. The book is well bound and printed. The illustrations are multiplied beyond the wants of any professional reader, be he practitioner or student. Who wants four illustrations of lipomata of the neck or eleven of rodent ulcer of the face? The histological illustrations are also plentiful, but are not very good. No details of magnification, source of the material, or different structures illustrated are given below the pictures. In fact, the superfluous illustrations have extended what would have made a good student's manual into an expensive monograph which is beyond the means of the average student.

TEXTBOOKS OF PATHOLOGY.

IN bringing out their *Textbook of Pathology for Students of Medicine*³ Professor ADAMI and Dr. McCRAE invite comparison with Professor Adami's larger work (*The Principles of Pathology*) which has been published in two volumes, the first appearing in 1909 and the second, written in collaboration with Professor Nicholls, in 1910. As these two bulky volumes cover more ground than the average medical student can be expected to master, this shorter treatise has been prepared to meet his needs. Like the larger work, the present volume lays main emphasis upon the study of underlying principles; it is not intended as a cram book, but as one which shall enable the student to think for himself. "It is not the number of unit bricks that is of importance so much as a knowledge of the principles of construction. To be brief, we have endeavoured first and foremost to make clear and intelligible what is known concerning the deeper meaning of morbid states, and have not hesitated to sacrifice lists of data and their names." With this view as to the proper method of teaching pathology we are to a large extent in agreement; and we particularly approve of the authors' method of constantly bringing the student back to physiology, and making him realize that processes of

³ *A Textbook of Pathology for Students of Medicine*. By J. George Adami, M.A., M.D., F.R.S., and John McCrae, M.D., M.R.C.P. London: Macmillan and Co. 1912. (Med. 8vo, pp. 759, with 304 engravings and 11 coloured plates. 25s. net.)

disease can only be understood when interpreted in the light of what is known about normal development and normal functions. At the same time attention should be called to a possible danger, doubtless foreseen by the authors, against which it is well to guard. Existing knowledge of pathology is built up by sound induction from accumulations of observed facts. The student must never be allowed to forget that the facts come before the theories, and it is an essential part of his scientific training that he should learn to observe facts accurately, irrespective of the particular theories or principles which may or may not serve to explain them. Just as in the wards he is taught to make a full clinical record of his cases before he attempts diagnosis, so in the pathological laboratory he must first be trained to see all that there is to be seen; not until he has acquired this power can he be trusted to sift essentials from unessentials and to co-ordinate his facts in the light of general principles. In emphasizing the importance of theory regard must be paid to differences in the temperaments of students; with some there is a danger that a habit of *a priori* generalization may be formed, and that this will conduce to slipshod observation. All students will welcome the authors' gifts of clear exposition, and will appreciate their happy knack of enlightening a difficult point by a homely phrase or an apt simile from everyday life. But they may consider that scant tribute to their intelligence is paid in the elementary platitudes which crop up occasionally. Here is an example from the chapter on the urinary system: "The bladder is specially concerned in regulating the function of urination. Were it not for the bladder, the urine would be continually escaping; but it acts as a reservoir and at the proper time a mechanism for excretion." And again: "Incontinence of urine is the inability to retain it in the bladder." The candidate for a medical qualification who wrote wisdom such as this in his examination papers would not be likely to make a favourable impression upon his examiners. But these are only minor blemishes. If the writers would, as they easily might, cut out the platitudes, curb their desire to expatiate upon their own theories, and fill in the omissions with some of those "lists of data" which they "have not hesitated to sacrifice," their book would take the place it ought to occupy amongst the works best calculated to teach the student of pathology what he ought to know and how he ought to expand his knowledge with the experience which he will gain as a practitioner.

Professor HEWLETT'S *General and Special Pathology*⁴ has now reached a third edition, in which the text has been completely revised, though the general arrangement of the book remains as before. Writing for medical students who have only a comparatively short time to devote to the study of pathology, the author does not attempt to treat his subject exhaustively, but he succeeds remarkably well in setting out a great deal of valuable matter in a concise and attractive form. There is no "padding" in his book; he comes straight to the facts of essential importance, and limits himself to these, but, though he writes concisely, he never lapses into the tedium of a cut and dried epitome. The section on the etiology of neoplasms may be selected as an example of Professor Hewlett's skill as a teacher. The clear outline of the older theories and the excellent summary of recent cancer research are just what the student needs in order to obtain a firm grasp of this highly complicated and controversial subject. The difficult subject of immunity is also very well handled, and in the brief but very instructive account of epidemic poliomyelitis we are glad to see that due importance is given to the experimental researches of Flexner and others. Here, as elsewhere, it is evident that the author has spared no pains to bring his work up to date.

MUSCULAR SPASM AND DEGENERATION AS AN EARLY INDICATION OF CONSUMPTION.

A FRESH stimulus has been given to the study of the early diagnosis of consumption during the last few years by the

observations of Dr. F. M. POTTENGER in America and by other workers on the Continent with respect to the behaviour of the chest muscles which are in immediate relation with the apices of the lungs. The views of the former have now been published in this country in the form of a handsomely prepared volume,⁵ well illustrated and not too long. Briefly stated, the thesis he maintains is that muscles or groups of muscles obtaining their nerve supply from the same segment of the cord which receives the afferent nerves coming from the affected part of the lung are themselves put into a state of irritation and varying degrees of spasm, and that a process of degeneration may affect such muscles thereafter, causing them to become flabby and wasted. It will be seen that this theory owes its existence to the observations of Dr. Henry Head upon sensory nerves in relation to visceral disease. If the sensory nerves are affected, why not also those supplying the muscles? The early impairment of movement of an acutely affected apex is a matter of common experience, as is the subsequent flattening and immobility when disease has progressed and set up gross lesions. But it is now claimed that the first manifestations of disease may be demonstrated by skilled palpation and trained inspection. Irritability of the muscles about the affected apex is to be detected long before the internal lesion has advanced far enough to produce coarser signs. Skill in the detection of minor variations by palpation and percussion is notoriously wanting in some individuals, while in others the erudite tact seems to be abnormally developed.

It must be assumed that Dr. Pottenger belongs to the latter class of clinical observers; at any rate, he is able to refer to an experience ranging over some thousands of cases during the past three years, and to affirm the existence of abnormal muscular spasm in acute cases and of degeneration, as shown by a wasted or flabby state of the muscles in chronic disease, and even of the coexistence of these conditions where one apex is acutely affected and the other showing signs of advanced tuberculosis. Although enthusiastic as to the practical value of his observations, Dr. Pottenger fully recognizes that they are open to other interpretations, and he discusses many of these very fully. He explains by means of diagrams and anatomical drawings the various actions of the neck muscles and the results that have been from time to time described as due to their over-action upon the upper ribs when fixed by ankylosis of their joints, but the arguments are ultimately summarized in favour of the explanation which he has undertaken to prove. The whole monograph is interesting both from the scientific and the purely clinical points of view, but it has yet to be ascertained whether the early changes which are described can be detected by the palpatory powers allotted to the average observer, or whether a special sense is needed which can, or cannot, be acquired.

OPOTHERAPY.

DR. NAAMÉ'S studies in endocrinology,⁶ despite their slender bulk, contain a number of interesting and suggestive observations, more, indeed, than may sometimes be found in volumes of quite portly dimensions. Like most of us, the author is deeply impressed by the significance of recent discoveries with regard to the action of the various internal secretions; but, not content with a mere academic interest, he has thought out many of the problems arising out of these discoveries, and put his provisional solutions to the test of therapeutic experiment, with gratifyingly successful results. He is a strong believer in the future of opotherapy, and he certainly advances weighty evidence in support of the faith that is in him. Among the conditions whose pathogeny and treatment are briefly but concisely discussed are cholera, seasickness, the vomiting, diarrhoea, and night-sweats of tuberculosis, hysteria, epilepsy, the vomiting and cravings of pregnancy, and neurasthenia. Dr. Naamé regards the choleraic syndrome as the manifestation of an acute failure of the suprarenal bodies, due

⁴ *Pathology, General and Special*. By R. Tanner Hewlett, M.D., F.R.C.P., D.P.H. Third edition. London: J. and A. Churchill, 1912. (Post 8vo, pp. 624; Bgs. 15, plates 32. 10s. 6d. net.)

⁵ *Muscle Spasm and Degeneration in Intrathoracic Inflammation and Light-touch Palpation*. By Francis Marion Pottenger, A.M., M.D., LL.D., Medical Director of the Pottenger Sanatorium, Monrovia, California. London: Henry Kimpton, 1912. (Roy. 8vo, pp. 104; 16 illustrations, 9s. net.)

⁶ *Études d'Endocrinologie*. Par Docteur Naamé. Paris: A. Maloine, 1913. (Gr. 8vo, pp. 72.)

to the action of bacillary toxins upon them; and his view is confirmed by the cures he has effected in grave cases of Asiatic cholera by the administration of adrenalin. Seasickness he attributes to a functional inhibition of the suprarenals by reflex impulses of abdominal source: this condition he also finds responsive to treatment by adrenalin. In the chapter dealing with the pathology and treatment of hysteria, the author suggests that cerebral stability is conditioned by the functional equilibrium of the thyroid and parathyroid glands, which he regards as antagonistic, the function of the first being trophic and excitant, that of the second antitoxic and inhibitory. On this hypothesis, the fundamental condition in hysteria is a functional insufficiency of the parathyroids, with secondary thyroid exhaustion. Dr. Naamé treats the malady with moderate doses of parathyroid, with one-tenth as much thyroid extract. He considers that the inhibition of the parathyroids is due to a reflex impulse, usually of ovarian origin. Epilepsy he regards as a somewhat similar condition—a toxæmia due to inhibition of the parathyroids, with suppression of their antitoxic function. The fact that epilepsy is particularly liable to supervene at or about puberty indicates a causal relation between the functional changes that then occur in the ovaries or testicles and the disease. The author suggests that these changes involve a severe demand upon the inhibitory function of the parathyroids, which, in epileptics, is not adequately met. The vomiting of pregnancy is attributed by Dr. Naamé to auto-intoxication consequent upon arrest of the internal secretion of the ovaries, aggravated, during those early months when the symptoms are often most acute, by thyroid insufficiency. He has obtained good results by the administration of the combined ovarian and thyroid extracts.

VESICAL CALCULUS.

In a book of some 600 pages Professor SCHIAVONI¹ discusses with great fullness the subject of stone in the bladder. There are 134 illustrations, which really help the text and are good in themselves, a good bibliography, and a full index of proper names quoted in the book. The first six chapters deal with the physical and chemical properties of vesical calculi. Two chapters are allotted to the etiology and pathogenesis of cysto-lithiasis: symptoms, diagnosis, and prognosis each take up a chapter, then follows a historical retrospect of the various modes of treatment, a good account of the anatomy of the perineal regions, and full and detailed chapters on the various modern methods—one chapter alone is given up to a careful comparison of the relative merits of perineal and hypogastric cystotomy. The author goes rather fully into the anatomical alterations which arise in the bladder as the result of the constant irritation of a stone, and how these set up various infective processes, from a mild cystitis up to definite malignant growths. Lithotripsy and lithoplaxy are adequately described, and a comparison between these and cystotomy, with a final summing up as to the indications and contraindications for each method is given. A useful chapter at the end is devoted to certain considerations as to the general hygiene of these cases, whether operated upon or not. Looked at merely from the point of view of a compendium of recent and up-to-date knowledge about stone in the bladder, the work deserves high praise; it collects into one volume data as to analyses and syntheses which are scattered about in many different treatises, and large and wide as are the aspects of such a subject, it is hard to find a section that has escaped the notice of the author. The illustrations, which even in these days too often obscure rather than elucidate the text, are in this case conspicuously useful, relevant, and not redundant. Professor Roncali contributes a short commendatory preface.

¹ *Patologia e Terapia chirurgica dei Calcoli della Vesica Urinaria*. Del Professor M. Schiavoni. Turin: U. Tipografico. 1912. (Royal 8vo, pp. 615; plates 134.)

MAJOR R. J. BLACKHAM, R.A.M.C., who has been associated with Colonel Roberts, I.M.S., in the treatment of His Excellency the Viceroy of India since the outrage at Delhi on December 23rd, has been appointed Honorary Surgeon on His Excellency's personal staff.

NOTES ON BOOKS.

THE "Wellcome" *Photographic Exposure Record and Diary*¹ is correctly described by its publishers as a photographic encyclopaedia in brief. It combines a reliable treatise on the modern methods of photography, with ample space for a complete record of exposures under varying conditions, and a diary sufficient to chronicle the work of each day in the year. The book is in the form of a pocket-book with wallet and pencil, and provides directions very useful to the tourist both at home and abroad. The directions and formulæ given refer exclusively to Messrs. Burroughs, Wellcome, and Co.'s tabloid products, but it is sufficient to say that they are of high excellence. Those who use them will avoid the painful experience of seeing their negatives hopelessly stained and spoiled by employing impure and stale solutions. Negatives so stained—always, alas! the best—are periodically brought forth to be "doctored" by the latest process, only to be sadly returned to the cabinet as "incurables." The useful table of weights and measures contains only one mistake—the equivalent in grains of the decigram. The various methods of development, useful to the inexperienced, are fully described. The expert will probably still continue to watch and control the development of his plate as heretofore. The methods of control during development do not seem to have received the careful description that they deserve. The treatment of over-exposure recommended—namely, by development for strong contrast and subsequent reduction—will be rejected by most workers in favour of early fixation followed by intensification. With reference to the "exposure calculator" which is included in this handy little pocket-book, it may be pointed out that the whole secret of successful photography lies in accurate exposure, and no "calculator" which does not register the actually existing conditions of light can be satisfactory. It seems probable that an exposure meter, on the lines of the "chronoscope" recently introduced by Messrs. Lumière, will shortly be invented, applicable to colour photography also, both for out-of-door and interior work, and to that most difficult branch of the art, colour photomicrography. Directions are given for the treatment of autochromic plates by rytol. Of this we have no experience, but would prefer to use the developer and method recommended by the maker of the plate in an operation of such difficulty and delicacy. All the other departments of photographic work receive adequate attention in this excellent little treatise.

The Paris journal, *La Presse Médicale*, has published a handbook² to medical institutions in Paris and the facilities afforded for medical education. The greater part of the volume is concerned with the various classes and clinics, but the particulars given with regard to some of the hospitals will be of value to visitors, who will, however, probably turn first to the introduction, which deals more generally with the subject, and contains a paragraph on the Continental Anglo-American Medical Society.

In these days of civilian ambulance corps, rescue brigades, and voluntary aid detachments, books dealing with first aid and emergency treatment seem to be in demand. The essentials for such a book are that (1) it should explain this emergency treatment in simple, and as far as possible non-technical language; (2) it should not go beyond the legitimate sphere of first aid or emergency treatment; and (3) it should be issued at a price within the reach of all. The National Health Society, in their *Aid to the Injured and Sick*,³ seem to have met these essentials, and the issue of the thirty-seventh edition since its first publication twenty-five years ago is ample proof of this. The new edition has been brought up to date, and a special chapter has been added on the methods of carrying injured persons. Schäfer's artificial respiration has also been substituted for Sylvester's.

In quite a different category from the foregoing must be placed *Prompt Aid to the Injured*,⁴ now in its fifth edition. Although designed to be of practical value for home use

¹ The "Wellcome" *Photographic Exposure Record and Diary*, 1913. London: Burroughs, Wellcome, and Co. (Is.)

² *L'Enseignement Médical à Paris en 1912-1913*. Paris: Masson et Cie. 1913. (Demy 8vo, pp. 128. Fr. 0.50.)

³ *Aid to the Injured and Sick*. By Henry W. Gell, M.A., M.B. Oxon., M.R.C.S. Thirty-seventh edition. London: The National Health Society, 1912. (Fcap. 8vo, pp. 40. Price 2d.)

⁴ *Prompt Aid to the Injured*. By Alvah H. Potts, M.D. Fifth edition. New York: D. Appleton and Co. 1912. (Cr. 8vo, pp. 245; figs. 85. 6s. net.)

and among workmen, we find much of its information wholly outside the domain of legitimate first aid. We are told, for example, that normal bone struck with a probe gives a dull sound, but when the periosteum is removed it feels hard and rough, and gives a metallic sound; that a tampon should not be left in a wound longer than twelve hours; that poultices are employed to hasten the removal of a slough; that the alkaloid of a drug should be selected for hypodermic medication; and that the stomach may be emptied by siphonage, which is described. This information, as also the description of the spleen, the ligamenta subflava, the varieties of ligament, and granulation tissue, are all beyond that prompt aid in emergency by unskilled people which alone should be taught. We do not think any good purpose can be served by giving such anatomical, medical, and surgical details to miners and factory hands, the class for whom, according to the preface, this book is specially meant.

NOVA ET VETERA.

PROVERBIAL MEDICINE.

PROVERBS REGARDING ALCOHOL.

IN a previous article (p. 291) proverbs relating to diet in general were dealt with; now, some consideration must be given to those which are attached to special kinds of food. Indeed, some of the most interesting of medical or health maxims are connected with the meat and drink which satisfy or stimulate our appetite and nourish our frames.

First, some space may be given to the proverbs for and against alcohol. "And it came to pass . . . that they cried out and said O man of God, there is death in the pot";¹ and *mors in olla*² (death in the pot) has become a proverb. Now, notwithstanding the fact that the context of this passage makes it plain that gourds from a wild vine had been put in the pot, it has not been customary to think of this proverb as one that might be urged in support of total abstinence. Lean, however, in his *Collectanea*,³ has this interesting note: "This, I take it, does not mean the stewpot, but the drinking vessel. . . . If so, it is the earliest authority for total abstinence." It is, of course, quite certain that "in his pots" used to mean in a state of intoxication, just as "in his cups" means so still.

Though we can perhaps hardly find in Lean's argument sufficient proof to warrant the placing of *mors in olla* among the teetotal maxims, there are some sayings which may be legitimately used to strengthen the cause of temperance, and they deserve passing notice. "He that can master his thirst is master of his health" is one proverb, and it has a French equivalent—*Qui est maître de sa soif est maître de sa santé*. The Scottish poet, Henryson⁴ writing in the second half of the fifteenth century, gave the oft-quoted lines, "They drank the water clear. Instead of wine, but yet they made good cheer," expressing a sentiment encouraging to the temperance orator loath to admit that the cup cheers as well as inebriates. A series of sayings affirm that the mental output associated with alcohol is of poor quality. Longfellow, in his prose work *Hyperion* (Bk. IV, c. iii), wrote, "He who drinks beer thinks beer, and he who drinks wine thinks wine." Washington Irving, in that delightful part of *The Sketch Book* which is entitled "Stratford-on-Avon," tells the story of the drinking match at Bedford where Shakespeare, in spite of the proverb that "they who drink beer will think beer," was as true to his ale as Falstaff to his sack. Swift,⁵ in one of his letters to Mrs. Johnson (Stella), was evidently referring to the same maxim when he wrote, "We were to do more business after dinner, but after dinner is after dinner—an old saying and a true, much drinking, little thinking"; but the authorship of the saying is uncertain, for, although it has been attributed to Warburton,⁶ it is probably of earlier origin.

The teetotaler is not left wholly in triumph, for there is an antagonist's touch in the phrase, "They who drink water will think water." "Deep drinkers have ever

shallow memories" expresses a result of alcoholism in an easily remembered form; and in almost every language there is a proverb for the idea that "where the wine goes in there the wit goes out." Thus we have Pliny's statement:⁷ *In proverbiam cessit, sapientiam vino obumbrari* (It has become a proverb that wisdom is clouded by wine); there is the short and expressive German *voll, toll* (full, mad); there are two sayings in Italian containing the same notion, namely, *l'ino dentro, senno fuora* and *Dove entra il bere, se n' esce il sapere*; and there is the Dutch *Als de wijn ingaat, gaat de wijsheid uit*. Another result of alcoholic excess is hinted at in the Italian proverb, *Dove entra il vino, esce la vergogna* (Where wine enters, shame departs); and in Terence's play⁸ of *The Eunuch*, Chremes admits that the wine he has drunk has got the upper hand, finds that his female companion has become much more charming, and announces that it is a true saying that "Venus grows cold without Ceres and Bacchus" (*Sine Cerere et Libero friget Venus*).

The loss, under the influence of wine, of the intellectual powers and the domination of the mind by the lower desires are referred to in strong terms by the Pardoner in Chaucer's *Canterbury Tales*⁹; he is there made to say:

For dronkenesse is verray sepulture
Of maunnes wit and his diserecioun,
In whom that drynke hath dominiacioun,
He kan no conseil kepe, it is no drede;

and again, "A lecherous thyng is wyn." The loquacity born of alcohol is put in proverbial form in the Latin saying,¹⁰ *Quod in corde sobrii, id in lingua ebrii* (What is kept in the heart of a man sober is found in the tongue of a man drunk); and Horace¹¹ asks (*Quid non ebrietas designat?*) (What strange thing does not drink effect?) and answers, *Operta recludit* (It discloses secrets). Yet another maxim is "Wine neither keeps secrets nor fulfils promises."

A few proverbs are yet more condemnatory of the taking of alcohol. *Pures crapula quam gladius* (Drunkenness kills more than the sword) is a Latin saying, and "More men die of drink than of thirst" is an English equivalent; there are also two German ones, *Es trinken tausend sich den Tod, ehe einer stirbt vor Durstes Noth* (A thousand will drink themselves to death before one dies of thirst), and *Im Becher ersaufen mehr als im Meer* (More are drowned in the goblet than in the sea). The play upon words in the saying¹² "Beer fills many a bottle and bottle fills many a bier" has a smack of modernity about it.

Then there are the sayings which compare inebriety to insanity. There is, for instance, Sir Edward Coke's dictum,¹³ "As for a drunkard, who is *voluntarius dæmon*, he hath no privilege thereby, but what hurt or ill so ever he doeth, his drunkenness doth aggravate it"; and Coke's *voluntarius dæmon* is foreshadowed in the Latin proverb, *Nil similis insano quam ebrius* (Nothing is more like a madman than a drunk person). Cassio¹⁴ bitterly calls out, "O God, that men should put an enemy in their mouths to steal away their brains"; but Iago answers, "Come, come, good wine is a good familiar creature if it be well used; exclaim no more against it"; but Carlyle¹⁵ is with Cassio, for he blazes forth in his denunciation of gin, "liquid madness sold at tenpence the quartern!"

The well-known effect of alcohol upon the continuous smoothness and regularity of locomotion is found expressed in the Latin quotation from Plautus,¹⁶ who makes Pseudolus say, "*Magnum hoc vitium vino est, pedes captat primum, luctator dolosus est*," which may be rendered that "The great fault in wine is that it first trips up your feet; it is a cunning wrestler." Our own George Herbert,¹⁷ too, has the same idea in his lines:

 Pour the shame
Which it would pour on thee, upon the floore.
It is most just to throw that on the ground
Which would throw me there if I keep the round.

⁵ Swift, Jonathan, *Journal to Stella*, Letter XLII.

⁶ Benham, *Book of Quotations*, p. 446.

Herbert also refers to the disfigurement caused by alcoholic indulgence in the words :

Stay at the third cup or forego the place,
Wine above all things does God's stamp deface.

As one may quote, "The nose that is red cannot be hid."

"A morning sun, and a wine-bred child, and a Latin-bred woman seldom end well" comes from George Herbert's *Outlandish Proverbs*; and several sayings contain the idea that the child who is conceived in drunkenness seldom begins well. The ancient writers saw in Vulcan's deformity the result of Jupiter's inebriety. Burton,¹⁸ in his famous work, quoting from Plutarch,¹⁹ wrote, "*Ebrii gignant ebrios*" (One drunkard begets another), and cited Læmmius, Alvarius Crutius, Macrobinus, Avicenna, and Aristotle himself as of the same opinion. Plutarch¹⁹ reported of Diogenes that one day seeing a youth out of his mind and crazy, he said, "Young man, your father was drunk when he begot you" (*Adolescens, pater te ebrius genuit*). Other sayings refer to the lesser penalty of a conception under alcohol—the birth of a female infant. Lean, in his *Collectanea*,²⁰ has gathered from the old dramatists a number of quotations illustrating this belief—for example, "I lay my life 'twill prove a girl, because 'twas got in drink"; and "Till drunk he went to bed, and in that fit He got the second birth, a female chit."

Other proverbs, without actually condemning alcohol, do so by imputation by reason of their strongly expressed approbation of temperance. There is, for instance, the saying, "Temperance is a bridle of gold," which is found in Burton's *Anatomy of Melancholy*; there is also, "Temperance is the nurse of chastity,"²¹ and Pope's saying,²² "Health consists with temperance alone." Cicero wrote long ago, *Potest exercitatio et temperantia etiam in senectute conservare aliquid pristini roboris* (Exercise and temperance can preserve something of our early strength even in old age); and Rousseau, in more recent times, added his testimony—*La tempérance et le travail sont les deux vrais médecins de l'homme*. "Drinking water neither makes a man ill nor his wife a widow" is one of Kaye's proverbs,²³ and one quoted by Lean²¹ is "if you'd be healthy, happy, and stout, use nothing but water within and without."

