INDEX TO VOLUME I FOR 1913.

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria and Sugar; Light, Roentgen, Radium, X Rays; Status Lymphaticus and Thymus; Eye, Ophthalmia and Vision; Bicycle and Cycle; Motor and Automobile; Association, Institution, and Society; Paris, France; Berlin, Prussia, Germany; Vienna, Austria, etc. Subjects dealt with under the various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Act. Workmen's Compensation," "Correspondence," "Leading Articles," "Literary Notes," etc.; while under "Original Articles," will be found a list of those who have contributed papers on scientific and clinical subjects, with the titles of their contributions.

A.

Abattoir, hygiene of, 463
 Abattoirs in Liverpool, 1136
 Abdomen, cystic angioma of (Gorse), 969
 Abdomen, drainage of under various conditions of inflammation (Arthur E. Barker), 103
 Abdominal aneurysm. *See* Aneurysm
 Abdominal conditions, acute, in children, diagnosis of (Edmund Cautley), 504
 Abdominal operations, review of books on, 174
 Abdominal retractor, 776
 Abdominal section, specimens from cases of (F. N. Cookson), 881
 Aberdeen dental clinic, 580
 ABERCROMBIE, Rodolph: The treatment of muscular paresis by means of eccentric movements, 277—Apparatus for treating injuries of the hands, 503
 Aberdeen University Club dinner, 1255, 1283—Verses by Mr. Cantlie, 1283
 ABERGEE Sanatorium. *See* Sanatorium
 ABNEY, Sir William de W.: *Researches in Colour Vision and the Trichromatic Theory*, rev., 395
 Abortion, epizootic (parliamentary question), 742
 Abortion sac (Dr. Lindsay), 74
 Abortion, attempted self, 357
 Abortion, tubal, with extensive pelvic hæmatocele (William Smith), 885
 ABRAM A.: *English Life and Manners in the Late Middle Ages*, 839
 Abscess, hepatic, treatment of, 574—Emetine in treatment of, 634, 1036, 1206—(S. Mallanah), 1206
 Abscess of liver (Philip Turner), 118
 Abscess, pulmonary (Dr. Gulland), 22
 Abscess, otitic, of pterygoid origin (Dan McKenzie), 448
 Abstinence, total, from water, 804
 Académie Française awards Grand Prix Broquette-Gouin to Professor Grasset, 1232, 1284
 ACADEMY, ROYAL, OF MEDICINE IN IRELAND, 21, 73, 221, 284, 391, 500, 558, 612, 663, 716, 827, 1059, 1112, 1208—J. B. Coleman: Iodoform and benzoyl chloride treatment of pulmonary tuberculosis, 1112
Section of Anatomy and Physiology.—T. H. Milroy: The adequate stimuli of the respiratory centre, 501—M. T. McMahon: Thrombin and antithrombin, 501—W. H. Thompson: Creatinin and urea, 502
Section of Medicine.—Dr. Crofton: Specific treatment of pulmonary tuberculosis, 21—Dr. O'Carroll: Case of polycythaemia, 391—T. Gillman Moorhead: Early tabes dorsalis, 391—C. M. O'Brien: Foot and mouth disease in man—aphthous fever, 391—Dr. Purser: An unusual nervous case, 663—Dr. Drury: The colic affection, 663—Dr. Nesbitt: Tests for liver function, 1203

ACADEMY, ROYAL, OF MEDICINE IN IRELAND (continued)
Section of Obstetrics.—E. H. Tweedy: Diagnosis of uterine inversion, 73—Alfred Smith: Complications of hysterectomy, 73—Dr. Madill: Two cases of rupture of uterus, 500—E. H. Tweedy: Wertheim's hysterectomy, 500—Dr. Jellet: Surgical treatment of septic pelvic thrombosis, 501; Genital tuberculosis, 716—Dr. Sheill: Uterine rupture, 716—Gibbon FitzGibbon: Gonorrhoeal vaginitis treated by vaccines, 716
Section of Pathology.—W. G. Harvey: Norwegian scabies, 222—William Pearson: Congenital tumour of gum, 612—E. J. McWeeney: Gunma of heart, 613—Mervyn Crofton: The theory of immunity and therapeutic immunization, 613
Section of State Medicine.—R. J. Rowlette: Sanatorium benefit in Ireland, 284—W. R. Dawson: The Mental Deficiency Bill and its proposed extension to Ireland, 285—T. T. O'Farrell: Hospital statistics of Dublin, 1059
Section of Surgery.—W. I. de C. Wheeler: Tuberculosis of lower jaw, 221—W. Pearson: Scapular crepitation, 221—R. Charles R. Maunsell: Aneurysm of abdominal aorta cured by operation, 221—J. Boyd Barrett: Child with webbed fingers and toes, 222—C. Arthur Ball: Nephrectomy, 558—A. A. McConnell: Location of pus in the hand, 559—H. de L. Crawford: Intratracheal insufflation of ether, 827—W. I. de C. Wheeler: Intestinal stasis, 1208—Maurice Hayes: The Intestinal tract, 1208
 Academy of Sciences, Paris, awards prizes to, Carlos Finlay and Aristides Agramonte, 1003
 Accident, what is an? (Charles Corfield), 996
 Acetan for household use, 469
 Acetone soap, 1117
 Acetylene gas, 177
 Acetyl-salicylic acid, soluble salts of, 1278
 ACHARD: Haemolysis, 94
 ACHARD, Ch.: *Manuel des maladies de la nutrition*, rev., 76
 Achill, medical officership of, 1245
 acholuric jaundice. *See* Jaundice
 Achondroplasia (A. S. Blundell Bankart), 769
 Achondroplasia, review of books on, 345
 Acid, amino. *See* Amino
 Acids, various, hæmolytic and anti-hæmolytic action of (Goldberger), 457
 ACKERBY, Dr.: Alimentary toxæmia, 939
 Act, Coroners', and the need for its amendment, 389
 Act, Housing of the Working Classes (Ireland), 1019
 Act at work, the. *See* Insurance