The proverbs, maxims, and common sayings which have been taken notice of above may all be described as taking their stand on the temperance platform; but it can by no means be claimed that they are more numerous or more influential than those which gather themselves together on behalf of alcohol as a primo cause of well-being and conviviality. Indeed, proverbial biology must be regarded as a dangerous two-edged weapon in the hand of an ardent temperance reformer; he cannot safely trust to it in his contest with the evils of alcoholism.

Some proverbs recognize the dangers of wine, but hint that the same risks exist apart altogether from its use. There is, for instance, the proverb in Ray's collection that reads, "Drink wine and have the gout, drink no wine and have it too," a saying which is wittily transformed by Sydenham into, "If you drink wine you will have the gout, and if you do not drink wine the gout will have you." Others admit the risks of imbibing, but regard them as inconsiderable if the practice be restricted to certain occasions. Ovid,²⁴ for instance, maintained that given at the proper time wine is good, but given at an unfitting time it is injurious (*Data tempore prosunt et data non apto tempore vinu nocent*)²⁵; and Porter, in his *Two Angry Women of Abingdon* (1599), affirmed that "he is a fool will take more than will do him good."

In addition to these sayings in favour of moderate or of well-timed recourse to the flowing bowl, there are the proverbs which boldly and firmly take their stand on the side of the drinker. Lean²⁷ has gathered together a number of these sayings, so convenient to repeat when the bottle is travelling round the table. Here are some :

"Drink is the best physic"; "It is a good wind that blows a man to the wine"; "Wine makes good blood"; "Good wine makes good blood"; "Of all the meat in the world, drink goes the best down"; and "Good drinkers think none ill." Some of these are to be found in other languages; thus, in Spanish we find *El buen vino es buena sangre*,²⁸ and in Italian, *Chi bere vino bere sangue e chi acqua cotta flemma* (Who drinks wine drinks blood, and who drinks water drinks phlegm); and in Latin there are *Nunc vino pellite curas*²⁹ (Dispel now your cares with wine), and *Vina parant animos, faciuntque coloribus aptos, cura fugit multo diluiturque mero*³⁰ (Wine stimulates the mind and makes it quick with heat, care flees and is dissolved in much drink). One of Allan Ramsay's paradoxical and humorous sayings is, "They that drink longest live longest," and in a certain sense this is unanswerable; another proverb³¹ from the north of the Tweed is "A dreigh (long) drink is better than a dry sermon." The wine-lover carries the war into the teetotal physician's territory in the proverb,³² *Es nicht mehr alte Weintrinker als alte Aerzte* (There are more old wine-bibbers than old doctors); and the same idea is found in the French of Rabelais:³³ *Il ya plus de vieux ivrognes qu'il y a de vieux médecins*; but George Herbert, in his *Outlandish Proverbs*, turns this statement round into "There are more physicians in health than drunkards." There are, of course fallacies in any such statement; for one thing, those who drink alcohol are more numerous as a class than are medical men; there are doctors who drink as well as doctors who abstain, and so on. Proverb or no proverb, the insurance companies look with mistrust upon the drinker and more especially upon the "soaker." "Often drunk and seldom sober falls like the leaves in October."

"The drunkard's argument," as it has been called, is set forth by T. Adams:³⁴ "He that drinks well sleeps well; he that sleeps well thinks no harm; he that thinks no harm is a good man; therefore he that drinks much is a good man." Lord John Russell brought home with him from Spain a version of this proverb which he had got from a priest there. It ran thus :

Qui bene bibit, bene dormit;
Qui dormit non peccat;
Qui non peccat salvatus erit.

Another specious statement is, "That which doth an old man good can do a young man no harm," founded, we suppose, upon the aphorism that "Wine is old men's milk,"³⁵ which appears in Italian as *Il vino è la letta di vecchi*, and in French, *Ainsi peut il estre des enfans qu'on a laict, le vin desquels est le laict, comme, au contraire, nous disons que le laict des vieux c'est le vin*. The Bible itself has been invoked on behalf of wine-drinking: "Wine that maketh glad the heart of man" (Psa. civ, 15; *Vinum bonum lactificet cor hominis* in the Vulgate), and "Be no longer a drinker of water, but use a little wine for thy stomach's sake and thine often infirmities" (1 Tim. v, 23, R.V.), have been many a time dragged into the argument, to be met, of course, by the countervailing texts: "Wine is a mocker, strong drink is raging" (Prov. xx, 1); "Who hath woe? . . . they that tarry long at the wine . . . Look not thou upon the wine when it is red . . . at the last it biteh like a serpent" (Prov. xxiii, 29-32); and "Woe unto them that are mighty to drink wine, and men of strength to mingle strong drink" (Isaiah v, 22).

Some proverbs give special approbation to ale: "Good ale is meat, drink, and cloth" is from Ray's *Complete Collection*, whence also come the following lines :

He that buys land buys many stones;
He that buys flesh buys many bones;
He that buys eggs buys many shells;
But he that buys good ale buys nothing else.

It would seem that in the opinion of the proverbialist ale, good ale at least, gives man what he needs without injurious or unnecessary ingredients or accompaniments;

but Fergusson, in his *Scottish Proverbs*,⁸⁶ has a saying which gives a modified appreciation—namely, "Better good sale (health) nor (than) good ale."

One proverb is bold enough to recommend a drinking bout once a month, on the pretext, we may suppose, that there will be then an accumulation of evil humours which call for correction or expulsion; for a similar purpose periodical bleeding was once practised. The proverb⁸⁷ is: *Qu'il faut à chaque mois, Du mois s'enivrer une fois* (Every month one ought to get drunk at least once). Surely the boldest saying, however, is the Scottish one:⁸⁸ "God is kind to fou (drunken) folk and bairns"; or, as it is in French; *Dieu aide à trois sortes de personnes—aux fous, aux enfants, et aux ivrognes*. It is true that children and drunken men often fall without seriously injuring themselves, but it is hardly necessary to invoke a special providence for them, the more probable explanation being the fact that they fall without making violent efforts to save themselves. At any rate, "Who can help sickness?" quo' the drunken wife when she fell into the gutter," as Thomas Fuller's proverbial witticism puts it (*Gnomologia*). Arguments in favour of the bottle, whether expressed in proverb form or not, are often ingenious, sometimes persuasive, but generally evasive. It is easy to find reasons for doing what one wishes to do; a sarcastic proverb says: "A bad excuse is better than none," and many things "prove an excuse for the glass."

So far as proverbs go, the battle over alcohol must be regarded as a drawn one; if there is any advantage at all, it is to be found on the side of the drinker rather than on that of the abstainer. But, if we look more particularly at the medical proverbs, it will be discovered that they give a stronger support to the latter; whilst the sayings which refer to conviviality and sprightliness and to a certain unbending of manners and flow of conversation go over in a body to the former. In this matter actual facts deserve more respect than proverbial wisdom. Indeed, many of the proverbs obviously are special pleaders, and some are brazen-facedly prejudiced. *In vino veritas* (*év αίνο ἀλήθεια*) may contain a truth, albeit an unwilling or involuntary one; but who shall say that *pro vino* arguments are unbiased? By the way, and before we pass from this subject, it will be news to some that the maxim "You can't make people sober by Act of Parliament" did not, as at first employed, refer to non-indulgence in alcohol at all; the word *sober* in it had the significance of moral or virtuous. Of recent years it has not uncommonly been used by those who are opposed to temperance legislation. The opinion it expresses may turn out to be true, but the proverb in its inception did not contain the thought which had been put into it.

NEMATODES IN THE PRODUCTION OF CANCER.

In cancerous and other tumour formations there may sometimes be observed either in the growth itself or in its surroundings certain animal parasites, especially helminthes, and it may be assumed that these parasites stand in a causal relationship to the neoplasm, just as chronic irritants of other kinds. In bilharziosis there occur tumours which are not only identical with carcinoma and sarcoma histologically, but which have been shown to produce metastatic growths when the primary lesion is in the bladder. Scattered throughout the literature of cancer are various observations on the presence of nematodes in human cancers, but it has not been justifiable to conclude that the concurrence of tumours and parasites is more than accidental. Borrel has laid great stress on the occurrence of endemic cancer of mice, holding that certain parasites—*Demodex*, *Nematodes*, *Cysticercus*, and others—may carry an unknown virus capable of producing tumour formation, and he has not only demonstrated such parasites in the tumours of mice, but he has found the *demodex* in human cancers, in early epithelioma of the face and in carcinoma of the breast. As far as his published papers go, it cannot be said that he has established his hypothesis because he had no controls wherewith to judge the

frequency with which these parasites existed in non-tumour conditions, and, as a matter of fact, Orth and Tsumoda proved the presence of the *demodex* in the nipples of women without cancer of the breast as well as with it. Italand, when working in the laboratories of the Imperial Cancer Research Fund, found nematodes in the mammary glands of a large number of old mice, and there was undoubted evidence that they produced pathological changes, intense inflammation, and sclerosis of the connective tissue, often accompanied by hypertrophy of the mammary epithelium. He considered that these interstitial changes might be the eliciting stimulus of malignant epithelial growth in view of the great frequency of carcinoma in the mammary glands of mice. Whatever view be taken regarding the relationship of such parasites to new growth, causal or casual, the use of such ideas as a working hypothesis needs no justification.

Gastric Tumours in the Rat.

In a communication appearing in the *Berliner klinische Wochenschrift* of February 17th, Professor Fibiger, of Copenhagen, has brought forward a very convincing proof that nematodes really have a pathogenetic significance. In 1907 he noticed, in performing autopsies on three rats which had been injected with tubercle bacilli and which had been kept in the same cage, that the stomachs were the seat of large papillomatous growths, the walls were much thickened, and the cavity of the stomach was almost obliterated. The growth was the same in all and was probably malignant in nature. The rest of the alimentary tract was normal; no other pathological changes except pneumonic patches in the lungs could be found; and there were no metastases in other organs. The tumour material was injected into a number of normal rats, subcutaneously or intraperitoneally, and four rats also were fed on tumour tissue, but in no case did a positive result follow. Microscopic examination of the tumours showed marked thickening of the stomach wall due to epithelial hyperplasia and papillomatous formation in the mucous membrane with a breaking through of the muscularis mucosa by the proliferating epithelium, and the formation of isolated cell-nests and islets of squamous epithelium in the submucosa. Here and there, extending through the muscular coat on to the serous covering, were cysts filled with cornified epithelium. There was considerable round-cell infiltration and irregular proliferation of the connective tissue. The pylorus in all cases was normal. It has to be borne in mind that the rat's stomach is separable into two parts—the fundus lined by squamous epithelium, and the pyloric part lined by cubical and columnar cells, and all these growths were of the nature of squamous epithelioma.

Nematode Eggs and Embryos in the Tumours.

On further investigation of the histological preparations Professor Fibiger found oval holes in the epithelium under the stratum corneum, while other similar spaces contained complex bodies suggestive of a parasite containing eggs. By serial sections he was able to reconstruct this parasite, apparently a nematode, measuring 1.6 cm. in length by 0.25 mm. in diameter. The eggs had a double contour, and contained coiled-up embryos. Such eggs were also found lying free between the upper layers of the epithelium. In later researches he succeeded in teasing out three complete nematodes from fixed tumour material. The nematode is of a hitherto undescribed species.

The Cockroach the Intermediate Host.

The interest of the investigation starts from this observation, and one cannot but admire the determined way in which Professor Fibiger set himself to discover whether the association of the parasites with the tumour formations was more than accidental. In order to obtain an idea of the frequency of cancer of the stomach of the rat and also of nematodes in the stomach of that animal—a very essential preliminary—he performed autopsies on 1,144 rats, and minutely examined the stomachs, with the result that he was able to pick out only 11 cases which showed, at most, very small ulcers or epithelial hyperplasias; nothing remotely resembling the condition of the cases above described could be found. In 12 of these rats the mucous membrane contained a nematode, and in 10 more another kind of nematode was found free in the cavity; in the former case the parasite belonged

⁸⁶ Fergusson, David, *Scottish Proverbs*, 1641.

⁸⁷ Benham, *Book of Quotations*, p. 728.

⁸⁸ *Ibid.*, p. 754.

to the trichosomes and in the latter to the ascarids, but in neither case did it resemble the parasites originally found in the three tumour rats. The series was therefore sterile as far as the tumours and parasites sought for. After much inquiry Fibiger managed to trace the three rats to Dorpat, in Russia. Presumably Danish mice were not affected with the disease. The problem was now to discover the life-cycle and habitats of the peculiar nematode, for it was possible that some intermediate host played a part in its development. In consequence of a communication by Galeb showing that the cockroach, *Periplaneta orientalis*, was the intermediate host of a filaria which in other stages was found in the stomachs of rats, attention was directed to this possibility, and a number of wild rats (*Mus decumanus*), in the stomachs of which could be found the *Periplaneta orientalis*, were obtained; but in none were nematodes or new growths discovered, and feeding experiments with these cockroaches were quite negative. Entirely different results accrued from the examination of a number of rats from a large sugar refinery, where the cockroaches belonged to the species *Periplaneta americana*. From the beginning of March till the end of December, 1911, 61 rats were caught in this locality; 25 of these were killed immediately and the rest were isolated in the laboratory and examined when they died spontaneously. In 21 of the whole number the fundus was normal and no parasites were found, but in the remaining 40 that part of the stomach showed nematodes, which in size, form, and the appearance of the eggs were identical with the long-sought-for nematodes. In 18 of the 40 rats the stomach showed striking pathological changes that might be considered as stages of definite tumour formation, and of these no less than 9 showed very advanced tumours of the same type as those originally found. The result, therefore, seemed to indicate that it was no accidental association, and that *Periplaneta americana* was the intermediate host of the parasite.

In order to establish more firmly this fact, 57 rats, bred and reared in the laboratory, were fed with *P. americana* from the sugar refinery. The feeding experiments lasted for five to twenty days, and the largest number of cockroaches given to any one animal was 94. These rats were isolated and examined only when they died. The result was that in 3 neither nematodes nor tumours were found; in 54 nematodes were discovered in the stomach; in 18 of these the fundus was normal, but in 36 the pathological changes of growth formation were obtained, being very marked in 7 and identical with the original type discovered. The nematodes also were identical in size, shape, and as regards the eggs. There was thus no doubt that the tumour formations were dependent on a particular nematode carried by *Periplaneta americana*. Free eggs were found in the excreta of animals infected with nematodes, but no embryos, nor did embryos develop from the eggs, even when the excreta were kept for six months. Further, it was impossible to infect rats with these eggs; the cockroach was necessary for the development of the embryo. Microscopic examination of *Periplaneta americana* did not reveal any parasite in the alimentary canal, but in the striated muscles of the extremities and in the prothorax, spiral, trichina-like bodies often surrounded by a fine capsule of connective tissue were easily discovered, and were unmistakably further stages of the eggs. In order to be quite certain that no other parasite existed, an endeavour was made to transfer the nematode to those cockroaches which already had been found not to harbour it naturally, namely, the *Periplaneta orientalis*, and it was easily accomplished in every case by allowing these latter cockroaches to feed on the eggs of the nematodes or on the excreta of the infected rats. When they were investigated forty-two to sixty days afterwards the same curled-up embryos were found in their muscles as were seen in *P. americana*. A new series of laboratory rats were now fed with the artificially infected *P. orientalis*. Out of 11 rats fed on cockroaches which had been infected from infected rat excreta, 7 showed nematodes in the stomach, and in 3 of these cases there was the marked hyperplasia of the mucous membrane as originally described; and in 12 more rats fed with cockroaches infected by the eggs parasites were found in 3 cases, in 1 of which marked tumour formation

was evident. As control experiments 43 fresh laboratory rats were fed on non-infected cockroaches, each getting 11 to 50 (as compared with half of the prothorax of a single cockroach in the infected experiments), and in no case did pathological changes in the stomach ensue. It could always be told in from six to eight weeks by an examination of the excreta, after administration of infected cockroaches, whether the rats developed nematodes or not, for the eggs are easily distinguished.

The Life-History of the Nematode.

The life-history of the nematode is as follows. It lives in the squamous epithelium of the rat's stomach, occasionally also in the gullet, and sometimes in the tongue; in these situations it matures, and gives off eggs, which are thrown off with the epithelium and excreted with the faeces. The cockroach eats this, and the eggs develop into free embryos in the muscles of the extremities and prothorax, where they can be detected as trichina-like bodies in six to eight weeks after ingestion; if such cockroaches be now eaten by the rat, the embryos escape from their capsule, and migrate to the fundus of the stomach where the female after two months commences to deposit eggs. The size of the male nematode is $\frac{1}{2}$ cm. long by 0.1 mm. to 0.16 mm. in diameter, and of the female 4 cm. to 5 cm. long, by 0.2 mm. to 0.25 mm. in diameter. The eggs are oval and clear, and are surrounded by a double contoured membrane, which is thicker at the poles. They measure 0.06 mm. by 0.04 mm., and contain curled-up embryos with ringed cuticle. The nematode is of a kind not hitherto described, but it can be assigned to the genus spiroptera.

The Pathological Changes Produced by Nematodes.

Of the 118 rats investigated, 61 from the sugar refinery and 57 experimentally infected in the laboratory, 94 contained spiroptera in the fundus of the stomach; in 40 the presence of the parasite was the only abnormality, whilst in 54 there were distinct anatomical changes. The parasite was only found in that part of the stomach lined by squamous epithelium. It lay between the stratum corneum and the stratum granulosum, though in a few cases it was found deeper in the epithelium. The pathological changes found were divisible into three stages shading into one another. In the case of 15 rats the changes were slight, the mucous membrane being thickened locally or diffusely, and appearing less opaque than normally; in 23 cases the change was marked, the mucous membrane was much thicker and the thickening was more diffuse, the surface was uneven and raised in papillomatous folds; in 16 rats the condition was advanced, the mucous membrane being covered with small and large papillomatous growths occluding the lumen, whilst the wall of the stomach was often over a centimetre in thickness. In 4 cases the cavity was obliterated by papillomatous excrescences which closed up the opening of the oesophagus and extended to the pylorus. The external surface was corrugated with dense solid projections or with polypoid nodules. In 3 cases instead of this multiple papillomatous condition the growth took the form of a single hard mass, of the size of a walnut, reaching from the fundus to the pylorus. In only one case were the changes in the gullet markedly papillomatous. These growths caused marked destruction of the stomach wall, and there could be no doubt about their infiltrative nature, and in at least four of the series it was very extensive. Certainly in 2 cases, and probably in 3, metastases were found in the lungs and retroperitoneal lymph glands, but no parasites were discovered in these secondary growths. Professor Fibiger gives a detailed account of the histological characters of the growths, and it is beyond doubt that in the advanced cases at least he had to deal with true malignant tumours a condition to which the other formations might quite well have attained if the animals had not succumbed to intercurrent maladies.

Conclusion.

The association of a definite parasite with a definite tumour of a certain locality is not the most striking feature of these carefully planned investigations and successfully accomplished results, for the association of *Bilharzia haematobia* with vesical carcinomata, pointed

out by Professor Ferguson of Cairo, is perhaps as noteworthy, but one must accord to Fibiger the honour which is his due, as being the first definitely to produce experimentally new growths.

LITERARY NOTES.

IN the interesting Life of Tolstoi written by his friend and admirer Mr. Aylmer Maude, there is an amusing account of a scene at which the author was present. The great moralist bitterly upbraided some philanthropic lady for her work amongst slum children, and declared that such establishments as crèches or day nurseries were both unnatural and unnecessary in a civilized country. This opinion is strongly characteristic of the sage, who, in matters of everyday life, was one of the least practical of men. Despite his objections, however, to the crèche as a substitute for the mother, these establishments still continue to increase and multiply; and many hundreds of working women at the present day have reason to bless an institution which enables them to earn bread for their families without being haunted by the fear that the children will come to harm in their absence. The February number of *The Child* contains an article by Dr. Bernard Myers, in which the important part which may be played by a well-managed day nursery in the slums of a great city is very clearly shown. It is not merely the child's bodily welfare that profits by his daily sojourn in the crèche. Besides being properly fed and cared for, he is preserved, during the daytime at least, from possible danger in his own home and from the certain contamination of the streets; and the hours spent in pure and wholesome surroundings can hardly fail to have as beneficial effect upon his moral as upon his physical growth. Moreover, many crèches include a school for mothers, where they may learn the "mother-craft" in which so many women of the working classes are lamentably deficient. Mother-craft is more or less a lost art with a large proportion of the present generation of women; and it is to remedy this defect in modern education that Dr. G. Finch (whose article on the feeding of infants appears in the February number of *The Child*) suggests that the training of every schoolgirl should include a certain amount of instruction in the care of young children. The same number also contains an interesting account by Dr. David J. Williamson, of the Kensal House open-air school for tuberculous children.

It is seldom indeed that a prophet receives from his own countrymen the honour which is his just due. The consumption of frozen meat, for instance, is far greater in England than in France; and yet it is to a Frenchman that we owe the foundation of the refrigerating system. The January number of *L'Hygiène* contains an interesting account by M. Henri Meurisse of Charles Tellier's discovery of this method of preserving meat, which hitherto has found more favour in other countries than in his native land. M. Meurisse does not share the common prejudice against frozen food. On the contrary, when it has been properly stored, he considers it to be almost as appetizing and nutritious as when fresh, and offers it to his readers as a satisfactory substitute for the expensive article sold by the Parisian butcher, and a convenient solution of the house-keeping problems brought about by the scarcity of good meat and its prohibitive price in France at the present moment. French meat, as a rule, is less palatable than English. The same number of our excellent contemporary contains a short account by Dr. Maurice de Fleury of neurasthenia in childhood; whilst Dr. V. Ch. Lefèvre writes on the heating of private houses by electricity, and Madame Augusta Moll-Weiss contributes another of her series of articles on the hygiene of the home.

The study of place-names is one of the by-ways of history which, if followed with care and discrimination, may lead to conclusions far more wide-reaching than might at first sight be anticipated. It demands a strict application of the scientific method, and an intimate acquaintance with the district, and with the changes in its population and topography which have occurred in historic times. These qualities are shown in a paper on Scotter and Scotton

contributed to the *Antiquary* at the end of last year by Dr. T. B. F. Eminson, of the former place. Both villages are in West Lindsey, a part of Lincolnshire extending from the east bank of the river Trent to the foot of the Cliff Hills. There is probably no part of northern Europe which promises better results from the study of place-names than the eastern side of England, for the inquirer may hope to throw light on the history of the successive invasions, how far they were mere raids and how far colonizations, and on the lines of traffic and the social organization of the people in the early days of our history. "Scot" occurs in a good many place-names in Lincolnshire, more, Dr. Eminson says, than in any other midland, perhaps than in any northern county. The prefix has nothing to do with the Scots or Scotland. It is really "cote" or "cote" with a contracted prefix which, he argues, signifies south. "Cott" is an Anglian word denoting a habitation, temporary or permanent, for man or animals, and survives in "dovecote." It was applied to the cotes or cottages of outlying cottages, and hamlets; it seems to have been extended to villages, but the proper term for a village was "tan," and the word is, or was until recently, applied in East Yorkshire and Lincolnshire to the smallest village. Dr. Eminson is able to show that Scott was once (*temp.* Henry VIII) Secotton, and maintains that "Se" is a contraction for "South," being led thereto, apparently, by the situation of Scotton and Scotter in relation to the river. Scotter appears in Domesday Book as Scotere, which we gather is to be dissected as S-cote-re, meaning South-cote reach (of the river); in support of this interpretation the fact that the surname Scotrick occurs in Lincolnshire is mentioned. From these beginnings Dr. Eminson launches out into an interesting discussion of the meaning of other place-names in the neighbourhood which he thinks—and he supports his opinion with many ingenious arguments—throw light on the lines of traffic in Roman and early English times. The district lay between the waterway of the Trent and the roadway of Ermin Street. The river and its tributaries, then navigable to a much greater distance from the main stream than to-day, formed the link which connected Doncaster and southern Yorkshire with Ermin Street. The traveller would take boat on the west bank of the Trent at Butterwick—in Domesday Book, Butrewic, which is to be interpreted "boat reach village"—and pass east to somewhere near the foot of the Cliff Hills along which Ermin Street ran.

Messrs. J. and A. Churchill are about to publish a book entitled *The Difficulties and Emergencies of Obstetric Practice*, by Mr. Comyns Berkeley and Mr. Victor Bonney, Obstetric and Gynecological Surgeons to the Middlesex Hospital. The book will contain a large number of original illustrations by an artist who is himself a medical man. The same publishers have just ready the sixth edition of *A Short Practice of Midwifery*, by Dr. Jellett, Master of the Rotunda Hospital, Dublin. The new edition is to be issued with a larger page; it has been revised throughout and contains many new illustrations. The popularity of the book is evident by the fact that 20,000 copies have been printed.

THE Permanent Committee of the International Congresses of Medicine gives notice that three prizes will be awarded during the International Medical Congress in London next August. The Moscow prize of 5,000 francs, instituted in commemoration of the twelfth congress, which was held in that city, is given for the best work done in medicine or hygiene or for distinguished services in the cause of suffering humanity. The Paris prize of 4,000 francs, founded at the thirteenth congress, will be awarded to the person judged to have made within the last ten years the most important original contributions to the advancement of medicine, surgery, obstetrics, or to anatomy or biology in their applications to medical science. The Hungary prize, which was established by the sixteenth congress at Budapest in 1909, is awarded for some work in medical science which has been published in the interval between one congress and the next. This prize is of the value of 3,000 crowns. The Permanent Committee is prepared to receive suggestions to guide it in the award of these prizes. Communications, which must reach it before June 1st next, should be addressed to the committee at 10, Hugo de Grootstraat, The Hague, Holland.