ACT, WORKMEN'S COMPENSATION, 146, 256, 263, 312
 Appendicitis or accident, 146
 Pneumonitis, two deaths from, 312
 Regulations (parliamentary question), 256
 Workmen's compensation, 263
 Actinomycosis (A. G. Haynes Lovell), 169
 Actinomycosis of liver (H. D. Rolleston), 118
 Actinomycosis treated by vaccine, an unusual experience in an alleged accident claim (Sir John Collie), 991
 Action for alleged negligence at an isolation hospital, 1189
 Actions for slander, 797
 ADAIR-DIGHTON, C. A.: Cavernous sinus thrombosis, 172
 ADAM James: Ulceration of the pharynx, palate, and larynx, 1275
 ADAMS, J. George (and John McCRAE): *A Textbook of Pathology for Students of Medicine*, rev., 395
 ADAMS, F.: Haemorrhage from a corpus luteum cyst, 712
 ADAMS, J. E.: Congenital fusion of radius with ulna, 578
 ADAMS, Percy E., presentation to, 146
 ADAMS, P. H., elected to Margaret Ogilvie Readership in Ophthalmology at University of Oxford, 434
 ADAMS, W. Coode: Fees to private patients, 310
 ADAMSON, Dr.: Alimentary toxæmia, 939
 ADDISON, Oswald L.: Cirroid aneurysm, 75—syphilitic disease of bones and joints in children, 715—Dislocation of patella, 828—Sporotrichosis, 828
 Aden, proposed female hospital to commemorate visit of King George to, 751
 Adenitis, cervical, avoidance of unsightly scar deformities in the operative treatment of (J. H. Nicoll), 668
 Adenoids removed under gas anaesthesia (John F. O'Malley), 699
 Adenoids and enlarged tonsils treated without operation (W. Stewart), 1157
 Adenoids and enlarged tonsils treated with lymphatic gland extract (Hugh T. Ashby), 1159
 Adeno-myomas of the recto-uterine and recto-vaginal septa (Outhbert Lockyer), 284
 Admiralty and Board of Trade sight tests, 849
 Adrenalin in chloroform anaesthesia (H. T. Depree), 379—Correspondence on, 1028, 1350
 Adrenalin in the emergency treatment of non-corrosive poisoning by the mouth (Judah Leon Jona), 271
 Adrenalin mydriasis in diagnosis (leading article), 572
 Adrenalin, late vasomotor paresis due to (Harold Whale), 273
 Adrenin, action of on veins (J. A. Gunn and F. B. Chavasse), 340

- Adrianople, hospital patients at, 40
 Advance, Australia, 1623, 739
 Advertisement, flourishes of, 1240
Le-scudape, 1124, 1290
 Advertisements in religious papers, 424
 Advertising, fraudulent, 976
 Aesthetics of medicine. *See* Medicine.
 After-Care Association. *See* Association
 After-pains, 264
 Agar, W. E.: Transmission of environmental effects, 525
 Aged and infirm members of approved societies. *See* Insurance Act
 Agra Medical School, stretcher drill at, 793
 AGRAMONTE, Aristides, awarded prize by Paris Academy of Sciences, 1003
 Agrégé, examinations for rank of, 634
 AHEIN, Michael, obituary notice of, 750
 AHELFELD: Sex of infants and age of mothers, 135
 AIRENS, Charlotte A.: *Primary Studies for Nurses: A Textbook for First-Year Pupils* *Nurses*, rev., 28—*Clinical Studies for Nurses: A Textbook for Second and Third Year Pupils Nurses, and a Handbook for all who are engaged in Caring for the Sick*, rev., 28
 AIEMAN, J.: Suggested operation for relief of prostatic hypertrophy, 880
 Albinism and piebaldism, heredity of (Karl Pearson), 457
 Albuminuria, influence of Marienbad sulphate water on (Max Porges), 1320
 Alcock, Nathaniel H., obituary notice of, 1353
 Alcohol conference. *See* Conference
 Alcoholism, review of books on, 454
 ALDEN, Henry Mills: *A Study of Death*, rev., 517
 ALDERSON, W. E.: *Dental Anaesthetics*, rev., 832
 ALDOUS, George F.: Immediate operation in appendicitis, 795
 Alimentary canal, bacteriology of (F. W. Andrews), 539
 Alimentary toxæmia. *See* Toxæmia
 ALLAN, C. J., memorial to, 423
 ALLAN, James W.: Controlled therapeutic use of new tuberculin, 415—Evidence for and against tuberculin, 1140, 1298

THE
British Medical Journal.

THE JOURNAL OF THE BRITISH MEDICAL ASSOCIATION.

LONDON: SATURDAY, JANUARY 4TH, 1913.

The Horace Dobell Lectures
ON
INSECT PORTERS OF BACTERIAL INFECTIONS.

DELIVERED BEFORE THE ROYAL COLLEGE OF
PHYSICIANS.

BY C. J. MARTIN, M.D., D.Sc., F.R.S.,
DIRECTOR OF THE LISTER INSTITUTE OF PREVENTIVE MEDICINE.

LECTURE I.

To intervene successfully in bacterial diseases of man and animals it is most important to know accurately the life-history of the parasite outside the host—how it leaves the old host, how it enters a new host, and where and how it passes the intervening period. If we are in possession of these facts, our efforts in the struggle can, at any rate, be intelligently directed and concentrated against the most vulnerable point of the enemy. The exercise of an adverse influence upon bacteria, once they have gained a footing in the body, has hitherto not been generally successful, although recent developments in chemotherapy have shown that there is ground for optimism in this direction.

In the early days of bacteriology, before the large number of pathogenic bacteria had been discovered and their peculiarities had been studied, it was generally assumed that bacteria once let loose from the body survived long periods upon inanimate objects and in water, soil, etc.; and efforts at prevention were directed to an indiscriminate disinfection of the belongings and surroundings of the patient. Some bacteria do, indeed, possess considerable powers of survival under such circumstances, and I would not be understood to deprecate measures of general disinfection. The majority of pathogenic organisms, however, are fortunately delicate creatures, and rapidly succumb to such adverse influences as drying and sunlight.

Another factor which must not be lost sight of is that many organisms which have acquired by selection the property of withstanding the adverse influence obtaining in the animal body fare ill in the competition with hardy saprophytic colleagues outside the body, and, if certain individuals do survive, these, whilst acquiring the capacity to live upon extracorporeal nutriment, diminish at the same time in pathogenicity. In other words, the conditions select a strain tending more and more towards saprophytism and away from parasitism. For these reasons it behoves us to be especially on the look-out for any machinery through the agency of which bacteria may be rapidly conveyed from sick to healthy, and their travels made easier for them.

In not a few diseases the infective agent usually passes almost directly from patient to patient, such as the organisms of syphilis, plague-pneumonia, diphtheria, measles, scarlet fever, small-pox, and numerous parasitic skin disease. The spread of such highly infectious diseases can be dealt with by isolation and segregation of contacts, for their range is small.