British Medical Journal.

SATURDAY, FEBRUARY 22ND, 1913.

THE REFORM OF THE HOSPITAL OUT-PATIENT DEPARTMENT.

THE attention of the profession has been so entirely concentrated on the Insurance Act that other matters, even those in which in normal times it is most interested, have received scant notice. Thus it was that the Report on Hospital Out-patient Departments, issued in July last by the Committee of Enquiry appointed by King Edward's Hospital Fund, received comparatively little attention. It is, however, a most interesting and important document, especially to members of the British Medical Association, for it is a striking endorsement by the most important hospital authority in this country of the views arrived at by the Association after a good many years of patient and apparently hopeless work. We would urge those who are interested in this subject to read in the SUPPLEMENT to this issue, first the Memorandum of evidence placed by the Association before the Committee, and afterwards the Report of the Committee.

The question of hospital abuse, which has always been largely a matter of abuse of the out-patient department, has occupied the attention of several generations of medical reformers, and after the reorganization of the Association in 1903 it became one of the chief items in its programme. Gradually, year by year, from 1905 onwards, the Representative Body built up its policy, partly by discussion in the Divisions, in Committees, and in the Representative Meeting, partly by conferences between the Association and representatives of the hospitals. The aim of the Association to elevate the out-patient department from its present position as a mere casual dumping ground for all kinds of complaints, from the most trivial to the most severe, to its proper place in the organized medical service of the nation, steadily gained acceptance amongst those whose opinion was best worth having. But individual hospitals, although they might be convinced, were afraid that if they took isolated action they would suffer in the competition which is such a marked feature of the hospital world. To cut down the numbers swarming into the hospitals was to abandon the most telling appeal to the charitable but unthinking public—no case ever refused, so many thousand more patients relieved than last year. A lead was required. When in January, 1911, the governors of the King Edward's Fund appointed their Committee the Association gladly took advantage of the opportunity of placing evidence before it, for, apart from the power of the purse which the Fund exercises over so many of the London hospitals, there is no doubt that any decision taken by the Fund as to the principles of hospital management will have far-reaching influence.

The Report of the Committee is almost entirely in consonance with the principles the Association has enunciated, often, indeed, the very words of the Association are used. The Report states plainly that

the out-patient department is not a fitting place for the treatment of trivial complaints, and that these should be sent away untreated except where it is deemed necessary to give first aid. It declares that the most appropriate function of the hospitals is to act as specialist and consultative agencies. It acknowledges that the out-patient departments are at present competitors with general practitioners and provident medical institutions for the attendance on persons suffering from ordinary ailments and quite able to pay small fees. It declares that the out-patient department as at present conducted hinders the establishment of provident medical services and so discourages thrift, and that the overcrowded department tends to hurried diagnosis and superficial treatment. The Committee concurs in the recommendations of the Association that the use of subscribers' letters and the system of payment by patients should both be abolished.

The Association long ago formed the opinion that the out-patient department should be a centre at which the very best medical and surgical advice should be available for those cases which could not get it elsewhere, and that this advice should be given in co-operation with the outside medical attendant of the patient, not merely in the interests of the general practitioner, but in order that the medical service of the poorer classes should be improved, and some order evolved out of what is at present chaos. Every person should have an ordinary medical attendant, either his private doctor or one attached to the provident organization of which he is a member, or, if he is too poor for this, then the parish doctor. Practitioners should be encouraged to send up their difficult or obscure cases to the hospital, secure in the certainty that the case would either be referred back to them with the opinion of the hospital expert, or, if thought advisable by the two doctors concerned, retained at the hospital for some form of treatment not available outside. The acceptance of these ideals involved, in the opinion of the Association, the acceptance of the proposition that, with the exception of emergency cases, no patients should be received at the out-patient departments except those sent there on the recommendation of an outside practitioner.

While the Committee thoroughly endorses the view that the ideal system is that outlined by the Association, it is not convinced that the selection of patients for the department can be safely left to the general practitioner alone, and, while recognizing the necessity of encouraging his co-operation to the fullest extent, is of opinion that a large development of the almoner system is essential. It will be seen that the views of the Association and the Committee are by no means incompatible. They overlap, for while the Association would rely chiefly on the co-operation of the general practitioner and would employ the almoner as an auxiliary, the Committee in its scheme puts the almoner first, giving that official various important duties, one of which is the development of the co-operation with the general practitioner. We are not convinced that the almoner system will do all that the Committee hopes from it, and we believe that the full development of the efficient out-patient department depends much more on the help of the general practitioner than the Committee yet realizes, but only experience will show the relative usefulness of the two methods. We shall not quarrel over their comparative importance, and we would welcome a thorough trial of the recommendations of the Committee just as they stand. We heartily congratulate Lord Mersey and the Bishop

of Stepney on a sound piece of work, destined, if not pigeon-holed, to be of great public usefulness.

The next step rests with the King Edward's Hospital Fund. It is believed to be watching the new hospital developments which are taking place under the stimulus of the Insurance Act before taking action, and a certain amount of delay is justifiable, for the action of St. Bartholomew's Hospital, followed as it has been by many other hospitals, is doing much to exclude unsuitable cases from the out-patient department. But this action will only exclude unsuitable cases among insured persons, who are in a minority in most out-patient departments. We trust that King Edward's Fund will not follow the example of Parliament as regards too many of the reports which are presented to it by commissions and committees, but will shortly proceed to exercise its persuasive powers with the hospitals to which it gives grants. The Fund has a great responsibility in this matter, for in the eyes of the public it stands for co-ordination and economy with efficiency. If the waste of money through the misuse of the hospitals, their overlapping and competition, could only be brought home to the public, the difficulties of raising the large annual sum necessary for the upkeep of the London hospitals, already formidable, would become unmanageable. For the Association the report of the Committee, following as it does on the emphatic endorsement of the hospital policy of the Association by the majority of the Poor Law Commission, is a most encouraging recognition of its past work and of the soundness of the principles which it has evolved and adopted.

IMMEDIATE OPERATION IN APPENDICITIS.

"Is the best result in the treatment of appendicitis to be obtained in the greatest number of cases by immediate operation or by temporizing?" This was the question put by Mr. Edmund Owen to the Medical Society of London on February 10th. His answer and the answer of all who took part in the discussion, it will have been seen from the reports published last week, is in favour of immediate operation—that is, operation as soon as the diagnosis is made, within the first twelve hours of illness if possible.

The appendix region is the seat of many surgical surprises. A case may present almost typical symptoms of inflammation of the appendix, and yet the appendix may be found to be practically normal; on the other hand, a case may present an extraordinary absence of definite symptoms, sometimes absence of symptoms altogether, and yet at operation the appendix may be found on the verge of gangrene. It is on this account that waiting for the "quiet stage" is condemned. There is, in the pathological sense, essentially no such thing as the quiet stage. Mr. Owen thinks the term unfortunate, for though there are cases in which the clinical evidences appear to subside, no one can tell with certainty what is then really going on inside the abdomen. Unless we see, we cannot know whether the inflammation has subsided, whether the appendix is "walled off," or whether the pathological process is about to hurry on to enter a worse stage. Is there, then, danger in waiting? Is it better to take a little increased risk by waiting in some few cases rather than subject many patients to unnecessary operations? To that the reply made is that the surgeon who waits cannot measure or control the risk to which he is

subjecting his patient. Delay of a few hours may be, and often is, harmless, but it may prove to be fatal. There is no need to rush the patient into an operating theatre for a simple right iliac colic, but let him be seen again in a short time—that is, in a few hours, repeatedly, if need be, and the diagnosis will usually become established. But if doubt still exists, a small exploratory incision can be made with almost perfect safety, and "that small incision is part of the scheme for arriving at a sure diagnosis." Mr. Owen does not think that it is a terrible calamity that an incision should be made to explore a suspected appendix and nothing found wrong. It is far better to make that kind of mistake and make certain of the patient's safety than to wait for signs and symptoms of such definite kind that, though the diagnosis is perfectly certain, the result of the operation is not. Mr. Owen would have us "Look and see" as early as possible. It must never be forgotten that there may be comparative absence of clinical evidences in the presence of advanced and perilous disease. The pulse and temperature may be normal yet the appendix may be gangrenous or perforated; there may be no fullness, even no rigidity in the right iliac fossa, there may be very little local tenderness, the patient may be actually cheerful and inclined to chaff the doctor. It is in these "stealthy cases" that the precious hours are so often lost.

Surgery will probably never become amenable to fixed rule. But fixed rules appeal to all men: we seek guidance, we hope for relief from responsibility. Here, then, is the rule for the treatment of appendicitis which Mr. Owen and every surgeon who took part in the discussion in the Medical Society have been driven by their own experience to adopt: Have the inflamed appendix removed as soon as you know it is inflamed; if your diagnosis is uncertain, see the patient frequently till it is certain; if you are still in doubt ask a surgeon's opinion, and even then if doubt exists let an exploratory incision be made rather than wait longer.

In the animated correspondence on "Appendicitis—and Quickness," in the *JOURNAL* in the early part of last summer, and in the debate on appendicitis in the Surgical Section at Liverpool in July, the preponderating weight of opinion was in favour of operation as soon as the case was known to be indubitable appendicitis. So far as we remember, the only opinion in favour of temporizing was that of Sir George T. Beatson, an able and earnest controversialist. His views are crystallized in a paper in the November issue of the *Glasgow Medical Journal*. In discussing "Three Hundred Consecutive Cases of Appendicitis," he says that it is not sufficient to make a simple general diagnosis of appendicitis, but that with care and experience the type of attack may be recognized and the line of treatment suitable to it decided upon. He recognizes that cases of general suppurative peritonitis, whether developing quickly or spreading from a local focus, require immediate operation. But "all the other types of acute appendicitis are best dealt with by the expectant method of treatment—unless a collection of pus points externally when it is opened—and operated on when pulse, temperature, and blood count are normal—that is to say, when they are in the quiescent stage." He says further: "If the presence of a local abscess is indicated by a high blood count the operation is postponed till it becomes normal or sufficient time has elapsed to allow the pus to lose its virulence; clinical experience has shown that this comes about in three weeks." In his opinion the teaching that a localized intra-peritoneal abscess should be at once dealt with is

wrong and responsible for many deaths; this localized abscess should be given time to form adhesions to the parietal peritoneum. These opinions, in which Sir George Beatson finds little support from other surgeons of experience, he supports by his statistics. Excluding interval cases and cases with general suppurative peritonitis, in 164 cases, 69 of which had localized abscess, the death-rate was only 2.4 per cent. But Mr. Grey Turner's statistics on the other side seem equally convincing. In 130 cases of acute appendicitis with localized peritonitis the mortality was 2.3 per cent. Sir George Beatson's success is due in great measure to the fact that his cases are kept under highly-trained observation and very carefully nursed. But it cannot be ignored that if his views were generally accepted practitioners in family practice would be tempted to keep the patients too long at home, and so often to court disaster. If we were all possessed of Sir George Beatson's experience and ability to tell the type of attack, we might trust ourselves to see the patients safely through the present illness, but the family practitioner's first duty is to see the appendix case safely into the hands of the surgeon at the earliest possible moment. Then, again, the factor of length of illness must be taken into account. In Sir George Beatson's cases operation may not have been performed until three weeks after admission; by that time most cases leave the hospital.

It seems to us that Mr. Stiles's convincing speech at the Surgical Section in Liverpool carried the truth with it when he said that we must give up our old fear of the peritoneum, that the incision should be big enough to make sure of finding the appendix, *fons et origo mali*, and that in ether as anaesthetic, the Fowler position, and the administration of saline solution in the after-treatment we possess agencies powerful enough to combat and conquer the risks of immediate operation.

A NEMATODE IN RAT CANCER.

THERE can be no doubt that the investigations reported to the Medical Society of Copenhagen on January 7th, by Dr. Johannes Fibiger, Professor of Pathological Anatomy in the University of Copenhagen, are a very notable contribution to our knowledge of the etiology of cancer. It has, therefore, seemed well to publish elsewhere in this issue (p. 400) a full account of the observations recorded in a paper he published in the *Berliner klinische Wochenschrift* for February 17th; a further and fuller report is to be published later in the *Zeitschrift für Krebsforschung*. Meanwhile, however, the paper already published is sufficiently detailed to show that Professor Fibiger, by a long series of most careful and painstaking researches, during the prosecution of which it is clear he has been fully alive to the many sources of fallacy by which the subject is beset, has been successful in showing that a certain nematode, a new species belonging to the genus *Spiroptera*, has an intimate connexion with gastric carcinoma of the rat and that the cockroach is the intermediate host of this parasite. In discussing the results of his researches he cautions his readers against applying to man conclusions which he has proved to be highly probable for rats, and he observes that while some evidence has been brought forward at various times tending to prove that helminths may play a part in the causation of human cancers, this part may be quite a minor one, and that, in spite of the work of Klopsch in

1863, and of Langenbeck, Linstow, Babés, Groth, and Strandgaard, we do not yet know what the relation is between trichinae and carcinoma.

Professor Fibiger tells his story in a quiet and un-sensational manner. It goes back to 1907, when he came across three rats from the same cage with marked papillomatous changes in the stomach which proved to be fibro-epithelial tumours, and were thought to be probably malignant, though attempts to transplant these tumours into other rats failed. On microscopic examination of the stomach of the three original rats he noticed in the epithelium of the affected parts round or oval spaces close to the stratum corneum. Some of these spaces contained small bodies presenting a complicated structure which suggested sections of a parasite containing eggs. Every one must admire the skill and patience with which Fibiger set himself to, as it were, reconstruct those parts of the tumours from his serial sections so as to ascertain the nature of these bodies. Eventually he was able to satisfy himself that what he saw were sections of a nematode about 1.6 cm. (about $\frac{3}{4}$ in.) long and about 0.25 mm. in diameter. The nematode contained eggs, and in the eggs were band-shaped embryos rolled up into a coil. His next step was to determine whether this gastric lesion in rats was rare or common. Upwards of 1,144 rats were examined; but although other stomach lesions and other parasites were found, the peculiar form of tumour and this special nematode were not met with in a single instance. He concluded that this gastric carcinoma was rare in Danish rats, and he succeeded in ascertaining that the three rats in which he had originally found it came from Dorpat. He argued that if the nematode had a causal relation to the disease it must have an intermediate host. Galeb had stated in 1878 that the common host of *Filaria rhytipleurites*, which infests the stomach in rats, was a species of cockroach, *Periplaneta orientalis*, and Fibiger accordingly turned his attention to this common object of the town scullery. His first experiments yielded only negative results. From rats in a sugar refinery infested by another kind of cockroach, *P. americana*,^{*} however, he got positive evidence: 61 rats were caught, and in the fundus of the stomach of 40 of them nematodes were found, corresponding to those seen in the three original rats. In 18 of these 40 rats there were changes in the stomach which might be interpreted as due to an early stage of tumour formation, and in 9 cases there were tumours identical with those found in the three original rats. This confirmed the opinion that the association of the nematode with tumour formation was not accidental. He thereupon selected 4 wild and 53 laboratory rats which had not been in contact with cockroaches, and fed them on the American cockroach for from five to twenty-five days. Only 3 rats were found after death to be free from the nematodes, and 36 of the 57 showed changes in the stomach, while 7 of them presented tumours identical in character with those in the original three. He next sought and found the nematode in the bodies of the cockroaches. He found also that the other species of cockroach—*P. orientalis*—was easily infected with the nematode by feeding on the ova or on the excreta of infected rats. The embryos were found in the striped muscles of the prothorax and extremities of the cockroach.

The nature of the stomach lesion was studied in 118 rats, 61 from the sugar refinery, and 57 experimental animals. *Spiroptera* were present in 94, and

* *P. orientalis* and *P. americana* are two of the three commonest species of cockroach.

in 54 there were anatomical changes the extent and nature of which varied, possibly in relation to the number of parasites and to the duration of infestation. At any rate in four rats, which lived from 214 to 275 days after feeding on the cockroaches, the tumours had a carcinomatous structure. In two of the four there was metastasis in the lungs and retroperitoneal glands; in a third there was a tumour in the bladder, which may or may not have been metastatic. Nematodes were not found in the secondary growths.

If, as seems inevitable, we accept the conclusion that the nematodes stand in causal relationship with the tumours, the question how the parasite produces this effect arises. Professor Fibiger discusses the hypotheses that the nematodes act as carriers of a bacterial infection, or merely as irritants, but arrives at the conclusion that the facts he has observed are in favour of the hypothesis that the nematodes have a specific effect. This, he suggests, may be due to a toxic action, such as is known to be produced by other nematodes; one piece of evidence in favour of this view is the appearance of eosinophile cells in excess. If further investigations should establish the theory of a specific connexion between nematode and cancer, then Professor Fibiger's prolonged, ingenious, and careful researches will prove to have even greater importance than they can at present with certainty be held to possess.

THE INQUIRY ADDRESSED TO REGISTERED MEDICAL PRACTITIONERS.

THERE are doubtless many reasons why members of the profession, after the long and strenuous fight against heavy odds for the amendment of the conditions of medical benefit under the Insurance Act, should feel disinclined to answer more questions, but it is very desirable that all should answer the list of questions sent out by the British Medical Association about ten days ago. It is, we fear, too true, that the life of many medical practitioners has been made a burden by the recent excess of clerical work in the shape of signing "strawberry" cards, day-book entries, triple prescriptions, and all the other things demanded of the Act and regulations, and it is easy to appreciate the disinclination to incur further trouble. The regulations with regard to clerical work are now to be modified, and the amount will be reduced; and, in any case, this is not the time to give way to slackness, or to appear to encourage a policy of inactivity. It is above all things necessary that the profession at the present juncture should be alert, steady, and courageous, and do everything in its power to supply the information without which these who are waltzing over the interests of every member cannot act with the confidence which full information will afford. It is essential that the central organization of the British Medical Association should at an early date learn the views of those who are working the Act, and also the views of those who have not undertaken to do so. The necessary information can only be obtained if each man will do his duty in this respect, and every member can now help by sending in replies to the questions; they can be answered in a few minutes, and should be answered at once.

LOCAL MEDICAL COMMITTEES.

WE desire to call special attention to the resolutions of the State Sickness Insurance Committee of the British Medical Association adopted on February 20th, and printed in full in the SUPPLEMENT (p. 197). The Committee is anxious to obtain information with regard

to the constitution and action of Medical Committees and the names of medical members of Local Insurance Committees, whether directly elected by medical practitioners in the locality or otherwise appointed. The Committee is anxious also to have information with regard to the action taken by Local Medical Committees, and reports of their proceedings will be published in the SUPPLEMENT. If received not later than Tuesday in each week, it will as a rule be possible to publish a report in the issue of that week.

NAVAL MEDICAL OFFICERS AND CORONERS' INQUESTS.

EARLY in 1909 the attention of the British Medical Association was called to an Order of the Admiralty, issued in June, 1907, prohibiting naval surgeons from accepting fees from coroners for evidence given at inquests and for making *post-mortem* examinations, although the officers were left under the statutory obligation to give such evidence and make *post-mortem* examinations when so ordered by a coroner. In April, 1909, the Association submitted a memorandum upon the question to the Admiralty, pointing out the anomaly and injustice created by the Order and the fact that a similar disability was not imposed on officers of the Royal Army Medical Corps. The Admiralty, however, declined to depart from its previous decision. No further action was taken until March, 1912, when, evidence being forthcoming that the Order was the cause of considerable dissatisfaction in the service, a further memorandum was sent reiterating the previous arguments of the Association in favour of the abolition of the Order and informing the Admiralty that it was causing quite unnecessary irritation to the officers concerned. In August, 1912, a revised form of the Order was issued, which stated that a naval medical officer attached to a naval hospital could accept fees for giving evidence or making a *post-mortem* examination if the death did not occur in the hospital. The Council of the Association thereupon made further representations to the Admiralty, expressing its appreciation of the fact that the authorities had shown their readiness to reconsider the matter, pointing out that the new Order contained quite unnecessary limitations, and urging that naval surgeons should be placed on exactly the same footing as other members of the medical profession. The matter has now been reconsidered by the Admiralty, and a communication has been received by the Association to the effect that although the Lords of the Admiralty are advised that the Coroners Act, 1887, does not apply to naval medical officers serving on His Majesty's ships, in order to avoid further controversy on the subject they have decided to reissue the Order relating to this matter in the following form: "When called upon under the Coroners Act of 1887 to act at an inquest, a naval medical officer may accept the usual fees tendered to him by the coroner for his services." Thus a source of grievance to the naval medical service, which though small was irritating, has been removed, and we may congratulate all concerned—those naval officers who, feeling it to be their duty to try to get this anomaly removed, made representations to the Association, the Association for its persistency, and the Admiralty for its frank recognition that the old position was untenable.

THE INDIVIDUALIZATION OF THE INEBRIATE.

IT has been urged by many who scarcely realize the nature of the material with which inebriate homes deal, that the results obtained by the homes are not commensurate with their cost. An American physician, Dr. Irwin H. Neff, in a paper¹ read at the International

¹ *The Problem of Drunkenness*. By Irwin H. Neff, M.D. Boston Medical and Surgical Journal, December 26th, 1912, p. 911.

Congress of Hygiene and Demography, held at Washington last September, maintained that the want of provision for segregating different types of inebriates explained the poor results. He describes the system adopted at the Massachusetts Hospital, with which he is connected. He regards drunkenness as a form of nervous weakness, not sufficient, however, to absolve the patient from working out his cure in co-operation with the physician. Each inebriate is a study; in each the personal equation is the dominant feature, and to throw inebriates together indiscriminately is to lose the opportunity for individual study. In Massachusetts the colony system is adopted. Cottages have been erected for "cottage grouping," and, with the exception of the receiving ward, the hospital and service buildings, or administration group, each building is detached and administered as a separate unit. Each patient having been studied in the receiving ward is drafted to the cottage group for which his temperament, social status, former mode of living, and the results desired from educational treatment fit him. Of those amenable to treatment not more than fifteen are grouped together. With a bigger group individual study and care has been found impracticable, although in the chronically incurable, the custodial group, twenty-five, are allowed. Dr. Neff claims that segregated colonies, though initially costly, are in the long run economical. It is cheaper to cure or care for an inebriate than to pay for recurring committals to prison; the sale of surplus farm produce secured by the labour of the inebriates provides revenue, and the greater part of constructional and repair work is undertaken by them. For twenty years Massachusetts has had an inebriates' hospital, and in 1911 land was secured sufficient for agricultural development, for industrial training and workshops, for segregation of diverse types, and for the treatment of both sexes. Dr. Neff's experience is that all of these objects are essential, and that the system is elastic, and permits of differentiation, segregation, and individualization. Moreover, committal to a hospital has none of the stigma of a prison sentence, whilst colonization and segregation of types facilitate the observation of contrasts in the cases, and supply what is most needed, opportunities for a scientific study of the problems of drunkenness. Dr. Neff's views are of considerable interest; his scheme is suggestive, and the profession, and especially those members of it who have to treat inebriates, will be interested to learn the results, and how they compare with those of other inebriate homes in helping to the solution of one of the most difficult of the problems which confront the general practitioner no less than the specialist.

GAUZE PAD IN PERITONEAL CAVITY.

The somewhat lengthy annals of foreign bodies left in the peritoneal cavity are wholesome though melancholy reading to the surgeon, and Professor Doléris has reported¹ yet another instance of this unfortunate accident. The patient's first pregnancy had ended in November, 1909, in a miscarriage in the fourth month; then pelvic pains set in, and an operation was performed on November 16th, 1910. The left appendages were amputated, and the right ovary touched with the cautery. Lumbar pains continued to trouble the patient after convalescence. She became pregnant once more, and gestation went on without complication. Towards term the patient consulted M. Doléris. The head lay at the inlet, not engaged, and the fetus seemed very mobile, but the cervix was unaccountably high up behind the symphysis, and a tense, bulky mass filled Douglas's pouch. It was quite fixed, and simulated an adherent dermoid. On June 12th, 1912, pains set in, and on the following day Caesarean section was performed. The vertical incision through the uterine wall passed down along the placenta:

the bleeding, however, was controlled, and a female infant, over 6 lb. in weight, delivered. The placenta was extracted and the uterine wound sutured. The uterus was then drawn forwards, and it was found that a sheet of false membrane united the back of the uterus to the colon, omentum, and loins. The surface was quite smooth, simulating normal peritoneum. The right appendages were small and healthy. On carefully opening the sheet by scissors after the liberation of some adherent bowel and omentum, a quantity of thick pus welled up, and a gauze pad was discovered, filling Douglas's pouch. When removed and laid out flat, it was found to measure nearly 6 in. in diameter. The inner surface of the sheet of false membrane, where it came in contact with the pad, was lined with fine granulations. Doléris, finding the conditions so different to what had been expected, removed the uterus and placed a drainage tube in Douglas's pouch. The patient's condition was bad for several days; a rash-like urticaria appeared on the second day, but disappeared within twenty-four hours. The right parotid gland became tender on the fourth day, but subsided; on the next day the fluid in the dressings was faecal, no doubt, Doléris admits, owing to damage of the rectal walls by the tube. A smaller drain was inserted into Douglas's pouch. On the ninth day, when the report was concluded for publication, the patient seemed to be doing well, but a little turbid fluid still issued from the drainage tract. It is remarkable that the forgotten pad gave rise to no symptoms until the end of the pregnancy. Many methods are practised by skilled operators for avoiding oversights of this kind. Wakefield of San Francisco suggests the employment of continuous fixed gauze sponges,² and has entirely discarded the use of loose sponges in abdominal surgery. He employs long folds of gauze each packed in a bag. One end is stitched to the bottom of the bag, the other is left free at the top; thus the fold forms a continuous sponge which is pulled out little by little as required. Two sizes are found to be quite sufficient. The sheet applied to the abdomen contains three pockets, one on either side at the upper border of the oval opening cut in the sheet for exposing the abdominal walls around the area of operation. Into this pocket is fastened the bag containing the broader sheet of gauze which is used for packing back the intestines or walling off local infective areas. In each side pocket is fastened one of the narrower strips which is used by the operator and his assistant for keeping the field clear of blood or doing any work where a sponge is needful. The pockets in the laparotomy sheet are much wider than the sponge bag, and the used-up part of the sponge is tucked away in the pocket, leaving a clean portion of the strip always under the operator's fingers ready for use.