Of recent years much attention has been bestowed upon the study of the rôle of insects in the transmission of

disease. It is not my intention to deal with these discoveries as to the essential part played by insects in the transmission of protozoological parasites made by Smith and Kilbourne, Bruce, Ross; Reed, Carrol, and Agramonte, regarding the transmission of Texas fever, nagana, sleeping sickness, malaria of birds and animals, and yellow fever respectively, further than to point out that it was these researches which focussed attention upon the possibility of bacterial diseases being conveyed by a similar agency. In the latter case the insect plays a less essential part, and no particular phase in the life-history of the parasite takes place within it. I have accordingly, following a suggestion of my friend, Colonel Alcock, employed the term "porters" to describe this passive rôle of insects in the spread of contagion.

HOUSE-FLIES.

A deal of attention has been paid to flies lately in view of their possible influence in the dissemination of infection, more particularly in the case of such diseases as cholera, typhoid, and infantile diarrhoea, in which the infective agent escapes from the intestine and new infections are taken in by the mouth.

The first question is—Can the fly convey infection? Before referring to the numerous experiments which have afforded an answer, I will briefly refer to those points in the life-history, structure and habits of the house-fly which are of assistance in appreciating how it may play such a rôle. These subjects have been submitted to careful

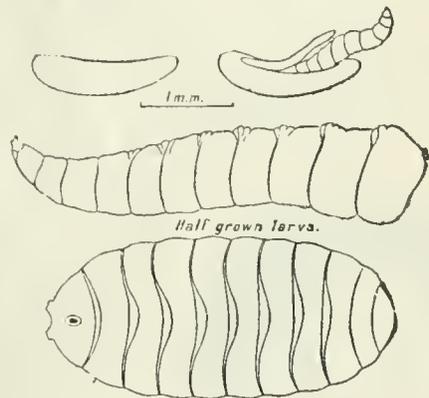

Fig. 1.

inquiry during the last few years, particularly in America and this country, and thanks to the observations of Lowne (1890), Howard (1912), Newstead (1907-9), Griffith (1908), Hewitt (1910), and Graham Smith (1910), we are now well acquainted with this insect, intimate knowledge of which was, until recently, curiously lacking.

The female fly lays about 120 eggs at each laying, and may produce four broods. Under ordinary conditions the eggs are mostly laid on horse, pig, or cow manure, but the excreta of almost any animal, or other fermenting refuse, suffices. The eggs are sausage-shaped with one end sharp, glistening white in colour, and about 1.5 mm. in length and 0.3 mm. in their greatest diameter. The eggs hatch in from three days to eight hours, according as the temperature ranges from 50° F. to 80° F. The larva is a little, active grub 2 mm. long, with a sharp anterior and blunt posterior end (Fig. 1). The larval stage lasts five days to

three weeks, according to temperature. At the time of pupation the grub is 6 to 9 mm. in length. Pupation lasts five days to a month, according to temperature. Thus the whole cycle from laying of egg to emergence of the fly occupies ten days to two months, according as the weather be warm or cold. Shortly after emergence from the chrysalis the young fly spreads its wings, which soon harden, and flies away in search of food. The young female is ready to lay its first batch of eggs in about ten days, or even sooner in warm weather. During winter a few flies survive in warm and secluded places. In the spring these start the next year's supply. The possible progeny of one female fly from April to September have been estimated at 10¹⁰. Howard, of the United States Department of Agriculture, estimates that in forty days the descendants of one fly might number 12 million, or 800 lb. weight.

The only points in the structure of the fly it is essential to direct your attention to are the legs and feet and the general arrangement of the alimentary apparatus. These will be sufficiently obvious from the diagrams (Figs. 2 and 5). Please note that the feet are covered with minute hairs.

FIG. 2.

The litterary, indeed, more numerous and finer than in the diagram, and extremely fine ones are also placed upon the pads, these are stated to secrete a sticky substance, by means of which the fly grips, the basal part of the claws, and the distal stiff hair which projects from the end of the last joint of the tarsus. Each leg is like a minute paint brush, which is applied to the surface of whatever it rests upon.

FIG. 3.

When this is water the hairs do not appear to be wetted. The essential parts of the alimentary canal are a gullet, stomach, crop, intestine and rectum. (See Fig. 3.) The gullet is prolonged to a minute opening between the flaps of the proboscis, halfway down which it is joined by the salivary duct. At the entrance to the stomach it is bifurcated, and one limb of the bifurcation is extended backwards to the bilobed crop.

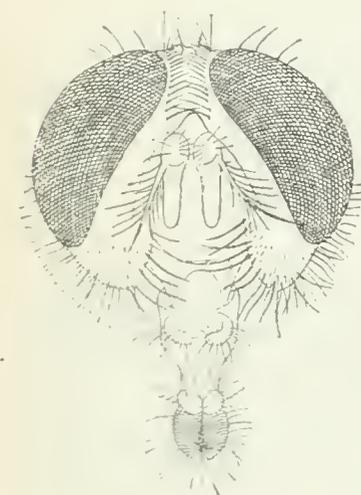

FIG. 4.

By a valvular apparatus at the entrance to the stomach, the insect can direct the liquid driven by the pump in its trunk into either the stomach or crop. The proboscis is a highly elastic muscular organ with universal movement. At the end are two flaps or labella (only one of which is shown), which it can open out like the leaves of a book, and apply the medial surfaces to the material it feeds upon. From the middle line or hinge minute chitinous channels pass outwards to the margin. These are seen in the diagram of the front view of the head of a fly (Fig. 4) in which the labella are shown opened out and facing forwards. These tubular structures are

strengthened at frequent intervals by chitinous rings like a trachea, but are not complete tubes, being open to the surface by a minute linear channel with lateral bays in it. At the base of the trunk a number of muscle fibres are attached to the gullet by the peristaltic contraction of which fluid is pumped up from the mouth and propelled into the stomach or crop. The structural arrangement of the flaps of the trunk acts as a filter. Graham Smith (1911) is of opinion that solid objects larger than 0.006 mm. seldom pass into the gullet. According to Nicoll (1911) the ova of such tapeworms as do not exceed 0.035 mm. in their smallest diameter may be swallowed. These must therefore get into the mouth direct. When feeding on a liquid, the fly applies the labella to the surface, and sucks the liquid through the "strainer" first of all into the crop. When this is full some goes into the stomach. In the case of solid material such as sugar, dried blood or sputum, the insect must first dissolve the material. This is done by pouring saliva upon it or more generally by regurgitating some of the contents of the crop (Graham Smith, 1910).