HUMAN INFECTION BY DOG MANGE.

DR. A. WHITFIELD and MR. F. HOBDAY, F.R.C.V.S., have contributed to the *Veterinary Journal* an interesting practical note on the transmission of the sarcoptic mange of the dog to man. It has long been known that this may happen, and the main point of the paper is to call practical attention to the fact that it occurs pretty frequently. The writers have seen seventeen cases, and Dr. Whitfield has met with five in ordinary private practice. All parts of the body may be attacked, the eruption produced being vesicular in type. The individual lesion is a very small and rather thin-walled vesicle, rather smaller than the ordinary eczema vesicle, and surrounded by a narrow zone of hyperaemia; the primary lesion, it is stated, is very like that of varicella, but of only about one-eighth the size. The lesions are scattered discretely over the surface, and in no case have groups or aggregations been seen. The scratching of the patient—for

¹ *Bulletin de la Soc. d'Obstet. et de Gyn. de Paris*, etc., 1912, p. 771.

² *Amer. Journ. of Obstet.*, October, 1912, p. 519.

the rash is intensely pruritic—leads to the decapitation of the little vesicles, and their original site then becomes covered with either a serous or a blood scab. No burrows are to be seen, and hence it is extremely difficult to find the actual parasite. Cats are subject to the same parasitic disease, and in a recent instance the transmitted disease in the human being was sufficiently characteristic to lead to a diagnosis in the cats, though the disease was not well marked in them; the diagnosis was confirmed by the demonstration of the acarus in a crust taken from one of the cats. The ordinary treatment for human scabies is quite efficient, and the disease shows less tendency to relapse, probably because the dog acarus does not form burrows. That there is considerable practical value in the observation is proved by the fact that in one of the five cases mentioned above as having been seen in private practice the patient had had the disease three times at short intervals. He had been treated for scabies, but inquiry showed that his dog had what was called *eczema*.

ARTERIO-VENOUS TRANSFUSION IN PUERPERAL HAEMORRHAGE.

SALINE transfusion has saved numerous lives without doubt, but it has its disadvantages, and is not prompt enough in its action when the patient is in a desperate condition from sudden loss of blood. Professor Oui, of Lille,¹ states that he has attended a large number of cases of flooding, and has often availed himself of intravenous saline injections. Yet they never in his experience produce the immediate change for the better in pulse and general condition which he has noted after arterio-venous transfusion. On that account he employed the latter in a recent case. A young woman who had borne five children to term, all delivered spontaneously, became pregnant once more, and symptoms of disease of the right kidney developed. Much pus came away in the urine. She was placed on the usual lacto-vegetarian diet and urotropin, and other antiseptic drugs were given, without any general benefit or improvement in the character of the urine, and anasarca of the lower extremities developed. The patient did not strictly carry out the prescribed dietary. Close on term a slight haemorrhage occurred, M. Oui, who was sent for, found the fetal head presenting; a quantity of blood and clot came away, and the membranes were ruptured. The head became well engaged in the pelvis, but the uterus grew bigger and harder. The head was delivered, but there was difficulty in disengaging the shoulders. At length the child, a big male, was delivered alive, but it soon died. Very copious flooding followed extraction; the placenta had become completely detached, and M. Oui emptied the uterus of clots, and threw a hot water injection into its cavity. The uterine walls immediately contracted; but the patient's condition was very bad. Ether, caffeine, and camphorated oil, and later 500 c.c.m. of saline fluid, were injected. Only temporary improvement followed, and M. Oui determined to transfuse by the arterio-venous method. The patient was a lady living in a house over twelve miles from Lille. M. Oui telephoned for his colleague M. Lambret. While awaiting his arrival M. Oui administered alcohol freely, and injected camphorated oil and ether, but the patient became quite unconscious. When an hour and a half later Mr. Lambret arrived, the husband's right radial artery was anastomosed with the patient's right median cephalic vein. Local anaesthesia was employed for the husband. In about five minutes the patient's lips became coloured, the pulse was again perceptible, and the eyelids opened. The radial artery of the husband underwent spasmodic contraction occasionally, and the transfusion was continued for nearly an hour without any sign of syncope on the part of the giver. At the end of the administration of arterial blood the

patient's condition had greatly improved. The pulse was 130. The anastomosed vein and artery were resected a little above the line of suture, and no contraction or coagulum could be detected. Convalescence was protracted. The symptoms of pyelonephritis continued, urotropine was given and albumen disappeared from the urine, but oedema of the lower extremities did not entirely subside. The patient went to the baths of Evian and returned free from oedema, and excreting perfectly clear urine. M. Oui states that his is the first case in which arterio-venous transfusion has been practised in France for *post-partum* haemorrhage. It should, he thinks, be performed unhesitatingly in very acute cases.

A BARBER-SURGEON OF TO-DAY.

THE association of shaving with surgery was not peculiar to the France and England of a few centuries ago, and it still persists here and there in semi-civilized countries. Thus Commandant G. Reynaud, in describing the way of life in Morocco to-day, says that the barber-surgeon flourishes there, in a humble way indeed, and on very modest fees. His tent is part of the picture of a Moroccan market. The nomad, from the nature of his mode of life, does not frequent shops, and a shop is an institution unknown to the ordinary Moroccan village of the more settled parts. Every household sends some of its number to market weekly, and the expedition seems to be the one distraction in the life of the women. Commandant Reynaud describes the market of Sok-el-had in the neighbourhood of Melilla. It draws the peasants from twelve miles round; the man rides the mule to market, the woman drives the laden ass. Some 2,500 families depend on this market, and its weekly turnover may amount to as much as £3,000. The market-place is not in a town, but in the open country, a bare patch some forty acres in extent, where the regular traders set up booths and tents for the day. Everything is sold, from mint tea to butcher's meat. Mint tea well sweetened, it seems, is a beverage in which the Moroccan is ready to indulge at any hour. In one part of the market are sheep for sale, and hard by sits a Jew in the classic kaftan and a black fez, with his collection of trinkets and brooches spread out before him; "a little further on the Moorish doctor squats in a small tent; he combines with his medical functions those of a barber, and shaves or bleeds indifferently. The fee for a consultation is one sou, but for blood-letting, which is a favourite remedy, four sous. Not far off is the temple of Themis, a wooden shed, where the Kaïd sits to administer justice," and so on. In a recent lecture on the mysteries and crafts of Morocco, Mr. H. J. B. Ward, B.A., gave an account of the people illustrated by lantern slides, showing all the principal arts and crafts of the country, town architecture, markets, streets, and bazaars, with their sorcerers, snake charmers, and conjurers. He described the position of women, who are the playthings of the rich and the hard-worked servants of the poor, and concluded by a detailed account of the slave market at Marrakesh, one of the very few open slave-marts now left in the world. "Whether we agree or disagree with the general policy of the French in annexing the land of a people to whom they are totally antipathetic," he said, "every friend of humanity must rejoice at the inevitable sweeping away of such revolting spectacles as these."

SANITARY PROGRESS IN INDIA.

AN important blue book has recently been presented to both Houses of Parliament on the Progress of Sanitary Measures in India. It contains valuable information on the discussions and researches which have in recent years taken place in India, having in view the prevention of malarial and other destructive diseases, and the development of sanitary administration. It is impossible to

¹ *Annales de gynéc. et d'obstét.*, November, 1912, p. 617.

summarize within reasonable compass the 245 folio pages composing this volume, or to do otherwise than briefly indicate its contents. Most of the matters have, indeed, been noted in the JOURNAL from time to time. The first 97 pages are devoted to a full report of the "Imperial Malaria Conference" held in Bombay on October 12th to 18th, 1909, at which the subject was very ably and exhaustively treated in a series of papers and discussions, and resolutions regarding future action were formulated. The proceedings of a second meeting of the General Malaria Committee, held in Bombay on November 16th and 17th, 1911, are printed in succession, and indicate that the points mooted at the first meeting had received practical and useful attention. More extensive in scope were the transactions of the "All India Sanitary Conference" held in Bombay on the 13th and 14th of the same month. The subjects discussed at this conference were urban sanitation, congested areas and town planning, water supply, conservancy and drainage, rural sanitation, food supplies, adulteration of food and drugs, registration of vital statistics, water analysis, infantile mortality, plague and other epidemic diseases. This enumeration will suffice to show how wide an area of sanitary work these proceedings covered. Appended to the report of the conference are the reports and papers which constituted the foundation of the discussions. Finally, this Blue Book contains dispatches touching sanitary organization in India, the purport of which has been indicated in the JOURNAL at the time of their first publication. The contents of this volume by no means belie its title, and no better or more practical evidence of the sincerity and reality of the endeavours which the Indian Government is making in the matter of sanitation can be offered than the concluding sentence, which states that "during the preceding two years the imperial grants for sanitation have aggregated 181½ lakhs (£1,210,000), and for research work 15 lakhs (£100,000)." These grants were in addition to the very considerable sums expended by local governments, municipalities, and district boards.

THE BOARD OF TRADE AND SIGHT TESTING.

THE letter by Dr. F. W. Edridge-Green, published in the JOURNAL of February 8th, is well worthy of serious consideration. It will be remembered that a Departmental Committee was appointed in 1910 to inquire into the question of the sight tests as applied to seamen and engine drivers. Their findings were printed last year, and in commenting on them (August 17th, 1912, p. 390) the opinion was expressed that the report was not satisfactory, and that the measures recommended would fail to bring about any real improvement in the visual tests, especially those for colour blindness. Dr. Edridge-Green states that he has had the opportunity of examining the instruments which have been provided on the strength of the report. He finds that in the test for form vision the letters are "printed on canvas, to which a piece of wood is attached. In the normal position this rolls up at the bottom, and has to be held down by the examiner." Inasmuch as this can never really hang straight, it is bound to cause distortion, so that the possession of a certain amount of astigmatism by the candidate might be a positive advantage to him, and it would anyhow render the letters far more difficult to be read by a normal eye than if it were mounted on a stiff background. A distant test of this sort should be arranged so that each letter should form a known angle on the retina, but this would vary with the amount of concavity or convexity which must be present if such a sheet be kept rolled up when not in actual use. Any device more certain to give fallacious results would be difficult to imagine. The wool test, in spite of the modifications suggested, does not seem to have been improved, and as regards the lantern it is quite as bad as we predicted it would be when we saw its

description in the report. There is no means of modifying the light, and the only lights it shows are white, red, and green, so that candidates would quickly get to know this, and a man must be very defective in colour vision to be detected by this means; further, the examiners are told to show the lights individually to the candidates before they are asked to name them: such a lantern used in this way could only bring this most useful test into disrepute. Evidently we cannot hope for any serious improvement at present in the results which the Board of Trade publishes of their vision testing.

THE HUNTERIAN FESTIVAL IN LONDON.

THE Hunterian Festival of the Royal College of Surgeons of England was celebrated on February 14th. In the afternoon the President, Sir Rickman J. Godlee, gave the Hunterian Oration, which is published in full elsewhere in this issue, and in the evening the President and Council entertained a large party of guests to dinner in the library. The guests, who were received by the President and by the Vice-Presidents (Mr. Edmund Owen and Mr. G. H. Makins), included the Presidents of the Royal College of Physicians of London, of the Royal Colleges of Surgeons in Edinburgh and in Ireland, and of the Royal Society, the Master of the Society of Apothecaries, the Presidents of the Royal Institute of British Architects and of the Institution of Civil Engineers, the Archdeacon of London, the Director of the Royal Botanic Gardens, Kew, the Directors-General of the Royal Navy and Army Medical Services, the President of the Law Society, the Treasurer of Gray's Inn and Lincoln's Inn, and the Masters of several of the City Companies. After the usual loyal toasts had been honoured and the memory of John Hunter had been drunk in silence, the toast of "The Visitors" was proposed by Mr. Makins, who, in a very happy speech, contrived to make reference to nearly every one of the distinguished persons present. The toast was acknowledged by Lord Justice Hamilton, who made the observation that the help of the medical profession to keep a man fit for his work was by many more highly esteemed than the success of its efforts to prolong life. Lord Reay, President of University College, in proposing the toast to Sir Rickman Godlee, said that the report of the Royal Commission on the University of London which was shortly to be issued would, he hoped, have the result of placing the higher education of London on a more satisfactory basis than it occupied at present. A brief response by the President brought the proceedings to an end.

ALIMENTARY TOXAEMIA.

ONE of the best marked tendencies of medical thought and observation during the last decade has been the disposition to attach increasing importance to the results of chronic infective processes in the alimentary canal. Efforts have been made to ascertain the etiological factors and to trace out the nature of the relation, if any, which the congeries of symptoms and disorders attributed to toxæmias originating from the alimentary organs actually bear to each other and to their assumed cause. Very many suggestions for treatment, ranging from intestinal antiseptics to more heroic methods, including some very drastic dietetic rules, have been made and put in practice. The subject certainly needs elucidation and is probably ripe for discussion; it will, we believe, therefore, generally be felt that the Royal Society of Medicine has done well to arrange a full-dress debate on it. It will commence on Monday, March 10th, at 5 p.m. On that day Dr. Halo White will open with a general survey. He will be followed by Dr. F. W. Andrewes, who will treat of the bacteriology of the alimentary canal, and by Dr. Vaughan Harley, who will

deal with the toxins of the alimentary canal; the consequences and treatment of alimentary toxæmia will be discussed by Professor Robert Saundby from the medical, by Mr. Arbuthnot Lane from the surgical, and by Mr. J. F. Colyer from the dental points of view respectively. The discussion will be resumed by Mr. J. B. Lawford on Monday, April 14th, at 5 p.m., and will be continued on succeeding Mondays.

We regret to record the death, on February 18th, of Sir Thomas Chavasse, consulting surgeon to the Birmingham General Hospital, and hope to be able to publish an obituary in a subsequent issue.

In memory of the late Sir William Allekin, Consulting Physician to Westminster Hospital and Physician Extraordinary to H.M. King George V, who died on February 8th, 1912, a brass tablet has been placed in the Hospital Chapel, and a replica of his portrait, painted by Sir Luke Fildes, R.A., and presented by Lady Allekin, has been hung in the Board Room, where it is believed many of his friends and former pupils will be glad of the opportunity of viewing it.

Medical Notes in Parliament.

[FROM OUR LONDON CORRESPONDENT.]

Vivisection.—On February 12th Mr. George Greenwood asked the Home Secretary a string of questions. The first referred to the memorandum signed by three of the Royal Commissioners on Vivisection in which they stated their opinion that the weight of evidence was opposed to the view that only administrative modifications were required in order to give effect to the changes which experience proved to be desirable in the law relating to experiments on living animals, and further expressed their doubt whether such modifications as were suggested in the report signed by all the Commissioners could be adequately carried out without legislation. Mr. Greenwood inquired whether legislation would be introduced in the next session of Parliament in order to give effect to such recommendations.—The Home Secretary said he had carefully considered the memorandum and the desirability of introducing legislation, and was satisfied that no legislation was necessary for the purpose of giving substantial effect to the recommendations of the Commission mentioned in the memorandum.

Mr. G. Greenwood next asked the Home Secretary whether, in view of the fact that the Cruelty to Animals Act, 1876, by statutory enactment divided the responsibility in regard to experiments on living animals, in the matter of the granting of licences and certificates to experimenters, between the Secretary of State and certain learned authorities, whereas the Royal Commissioners on Vivisection were unanimously of opinion that such responsibility should rest upon the Secretary of State alone, he would introduce legislation to amend the Act of 1876 in that respect.—Mr. McKenna replied that the majority of the Commission were of opinion that no change was necessary or desirable with regard to the present system of granting licences and certificates. He did not propose to introduce legislation on the matter. The Secretary of State had power to disallow or suspend any certificate, and the final responsibility, therefore, rested with him.

Mr. G. Greenwood also asked the Home Secretary whether his attention had been called to the recommendation made in the memorandum signed by three of the Royal Commissioners on Vivisection, and attached to the Report, that a provision should be inserted in the Act regulating experiments upon living animals, requiring all experimenters in every case in which obvious suffering of the animal had supervened forthwith painlessly, to destroy such animal, and whether he would introduce legislation in

order to give effect to such recommendation.—Mr. McKenna replied that the answer to the first part of the question was in the affirmative. The majority of the Commission were of opinion that the object in view could be sufficiently attained by means of the Secretary of State's power of attaching conditions to licences, and he was taking steps to carry out that recommendation. In the circumstances legislation appeared to be unnecessary.

Mr. G. Greenwood finally asked the Home Secretary whether, in the appointment of inspectors of places registered for the performance of experiments upon living animals, he would have regard to the recommendation made in the memorandum attached to the Report of the Royal Commission on Vivisection, and signed by Colonel Lockwood, Sir William Collins, and Dr. G. Wilson, to the effect that persons qualified in veterinary medicine and science ought not to be deemed ineligible for any of such inspectorships.—Mr. McKenna said that he considered that was a matter in which he ought to be generally guided by the advice of the majority of the Commission. He did not say that in no circumstances would he consider an application from a person qualified only in veterinary medicine and science, but he had invited applications from medical men, and he did not doubt that qualified candidates would be forthcoming.

Small-pox in Sussex.—Mr. Snowden asked the President of the Local Government Board, on February 12th, whether he would state the number of small-pox cases and deaths that had been notified at Newhaven within the last six months and the condition as to vaccination and revaccination of each case; whether a medical inspector had visited the locality and presented a report; and, if so, what was the sanitary condition of the locality in which the cases occurred.—Mr. Burns said that in Newhaven Urban District 18 cases of small-pox had been notified, all within the last four weeks (also 2 in the borough of Lewes, and 1 in the borough of Rye), making a total of 21. The outbreak had been inquired into by a medical inspector of the Board, in collaboration with the local medical officers of health. The condition as to vaccination of the patients was as follows:

| | Total. | Stated to have been Vaccinated in Infancy. | Unvaccinated. | Revaccinated. | Died. |
|-----------------------------|--------|--|---------------|---------------|-------|
| Cases under 10 years of age | 5 | 0 | 5 | 0 | 3 |
| Cases over 10 years of age | 16 | 15 | 1 | 2 | 1* |

* Stated to have been vaccinated in infancy.

The inspector reported that the houses in which the Newhaven cases occurred were in a somewhat overcrowded condition. The history pointed to the infection having been introduced from abroad by a sailor.

End of the Session.—The session of the House of Commons came to an end when the House rose on February 14th. The new session is to begin on Thursday, March 6th.

DR. HERSCHEL HARRIS, radiographer to the Royal Prince Alfred Hospital, Sydney, in a recent paper in the *Australasian Medical Gazette*, states that it is generally easy to detect hydatid of the lung with the fluorescent screen, but that a skiagram should also be taken, as a collapsed cyst may otherwise escape detection. It has been possible to detect a cyst no larger than a hen's egg, and the more difficult cases are those in which the whole side of the thoracic cavity is involved. Dr. MacCormick, of Sydney, had made the important observation that if the cyst be ruptured and partly full, the shadow with the patient in the upright position resembles that of a Dutch cheese with the top cut off, the horizontal part being uppermost and this upper line remains horizontal, no matter at what angle the patient be tilted. Air is always present in the cyst. If the cyst be ruptured and empty, a crinkled shadow appears, due to the crumpled-up cyst wall. Sometimes considerable well-defined areas are seen.

England and Wales.

(FROM OUR SPECIAL CORRESPONDENTS.)

WALES.

GIFT FOR A NEW PHYSIOLOGICAL LABORATORY IN CARDIFF.

At a meeting of the Council of University College, Cardiff, under the presidency of Lord Merthyr, on February 14th, the generous gift of £12,750 from Mr. W. J. Thomas, Ynishir, Glamorganshire, was accepted under the conditions which accompanied it. These were that a new physiological laboratory is to be built with the money in the Newport Road near the King Edward VII Hospital, and that the building is to commence within six months of the gift. The laboratory is, further, to be built by Colonel Bruce Vaughan, who was the architect of the King Edward VII Hospital. The Council of the College had met and considered the question previously, and had appointed an Accommodation Committee composed of those who were especially interested in the question of the new laboratory, and this committee had the advantage of the advice of Sir Isambard Owen, Vice-Chancellor of the University of Bristol. There were two currents of opinion with regard to the best site for the new laboratory. There were those who considered that it should be erected in Cathays Park with other buildings of the medical school near the university buildings. To this it was objected that the site was of insufficient extent, affording no room for future expansion, and that it would be a disadvantage to have the laboratory at a distance of about a mile from the hospital. Eventually, the opinion that it would be an advantage to have all the laboratories of the Cardiff Medical School close to the hospital prevailed, and in consequence, as has been said, the site in Newport Road had now been determined upon. Professor J. Berry Haycraft, who started an appeal for funds for the erection of a physiological laboratory less than two years ago, is to be congratulated on the success of his efforts. The munificent gift of Mr. W. J. Thomas will enable a beginning to be at once made and a laboratory to be erected which will meet the immediate needs of the Physiological Department of the Cardiff Medical School. No doubt in time extensions will be required, when it may be hoped that Mr. Thomas will find imitators.

LIVERPOOL.

THE ROYAL INFIRMARY.

The committee of the Royal Infirmary has decided to appoint an additional assistant physician, as well as filling up the vacancy caused by the death of Dr. O. T. Williams.

SANATORIUM BENEFIT.

The permanent scheme for the administration of sanatorium benefit in this area is now being formulated. It will make provision for all forms of treatment—domiciliary, dispensary, hospital, and sanatorium. Probably domiciliary treatment will be left in the hands of the general practitioner, who will have recourse to the tuberculosis dispensaries for consultation with specialists. These dispensaries will probably be formed in conjunction with the consumption hospital and the various general hospitals in the city. The hospitals will also undertake the indoor treatment of tuberculosis patients, and, if the provisional arrangements made with the consumption hospital may be taken as an indication, they will be paid 31s. 6d. a week for each person treated in the institution; of this sum 24s. will go for maintenance and the remaining 7s. 6d. to the medical staff of the institution. The available beds at the consumption hospital will be used for observation, the general hospitals for surgical tuberculosis, and the tuberculosis wards of the city infectious hospitals at Park Hill and Fazakerley for pulmonary phthisis.

Any scheme, however carefully drawn by the authorities, will require to be minutely studied by the profession if smoothness is to be attained in the working. It is hoped that the local Divisions of the British Medical Association as well as the Association of Hospital Physicians and Surgeons will have an opportunity of expressing their views on the scheme before it receives official sanction.

TUBERCLE BACILLI, HUMAN AND BOVINE.

Somewhat divergent views are held locally as to the relative frequency of these two types of bacilli in the production of human tuberculosis. At the last meeting of the Liverpool Medical Institution Dr. Nathan Raw brought forward some statistics and foreshadowed others supporting the opinion which has recently gained ground that surgical tuberculosis is for the most part due to the bovine type of bacillus, and pulmonary phthisis to the human type. Professor Ernest Glynn and others controverted this view and invoked statistics in support of their contention. Doubtless the discussion will be renewed on the publication of the further statistics from Edinburgh, which are promised at an early date.

MANCHESTER AND DISTRICT.

MANCHESTER ROYAL INFIRMARY.

The annual meeting of the trustees of the Manchester Royal Infirmary was held on February 14th. A summary of the annual report was given in the *JOURNAL* last week, and in moving its adoption Sir William Cobbett, who presided, laid special emphasis on the references in the report to the financial position of the infirmary. With an annual deficit of about £8,000 it would, he said, be necessary to encroach on the capital. The endowment capital could not be touched, and if continual encroachments had to be made on the disposable capital, the position of the hospital would become one which he would prefer not to contemplate. He also made a special appeal for money to meet the cost of the new central branch for accidents and out-patients, which was estimated to be about £25,000. The report was adopted, and a vote of thanks to the honorary physicians and surgeons was passed, to which Dr. Brockbank replied on behalf of the honorary staff. The trustees then agreed to some revisions of the rules, the most important being a new rule providing for the addition to the medical staff of an honorary assistant anal surgeon, and the deletion of the old rule which provided for the payment by employers of domestic servants and apprentices of the sum of 10s. 6d. a week towards maintenance during treatment as in-patients. The meeting closed with a vote of thanks to Sir William Cobbett for his services as chairman of the board of management.