Graham Smith (1910), by feeding experiments with coloured syrup, found that the meal was first taken into the crop, and subsequently transferred to the stomach at leisure. The fly could, however, first fill its crop and then its stomach. In a quarter of an hour the meal had passed on to the upper third of the intestine, and in a warm incubator at 37° C. reached the rectum within an hour. The fly seems to keep some of the fluid in its crop for days.

A well-fed fly deposits faeces abundantly. Graham Smith (1910) noticed flies to do this ten times in the first hour after feeding. A curious habit of flies, to which, so far as I know, attention was first drawn by Graham Smith, is the regurgitation of the contents of their crops. This has already been referred to as a means by which they are enabled to feed upon dry material soluble in water. They do this very frequently when walking over a clean glass, possibly with the idea of extracting nourishment from it. A fly, after a good meal, may often be seen blowing fluid bubbles from its trunk and sucking them in again, as in the diagram (Fig. 5), perhaps for practice.

From the above account it is clear that there are *a priori* reasons for suspecting the fly of carrying bacterial infection. Born in a dunghill, it spends its days biting between the sugar basin, milk pan, and any faecal matter available. Its hairy, probably sticky, feet and the habit of regurgitating the contents of the crop and defecating at frequent intervals suggests it to be an excellent inoculating agent for any bacteria it may pick up in the satisfaction of its unsavoury tastes.

That it does, indeed, operate in this way has been abundantly demonstrated. Flies which have wandered over cultures of organisms and afterwards been allowed to walk upon sterile agar plates leave a rich crop of germs as their footprints, which can be demonstrated by subsequent incubation. Castellani (1907) transferred yaws to monkeys in an analogous way.

The carriage of infection by the alimentary canal and its deposition by regurgitation or faeces has also been shown over and over again—Grassi (1885), Maddox (1885), Alessi (1888), Celli (1888), Sawtchenko (1892), Uffelmann (1892), Yersin (1894), Firth and Horrocks (1902), Manning (1902), Hayward (1904), Lord (1904), Chautemesse (1905), Buchanan (1907).

These modes are probably more important than the carriage of bacteria upon the exterior. Many pathogenic bacteria would soon die from desiccation on the appendages of the insect, and, at any rate, the number so conveyed is small compared to those contained in its crop and intestine.

Carriage within is certainly more lasting, for Graham Smith (1910), to whom we are indebted for the most

strengthened at frequent intervals by chitinous rings like a trachea, but are not complete tubes, being open to the surface by a minute linear channel with lateral bays in it. Carriage within is certainly more lasting, for Graham Smith (1910), to whom we are indebted for the most

FIG. 5.

thorough investigation of this subject, isolated typhoid and other bacilli from the intestinal contents of flies six days after feeding on material containing the organism under test. The faeces ceased to afford growths after two days when typhoid bacilli were the infecting organism used, but with a more robust organism, such as anthrax, which can protect itself from the effects of drying, the time was much longer.

The table below, taken from Dr. Graham Smith's report, summarizes the result of his experiments on the length of time after which various bacilli can be recovered from the outside and inside of flies fed on infected material. As the author is careful to point out, in these experiments gross infection was produced by feeding upon pure cultures, and they do not do more than indicate the duration of life of various pathogenic bacteria under favourable conditions.

Table showing the Longest Period after which Organisms were Recovered from Flies Fed on Cultures (Graham Smith).

| Organism. | Legs. | Wings. | Head. | Crop. | Gut. | Faeces. |
|----------------------------------|---------|---------|---------|---------|---------|---------|
| <i>B. typhosus</i> | — | — | — | — | 6 days | 2 days |
| <i>B. enteritidis</i> | 7 days | — | 7 days | 8 days | 7 days | — |

Cao (1906), Bacot (1911), Ledingham (1911), and Graham Smith (1911) have further shown that in the case of larvae fed on material infected with various organisms, *B. pyogenicans*, *B. typhosus*, and *B. anthracis* respectively, the infection may be carried through the chrysalis stage and recovered from the contents of the intestine of the fly after its emergence. Fortunately, however, according to Ledingham, *B. typhosus* leads a precarious existence in competition with the natural bacterial flora of the larvae and pupae.

There are numerous recorded instances in which the pathogenic organisms of cholera, typhoid, phthisis, anthrax, and plague have been recovered from the interior or dejections of flies which have been captured in the immediate neighbourhood of cases of the disease or, in the last two cases, of carcasses of animals dead of the disease. Cholera vibrios were isolated from wild flies under these circumstances by Tizzoni and Cattani (1886), Simmons (1892), Tsuzuki (1904); typhoid bacilli by Hamilton (1903), Ficker (1903), Faiebnic (on seven occasions) (1909), Bertarelli (1910), and Cochrane (1912); tubercle bacilli by Spillmann and Hanshalter (1886), Hofmann (1888), Lord (1904), Hayward (1904), Cobb (1905), and Buchanan (1907); anthrax by Cao, and plague bacilli by Versin (1894) and Hunter (1906).

The spread of ophthalmia in hot countries has, on good grounds, been attributed to the agency of flies in carrying the Koch-Weeks bacillus and the gonococcus from eye to eye—Budd (1862), Laveran (1880), Howe (1888), Axenfeld (1907). The seasonal and local prevalence of ophthalmia corresponds with that of flies, and a visit to Egypt during the fly season is sufficient to convince one that this must happen.

Are Flies the Determining Factor in Epidemics?

Although, however, flies may be discovered with the infection of a number of diseases in or upon them, and by their habits may not unlikely serve as agents in transferring infection, it by no means follows that they are the determining factor of epidemicity in the case of cholera, typhoid, dysentery, etc. In the case of fulminating epidemics of typhoid and cholera associated with an infected water supply this is obviously not so.

Flies in Relation to Typhoid Fever.

The conclusion that fly transmission is the principal means of spread of typhoid in military encampments and

stations has been arrived at by a number of competent observers, amongst them Veeder (1898), Reed, Vaughan, and Shakespeare (1900), in their report on the origin and spread of typhoid fever in the United States military camps during the Spanish war of 1898, and by Toth and Calverley (1901), Smith (1903), Purdy (1909), and Wanhill (quoted by Purdy).

The sanitary arrangements of a military camp are not exactly those of the Ritz Hotel, and the prevalence of flies in late summer can hardly be appreciated by those who have not had the experience. The conditions are most favourable for transmission by flies. The circumstantial evidence against them is so strong as to have left no doubt in the mind of the American Commission that these insects play a large share in disseminating infection, for page 28 of their general statement and conclusions reads thus: "Flies undoubtedly served as carriers of infection."

An estimate of the fly population and its relation to admissions of enteric was made by Ainsworth (1909) in Poona. The observations showed that enteric had a very definite season, commencing at the end of the hot dry weather with the onset of the rains, and reaching a maximum a few weeks after their cessation. The abundance of flies increased also soon after the beginning of the rains, but earlier than the admissions for enteric, and, speaking generally, the fly curve antedated that for enteric cases by about one month.

Taking into account the incubation period for the disease, this fact is in agreement with the view of a causal relation between cases and flies in Poona. The number of observations is unfortunately small.

In considering the possible influence of flies in the spread of typhoid in a well sewered city, it must be remembered that the opportunities for flies to pick up the infection are vastly less than under the conditions of a military encampment, or even in rural surroundings. In large cities, no doubt, dejecta and urine from patients may be left available to flies, but the bulk goes promptly into the main drain.

The discovery, in cities like London and Manchester, of the majority of cases of typhoid, and their removal to hospital before the period when the excreta contain large numbers of bacilli, must also greatly reduce the liability to the dissemination of the disease by flies. The typhoid-carriers, however, remain.

Dr. Niven (1910) has made observations upon the prevalence of flies in Manchester since 1904. Twelve to thirty-four bell traps were served out to the inhabitants of small dwellings in different quarters of the town and the catch collected every few days by his inspector. Data have thus been obtained which are sufficient to afford information as to the general time relationship between fly prevalence and the incidence both of enteric and infantile diarrhoea.

It must be remembered, however, that the number of flies entrapped in twelve or seventeen rooms indicates only in a general way the prevalence of these insects in a large city, so that too much significance must not be attached to other than the main features of the record.

On pages 62 to 69 of Dr. Niven's paper are plotted the numbers of cases of enteric (commencement) and the diarrhoea deaths for each week of the year from 1891 to 1908. Whilst the latter show well-marked rises during some ten to twelve weeks of the summer, the seasonal prevalence of the latter is not striking. Speaking generally, the typhoid season in Manchester is considerably later than the diarrhoea season, and the enteric cases reach a maximum in late autumn, at a time when most of the flies have already disappeared.

The census of flies commenced in 1904, and, for the years 1904-9, coincides fairly well in time with the diarrhoea deaths if these are antedated ten days to allow for the average period ensuing between commencement of the disease and death.

If we assume that the same close time relation existed throughout, the observations taken as a whole seem to me to lend little support to the view that typhoid in Manchester is to any material extent dependent upon transmission by flies.

The time relation of fly prevalence and typhoid cases was also studied in Washington during 1908 by Rosenau, Lumsden and Kartle (1909) in collaboration with Howard, Entomologist to the United States Department of Agriculture.

In Washington in 1908 the flies (*Musca domestica*) appeared in considerable numbers in April, and reached a maximum in July. During August and September they steadily diminished to about one-third, and rose again in October. The relation of the two curves was not such as to suggest that flies play much of a rôle in the transmission of typhoid fever in Washington.

In a subsequent report on typhoid fever in Washington Lennoden and Anderson (1911), from an analysis of the incidence of typhoid upon the population using privies or yard closets, discovered that the greater prevalence of typhoid among these persons during the summer coincided with the fly season.

Fig. 6 shows the time relation of fly prevalence to enteric fever notifications for London during 1908. The

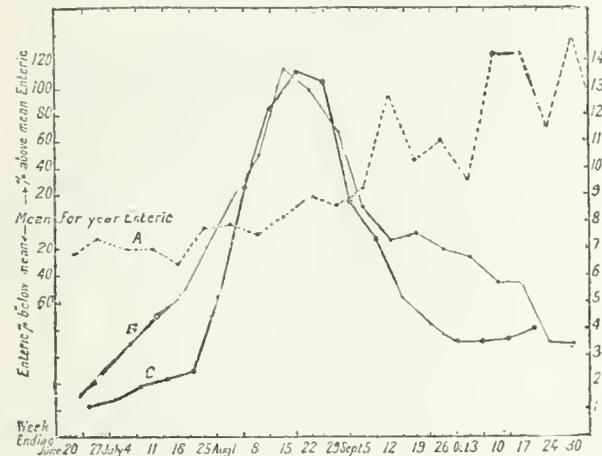

Fig. 6.—Relation in point of time between prevalence of flies, diarrhoea mortality, and cases of enteric fever, London, 1908. The deaths from diarrhoea have been antedated ten days; the cases of enteric notified have been antedated three weeks. A, Enteric cases. B, Flies caught per day \div 9,600. C, Diarrhoea deaths per week \div 20.

data are taken from Dr. Hamer's (1909) observations giving the mean number of flies caught each day in 141 situations grouped around 9 centres. The observations being upon a larger scale, the sampling was presumably more representative of the fly population than the records in Manchester. I have antedated the records of the number of cases of enteric fever by three weeks—ten days for average lapse of time prior to notification, and eleven days for average incubation period. It will be seen that the number of cases of enteric fever rises steadily during the fly season, but that the rise continues independent of the fact that flies are rapidly diminishing, and reaches a maximum at a time when they have retired for the winter.

As regards seasonal incidence of typhoid fever, 1908 is fairly typical of what has occurred in London during the last twenty years. As the weather became warmer, the number of infections with typhoid increased, and was not cut short by the fall in temperature usually occurring in September, but reached a maximum in October and November—that is, at a time when there are hardly any flies about. Whether, as Dr. Niven believes, increased fly prevalence is a factor in determining the increasing incidence in Manchester and London at the end of the summer, it seems to me impossible to say, but, taking into account the circumstantial evidence against the fly, this may not unlikely be the case. It is clear, however, that other causes are operative, and that epidemics of typhoid occur in these cities in the absence of flies.

This is in striking contrast to the observations in military camps both during the Spanish-American war and the Boer war. In both these instances, with the onset of cooler weather and the first frosty nights, the nuisance from flies was at once relieved, and the cases of enteric diminished shortly afterwards.

Flies in Relation to Infantile Diarrhoea.