MANCHESTER SCHOOL FOR MOTHERS.

The School for Mothers was established primarily with the object of reducing the high infant mortality-rate, first, by giving instruction in the care, management, and feeding of infants and in general hygiene, and by providing meals at low charges for expectant and nursing mothers. There are at present four branches of the institution in Ancoats, Collyhurst, Openshaw, and Hulme, and at the fifth annual meeting, held on February 14th, it was stated that in the last year 2,057 persons had been members of the schools. The mothers attended regularly for the weighing of their infants, and the number weighed averaged 216 per week. The number of dinners served, at a charge of 2d. a head, was 10,216. The report of the Medical Subcommittee described the two special branches of the work carried on under its supervision. One is the ordinary work of the schools, which included medical consultations and investigations, and the other is the special investigation at Openshaw, where in two districts practically every infant is visited monthly during the first year of life with the object of observing the effects of expert advice on the infant mortality-rate. This inquiry will form the subject of a special report when sufficient figures are available. The feeling was expressed that it was important as soon as possible to establish additional branches, but the finances would not allow of this at present. It was estimated that the sum of £1 would rather more than provide for the care and supervision of one infant for a year. Dr. Niven, M.O.H. Manchester, said the schools were doing a most important work in assisting in lowering the infant mortality-rate, and the crowning part of their work had been the establishing of consultative centres where mothers could get the best medical advice.

LONDON.

LONDON COUNTY COUNCIL.

Ambulance Service for the Metropolis.

SOME discussion of the question of an ambulance service for the county of London took place at the meeting of the London County Council on February 18th, on a report that a coroner's jury, in an inquest on the body of a man taken ill at the Islington Empire music hall, had added the following rider to the verdict:

The jurors are of opinion that a more up-to-date ambulance system is required in London, similar to the electric motor ambulance system of the City of London.

Mr. E. Smallwood reminded the Council that since the passing in 1909 of the bill promoted by Sir William Collins it had possessed power to provide an ambulance service. Such cases as that which had been notified by the coroner's jury were a disgrace to the richest city in the world.

Mr. H. L. Jephson, alluding to the recent decision of the Council to seek parliamentary powers this year to co-ordinate and utilize existing ambulance services (BRITISH MEDICAL JOURNAL, November 16th, 1912, p. 1419), remarked that authorities which now maintained ambulance services had no power to use them for other purposes than those for which they were established, and doubtless they were fully occupied in meeting present demands upon them.

Mr. Edward Smith mentioned a case at Clapham in which an old lady of 90, who met with an accident in the street, had to lie on the pavement for half an hour before any conveyance could be found, and had to be taken half an hour's journey in a hand barrow to the Bolingbroke Hospital.

Mr. Hayes Fisher, M.P., expressed the hope that, if the Government did not place further burdens upon the ratepayers, London before many years were over would have an efficient ambulance service.

From this point the debate drifted into the question whether Liberal or Conservative Governments had placed the greater burdens upon the ratepayers.

The Rev. J. Scott Lidgett inquired whether any steps had been taken to ascertain the extent to which other authorities were willing to co-operate with the Council in this matter. The specific duties for which these services were established must take preference in any co-operative scheme, and he was afraid most of the existing appliances were antiquated.

Mr. Cyril Jackson said there was a very large ambulance service in London which ought to be co-ordinated. It would be ludicrous to propose a scheme, for instance, which left the police out of account.

Mr. H. J. Greenwood, Chairman of the General Purposes Committee, which has the question under consideration, declared there was no better way of improving the ambulance service than by co-operating with and extending the existing services. A conference with the various authorities concerned would be obtained when the parliamentary powers asked for had been granted.

Mr. J. D. Gilbert, a member of the General Purposes Committee, said that he was not aware that it had been definitely decided to seek parliamentary powers this year, and there was a danger that no authority of the kind asked for would be obtained until the end of 1914. The Council had made no use of the powers it had possessed since 1909.

On a division the report was received by 57 votes to 45.

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

LISTER MEMORIAL, GLASGOW COMMITTEE.

At a meeting held last week of the Executive Committee of the Glasgow Committee of the Lord Lister Memorial, the Honorary Secretary reported subscriptions amounting to upwards of £770. In some cases no intimation had been given as to what proportion of the contribution was to be assigned to the local and international funds respectively. The local fund was to take the form of a suitable monument in Glasgow and the provision of what-

ever endowment might be necessary for the equipment and maintenance of a Lister Museum at the Royal Infirmary, should that prove to be practicable. The International Memorial Fund was intended to endow an international award to be given from time to time for the most notable contribution to the advancement of surgery in any part of the world, and the establishment of a Lister Research Fund with fellowships, scholarships, or grants for promoting investigations likely to improve surgery. A subcommittee consisting of Mr. A. E. Maylard, Sir Hector Cameron, Professor Teacher, and Mr. Hedderwick, was appointed to deal with the question of the equipment and maintenance of a Lister Museum in the Royal Infirmary.

PRESENTATION OF PORTRAIT OF PRINCIPAL SIR WILLIAM TURNER.

On Thursday, February 15th, the portrait of Sir William Turner, K.C.B., painted by Sir James Guthrie, P.R.S.A., was presented to Edinburgh University. Sir William Turner's connexion with the university over which he now presides as Principal and Vice-Chancellor, from the days when he acted as Demonstrator in Anatomy under Professor Goodsir all through the long and fruitful years of his own holding of the Chair of Anatomy down to the more recent time of his occupancy of the Principality, extends to nearly sixty years. Born in Lancaster, receiving his medical training in St. Bartholomew's Hospital, London, and spending the rest of his life in Edinburgh, the Principal was particularly well qualified to guide the destinies of a university which draws its medical undergraduates from England almost as much as from Scotland. Sir Robert Finlay, K.C., M.P. for the Universities of Edinburgh and St. Andrews, in making the presentation, referred to the fact that it was in the days of the Crimean War that the subject of the portrait first came to be connected with the university, and many of the spectators, looking at the Principal, hale and hearty at over four-score years, must have felt it difficult to realize that it was even so. The Chancellor, Mr. A. J. Balfour, M.P., in accepting the portrait for the university, said the picture would serve in the future to let those who came after know something of the appearance of the man who had done so much for their university; but, he continued, "round about us, not far from this building where I am speaking, are many monuments of Sir William's administrative greatness; there are buildings, additions to the university, conveniences for teaching, all the apparatus of the modern university, which he has done so much to create, and in one sense they are his greatest and truest memorial; yet, ladies and gentlemen, I think we could ill spare a living and perpetual image of the very man who did it." Lord Provost Inches, whose presence by the side of the Chancellor was a reminder, if any such were needed, of the long connexion which had existed between the university and the city, spoke of the high place Sir William held in the appreciation of the Corporation—an appreciation which had recently taken form in the conferment of the freedom of the city upon the Principal of the university. Sir William Turner, in well-chosen and kindly words, replied, saying that "little did he suppose when he came to Edinburgh that Edinburgh would become his home, and it never would have become his home unless he had felt, when he became associated with the university, that there was something in the spirit of teaching in the university that loudly appealed to him. That something was the combination of the spirit of science with practical ability. Might that spirit always endure." With a few words from Sir Ludovic Grant came the conclusion of a very memorable ceremony. Edinburgh University has had some distinguished Principals, including Sir David Brewster, whose statue stands in the old quadrangle, and Sir William Muir, whose life-work was in that Eastern land so many of whose sons now come to Edinburgh for learning, but Principal Sir William Turner need not dread comparison with any of them.

ROYAL INFIRMARY, GLASGOW.

The annual meeting of qualified subscribers of the infirmary was of special interest, as it was the first held after the Insurance Act had come into full operation. During the last two months of the year especially there was a slight falling off in the subscriptions, both of the

general public and of the workmen. This had naturally caused the directors anxiety as it occurred at a period when trade was unusually good. In moving the adoption of the report, the Lord Provost, who is also chairman of the Glasgow District Insurance Committee, made it quite clear to the subscribers that the need of hospitals for the treatment of serious accidents and diseases was still as great as before the Act, which only secured such treatment as the ordinary practitioners could give. There would, therefore, be little change in the working of the hospital except in the out-patient department. In seconding the report, Mr. Hedderwick expressed the opinion that this diminution in subscriptions, however slight it was, was one of the first-fruits of the Insurance Act. He trusted the falling-off would go no further, and that on consideration the public generally would see the great need of maintaining the hospitals. Especially for the working men it was important to maintain the voluntary hospitals with their resources unimpaired as something infinitely better than any possible substitute. The net result of last year's working was that it had been necessary to take £5,184 from stock account to meet the deficit. With the sum of £4,800 spent on reconstruction, over £10,000 had been withdrawn from the stock account. The new year had, however, opened well with a donation of £15,000 from the trustees of the late Mr. Edward Davies, and it was decided to commemorate the splendid gift by naming two wards after the testator. Speaking of the reconstruction scheme, he alluded to the dangerous conditions in which the oldest part of the building had been found. Some people had criticized the delay in beginning the reconstruction, but, as a matter of fact, it had been profitable to delay, as the operations were begun when building was very cheap, and the accumulated interest had provided £50,000. The long delay in completing the reconstruction had been caused chiefly by the necessity of carrying on the full daily work of the institution. Consequently it had been necessary to reconstruct in three main divisions, two of which were finished and occupied in 1908 and 1912 respectively, while the last would be completed in the autumn of next year. It was subsequently agreed that, to remove apprehension on the part of the workers regarding the position of the infirmary since the passing of the Insurance Act, the following statement should be issued:

1. The hospital will give insured persons everything it has given in the past which the Act does not give.
2. Regarding in-patients subject to the rules and statutes, all insured persons will be admitted as in-patients as heretofore.
3. Regarding out-patients, all insured persons requiring special treatment will be treated as heretofore.
4. All insured persons suffering from serious accidents will be treated as heretofore.
5. All insured persons attending the out-patient or casualty department will be examined and treated if necessary for the first time. Such as, in the opinion of a member of the medical staff, are suitable cases for home treatment will be referred to their panel doctor for further attention; but hospital treatment will be continued for such cases as, in the opinion of the member of the medical staff, cannot receive proper treatment at home, or which require to be under further observation.

MEMORIAL TO THE LATE DR. SOPHIA JEX-BLAKE.

After the ordinary business of the annual meeting of the Edinburgh Hospital and Dispensary for Women and Children, on February 17th, Lady Helen Munro Ferguson, Vice-President, in the chair, a tablet to the memory of the founder of the hospital, Dr. Sophia Jex-Blake, was unveiled by Miss S. E. S. Mair. The tablet, which is in the hall of the institution, is of cast bronze, with the letters ornamented in relief. A simple wreath forms a border, and within this at the top are crests of Dr. Jex-Blake's family. The bronze is mounted on a slightly-moulded slab of Verde antique marble. Miss Mair gave a brief survey of the part Dr. Jex-Blake played in the admission of women to the medical profession in the founding and development of the hospital. The tablet bears the following legend:

In affectionate remembrance of Sophia Jex-Blake, M.D., founder of this Hospital, to whose large courage, insight, and constancy the admission of women to the profession of medicine in this country is mainly due.

THE WALDIE MEMORIAL.

The Waldie centenary memorial proposal, to erect a bronze mural tablet, suitably inscribed, on the house in

Linlithgow, where Dr. David Waldie (who was associated in the discovery of the anaesthetic properties of chloroform) lived and practised as a surgeon and druggist, has now assumed definite shape, and the scheme is progressing satisfactorily, being supported by some of the leading men in the medical and chemical world; subscriptions have been received from New York, Calcutta, Aberdeen, London, Glasgow, Edinburgh, and Liverpool. Subscriptions, however small the sum, will be welcome, and should be sent as soon as possible to the Honorary Treasurer, Mr. John McWhirter, Union Bank House, Leslie, Fife, or to Mr. Alexander Spence, M.P.S., 43, High Street, Leslie, Fife.

MEDICINE AND LITERATURE.

In the report of Dr. J. W. Ballantyne's address on this subject which appeared in the *JOURNAL* of February 15th, p. 366, a printer's error was, we regret, allowed to creep in. The name "Wellesley" in the sixth line from the end of the paragraph should, of course, be Wesley.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

FRIENDLY SOCIETIES AND THE CONTROL OF DOCTORS.

MR. J. D. NUGENT, President of the Dublin Benefit Societies' Union, gave a timely warning to the medical profession in Ireland as to the position they must expect to occupy if medical benefit is extended to Ireland. Speaking at a general meeting of the Societies' Union on February 9th, he said that two important points had to be settled before the societies would agree to the medical benefits being applied to Ireland. First, they must get the £197,068 grant that was at present given to Ireland under the Medical Relief Act for Dispensaries; and, secondly, the societies must have the right to nominate or strike off the doctors from the panels. The societies and not the County Insurance Committees should have the control of the doctors. The doctors' terms should be made known and settled, and must include attendance on the wife and dependants of every insured person. The first of these demands means presumably the abolition of the Poor Law Medical Service and the end of the salaries of the dispensary doctors; and the second and third demands mean that the societies are to have complete control of the medical attendance on the members of their society, and that the great majority of the doctors throughout the country are to be placed completely in the power of the friendly societies. Now that the members of the profession are clearly warned it will be their own fault if they acquiesce in such a condition being brought about, and their thanks are due to the president's timely, though probably unintentional, warning.

MATERNITY BENEFIT AND DISPENSARY TICKETS.

The circular regarding the giving of dispensary tickets to women in receipt of maternity benefit, referred to last week (p. 366), has now been sent by the Local Government Board to the boards of guardians throughout Ireland. In it the Board emphasizes the duty of the guardians and relieving officers, before issuing tickets for free medical attendance and medicine, to satisfy themselves by careful inquiries that the applicant could not otherwise obtain this aid. The Board points out that in a number of cases it will probably be found that the recipients of maternity benefit under the National Insurance Act would not in addition be entitled to relief from the rates under the Medical Charities Act; but, on the other hand, there will no doubt be many cases of exceptional poverty with regard to which this view could not be maintained. The Board therefore expresses the opinion that a relieving officer or board of guardians, on being satisfied as to the existence of these exceptional circumstances, would be justified in issuing tickets entitling insured persons to dispensary relief, notwithstanding the fact that they were in receipt of maternity benefit under the Insurance Act. It suggests that guardians should try to make arrangements regarding the amount of the fees of the medical officer and midwife, bearing in mind that the 30s. is intended for the provision of other comforts besides medical attendance.

At the last meeting of the County Dublin Insurance Committee the following resolution on the subject of maternity benefit was unanimously adopted, and the Secretary was directed to send a copy to the Irish Insurance Commission:

The County Dublin Insurance Committee begs to draw the attention of the Insurance Commission to the grave danger which may arise in maternity cases where a nurse attending a patient fails to call in medical assistance in serious complications in proper time, fearing that the doctor's fee may have to be paid out of the maternity grant. The Committee feels strongly that the medical fee should be disbursed from funds other than those allocated for maternity benefit.

ULSTER MEDICAL SOCIETY.

At the fourth meeting of the session, the President (Dr. R. W. Leslie) in the chair, Mr. T. S. Kirk read notes and showed lantern slides of developmental bands of the mesentery. Dr. J. Campbell, Mr. Fullerton, Mr. R. J. Johnstone, Mr. Hick, Mr. Irwin, and Mr. Crymble all joined in a vigorous and spirited debate, and Mr. Kirk replied. Dr. C. G. Lowry read a paper on puerperal septicaemia occurring twice in the one patient, which was ably criticized by Dr. John Campbell and Dr. T. Houston, and Dr. Lowry replied.

On the evening of January 24th the President (Dr. R. W. Leslie) entertained the Fellows, members, and some friends at a smoking concert in the Medical Institute. The chief lecture room was used for the purpose, and was barely sufficient to hold the large number that accepted the kind invitation. Tea, coffee, and light refreshment were served, and some excellent songs, recitations, and slight-of-hand exhibitions combined to make the evening successful. Every one appreciated the kindness and hospitality of the President, and manifested their enjoyment by hearty congratulations to him and frequent applause of those who so artistically helped.

Correspondence.

IMMEDIATE OPERATION IN APPENDICITIS.

SIR,—I have read with the greatest interest Mr. Owen's excellent address. There is, however, one point of view Mr. Owen and nearly all other surgeons overlook in their teaching on this point.

Mr. Owen scoffs, and I think rightly, at the "illustrious" physician; only (may I add?) there are very few such as he describes, at all events in London, and also, what is important, that no practitioner should waste time in calling in a physician except at the express demand of the patient, and then only with the understanding that a surgeon shall be called in in case of disagreement.

Mr. Owen speaks from the surgeon's point of view, and gives advice which ought to be followed out—namely, "When in doubt look and see"—but when he comes to himself what a falling off there is! If he thinks his feelings over he will perhaps understand better the feelings of the patient in doubtful cases. He calls in his surgical friend, and if he says, "Yes, I think your appendix is at fault," he asks leave for another surgical opinion. Why? What if the second opinion differs? Is there to be a third? No. If the surgeon answers as above he ought to be asked to operate at once, if only to look and see. The second opinion should only be asked for if the surgical colleague is in doubt and advises delay.

The third point of view, which is so often overlooked, is the point of view of the patient, which must affect his medical attendant, and in which the surgeon can help. And here may I suggest that Mr. Owen is a little wrong in comparing appendicitis with strangulated hernia? Taking his figures, the perfect recovery in the former, when not operated on, is about 30 per cent., while the vast majority of the remaining 70 do not die. In unoperated strangulated hernia practically all die. This brings me to the point I am leading up to. What is to be done when the head of a house (or one of his family) who is in good position socially but not financially, who lives up to his small income and has saved nothing, gets a slight attack apparently of appendicitis? The doctor advises immediate operation. He is asked, "What will be the expense?"

The answer must be, even with a moderate surgeon's fee, "Anything between £50 and £100." The next question is, "If operated on, when can I go back to work again?" A sanguine reply would be six to eight weeks, but the patient is seldom himself again for at least three months. The last question is, "What are the prospects if I am not operated on?" Mr. Owen's statistics give the answer. Is it a matter of surprise that the patient says, "Doctor, you know my position. Even if I can raise the money—which I can't—I cannot spare the time. I will run the risk. When the second attack you talk about comes on, my position may be improved, and I may be able to spare the time and raise the money."

Nothing can be done as far as lost time is concerned, and the doctor must let the patient or head of the family decide, but the surgeon can help in the direction of fees. Many surgeons, even juniors, think it derogatory to take low fees, and send the patient to a hospital, if there is one, much as the patient may dislike it. On the other hand, I hold that, if he can trust the practitioner, the surgeon should be ready to operate at a considerable reduction to his ordinary fee, and the junior surgeon at even a nominal fee, without any fear of being looked down upon by his colleagues. And what I have said about appendicitis is more—much more—true about special operations which are in the hands of a few.

May I close this somewhat lengthy communication with short notes of a case which brings out the importance of Mr. Owen's "Look and see"?

A lad of very good but a very poor family was playing football at Vincent Square on a Saturday afternoon in perfect health, except for habitual constipation. On Sunday morning he had "colic." His mother gave him castor oil, which made him sick. I was called in the same evening. His temperature was 98.4, his pulse 60. The abdomen was somewhat hard, as in some forms of real colic, and there was generalized pain. There was no tenderness, except very slightly on deep pressure in the appendix region. Nothing else abnormal. I was bold enough to prophesy "appendicitis." Early the next morning he was, when I saw him, "much better." The temperature was 98.6°, pulse 72; pain had gone, the abdomen was soft, but the tenderness in the iliac fossa was more distinct—quite marked—and there was very slight evening rigidity. I asked and obtained leave to have a surgeon to operate if I could get one at a really reduced fee. Fortunately, I knew of one I could ask, and the patient was operated on the same afternoon, when a very tense, inflamed, banana-looking appendix was found on the point of bursting. He returned to his office just under three months.—I am, etc.,

Upper Clapton, Feb. 16th.

J. W. HUNT.

THE REPORT OF THE COMMITTEE ON FRACTURES.

SIR,—This report was presented and discussed at the Liverpool meeting of the Association in July, 1912, at the Section of Surgery, of which I had the honour to be President. That particular (extra) meeting of the Section was the only one from which I was absent; but if I had been able to attend I should probably have felt bound to state briefly the opinion I have always held on the question of non-operative or primary operative treatment in simple fractures, without prejudice to the ability displayed in that report and in the discussion upon it.

But it would be impossible for me, or any one, to state that opinion better than, if even as well as, it is stated in the single column of this JOURNAL of February 15th, 1913, p. 370, in the letter of Mr. R. Hamilton Russell, of Melbourne.

My object in writing this is to express my admiration for the way in which the case is there put by him: the clearness of his exposition, the sound surgical and artistic principles underlying it, and his modest advocacy of the position.

If it can attract closer and more general attention to the whole of his letter, the quotation of the following paragraph will be justified:

... Personally I have experienced great interest and learnt much that I deem of great value through habitually setting to work with my students over every case of fracture in the endeavour to

devise some simple and effective plan of treatment that will be of value to them when they go out into practice; and this, if I may be absolved from arrogance, is in my opinion just what a hospital surgeon and teacher ought to do. . . .

—I am, etc.,

RUSHTON PARKER,

Professor of Surgery in the University of Liverpool,
February 16th.

THE CONTROLLED THERAPEUTIC USE OF NEW TUBERCULIN.

SIR,—I am so pleased with the able paper On the "Controlled" Therapeutic use of New Tuberculin in the Treatment of Pulmonary Tuberculosis, which appears in the BRITISH MEDICAL JOURNAL for February 1st, that I cannot deny myself the pleasure of congratulating Dr. Rigg thereon, and expressing the hope that in future we may have reports of the results of tuberculin treatment cast on the same lines.

Any one with practical experience of the disease will admit that only limited—very limited—importance is to be attached to such statements as "patient feeling better," "patient looking better," "weight increased," and so on. With these improvements there may coexist stationary, or even advancing, lesions in the lungs. We are all sadly familiar with cases which improve in appearance and put on weight, and yet on stethoscopic examination are found to give evidence of pulmonary lesions *in statu quo*. And as these physical signs constitute the most reliable criterion as regards the progress of the cases—the most definite evidence on which a judgement may be founded—Dr. Batty Shaw and Dr. Rigg wisely selected them in measuring the results of tuberculin treatment.

Whilst signs of active disease in the lungs persist we cannot lull ourselves into the belief that all is well with the patient—however well he may look and feel—for an active lesion in the lung constitutes a breeding ground for the tubercle bacillus. No doubt, in such a case, when the temperature becomes normal and the weight increases and the patient feels better, we have some reason to congratulate ourselves in so far that we have evidence of the patient's powers of resistance having got the upper hand, and therefore we are justified in considering him on the road to recovery. But so long as there are physical signs of active disease in the lungs we know that the evil is still at work.

In ordinary sanatorium treatment, without tuberculin injections, it is a common experience to have cases rapidly improving in appearance, putting on weight, and in some cases showing improvement in the physical signs, or even leaving the institution with no signs of active disease.

We have reason, therefore, for being cautious in giving tuberculin credit for improvement in a patient's condition when that patient is at the same time having plenty of good food, rest, and fresh air. If tuberculin is a powerfully curative agent we may reasonably look for a marked improvement in the condition of the patient's lungs during its administration. Otherwise, to my mind, the verdict is "not proven."

I have used tuberculin—after Sahli's method (Beraneck's tuberculin)—but only in a very limited way, and therefore I have no personal opinion to express. I have a perfectly open mind with regard to the value of tuberculin injection. It may yet prove to be the most effectual means of controlling or arresting tuberculosis. But in the meantime medical opinion—even expert medical opinion—presents such a troubled sea of contradictory views, theories, and results that one welcomes a report such as that furnished by Dr. Rigg, founded on definite and measurable data.—I am, etc.,

JAMES W. ALLAN, M.B., C.M.

Bellefield Sanatorium, Lanark, Feb. 4th.

OPEN-AIR RIVER SCHOOLS.

SIR,—At the present time, when so much attention is being directed all over the country towards the prevention and cure of tuberculosis, especially at an early age, it must occur to those who are interested in the matter that, in the provision of open-air schools for children actually suffering from the disease, or who are daily exposed to the

risk of acquiring it from tuberculous relatives, London lags far behind the provinces.

The great argument against such schools for the metropolis is the difficulty of providing the necessary open spaces in so large a city, and my object in writing is to offer the suggestion that that difficulty might be overcome by utilizing the river, mooring disused steamboats or converted barges in easily accessible reaches. Such a scheme could, I believe, be made a success not only from a health point of view, but also as an educational factor.—I am, etc.,

JAMES P. CULLEN, M.D. (LOND.), D.P.H.

Poplar Dispensary for the Prevention of
Consumption, Feb. 12th.

THE SUPPORTS OF THE UTERUS.

SIR,—I must thank your reviewer for his kindly response to my submission that he is unduly agnostic on the subject of prolapse. But is it not possible to pay too much attention to the opinions of "authorities"? Some of them secure repute by bringing forward new work; others gain notoriety by defending views already hallowed by age. Their weight also varies.