As the infective agent of infantile diarrhoea has not been identified, no direct evidence that flies do, on occasion, convey the germs of this disease is available. It is probable that more than one etiological factor for infantile diarrhoea exists. Different organisms have been

found to be particularly prevalent in the stools in different epidemics in various localities. In America some of the epidemics have been associated with the presence of a dysentery bacillus (Flexner's bacillus) in the stools, Wollstein (1903), Park (1903), Duval and Schorer (1903), Cordes (1903), Weaver and Tunnicliffe (1905). In other epidemics (in America) no dysentery bacilli were found, and an epidemic in Vienna investigated by Jehle and Charleton (1905) was not found to be associated with dysentery bacilli. Metchnikoff (1909) is of opinion that *B. vulgare* is the causative organism.

A search for evidence of a causal agent was conducted on a large scale by Morgan (1906, 1907, 1909) and his colleagues of the Lister Institute during the epidemic in London in the years 1905, 1906, 1907, and 1908. The search was restricted to aerobic bacilli which neither fermented lactose nor liquefied gelatin—that is, to a group which includes the dysentery, typhoid and paratyphoid, and Gaertner bacilli. Stools and autopsy material were examined from several hundred cases of the disease and from other children. A very large number of organisms were isolated and examined, but the only one whose prevalence was found to be related to infantile diarrhoea was a non-motile bacillus of this group, which was peculiar in that it failed to ferment mannite and is now generally known as Morgan's bacillus No. 1. This organism was not infrequently recovered from the organs in fatal cases and produced diarrhoea when fed to monkeys and young rats. It was rarely encountered in children not suffering from acute diarrhoea.

Morgan's bacillus has been found in flies captured from houses in which cases of diarrhoea occurred, but until its causal relation to the human disease is proven too much significance cannot be attributed to these observations.

We are therefore entirely dependent upon epidemiological facts in testing whether the belief in the dominant influence of the house-fly upon the occurrence of epidemics of infantile diarrhoea, a view which has been warmly exposed by many excellent observers, is valid.

THE RELATIONS IN TIME BETWEEN CASES OF DIARRHOEA AND PREVALENCE OF FLIES.

Unlike the case of typhoid, which has just been discussed, epidemics of infantile diarrhoea in towns exhibit a close time-relation with fly prevalence. Epidemic diarrhoea of children does not occur except during that season of the year when flies are abundant and active, and, as will be seen on studying the charts, the relation between

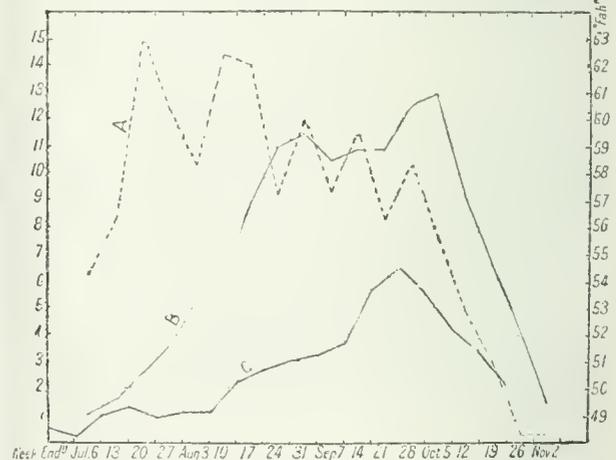

Fig. 7.—Dr. Hamer's observations on the relation in point of time between prevalence of flies and diarrhoea mortality in London, 1907 (163 fly-collecting centres). The deaths from diarrhoea have been antedated ten days. A, Weekly mean atmospheric temperature. B, Number of flies caught per day \div 10,000. C, Diarrhoea deaths per week \div 20.

fly population and diarrhoea cases is so striking as to suggest something more than a mere accidental dependence upon the same phenomena.

The charts, Figs. 7, 8, 9, 10, and 11, show the relation of diarrhoea and fly-prevalence in time. The three first are derived from Dr. Hamer's observations in London in 1907, 1908, and 1909. Figs. 10 and 11 are constructed from Dr. Niven's (1910) observations in Manchester in 1904 and

1906. I have selected these particular years from the Manchester data because they represent what happened in a warm summer in which the number of cases was considerable.

The charts have undergone some manipulation at my hands. I have antedated the deaths by ten days, which, according to Dr. Niven's observations, represents the average period intervening between onset and death. They ought no doubt to be antedated further to include the incubation period, but I have no data to determine what this should be. In the case of Dr.

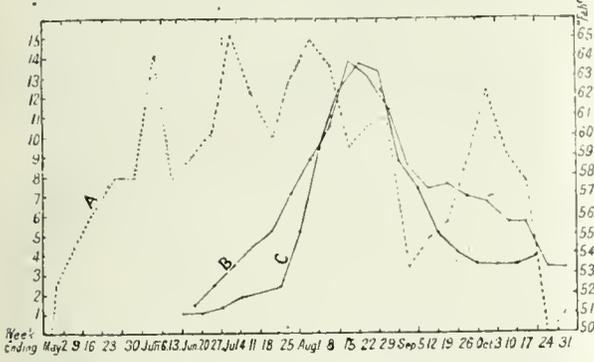

Fig. 8.—Dr. Hamer's observations on the relation in point of time between prevalence of flies and diarrhoea mortality in London, 1908. The deaths from diarrhoea have been antedated ten days. A, Mean atmospheric temperature for the week. B, Number of flies caught per week \div 9,600. C, Diarrhoea deaths per week \div 20.

Hamer's observations, I have summed his tri-weekly observations and plotted the fly-catch for the whole week. In this way I have eliminated most of the irregularities and obtained smoother curves. I have also added the weekly mean temperature for London for the period comprised by Dr. Hamer's observations, and (in Fig. 8) for about two months previously.