Ballantyne says (*Essentials of Gynaecology*, page 2) that "Plato and the Arabians held curious views about the uterus wandering about in the body like a wild beast, and capable of being enticed into the vagina." But the modern uterus is tethered on either side by the parametric connective tissue. It has two broad, vascular, lateral pedicles. It forms the central portion of a sort of swing bridge which crosses the pelvis from side to side.

Gladly, then, let us turn, at the request of your reviewer, to the musculature of the pelvic floor; and let us ask if it really is, as authorities still maintain, "a most important matter in respect of prolapses."

If a bull is well tethered in a field which has a small gap in its hedge, you cannot let the bull out of the field by enlarging the hole in the hedge. You must loose the bull; then he will attend to the hedge.

Tearing the pelvic musculature does not loosen the connective tissue attachments of the uterus, and cannot bring about prolapse. But if the parametric swing bridge is relaxed, the loose uterus comes down and gradually dilates the vaginal orifice. If this has previously been enlarged by tearing, the loose uterus descends all the quicker.

If this is not sound pathology, how is it that we see women every day who have no prolapse, although their perineums have been torn into the rectum for years? The levatores ani have been stretched and thinned beyond recognition in other women who have no prolapse; and, in doing paravaginal section, we cut through the levator ani into the ischio-rectal fossa without loosening the uterus.

Though the nature and pathology of prolapse seem fairly clear, its cause certainly remains obscure. For who can say why one woman's uterus becomes loose after a single normal confinement, while that of another woman remains properly attached after a dozen?—I am, etc.,

Manchester, Feb. 17th.

W. E. FOTHERGILL.

SIR,—Since my name has been mentioned in the discussion on this subject, may I say that the practical conclusions of my paper "On the Nature of the So-called Ligaments of Mackenrodt" are that it is impossible to differentiate without artificial means, namely, by removing piecemeal the superior portion of the parametrium, the lower border of this tissue, called by Mackenrodt the "ligamenta transversa cervicalis," and the remaining parametric tissue; in fact, his ligaments are artefacts? I agreed that the uterus was held in position by the parametric tissues. This fact was made little of by the reviewer, and he turns to the pelvic diaphragm. The attachments and relations of the uterus to the pelvic diaphragm are purely secondary, brought about through the intervention of the parametrium. The visceral aspects of the levatores ani muscles are covered entirely by parametrium. This consists of masses of smooth muscle, perivascular and perineural sheaths, together with blood sinuses and lymphatics. This tissue, originally undifferentiated mesoblast, runs in one continuous sheet round the uterus, bladder, and urethra. It undoubtedly forms the chief support of the pelvic viscera. As long as the parametrium is healthy, it is impossible for the uterus to come down.

I had the good fortune recently to perform a complete *post-mortem* examination on a female with procidentia. Fully two-thirds of the uterus, which was large, lay outside the body and the remaining third was in the vagina. The parametrium was stretched into two long ribbon-like folds; it was thin and scanty. The pelvic diaphragm was healthy and normal. Beyond an increase in the size of the vulval orifice, obviously mechanical in origin, no pathological changes existed. The musculature of the pelvic diaphragm was well developed. I have satisfied myself, and have specimens to demonstrate, that efficient colporrhaphies are successful only because they tighten up the parametrium, though some surgeons who practise these operations may not quite realize this.—I am, etc.,

The Anatomical Department,
Manchester University, Feb. 17th.

MANFRED MORITZ.

THE NEGLECT OF VACCINATION.

SIR,—In the *Times* for February 1st a condensed report is published of the speeches at the annual dinner of the Association of Public Vaccinators,* from which it appears that the president (Dr. Arthur Maude) and the retiring president (Dr. A. H. Martin) made some strong remarks about the "red terror" which was some day going to overtake this country as a punishment for neglecting vaccination, and about the culpable responsibility of a Government which allowed such neglect to continue.

I write as a thorough believer in the efficacy of vaccination in protecting the individual (for a limited period), and I do not doubt the sincerity of Drs. Maude and Martin in their gloomy prophecies and denunciation. I venture to suggest, however, that these are, to say the least of it, rather ill timed at a period when, with steadily increasing neglect of vaccination, this country is showing a markedly increased success in dealing effectively with outbreaks of small-pox! One cannot help wondering whether these gentlemen, who talk so emphatically about the impossibility of dealing effectually with small-pox without recourse to infantile vaccination, have ever taken the trouble to make themselves familiar with the experience of Leicester, a town of 230,000 inhabitants, which has practically dispensed with infantile vaccination for the past thirty years, and which, in spite of all the positive predictions to the contrary, has dealt quite as successfully with small-pox as any other large industrial centre.

Have they considered, also, that infantile vaccination only protects (from attack) during the period of infancy and childhood, and that this period is the one least exposed (under modern conditions) to the danger of small-pox infection? Hence the remarkable fact, as yet hardly realized by pro-vaccinists, that in spite of increasing neglect of infantile vaccination, the relative incidence of small-pox mortality upon the age-period under 5 years, so far from increasing (as it ought to have done according to pro-vaccinist theories) has actually diminished!

One wonders, too, if these gentlemen have ever considered that our present system of infantile vaccination, which is not followed by revaccination, has one very serious drawback which (under modern conditions) probably goes far to neutralize, or even to more than neutralize, any benefit which might otherwise accrue from partial protection of the community? I refer to its undoubted effect in causing slight atypical forms of small-pox which are easily overlooked, and which thereby frequently lead to serious outbreaks of the disease, which outbreaks would not have occurred had the first cases been of the straightforward, easily recognized type which one usually finds in unvaccinated subjects. The serious outbreak in the East End of London in 1911—which was so successfully controlled by the prompt application of the same measures which have proved so effectual in Leicester—as also the serious outbreak last autumn in Kirkealdy (the one causing over 60 cases with 8 deaths and the other over 40 cases with 13 deaths), originated in both instances in mild unrecognized cases in vaccinated subjects. I say advisedly that it is very probable neither of these outbreaks would have occurred, or at least would not have spread beyond the first few cases, had the persons first attacked in each case been unvaccinated. No doubt

* A report of the annual meeting and dinner of the Association of Public Vaccinators was published in the *JOURNAL* last week, p. 350.—Ed. B. M. J.

it would have been worse for those two individuals, but how much better for all those whose lives were sacrificed! These examples are very far from being exceptional.

If I may venture to give a word of friendly advice to Drs. Maude and Martin it is that they should bow to the inevitable and recognize, as many of us have now done for some time, that the occupation of the public vaccinator must be ranked as one of our dying industries. Happily for them the National Insurance Act has opened up fresh fields of useful and remunerative work. If, however, they have conscientious objections to "serving on a panel," let them enter the ranks of the Public Health Service, where I can assure them they will find ample scope for their undoubted abilities. If they still feel it their duty to prophesy evil and not good let them do so by all means, but let them point to sanitary reform, in its widest sense, rather than to the resuscitation of a system which, to all appearances, has had its day, as the proper course for the country to adopt if it really wishes to set its house in order. Of one thing I am confident, and that is that the future as regards small-pox prevention in this country lies with the medical officer of health rather than with the public vaccinator.

Personally, I am far from being satisfied that the "passing" of compulsory vaccination is a matter for serious alarm. If it leads to increased attention being paid to public health measures, as has been the case in Leicester, it may even prove a blessing in disguise.—I am, etc.,

C. KILLICK MILLARD, M.D., D.Sc.,
Leicester, Feb. 11th. Medical Officer of Health.

CHEWING GUM.

SIR,—A case having occurred recently in the North of England in which death was suspected to have been caused to some extent at least by the use of chewing gum, it appeared to me advisable to have samples of this article analysed. The following is the gist of the report received:

The samples are free from poisonous metals and actively harmful ingredients. They are compounded of a vegetable gum, known as chicle gum, which is allied in its nature to gutta-percha, with sugar and flavouring essences. The gum present in these samples to the extent of 17 to 25 per cent. is not actively poisonous or harmful chemically, but is quite insoluble and indigestible. The use of these chewing gums by children especially, who are likely to swallow the whole, is much to be deprecated, and should be discouraged by all available means.

Before taking any further steps I feel that I should have some definite evidence to put forward.

If, therefore, any of your readers have had experience of actual cases in which harmful results accrued from the use of these substances, I should take it as a great favour if they would communicate the facts to me.—I am, etc.,

H. KERR,
Newcastle-upon-Tyne, Feb. 12th. Medical Officer of Health.

THE CONSTITUTION OF THE ASSOCIATION.

SIR,—I am perfectly convinced that you and Dr. Davy and the leader writer in the *Times* are wrong in thinking that the "referendum" of the Association last December, and the consequent vote of the Representative Body on December 21st, was not in accordance with the real opinion of the profession as a whole at that time. To argue to the contrary is to deny that the majority went on the panels against their will. Besides the voting at our Divisional meeting I knew the opinions of a fair proportion of those who were unable to be present. Doubtless other Representatives can say the same.

The fact is that when it came to the point we found ourselves unable to refuse service, except with the help of the contracting-out clauses, because we are so closely bound to our patients, whether insured persons or employers, by professional and economic ties. They had submitted to the Act; we, being a profession and not a trade, could not refuse them the benefits for which they had paid. We have not changed our opinion of the Act, but we have been forced, in our patients' interests, to abandon an untenable position.

Similarly I hold that the Representatives do represent their Divisions and are generally the best men available.

I do not understand that there is great competition for these posts, or that Representatives find great difficulty in ascertaining the opinions of men in their Divisions. Therefore I cannot see much advantage in altering our constitution as to the mode of electing and instructing Representatives.

But our constitution does require alteration in two particulars. Every one who attended the last three Special Representative Meetings must feel shame and amazement at the way in which we conduct our business. On January 17th we disputed for a whole day, at a cost to the Association of £1,000, and did not even succeed in recording the votes we came pledged to give. The agenda ought to be drawn up by the Council, and include such resolutions as will allow of a debate and decision on every point at issue, and neither amendments nor riders by Divisions or individuals should be permitted. Each resolution should be moved by a member of Council, who should make its import clear. The solicitor's opinion upon the exact import and validity of each resolution should be taken before the meeting is held. All questions, not points of order, should be submitted in writing. For a body of 250 men, skilled indeed in medicine, but profoundly ignorant of law, to frame, alter and redraft in a few hours a resolution which, when passed without anything deserving the name of debate, is intended to bind the whole profession, can only be called legislation by nightmare.

The whole matter is too big to be discussed in a single letter. I hope others will take it up and thresh it out in time to tabulate the necessary alterations for the Annual Representative Meeting. Could not the Council appoint a small subcommittee *ad hoc*?

If the procedure of the Representative Body is not reformed I fear that a good many of the most valuable members will find that they cannot afford the time and trouble involved in representing their Divisions in future, and the Association will relapse into the unrepresentative state from which this war aroused it.

The Representative Body should confine itself to debate and decision on broad questions of policy.

Greater trust should be placed in the Council, which should have executive powers in all details of policy.—I am, etc.,

February 17th.

P. NAPIER JONES,
Representative Reading Division.

SIR,—In your issue of February 15th, Dr. Laehlan Fraser demands that we (the British Medical Association) should, "no matter at what cost, transform ourselves into a strong trades union." This, it appears, is in order that we may "protect ourselves against our two natural enemies—the Insurance Committees and the approved societies." If one may judge from his letter, Dr. Fraser is himself one of those unfortunate members of our profession who have been driven, against their own inclination, on to the panel, and it must be obvious to anybody that, having once placed their necks under the yoke, the insurance doctors will now have no option but to form some big central combine in order to defend their economic interests against the inevitable exactions of their new task-masters. But, in the name of all that is best in the traditions of medicine, I protest against Dr. Fraser's proposal that the British Medical Association should be commandeered for such purposes; that this body, whose one essential and primary object hitherto has been the advancement of the science and art of healing, should forthwith be converted into an organization for protecting the financial interests of a section of the profession. Doubtless the doctors on the panel need to combine for self-preservation, and, by all means, if they feel like it, let them form a union *ad hoc*. But I hope that all members of the profession, whether on or off the panel, will clearly recognize that this is not the purpose for which the British Medical Association exists, and that if its machinery should ever be diverted from its present high social function to subserve such purely particularist ends, this would not only inflict another heavy blow on the prestige of medicine in this country, but would inevitably lead to the withdrawal from the Association of all these who still retain some sort of sense of proportion.—I am, etc.,

Edinburgh, Feb. 16th.

ARTHUR J. BROCK.

THE LATE CHAIRMAN OF THE CENTRAL ETHICAL COMMITTEE.

SIR,—In your current issue (SUPPLEMENT, p. 145) you report a resolution of the Council of the British Medical Association referring to the action of Dr. Lauriston Shaw in presiding at the inaugural meeting of the National Insurance Practitioners' Association. His dignified reply will satisfy all fair-minded men in the profession, but inasmuch as we were responsible for asking Dr. Shaw to honour us by presiding at the meeting, we feel that some statement from us is necessary.

It was evident to us that a considerable section of the profession felt that the situation was entirely altered when the final terms and conditions were announced by the Chancellor of the Exchequer in December, 1912, and which considered that the new conditions should be accepted, at least for a provisional period. The section of the profession which held these views had hitherto had little opportunity of giving expression to them. In order to support those in favour of working the Act, the National Insurance Practitioners' Association came into being. The course of events has amply justified the action taken, and there can be no doubt that the movement which was inaugurated at the meeting referred to was not only necessary, but obviously fair. We have carefully scrutinized the circular letter to which, apparently, the resolution refers, but we can find no expression whatever which would justify the pontifical action of the Council. It must be remembered also that at the meeting in question speaker after speaker, including the chairman himself, declared that the new association was not in any way hostile to the British Medical Association. Indeed, if the British Medical Association had been wise, there would not have been need of a Representative Meeting in January to reverse the decision of December.—We are, etc.,

H. G. COWIE,

Honorary Secretary,
National Insurance Practitioners' Association.

H. H. MILLS,

Honorary Treasurer,
National Insurance Practitioners' Association.

London, Feb. 18th.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following degrees have been conferred:

M.D.—J. R. Bentley.
M.B.—D. N. Macleod.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council was held on February 13th, Sir Rickman J. Godlee, Bart., President, in the chair.

Issue of Diplomas.

Diplomas of Membership were granted to ninety-eight candidates found qualified at the recent examination.

Diplomas of the Licence in Dental Surgery were granted to four candidates.

Diplomas in Public Health were granted, jointly with the College of Physicians, to twelve candidates.

Lister Memorial Fund.

The Council voted a sum of 50 guineas to the Lister Memorial Fund.

Primary Examination for the Fellowship.

The following recommendations of the Nomination Committee were adopted by the Council:

I. That Clause 7 of Section III of the Regulations relating to the Diploma of Fellow be altered from

"7. Of having attended a course of Practical Physiology during not less than six months at a recognized Medical School"

to the following:

7. Of having attended at a recognized Medical School
 - (a) A course of Experimental Physiology.
 - (b) A course of Chemical Physiology.
 - (c) A course of Histology.

II. That this alteration in the Regulations be made applicable to all candidates who are not Members of the College entering for the Examination in May, 1914, and for subsequent Examinations.

III. That two papers in Physiology, each containing four questions, of which the candidate must answer only two, be set, and that two hours be allotted to each paper.

IV. That the same arrangement be adopted for the written part of the Examination in Anatomy.

V. That these alterations with regard to the written papers be carried out at the next examination in May of this year.

Central Midwives Board.

Mr. Golding-Bird was re-elected as the representative of the College on the Central Midwives Board.

Bradshaw Lecturer.

Mr. G. H. Makins was chosen as the above lecturer for the ensuing collegiate year.

Gifts.

An offer was accepted, with thanks, from Lady Rutlin, to present to the College a replica of the portrait of her late husband by the Hon. John Collier, which was exhibited in the Royal Academy a few years ago.

The Secretary reported that he had received from the executors of the widow of Mr. Caesar Henry Hawkins a portrait by Zoffany of Mr. Pennell Hawkins, Master of the Company of Surgeons in 1778, and great uncle of Mr. Caesar Henry Hawkins, the picture having been bequeathed by Mr. Caesar Hawkins to his wife for life, and after her death to the Royal College of Surgeons, with the direction that it should be placed near the picture painted by Hogarth of Sir Caesar Hawkins, Bart., brother of Mr. Pennell Hawkins.

Board of Examiners in Dental Surgery.

A vacancy occasioned by the expiration of Mr. W. A. Maggs's period of office on the above Board will be filled up at the quarterly Council in April, Mr. Maggs not being eligible for re-election.

CONJOINT BOARD IN ENGLAND.

At a meeting of Comitia of the Royal College of Physicians on January 30th and of the Council of the Royal College of Surgeons on February 13th, diplomas of L.R.C.P. and M.R.C.S. were respectively conferred upon the following ninety-eight candidates, who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Examining Board and have complied with the necessary by-laws:

K. B. Aikman, C. H. P. Allen, G. S. Applegate, C. V. Aserappa, S. G. Askey, M. Avent, G. Bailey, J. H. Bennett, P. T. G. Bergougnan, A. C. L. O'S. Bilderbeck, W. F. Blandford, M. F. Bliss, E. C. Bowden, F. J. Y. Bra-h. R. T. Brochie, H. H. Brown, S. A. Burn, A. G. Clifford, A. G. W. Compton, W. J. Cran, W. H. Dakin-Smith, A. B. Danby, F. E. Daut, K. B. Dickson, P. G. Doxey, G. D. Eccles, E. A. C. Fazan, E. J. Foster, I. S. Gabe, N. Garrard, G. W. B. Garrett, H. C. Godding, E. M. Grace, B. Grellier, C. J. A. Griffin, F. A. Gunsekera, A. E. Halliran, W. E. Hallinan, S. H. Hay, A. M. Henry, P. M. S. Hulke, F. C. Hunot, T. J. J. Jeppe, D. W. John, R. E. Johnston, M. K. Joshi, W. H. Kauntze, K. J. T. Keer, P. H. Kelly, Merlin Kingsley, H. A. Lake, H. W. Latham, H. V. Leigh, F. G. Lescher, A. R. MacMillen, K. C. Mandana, H. H. Mathias, A. W. Matthew, L. M. J. Menagé, C. C. Messier, A. G. H. Moore, O. G. Morgan, D. E. Morley, L. Page, J. L. Perceval, O. Pitt, C. H. G. Pochm, Lao Htin Poh, H. M. Pope, S. B. Radley, S. O. Rashbrook, L. N. Reece, Minerva Ellen Reid, P. Roux, J. A. Ryle, W. H. P. Saunders, B. E. P. Sayers, W. Simpson, R. W. Spence, C. M. Stallard, R. Stansfeld, H. M. Stephenson, W. J. P. Symons, J. R. K. Thomson, M. L. Treston, H. de P. B. Veale, A. W. Venables, A. S. Wakely, H. F. W. Warden, H. A. Watermeyer, P. J. Watkin, C. A. Weller, E. W. Whiting, S. Wickenden, A. Wai-tak Woo, B. Woodhouse, W. W. Woods, L. D. Wright.

Diplomas in Public Health were conferred upon the following:

F. J. Ayre, H. Balme, Lieutenant Jansap Cursetji Bharucha, I.M.S., Elsie Mary Chubb, W. E. Cooke, A. Ferguson, Captain C. A. Gill, I.M.S., H. Hilliard, Major J. E. Hodgson, R.A.M.C., Captain H. M. H. Melhuish, I.M.S., Captain A. L. Otway, R.A.M.C., P. Rose.

CONJOINT BOARD IN IRELAND.

The following candidates have passed the examination indicated:

DIPLOMA IN PUBLIC HEALTH.—Captain T. C. Boyd, F.R.C.S.I., I.M.S., T. W. Conway, F.R.C.S.I., J. J. Cullen, L.R.C.P. and S.I., C. H. Denham, M.B. Dubl. Univ., Captain P. L. Harding, F.R.C.S.I., R.A.M.C., J. O'Regan, L.R.C.P. and S. Edin., T. E. Rice, L.S.A., R. F. Williams, M.B. Univ. Camb.

* Obtained honours.

Medico-Legal.

SANATORIUM BENEFIT.

Claim for Negligence.

At the Lambeth County Court, before Judge Parry and a jury, an action was brought on February 17th against the Insurance Commissioners and Mr. J. A. Dawes, M.P., chairman of the Insurance Committee for the County of London, by the widow of an insured contributor who claimed £100 on the ground that she and her two children had suffered damage from the negligence of the defendants in wrongfully neglecting to provide sanatorium benefit for her deceased husband and a sum of 10s. a week for the maintenance of herself and her two children, to which they were entitled under the Act. The Commissioners set up the defence that the administration of sanatorium benefit was entrusted to the Insurance Committee and not to them, and that no case was maintainable against them in respect of any act or default of the committee in relation to sanatorium

benefit. It was also alleged that no action was maintainable by any insured person against the Insurance Committee in relation to anything done or omitted by the Committee under Part I of the Act, and also that by reason of Section 8 of the Act no sum was payable in respect of sickness benefit or disablement benefit to the plaintiff's husband, and that the Insurance Committee was not guilty of any negligence or default, and that death was not caused or accelerated by any act or default of the Insurance Committee.

The deceased had been first seen by Dr. Mackeith on August 18th, and his diagnosis of pulmonary tuberculosis was confirmed at the Brompton Hospital. On the advice of Dr. Mackeith the patient's wife made application to the Insurance Committee, and was given two forms to fill up. On September 23rd, having heard nothing more, she again applied, indicating that she was depending for nourishment for her husband upon gifts from friends. Dr. Mackeith, on September 29th, reported that the patient required rest in bed, fresh air, and suitable nourishment. It was contended on behalf of the widow that her husband had been entitled to be treated under the Insurance Act and provided with extra nourishment, and that if he had been so treated the chances were in favour of his life being saved.

Dr. Mackeith, giving evidence, said that he did not regard the case as one for removal to a sanatorium, but that it should have been treated at home; he believed that the man might have recovered and returned to work.

Mr. J. A. Dawes said that the London Insurance Committee received a report on October 10th; the matter had first come before him on September 26th. The Committee could not do anything until they got the report of the patient's doctor and the insurance card.

It was submitted on behalf of the Commissioners that there was no case against them, and the judge ruled in their favour.

The case then proceeded as against the Insurance Committee. Dr. Priestley, M.O.H. Lambeth, said that the notification he received from Dr. Mackeith did not show that the case was urgent, and he had waited for the next meeting of the local subcommittee. In reply to the judge, he stated that nothing had been done by the local subcommittee to give the deceased sanatorium treatment.

The judge left the following questions to the jury: (1) Was the Committee guilty of negligent default in not providing suitable nourishment to deceased between September 29th and October 14th? (2) Did this negligent default cause the death of the deceased? (3) What monetary loss had the widow sustained? They answered the first question in the affirmative, the second in the negative, and fixed the monetary loss at £150.

Mr. Mathew, counsel for the Insurance Committee, asked for judgement on these findings, the jury having found that the man's death was not caused by negligence.

His Honour entered judgement for defendants with costs, stating that the jury's answers left everything in order for the widow to appeal.

CERTIFICATES BY UNREGISTERED DENTISTS.

At the Wimbledon Petty Sessions on January 29th, Henry Ramage, manager to "Wilson's Dental Surgery," 43, The Broadway, and W. G. Morris were summoned at the instance of the British Dental Association for offences under the Dentists' Act, s. 3. Mr. Turner appeared for the prosecution, Mr. P. Robinson defended.

It appeared that the Surrey County Council, when selecting boys for their technical colleges, required medical and dental certificates. A doctor, finding that a boy's teeth were not in order, would give him a printed notice to consult a dentist. This notice specified that the certificate must be signed by a duly qualified and registered dentist. It appears from the report in the *Wimbledon Borough News* that a lad named Stone, having been so served, went to 43, Broadway, and saw the defendant, Ramage, who said that he knew all about such notices. The documents supplied by Ramage were rejected, and the Dental Association was communicated with. It was not alleged that the work done for the boy was unsatisfactory.

It appeared that Ramage was not a registered dentist. He admitted that he had signed a certificate, which had been handed to him by his secretary without any statement that the certificate must show the boy had been passed by a qualified and registered dentist. He also swore that he had never seen the education authority's form and would not think of signing it. A second certificate was issued by his secretary. He denied that Mr. Stone showed him the form.

The Chairman announced that the Bench had decided to convict and would impose a penalty of £2 and costs. He added that the dental authorities were perfectly right in taking proceedings in such cases.

In Morris's case, the summonses were not contested, and he was fined £2, being also ordered to pay £1 ls. advocate's fee on each summons and 8s. 6d. costs.

ON the suggestion of the High Commissioner for Cyprus, the Secretary of State for the Colonies has arranged that a visit shall be paid to the island during March by Sir Ronald Ross, M.D., K.C.B., F.R.S., late Professor of Tropical Medicine in the University of Liverpool. The object of Sir Ronald Ross's visit is to investigate the cause of the prevalence of malarial fever in the island and to advise in regard to the best means of combating the disease.

Obituary.

EDWARD ADRIAN WILSON, B.A., M.B. CANTAB.,
HEAD OF SCIENTIFIC STAFF, NATIONAL ANTARCTIC
EXPEDITION, 1910.

The manner of the death of Edward Adrian Wilson will make his name to be remembered as long as his countrymen keep their love of quiet courage and of the spirit of adventure. No one can read unmoved Scott's story of that last month which began for them about a year ago. The physical suffering, the mental tension as they struggled on from one store of food and fuel to the next, the growing uncertainty, the falling hope, the noble death of their sick comrade, whose fate must have seemed a forecast of their own, cannot but have tried even their courage. It did not fail and they struggled on, for, indeed, with one fine day, or even a better store of food and fuel at their last camp, they could have won through. Wilson had chosen a life of adventure and research in the field, and in this last venture to the extreme south, for which he was proud to be chosen, since the choice was a proof of the confidence felt in his qualities of heart and mind, he knew—no one better—the risk to be taken. He took it and lost, and would have been the last to murmur because death in early manhood was the lot of the loser:—

I love
The name of honour more than I fear death.

He was a type of man of which any profession may be proud. Simple, unassuming, quietly efficient, he impressed every one as a comrade who could be trusted wholeheartedly, one who would not fail at a pinch. He was born in 1872, the son of Dr. E. T. Wilson, Consulting Physician to the Cheltenham General Hospital. He was at school at Cheltenham College, and went up to Cambridge with an exhibition at Caius College in 1891. The fact that in 1894 he took a first class in the Natural Science Tripos (Part I) is proof of the early bent of his mind and of his ability. He would probably have wished to go on with natural science as a career, but he was not a laboratory student, and a field naturalist must have leisure or some definite calling. He therefore, as have many like minded before him, turned to medicine, and went through the usual course at St. George's Hospital, where his simple, honourable, straightforward character, genial humour, and artistic talent won him many friends. During this period he worked at the Caius College Mission, and to this possibly was due the breakdown of his health, for in March, 1898, he developed pulmonary tuberculosis. The disease was well marked and the diagnosis certain. On Dr. Rolleston's advice he went to Davos in November, 1898. Though he recovered slowly, he was quite free from any signs of active disease when he started on his first Antarctic expedition. He graduated M.B. in 1900, but the peril he had gone through no doubt confirmed his natural inclination to the life of an open-air naturalist. He got his chance when in 1901 Captain Scott, trusting his own judgement of his recruit's character and capabilities, gave him a berth as surgeon and naturalist on the *Discovery*.

Professor J. STANLEY GARDINER, F.R.S., of Cambridge, has responded to our request for some contribution to this biography by the following tribute to Wilson's character and life-work, which may properly be introduced here:

E. A. Wilson came up to Gonville and Caius College as a freshman in October, 1891, the present writer coming up at the same time. He quickly became known to all his year on account of his extraordinary enthusiasm for everything which he took up. Rowing always claimed him, and he represented his College in his three undergraduate years in both the Lent and the May boats. He was an interesting figure in many ways, for we were a quarrelsome year, and he was always the mediator trusted by all sides. Although always in the midst of whatever fun was going, he yet kept curiously apart, for he had a peculiarly strong sense of duty of what he owed to his parents, to his College, and to himself. His rooms showed his tastes, much of his spare time being given to sketching, while there was always a litter of skulls, claws and odd bones of

animals lying around. We always felt that we could refer to him in any question of bones. He might not know the use or comparative morphology of the part, but he always knew what existed and what it was like. Wilson had no scholarship, but he obtained a First Class in his Tripos, and many of us felt that he ought to have been placed on the Foundation of his College.

Wilson's hospital work was noted for great thoroughness, but the chief change that the writer noticed in him at that time was an entire change in attitude, continual thought and inquiry as to the functions of all organs of the body in animals, together with a still greater interest in the habits of living animals. He developed greatly in other ways, and became tenacious to an extraordinary degree, and thought over his every action as to whether it was right or whether it was wrong. He became a strong man, one to whom his fellows looked up in their difficulties. Many of his hospital contemporaries owe much to him. Few really knew him, but all liked and respected him. At that time he was threatened with phthisis, about which then relatively little was known. I remember being told that his case was a bad one, but he was always cheerful about it, and ultimately, as we all know, completely recovered.

Wilson's chance came on the *Discovery* Expedition, to which he was appointed after some considerable doubt. Captain Scott told the writer that he was the life and soul of the party—the organizer of all amusements, the always good tempered and cheerful one, the ingenious person who could get round all difficulties; he knew no fear. To his splendid qualities and kindness all his comrades have borne testimony. He made the mammals and birds his own, publishing two large sections upon them in the reports of the expedition. They are not mere dull lists, but reports of enduring value, showing everywhere throughout the personal joyousness of their author. What could be more expressive than his drawings of the young chicks of the emperor penguin, or more maternal than that of the mother seal with her week-old baby? One feels what the strain must have been on such a man to have left his newly married wife to go on that expedition.

For some years subsequently Wilson was engaged in working up his results, and his very beautiful and artistic sketches of ice and snow, and life in the desolate Antarctic. He was also engaged in illustrating phases in bird life. Later, we find him investigating grouse disease, as zoologist to the recent inquiry. His mind, however, was set upon the South Pole. He was certain that Scott would arrange another expedition, that he would get there, and that he, Wilson, would be with him. He laughed at the danger, but at times he showed that he was quite alive to it. He thought, though, that it was his duty to go. For himself he sought no end. He wished to be there to help his friend, and to show what Englishmen could do and dare. How nobly he accomplished his ideal is apparent to all. May the memory of his heroic end and of that of his companions become an everlasting and cherished memory of our race.

We have also received the following contribution from one of Wilson's contemporaries at Caius and St. George's:

I knew Wilson intimately both at Caius and St. George's, and of all the men I have known he stands out by reason of the beauty of his character and the highness of his aims. He was a deeply religious man, and as an undergraduate he lived a life of ascetic purity; but he was quick to make friends and to see good in the wildest undergraduate, for his purity was of the quality of flame, which need fear no contamination. With even the lighter-minded undergraduates he was immensely popular, for he possessed that certain passport to the College's heart—a vein of delightful humour. When a medical student at St. George's, he lived in the poorest part of London, in order that he might give his service to the poor. He was a hard worker at his profession: indeed, I believe it was his prolonged work at the pathology of tuberculosis that brought about the infection that caused him to give up a medical career for that of a naturalist. As a naturalist I think his chief interest was in birds. I remember once walking through a wood with him in spring; from every note we heard he was able to tell me not only the species but the precise occupation at the moment of the bird that had

uttered it. Once, when on a walking tour in the Hartz Mountains, he found a hawk's nest in a pine tree. He climbed the tree, took one of the fledglings, carried it with him for the rest of the tour, brought it alive to England, reared it, and made a pet of it. His love of birds was as much that of an artist as of a naturalist. He would wait for hours until he had got a bird in a characteristic attitude in order that he might draw it. His artistic gifts were great, and would, I believe, have brought him name and fame had he devoted himself to art. Of his achievements I leave others to speak; I will only say that no one could meet him without being the better for it, and that it falls to few men's lot to be so deeply loved by his friends.

On his return from the Antarctic in 1904 he spent some time in working up his observations, and published reports on the scientific results of the *Discovery* expedition and on the distribution of Antarctic seals and birds. During the period before he left England with the second Antarctic expedition in 1910 he did field work for the Grouse Committee, and as to this we venture to quote the following tribute in the *Times*, signed "A. E. S.," initials which may be identified as those of Mr. A. E. Shipley, F.R.S., Master of Christ's College, Cambridge:

Although I had known him as a pupil in Cambridge about the middle of the Nineties, it was not until the departmental inquiry into the diseases of grouse was established in 1905, under the chairmanship of Lord Lovat, that I really came to know him intimately. From the beginning of our working together I appreciated the fact that my colleague was a man of the very highest character. He was indefatigable in his work, absolutely unselfish, never thinking of his own reputation, but very keen to advance knowledge and achieve results, singularly modest, with a quiet sense of fun and humour; so that altogether he was an ideal man to work with.

Dr. Wilson was a quite remarkable field naturalist. Little that went on in the open escaped his notice. He could not only see things which the ordinary eye passes by, but he could perpetuate them on paper. He was an artist of no mean merit. Those who are happy enough to possess any of his Antarctic sketches, with their vivid representations of the white waste and the blue skies, will recognize this. But his greater skill lay in depicting animal life. The present edition of Bell's *British Quadrupeds*, now in course of issue, owes much to his accurate and artistic pencil; and the report of the Grouse Disease Commission owes much of its interest to the fine plates which he prepared.

Then, again, he excelled as a lecturer. I have never heard a more entertaining or a more informing discourse than one he gave on "Penguins" after his first visit to the Antarctic.

Wilson was a man of indomitable courage, one who never spared himself—characters that were appreciated to the full by Captain Scott. He was very simple in all his habits and very direct in his thought and address, loyal to his friends, staunch to any cause he took up. He had, in fact, the characters of the finest type of an English gentleman.

He leaves behind him a wife who has been awaiting in New Zealand his return for the last eighteen months.

Lord Lovat, the Chairman of the Committee, in his introduction to the report published in 1911, wrote:

It is difficult to speak highly enough of Dr. Wilson's services, for not only was he an indefatigable worker in the field, but his ornithological knowledge, his scientific training, and his artistic skill, have been of the utmost value in every branch of the inquiry. Practically every grouse which was submitted to the Committee for examination was dissected and reported on by Dr. Wilson, and the results of these dissections, as shown in Appendix D, not only form a record of long and patient labour, but also provide an enormous mass of carefully arranged material which has been of great use to the Committee. Dr. Wilson has written or aided in writing ten out of the first fourteen chapters of the book, and has not only fully illustrated his own contributions, but has placed his artistic skill at the disposal of nearly all the other writers. In addition to his services as field observer and physiologist, Dr. Wilson conducted a series of experiments on live grouse at the Committee's Observation Area whereby the results obtained by Dr. Leiper, Dr. Shipley, and others were put to the test; these experiments entailed some years of hard and patient work, and required the closest co-operation with

the other members of the scientific staff. Dr. Wilson's personal qualities secured for him the willing assistance alike of local correspondents and scientific staff, and went far to ensure whatever success the Committee has achieved.

The first paper contributed to the report by Dr. Wilson was on the change of plumage in the red grouse in health and disease. The frontispiece is a spirited drawing of the red grouse in summer with young chicks, and in twenty-one other drawings the variations in the plumage of the grouse of both sexes at various times of the year, and in the several varieties, are fully illustrated. Other papers in the volume by Dr. Wilson were on the food of grouse, based on an examination of crop contents, on the physiology and anatomy and the weight of grouse, and papers on the causes of mortality in the red grouse, and on grouse disease, written in conjunction with Lord Lovat and Mr. A. S. Leslie respectively. In the volume of appendices to the report Dr. Wilson wrote a full account of the experiments on hand-reared grouse carried out in the Observation Area, as well as the long report referred to above by Lord Lovat as Appendix D.

When the National Antarctic Expedition of 1910 was decided on, Wilson was appointed head of the scientific staff. The *Terra Nova* sailed from Cardiff on June 15th, and reached Simons Bay about two months later. Captain Scott joined at Cape Town, and the ship, after touching at Australian ports, went on to Lyttelton, New Zealand, where ponies, dogs, motor sledges, and some additional stores were picked up. She left New Zealand on November 29th, 1910, entered the pack ice on December 9th, and eventually reached McMurdo Sound towards the end of January, 1911. After some exploration work she returned to winter quarters at Lyttelton, and the expeditionary party were left to their own resources on the Antarctic Continent for the winter. Last year the *Terra Nova* went again to McMurdo Sound and brought news that the party on shore were, with the exception of Commander Evans, who was recovering from scurvy, in good health and spirits, and that Captain Scott and the southern party were remaining for another year to continue and complete the investigations which had been planned. In the work during 1911 Wilson took his full share. He brought to it many qualities which made him a valuable member of the expedition. He was a keen and accurate observer, and his skill as an artist enabled him at once to record his observations and impressions. He was an indefatigable collector also, and a good helpful, resourceful, cheery comrade. On the last expedition he would seem to have proposed, in addition to general work, to give special attention to three subjects: the development of the chick of the emperor penguin, the embryology of seals, and the identification of certain varieties of whales which he had reason to believe had not been recorded. With the first object in view he headed a sledge party which started for the penguin rookery at Cape Crozier in mid-winter (June), 1911; it was a fortnight on the outward journey, encountering temperatures of 70° below zero and even lower. On the slopes of Mount Terror the party spent three days in building a stone hut, which they roofed with canvas. Comparatively few birds were found in the rookery, but fortunately these had already begun to lay, and eggs at different stages of development were secured. The same night a violent gale commenced to blow, and a tent and other articles, though carefully secured, were blown away. The canvas roof of the hut, after straining for fourteen hours, was torn to ribbons, and for thirty hours or more the travellers were confined to their frozen sleeping-bags, half-buried in snow and fragments of rock. Only after forty-eight hours did the wind decrease so far as to enable them to get a meal. The party returned, after five weeks' absence, encased in ice and suffering from want of sleep, but otherwise well. When the darkness and the extreme temperatures experienced are remembered, this winter journey in the Antarctic will always remain a remarkable feat of endurance.

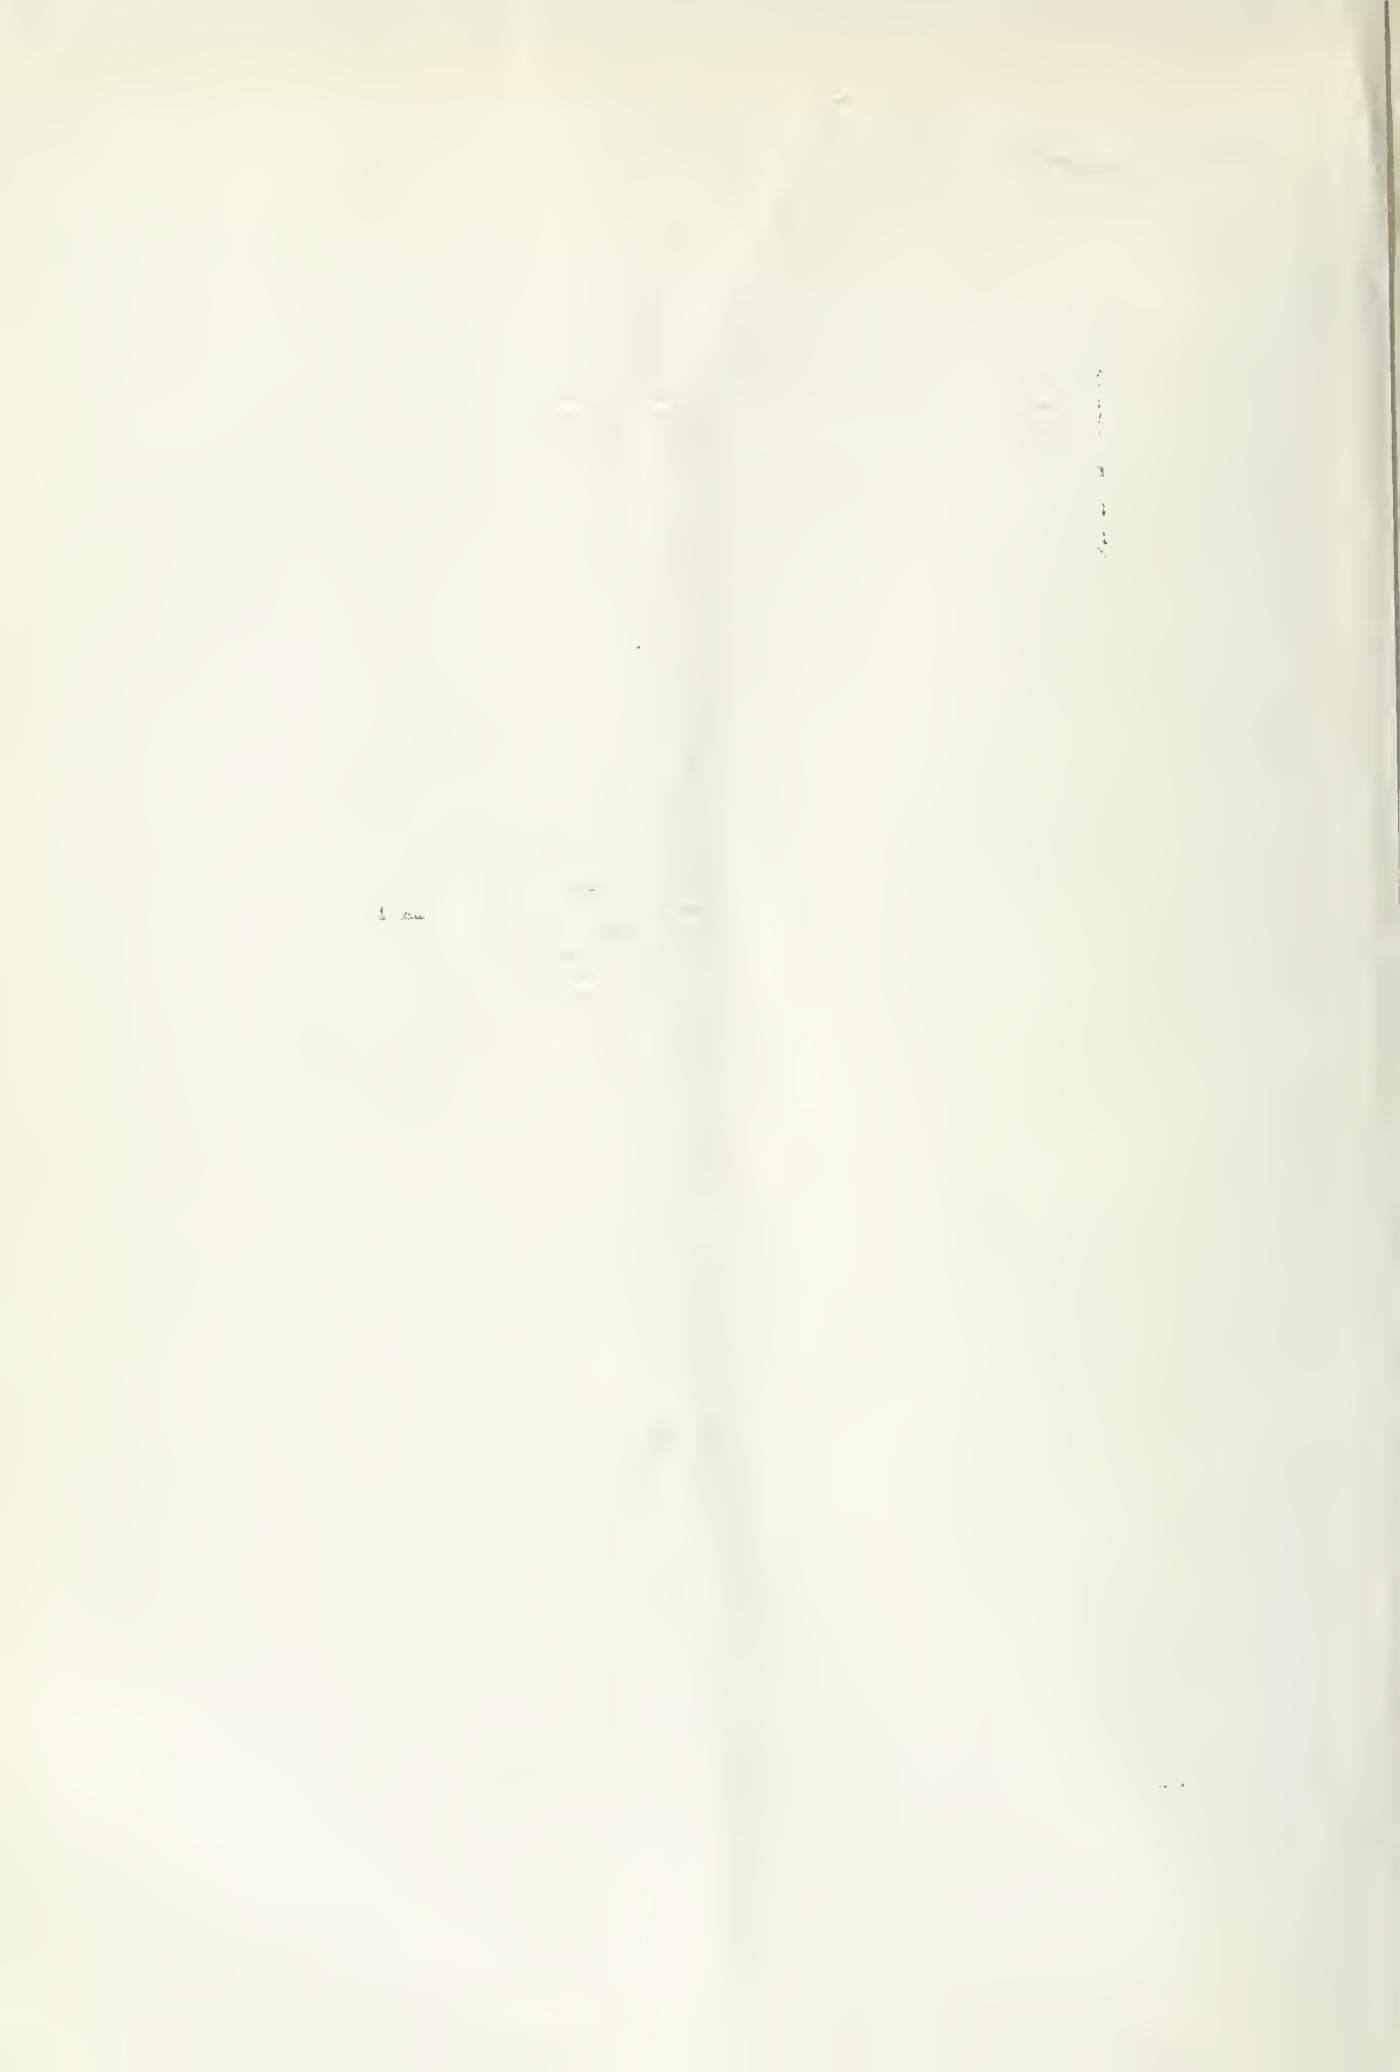

Wilson was one of the sixteen selected by Captain Scott for the South Polar party, which started on November 2nd, 1911, and was one of the four who accompanied their leader to the South Pole. His last letter to his father was written on January 3rd, just before the start on this final

E. A. WILSON.
(From a photograph taken by his father.)

M. M. MCHARDY.
(From a bust to be placed in the Royal Eye Hospital, Southwark.)

stage of the expedition. "I am fit and strong," he wrote, "and am just glad for all your sakes that I am one of the party for the Pole. We shall be at the Pole in less than a fortnight and back at winter quarters in the middle of March." Though the object of the whole expedition was scientific, every one of the party hoped that the Union Jack would be the first national flag to be planted at the South Pole, and it must have been a disappointment to that hope when they found that Amundsen had anticipated them by a few weeks. The cause of the delay in the return journey was twofold—the unusually inclement weather, the breakdown first of one member of the party and then the illness of another. The final catastrophe seems to have been determined by the failure of food and fuel during a prolonged blizzard. The bodies of the three men—Scott, Wilson, and Bowers—were found in their tent by the Southern search party on November 12th, 1912. Surgeon Atkinson and his companions gathered the records and effects of the dead men, read the burial service over their bodies, and erected a cairn and cross to their memory over the inner tent in which they were buried. We may hope that they will be allowed to rest there, and that the idea of bringing the bodies home may be abandoned. "Surely," as one who has a special right to speak has said to us, "it would be better, a thousand times, to let them sleep on amid the eternal snows with their great achievement as their noblest monument."

Dr. Wilson married immediately before his first journey to the Antarctic, and for more than a year his wife has been waiting for him in New Zealand. He leaves no children, but to his widow, to his father, and other members of his family the sympathy of the whole country has gone out.

A memorial service to Dr. Wilson was held in the Parish Church at Cheltenham last Sunday afternoon, and on the same day the Principal of the College preached to the boys on the text "Be thou faithful unto death." There is to be a special memorial service in the College chapel next month, on a day near the anniversary of Wilson's death.

It is satisfactory to be assured that all the scientific records and specimens collected by the party are safe, and it may reasonably be hoped that among these records will be notes and sketches by Dr. Wilson.

MALCOLM MACDONALD McHARDY, F.R.C.S. EDIN., LATE OPHTHALMIC SURGEON TO KING'S COLLEGE HOSPITAL.

It is with the greatest regret that we have to announce the death at Dumfries, on February 8th, of Mr. McHardy, late Ophthalmic Surgeon to King's College Hospital.

Malcolm Macdonald McHardy was born on March 15th, 1852, at Springfield, near Chelmsford, Essex; he was the sixth son of Admiral J. B. B. McHardy by Horatia, daughter of Admiral Pascoe, and grandson of Nelson's famous flag-lieutenant. He was educated at the Royal Naval School, then at New Cross, but subsequently removed to Eltham, in Kent; he left that institution at the age of 17, and was entered as a medical student at St. George's Hospital, and from that time forward entirely supported himself by his own earnings as an assistant, until he obtained the diploma of M.R.C.S. Eng., in 1873. He held several junior surgical appointments, being assistant house-surgeon to the Leicester Infirmary, house-surgeon to the Belgrave Hospital for Children, ophthalmic assistant and registrar to St. George's Hospital, surgical registrar to Charing Cross Hospital, and clinical assistant to the Royal Eye Hospital, Southwark. He thus obtained a practical and thorough all-round training before he specialized in ophthalmology.