The procedure adopted by Drs. Niven and Hamer to obtain data regarding fly prevalence was common in all cases. The number of flies caught on sticky paper, or entrapped in a series of domestic dwellings, generally in

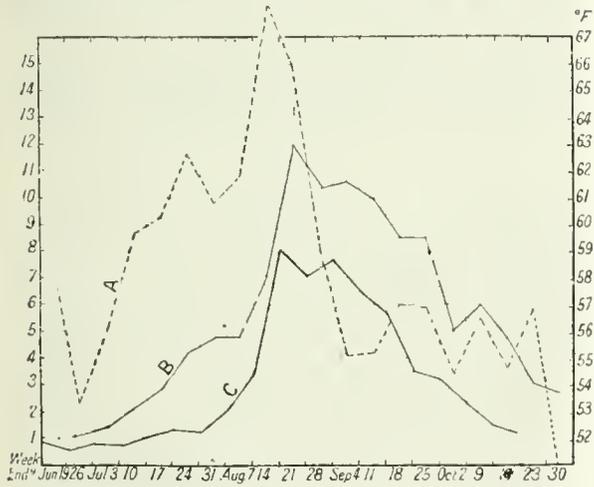

Fig. 9.—Dr. Hamer's observations on the relation in point of time between prevalence of flies and diarrhoea deaths, London, 1909 (thirty-five fly-collecting stations). The deaths have been antedated ten days. A, Weekly mean temperature of atmosphere. B, Number of flies caught daily \div 2,500 (weekly mean). C, Diarrhoea deaths weekly \div 20.

neighbourhoods inhabited by poor people, were recorded every two or three days. This estimate of the prevalence of flies, together with the deaths from diarrhoea, were then plotted as ordinates against weeks as abscissa. Dr. Niven's observations extend over five years, and refer to several districts in Manchester. Dr. Hamer's organization for the capture of flies was on a larger scale, and his observations were made at various parts of London during 1907 and 1908 and 1909, mostly in the neighbourhood of refuse and manure depôts, where flies are bred. Another excellent series of observations was made by Dr. Dudfield (1912) in Paddington during the summer of 1911. It

concerns a smaller number of cases, but this enabled a more intensive study of many factors contributing to the epidemic to be made.

The first point brought out by all these observations is the dependence of both the number of flies and the epidemic upon the cumulative effect of previous warm weather as, for instance, is indicated by the earth temperature 4 ft. below the surface, a fact to which attention was first drawn by Ballard (1889). The curve for flies rises first, followed soon by that for cases. The latter is longer in getting going; this is particularly marked in the

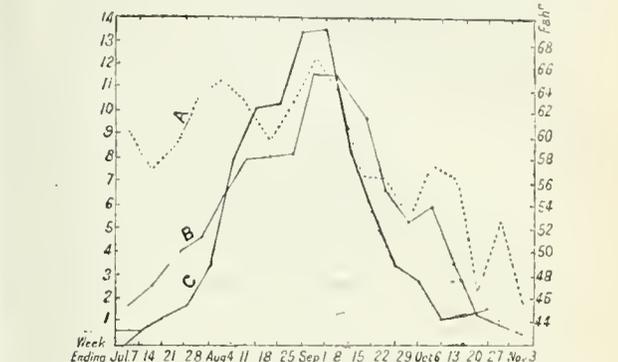

Fig. 10.—Dr. Niven's observations in Manchester, 1906. The deaths from diarrhoea are antedated ten days. A, Mean weekly temperature. B, Number of flies caught \div 2,000. C, Deaths from diarrhoea.

cool summer of 1907. Both flies and cases reach their maxima about the same time. In 1907 the number of cases is diminishing whilst flies are still on the increase. In 1908 and 1909 both curves decline together, but that for flies more gradually.

A notable feature of the curve is that the same fly population is accompanied by a rise in the number of cases in early August and with a fall in early September. This fact has been quite properly emphasized by the critics of those advocating the importance of flies.

If we propose to regard the time relations of fly prevalence and diarrhoea cases as more than an interesting

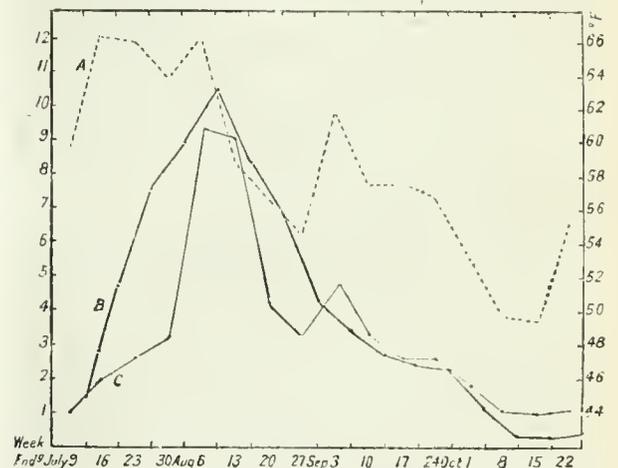

Fig. 11.—Dr. Niven's observations, Manchester, 1904. The deaths from diarrhoea have been antedated ten days. A, Mean weekly temperature. B, Deaths from diarrhoea \div 10. C, Number of flies caught \div 2,000.

coincidence, we must find a satisfactory explanation for the above facts. Let us consider for a moment how the dependence of diarrhoeal epidemics upon the accumulated effect of temperature might be explained.

The reason why the number of flies should be dependent upon this factor is obviously because the generation time (cycle from egg to egg) is dependent on temperature and requires three weeks or upwards in our climate. Months of warm weather are therefore required to produce any multitude of flies from the few surviving the winter.

Why the epidemic should exhibit this dependence is not obvious. Not knowing the etiology of diarrhoea, we must assume some sort of infective agent. From analogy with

typhoid, cholera, acute food poisoning, and dysentery, we will suppose that we have to deal with some form of bacterium with which our aliments might become infected. In this case, would the dose of infection be dependent upon the accumulated effect of temperature during the previous three months? Assuredly not. The generation time of bacteria is so short—in the case of *Bacillus coli* it is one hour at 20° C. and half an hour at 30° C.—that the number present at any moment is to all intents and purposes dependent only upon the mean temperature during the last few days. To take a homely illustration, whether one's milk sours does not depend upon the temperature last month but last night.

Rate of Multiplication (Maximum Observed).

| Days. | House-fly, August-September, 1907. Brighton. | | | <i>B. coli communis</i> , 20° C. |
|-------|---|----------|----------|-------------------------------------|
| | 1 (Female). | | | |
| | 1st Gen. | 2nd Gen. | 3rd Gen. | |
| 0 | | | | 1 |
| 1 | — | — | — | 10 ⁷ (10,000,000) |
| 2 | — | — | — | 10 ¹⁴ |
| 5 | — | — | — | 10 ³⁵ |
| 10 | — | — | — | 10 ⁷⁰ |
| 20 | 100 | — | — | |
| 30 | 100 | — | — | 10 ⁷⁵⁰ |
| 40 | 100 | 5,000 | — | |
| 50 | 100 | 5,000 | — | |
| 60 | — | 5,000 | 125,000 | 10 ¹⁴⁴⁰ |
| | Total | ... | ... | 150,000 |

In the accompanying table I have set out the rate of multiplication of *B. coli* at 20° C. and that of flies inside a house during a summer in England. You will observe that one female fly might under these conditions possess 150,000 progeny in sixty days, but the bacteria derived from one organism become innumerable in two days. Unless, therefore, the effect of two months' summer weather be to change the nature of the organism so as to enhance its virulence, it is quite impossible to account for this striking characteristic of the epidemic by chance contamination of food supply by pathogenic bacteria. In a state of innocence regarding the etiology of the disease, we have no means of knowing whether any such change in virulence occurs under the influence of continued warm weather, but it is just conceivable.