He made a voyage or two in the *ss. Kongs Sverre*, and in 1877 was admitted a Fellow of the Royal College of Surgeons of Edinburgh. In 1878 he was appointed surgeon to the Royal Eye Hospital, Southwark. To his efforts was mainly due the rebuilding of that institution, which, by his devotion and untiring energy, was remodelled and raised to its present high level of efficiency. In 1880 he was elected Professor of Ophthalmology in King's College, London, and surgeon to King's College Hospital.

Among his many writings and lectures the following were the most noteworthy: "On the operative treatment of immature senile cataract and its artificial ripening by massage"; on "The application of the electromagnet in the removal and diagnosis of iron and steel

chips from within the eye"; "A new self-registering perimeter"; "A case of double black cataract"; "The treatment of primary glaucoma by iridectomy"; "On the prognosis of albuminuric retinitis"; and "On localized tuberculosis of the choroid"; he edited the fourth edition of *Wells on Diseases of the Eye*, with an original ophthalmoscopic atlas.

McHardy was a master of many handicrafts, his father originally intending to make him an engineer, and this mechanical bent helped to raise him to the position of distinction and usefulness that he subsequently occupied in eye surgery. He was practical to his finger-tips, and his originality and resource were of that cool and calculating nature mostly to be found in engineers.

For thirty years McHardy was to be seen at the Royal Eye Hospital, treating the poor with as much devotion and consideration as he would his most valued patient in private, twice a week, and for six and seven hours at a stretch, and often until nine o'clock at night, with that light-hearted, genial, breezy manner of his that endeared him to his patients. It was said of McHardy's patients that they would wait hours to see him, without grumbling at the waiting. This was true, and largely due, not only to his sympathetic, kindly way of treating their ailments, but because he also had a good knowledge of most trades and occupations, so that he was able to converse with them on the ins-and-outs of their work, which greatly pleased them.

He was very thorough in examining his patients, and made most careful and complete notes of his cases. The two hospitals at which he worked contain piles of his valuable notes and comments, and he thus built up that storehouse of facts which, with his natural aptitude for the work, made him a thorough ophthalmic diagnostician.

McHardy was a most beautiful operator. All who ever studied under him, whether English or foreign, bestowed the highest praise upon his consummate skill and dexterity. His ability to ripen an immature lens by trituration, without causing iritis, etc., was very great, and somewhat unusual, since the operation is not in general use.

He was, it is said, the first operator systematically to draw up into, and leave in, the angle of the wound a strand of iris stroma, free from pigment, during the operation for primary chronic glaucoma, with the avowed object of obtaining a filtration cicatrix. This he was doing in the early nineties of the last century, with considerable success.

The self-registering perimeter which he invented in 1882 has held its position for thirty years. It is a masterpiece of mechanical construction, and was as ingeniously thought out as it was well made.

A man of fine physique and a good athlete, McHardy was a striking personality. He spoke in a brusque and forcible fashion, and needed to be studied to be understood. Beneath the rugged surface there was a large and kindly heart. Whoever needed a lift got the helping hand of McHardy freely extended to him, and his home at Margate was always at the disposal of any poor student at King's who might need a change of air. He was very generous to the poor of Southwark, and his hand was for ever in his pocket. He served on several philanthropic bodies, amongst which was the Society for the Promotion of the Welfare of the Blind. In worldly possessions he had little and wanted less; for he was self-sufficient, and easily satisfied with few personal belongings. Patients flocked to him in private as they did at the hospitals. He made money, but did not keep it. His house at Margate was a curiosity—the rooms were more like the cabins of a sailing ship, with little furniture except the bare necessities of daily life, and "no superfluities to cumber the place." His was an individuality of that clear, defined, strong type that to attempt to model would have been to attempt to spoil; and although all could not acquiesce in all of him, yet a few more fearless expositions to the world of a personality true to itself, unmasked by the cloak of convention or deceit, such as was his, would be all to the benefit of humanity.

The funeral took place at Dumfries on February 11th, and amongst those present at the graveside were representatives of the staffs of King's College Hospital and the Royal Eye Hospital. A memorial service

was held at the same time in the chapel of King's College, London, at which many of his former colleagues and students were present.

ALFRED BAYNARD DUFFIN, M.D. EDIN., F.R.C.P.,
F.R.C.S.,

CONSULTING PHYSICIAN TO KING'S COLLEGE HOSPITAL, AND
EMERITUS PROFESSOR OF MEDICINE, KING'S
COLLEGE MEDICAL SCHOOL.

We regret to announce the death of Dr. A. B. Duffin, which occurred on February 10th at his residence in Wallington, Surrey, at the age of 79.

Alfred Baynard Duffin was the son of a general practitioner in London, and was educated at King's College, London, and at the universities of Edinburgh and Berlin. In Berlin he came under the influence of Professor Virchow, and acquired the interest in pathology which was later to colour all his clinical and teaching work. He became M.R.C.S. Eng. in 1855, and graduated M.D. Edin. in 1857. In 1858 he was House-Physician at King's College Hospital under Dr. George Budd, Dr. Todd, and Dr. George Johnson, and often spoke of his experiences in the old building which preceded the present King's College Hospital, which itself is about to be abandoned for new premises in the south of London. He became Assistant Physician to the hospital in 1860, at the same time as Dr. Edward Living and the late Dr. E. Symes Thompson. He did not become Physician to In-patients until 1874, and during the latter part of this long service in the out-patient room he gave up one afternoon a week in seeing out-patients with skin diseases; his teaching in this subject was much appreciated by the students. In 1876 he succeeded Dr. Lionel Beale as Professor of Pathological Anatomy, and in 1893 he was elected to the Chair of the Principles and Practice of Medicine. After working alone for a few years, he shared the duties of the Professorship with Dr. Burney Yeo, who succeeded him when he became Professor of Clinical Medicine. He was an active member for many years of the Committee of Management of King's College Hospital, and on

DR. A. B. DUFFIN.

(From a photograph taken by and published with the permission of Mr. C. B. Tabourdin.)

retiring in 1898 from active service on the staff of the hospital he was made Consulting Physician and Emeritus Professor of Medicine. He was also an Honorary Fellow of King's College, London.

He was elected a Fellow of the Royal College of Physicians in 1873, was a member of the Council from 1894 to 1896, and was an examiner in medicine from 1889 to 1902. He was also an examiner in medicine at the University of Edinburgh. He took the Fellowship of the Royal College of Surgeons of England in 1859, and somewhat prided himself on being one of the few physicians practising medicine who possessed this distinction. For many years he was physician to the Church Missionary Society, and he was also examiner for various insurance societies. He was at one time a pretty regular attendant at the meetings of the Pathological Society and of the Clinical Society of London, and although he never published any of his lectures in book form, he contributed several articles to the *Transactions* of these societies, to the *King's College Hospital Reports*, and to the medical press. We are indebted for the above particulars to a former student and colleague, who adds the following tribute to his memory:

As a teacher Dr. Duffin's pupils remember him mainly for the readiness with which he imparted the fruit of his large store of experience and reading. A random question from a student in the wards often led to an informal lecture of considerable length, delivered with great fluency and rapidity. He was one of the most kindly of colleagues, ever ready to take broad views on matters under discussion, and very tolerant of differences of opinion. Owing possibly to his somewhat retiring disposition, he scarcely attained the professional recognition which his energy and work appeared to merit, but he made many firm friends, and was always ready to advise those who wished for guidance in professional difficulties.

Dr. Duffin never married, but devoted his life to the companionship and care of an invalid relative. During the time that he lived in Devonshire Street he was a constant attendant at Holy Trinity Church, Marylebone, being a man of strong religious convictions.

DR. FREDERICK WRIGHT, J.P., of Stamford Bridge, Yorks., died on Saturday, January 25th, in his seventy-seventh year, after a long and painful illness. Mr. Wright had long been recognized in Yorkshire as a leading authority in all matters pertaining to agriculture. He was the son of Dr. John Wright, and was born in Stamford Bridge in October, 1836. He was educated at Knaresborough Grammar School and Edinburgh University, and joined his father in practice after completing his professional education. "Towd doctor," as he was affectionately called by his friends and neighbours, always enjoyed, like his father before him, the complete confidence of the farmers. He devoted all his spare time to the cause of agriculture, beginning by the establishment of the Derwent District Agricultural Club, the forerunner of several similar institutions in the same part of Yorkshire. He predicted only a few years since that the young farmer who is content with rule-of-thumb methods will not find landlords ready to accept him as tenant, for this is the day of scientific tilling. Mr. Frederick Wright worked hard till a few months ago, when his health failed, and towards the end of January his condition became hopeless. He leaves a son, Dr. Cyril Wright, of Towcester, Northants. According to the deceased doctor's own desire, his remains were incinerated at the Lawnswood Crematorium, Leeds, and afterwards the ashes were interred at Catton Church, near Stamford Bridge; several agricultural clubs sent representatives, and the attendance was very large notwithstanding the inclemency of the weather.

It is with regret that we announce the death of Mr. HENRY SUTCLIFFE, which occurred on January 29th at Bournemouth, where he had resided since his retirement from general practice. He was born at Heptonstall, in Yorkshire, and commenced his medical career, when 18 years old, by being apprenticed to the house-surgeon at the Huddersfield Infirmary. He afterwards studied at University College, London, and obtained the diploma M.R.C.S. Eng. in 1861, and that of L.S.A. Lond. in 1862. Shortly afterwards he was elected house-surgeon to the Bradford Infirmary. In 1864 he commenced general practice in West Bromwich, and was appointed district medical officer to the West Bromwich Union. When the West Bromwich District Hospital was opened he was one of the three surgeons first elected. He took great interest in the business part of the institution, and was elected on the board of management. He was a careful and successful operator, and when he resigned was appointed on the honorary consulting staff. He was a member of the British Medical Association. As a town councillor of West Bromwich he did useful work, and for some years was chairman of the Sanitary Committee. As a justice of the peace for the borough he was regular in his attendances on the Bench until failing health caused his retirement. His decisions were marked by justice tempered with mercy. His death, which happened rather suddenly from heart failure, will be deplored by his old patients, his medical friends, and the inhabitants of the town where he had practised for so long a period.

THE death is announced of Geheimrat Dr. JULIUS BAUMGÄRTNER of Baden-Baden. He expired on February 11th, at the age of 76. He was born in 1837 in Freiburg in Breisgau, and he received his medical education in the university of his native city: he distinguished himself in valuable work in the field of physiology. He then went to Paris and studied in the clinics of Chassaignac, Nélaton, and Maisonneuve, and in 1862 came to England, where he attended the hospital practice of Baker Brown and Spencer Wells, and afterwards passed on to Dublin and Edinburgh. In 1863 he settled in Baden-Baden, and during the Franco-German war took charge of a hospital for French prisoners in Rastatt, for which he was, after the peace, rewarded by the Société de Secours aux Blessés at Paris, which bestowed on him its Croix d'Honneur. In 1879 Dr. Baumgärtner held the office of General Manager of the fifty-second meeting of German Naturalists and Doctors at Baden-Baden. He became one of the best known medical authorities at Baden-Baden, acquired friendships with numerous foreign visitors, and founded an excellent sanatorium in 1891. He died greatly loved and respected, and his funeral service was largely attended. It was held at the Friedhof Kapelle, well known to English visitors and residents.

Medical News.

THE annual meeting of the County of London Branch of the British Red Cross Society will be held at Grosvenor House on Friday, February 28th, when Viscount Esher will take the chair at 4 p.m.

At a meeting of the Hunterian Society at St. Bartholomew's Hospital on February 12th the President, Mr. A. H. Tubby, being in the chair, the annual oration was delivered by Dr. Edward W. Goodall on serum sickness.

A MEMORIAL to the late Dr. C. J. Allan of Lasswade, subscribed by the inhabitants of the district, was unveiled in Lasswade churchyard on February 8th. The memorial takes the form of a Celtic cross in granite. The Rev. R. Montgomerie Harris, who presided, made reference to Dr. Allan's valued work for nearly half a century, both professionally and as a member of various boards and institutions.

THE county-court judge stated the other day at the Newcastle County Court that he had recently received at the Gateshead Court a medical certificate, printed and initialled, stating that the man was unable to follow his employment owing to the death of a friend. The judge told the applicant he was addressing that a certificate presented to the court must be properly signed and not printed. That it should be properly signed is obvious, but that it should not be printed is an *obiter dictum* which could probably not be sustained if it were shown that a doctor kept a series of printed certificates to meet different conditions frequently recurring.

THE first of a course of six lectures on "National Eugenics" was delivered by Professor Karl Pearson on Tuesday evening, February 11th, in the Botanical Theatre of University College, the subject chosen being the effect of heredity, environment, and parental habits upon the welfare of the child. Despite all that had been written and said to the contrary, Professor Pearson reiterated the opinion that feeding and environment were of comparatively small importance, for the healthiest races were by no means necessarily those who lived under the best hygienic conditions. Statistical evidence proved that in the manufacturing towns of the north the most reproductive classes were not those of good health and good habits, but that the race was being carried on to a far greater extent by men and women of bad health and bad habits. The problem before the nation at the present moment was, therefore, how to encourage the right kind of potential parent to marry and bring up children. In his opinion, the money which was now being spent on insurance and old-age pensions would be better employed to give a differential advantage to those who possessed good health and practised good habits, and who were thus endowed with the qualifications necessary to carry on the race.

THE annual meeting of the Association of Certified Dispensers was held in the Court Room of the Apothecaries Hall, Blackfriars, E.C., on February, 6th. The financial statement showed a satisfactory balance to the credit of the association. The annual report stated that

the association had continued its work on behalf of the members in general, but the question of the long looked for by-law was still unsettled, and the proposed bill on behalf of dispensers still waited a suitable opportunity to be put before Parliament. Mr. Howell, who had recently qualified as a pharmacist, then gave in his resignation of the post of honorary secretary, and on behalf of the members was presented with a gold watch by the chairman, Mr. Montagu Smith, who said that the success of the association was due to Mr. Howell's untiring efforts. Mr. Howell was elected an honorary member for life. Mr. A. Mowbray Upton, Clerk to the Society of Apothecaries, also referred to the services of Mr. Howell to the association and to the correct attitude which had been maintained between the association and the society. Mr. Montagu G. Smith and Mr. A. L. Anderson were unanimously re-elected chairman and treasurer respectively, and Mr. F. E. Trayner (Hackney Infirmary), of 13, Carlton Road, Manor Park, E., was appointed honorary secretary.

THE first Conference of the Eugenic Education Society is to be held in the Large Hall of the University of London on Saturday, March 1st, when over five hundred head masters and mistresses will meet to discuss the question of introducing into the usual school curriculum a certain amount of judicious instruction on the subject of racial responsibility. There is to be a morning and an afternoon session. The former will be opened by the president of the society, Major L. Darwin, with a paper on "The Eugenic Ideal." This paper will be followed by others dealing with the difficulties of introducing eugenics into elementary schools, and the best means of overcoming the obstacles presented by ignorance and prejudice; and the session will close with a discussion on this subject opened by Miss Faithful, the Head Mistress of Cheltenham Ladies' College. In the afternoon the Head Master of Eton will read a paper on "Racial Responsibility as a Factor in the Formation of Character," and Professor J. Arthur Thomson, of the University of Aberdeen, will open a discussion on the ways and means of introducing the eugenic ideal into schools. It is proposed, should the general feeling of the audience at the close of the meeting appear to be in accordance with the suggestion, to pass a resolution requesting the President of the Board of Education to receive a deputation to ask that an inquiry should be held "as to the advisability of encouraging the presentation of the idea of racial responsibility to students in training and children at school." The papers read at the conference, together with a summary of the discussions, will be published in *The Eugenic Review* of April 15th.

A. ULRICH (*Munch. med. Woch.*, Nos. 36 and 37, 1912) points out that much difficulty has been experienced since the idea of limiting the chlorides in the diet of epileptics, and substituting bromides, was introduced owing to the fact that the treatment must be continuous, and must therefore be of a kind that the patient will take with appetite, and that will not tax the ordinary kitchen. If the diet is rendered too poor in chlorides, the patient may become highly susceptible to them, and any increase in quantity may induce fresh epileptic attacks. Ulrich starts by withdrawing all salt from the soup, which he states means a reduction of from 10 to 20 grams daily. If this is well tolerated the salt used in cooking other food is gradually reduced until a further 5 to 12 grams is got rid of. As soup without salt is unpalatable he uses tablets consisting of 1.1 gram of sodium bromide, 0.1 gram of sodium chloride with extractives of vegetable albumen, fats, and spices. One tablet, weighing 2 grams, with 1 to 2 decilitre of boiling water makes, he says, an excellent soup. All his patients liked it, and appetite had been well maintained. He calls the tablets "sodo-tablets," and they can be obtained from Hoffmann-La Roche and Co. Other flavourings can be added to the soup provided they contain no common salt. He maintains further that when given in this way the bromide acts more powerfully than when administered in the ordinary fashion. The dose given was 1 or 2 tablets a day, increased to 3, and for severe cases to 4 or 5. If bromism occurred he waited to see if the symptoms diminished without altering the medication; if they got worse he lowered the dose, but found it necessary to stop the bromine altogether for a few days in rare cases only. In some cases it was found expedient to continue the bromides and to give at the same time from 1 to 5 grams of chloride extra for a few days. Hans W. Maier (*Munch. med. Woch.*, September 3rd, 1912) has tested the method in the psychiatric clinic of the University of Zürich in 20 cases for four months, and expresses himself distinctly in favour of it. He found that it did not disturb digestion. The result in his cases was good, and no case of bromism was observed.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 429, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 429, Strand, London, W.C.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Zitology, Westrand, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*.

TELEPHONE (National):—
2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

FAIRLANDS asks for suggestions for the relief of attacks of rectal pain which have occurred during the last two years in a man, aged 62, suffering from tabes; morphine gives only temporary relief.

R. (West Indies) asks for advice in the treatment of a patient, aged about 21, of European parentage, who has been suffering from granular pharyngitis and post-nasal catarrh for about a year. The mucous membrane of the middle third of the roof of his mouth is pale and wrinkled at the sides, and sensation is lessened.

DR. WILLIAM HARDMAN, of Bispham, near Blackpool, who has been struck by Dr. Laing's statement (p. 280) that the patient in the case there described suffered a sensation of stomach dropping as a result of the heavy blows received as a prize-fighter, asks what is the state of professional boxers who have followed that occupation for some years.

ANSWERS.

SARTORIUS.—We believe that it is not customary to put an assistant's brass plate up alongside that of the principal; such a proceeding might be interpreted as implying that the assistant was in fact a partner.

LETTERS, NOTES, ETC.

PROVERBIAL MEDICINE.

DR. WM. BRAMWELL (Liverpool) writes: With reference to my note in last week's issue; in consequence of my not having received a proof for correction, which was the printer's fault, and my being a somewhat illegible writer, which is my own fault, there were misprints in the passages relating to my quotation from Homer, which should have read as follows:

"It is Hector's rebuke to his mother because she offered him wine when he made that short visit to his home in order to induce his brother Paris to return to the battle—

Μῆ μοι οἶνον ἄειρε μέλιφρονά, πότνια μήτηρ,
Μῆ μ' ἀπογυνώσῃς, μενέος ἢ ἀλλοῆς τε λάθομαι.

(Do not raise wine, that cheers the heart, to me, revered mother, lest thou unnerve me, and I forget my might and my vigour.)"

With reference to my illegibility of handwriting, which I am anxious should be an excuse for the printer, it may interest him to know that it has got me into trouble on more than one occasion. But in one instance at least I have reason to believe it proved of great service to me; for in the physiology paper at T.C.D., it turned out, to the astonishment of my friends, that I had gained the highest marks of my year. The secret, however, was divulged at the viva voce examination when the examiner informed me that he had had great difficulty in reading my writing. Whilst another examiner on another occasion paid me the high compliment of saying that I was the most abominable writer he had ever had the misfortune to examine. So that how much credit I have had for what I have never known I dare not think.

THE TREATMENT OF SCURVY.

DR. REGINALD A. YELD (Whiteman's Creek, Okanagan Lake, B.C.) writes: In a book entitled *Builders of Canada*, edited by T. G. Marquis, I find a reference (on p. 14) to a treatment for scurvy which may perhaps be new to your readers. It is related there how the French sailor, Jacques Cartier, with his band of 110 men, were attacked by scurvy, while wintering at Stadacona, on the St. Lawrence, in 1536, to such an extent that only three or four healthy men were left to wait upon the sick. Twenty-six of his men died before April. Fortunately a young Indian guide named Degegaya, "who had himself been a sufferer from the scurvy, and had recovered, told Cartier of the remedy which had cured him—a decoction from an evergreen called Ameda, supposed to have been the spruce fir. The sick men eagerly tried it and drank it in such quantities that in six days they had boiled down a tree as large as a French oak; and very soon all the invalids were restored to health, courage, and hope."

SALVARSAN.

DR. THEO. M. KENDALL (London, E.C.) writes: When any remedy which has been brought out with a view to abort or cure a special disease becomes a cure-all, then one begins to doubt its efficacy. When salvarsan was first introduced to the profession certain claims were made as regards its efficacy in the treatment of syphilis, and every one was prepared to give the remedy a trial. Unfortunately, certain risks in the using were not at first understood, and at times one was confronted with seeming disaster. Further, the administration of the remedy was costly, and the unfortunate patient was put to some inconvenience at the time of administration. It cannot be said in all strict truth that this remedy has been a distinct success, nor can it be said that it has proved a certain cure. It certainly has lulled sufferers into a state of fictitious safety, but unfortunately this state has been succeeded by many relapses of the disease. Up to the present we have had no cogent reason presented to us for abandoning the old tried method of mercurial treatment of syphilis, which if persisted in will effectually abolish the disease, and we have no justification in testing this so-called remedy at the expense of the patient. Now that it has become a cure-all there is less reason why we should put any faith in it. My experience of twenty-six years has taught me to be very cautious before abandoning a tried treatment for one so chimerical as salvarsan, and the many relapses I have seen after its use confirm me more surely in this conviction.

THE PURCHASING POWER OF THE SOVEREIGN.

FOR the information of the Select Committee inquiring into the conditions of employment in the Postal Service, Mr. G. S. Barnes, C.B., of the Labour Department of the Board of Trade, has prepared the following table showing the fluctuations in value of a sovereign during the last eighteen years, measured by its capacity to purchase quantities of twenty-three selected articles of food:

| Year. | s. | d. | Year. | s. | d. |
|-------------|----|----|-------------|----|----|
| 1895 | 20 | 0 | 1904 | 18 | 0 |
| 1896 | 20 | 0 | 1905 | 17 | 11 |
| 1897 | 19 | 3 | 1906 | 18 | 0 |
| 1898 | 18 | 6 | 1907 | 17 | 7 |
| 1899 | 19 | 4 | 1908 | 17 | 2 |
| 1900 | 18 | 5 | 1909 | 17 | 3 |
| 1901 | 18 | 4 | 1910 | 16 | 11 |
| 1902 | 18 | 3 | 1911 | 17 | 0 |
| 1903 | 17 | 11 | 1912 | 16 | 3 |

ADVERTISEMENTS IN RELIGIOUS PAPERS.

THE parish magazine of Holy Trinity, Darwen (of which the Rev. Louis Savatard is vicar) for February 1st has a very outspoken article, entitled "Disgraceful Advertisements in Religious Papers." Several types are quoted, and in commenting upon them it is said that "in the lowest class of publications such advertisements are dishonest; in a religious paper they are a scandal."

SMELLING THE BABY.

W. sends the following conversation between two children overheard just before an operation was to take place in a private house.

Betty, aged 8: "I think, Rachel, we shall have a new baby to-day; I can smell it."

Rachel, aged 7, was the victim, and the nursery was being turned into an operating theatre.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|-----|
| Eight lines and under | ... | ... | ... |
| Each additional line | ... | ... | ... |
| A whole column | ... | ... | ... |
| A page | ... | ... | ... |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so guaranteed.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restant* letters addressed either in initials or numbers.

The Goulstonian Lectures

ON

DEATH BY ELECTRIC CURRENTS AND BY LIGHTNING.

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON.

BY A. J. JEX-BLAKE, M.A., M.B., B.Ch. Oxon.,
F.R.C.P. Lond.

ASSISTANT PHYSICIAN TO ST. GEORGE'S HOSPITAL AND TO THE
HOSPITAL FOR CONSUMPTION, BROMPTON.

LECTURE I.—DEATH BY ELECTRIC CURRENTS.

In these lectures I propose to consider, first, the subject of death by electric currents, and next, death by lightning. I do this because a good deal is known for certain as to the way in which industrial and domestic electric currents bring about death in man, and much valuable experimental work has been done illustrating the effects of such currents upon the lower animals. In the case of lightning, however, although plenty of observations upon its victims have been made, the nature of lightning itself has always prevented the making of experimental observations of its effects upon living creatures. It is true that in the middle of the eighteenth century a few desultory experiments were made with the electric discharges brought down from heaven during thunderstorms by kites and lightning conductors of various kinds. But all experimentation of this kind came to an abrupt end when, in 1763, Professor Richmann of St. Petersburg was killed outright in his own laboratory by a miniature lightning stroke a foot long, while investigating the nature of the discharges collected by a lightning-rod set up on his roof above and brought down into his room (Arago).

Death by Electric Currents.