On the other hand, we have excellent *a priori* reasons for supposing that flies could transmit the infective agent of diarrhoea. Any one familiar with the domestic *ménage* of the average working man on a hot summer day, with the baby sick with diarrhoea and other small children to care for, must realize that the opportunities afforded for fly transmission are adequate enough.

It seems to me, therefore, that before abandoning the view that diarrhoea is a bacterial infection, or making the gratuitous assumption that a long spell of warm weather is necessary to awaken pathogenicity, one must carefully examine the adequacy of the view that the dependence of the epidemic on accumulated temperature is to be accounted for by the operation of this factor upon the means of transmission.

We will now see whether this interpretation fits the rest of the facts.

The greater steepness of the rise of the diarrhoea curve is consistent with this view, for at first the opportunities for a fly to transmit the infection are small, but as the cases increase opportunities increase likewise.

As has been pointed out by Hamer and Peters (*loc. cit.*), if variation in the number of fly transmitters of an infective agent existing in the stools of patients were the sole factors concerned, the curve for diarrhoea cases should shoot up beyond and come down later and more slowly than that representing the number of flies, because the opportunities afforded to flies to pick up the infective agent are increasing *pari passu* with the development of the epidemic. This is, however, not what happens. On

the contrary, the epidemic is arrested while flies are numerous and declines more quickly than the fly population. We are therefore confronted with the question, What arrests the rise in the epidemic wave?

Exhaustion of susceptible material has been suggested. This obviously plays a part in every epidemic, and the observations of Peters (1910) in Mansfield, where, under similar conditions, in one section of the town the epidemic was nearly finished whilst in another it was beginning, afford a demonstration that it is a factor of importance. As, however, small epidemics in cool summers exhibit the same feature, this cannot be entirely responsible for the arrest.

Another factor which must be taken into account is the atmospheric temperature at the time. A glance at the charts (Figs. 7, 8, 9, 10, 11), in which the weekly mean temperature is also shown, suggests that this is playing an important part, for the decline of the epidemic occurs immediately upon a considerable drop in mean temperature, and a diminution of fly prevalence often follows shortly afterwards. The influence of atmospheric temperature appears to be more marked upon the number of infections than upon the number of flies. Whereas in London, 1908 and 1909, following shortly upon the colder weather, both curves drop in a remarkably similar fashion; in the small epidemic of 1907 the number of flies still remains up and even increasing, whilst the epidemic is rapidly disappearing. The same general facts emerge from the Manchester observations. We might invoke the assistance of coincident exhaustion of susceptible material or diminished activity of flies, although still numerically sufficient, in explanation of this. They may indeed be operative, but I think that a completely satisfactory interpretation of the above facts, and also of the fact that, with a given number of flies, the epidemic wave is ascending during the early weeks of an epidemic and subsiding a month or six weeks later, is afforded by taking into account the influence of the variations in atmospheric temperature upon the rate of multiplication of the infective agent. Regard for a moment (Fig. 8) the chart expressing the results of Dr. Hamer's observations in London, 1908. Take the weeks ending August 25th and September 12th, in which approximately the same number of flies were caught. The mean temperature for the former week was 62.6° F.; for the latter it was 54.8° F., and it had been down to 53° F.

The atmospheric temperature is a factor to which insufficient attention has been given, since the origin of the epidemic showed but small relation to it. It is capable, however, of explaining why the epidemic wave rises in August and falls in September, although the number of flies may be the same. Assuming, for the sake of argument, some form of bacterial infection is the etiological factor in infantile diarrhoea, it would be in accordance with general experience to suppose that the chance of infection is determined by the quantity of the infecting agent imbibed.

This will depend upon the multiplication which has taken place in the infected medium prior to ingestion; this, in turn, is a function of the temperature at which the milk or other foodstuff has been kept. The temperature coefficient of bacterial multiplication is not higher than that governing ordinary chemical processes—namely, two to three times for 10° C.—but as bacterial multiplication proceeds logarithmically a comparatively small change in rate is sufficient to produce a large difference in the number of organisms contained in, say, an infected milk, if an interval of some hours elapses between inoculation and drinking. Thus if *N* *Bacilli coli* be inoculated in milk at 60° F. and 70° F. respectively, the number after twelve hours will be 126 *N* and 4,000 *N* respectively.*

We have, then, two factors which may contribute in varying degree to the decline of the epidemic.

1. A fall in temperature diminishing (a) the activity and number of supposed transmitters, and (b) the dose of infection which the child ingests owing to the effect upon the rate of multiplication of the infective agent.

2. The exhaustion of the more susceptible individuals. Sometimes one, sometimes another of the above factors appears to predominate. For instance, we have the fact to

* For the observations on which this calculation is based, see Dr. Janet Lane-Claydon's paper, "Multiplication of Bacteria and the Influence of Temperature thereon," *Journ. of Hygiene*, ix (1909), p. 239.

which attention was drawn by Peters (1909), that in a much hotter climate, such as Australia, the epidemic often declines, notwithstanding the fact that the temperature may continue to rise for several weeks. In Fig. 12 below I have plotted from a paper by Stawell (1899) the monthly mean temperature and monthly diarrhoea mortality in Melbourne for the years 1895-96. In this city, where winter and summer succeed one another without the long intervening periods we have here, the epidemic lasts for six months instead of six weeks. It will be noticed that in 1895 the temperature continued to mount for two months after the summit of the epidemic. In Melbourne the decline cannot be due to diminished dose of the poison owing to slower rate of bacterial growth, but must be attributed to exhaustion of susceptible individuals or to the effect upon the presumed transmitting agents, the flies. In

be a source of infection to the neighbours adjacent to the house within the precincts of which his excreta, if infectious, would most likely be deposited. This, he points out, could be most readily explained by the supposition that flies were the agents of dissemination of the infection, but from the frequent want of correspondence in different localities between numbers of flies and amount of diarrhoea, although not negating it, gave no support to this view.

I doubt very much whether any evidence of great value could be obtained upon this point. Even supposing it to be true that fly-carriage is of first importance, I should expect that, if all the facts were known, a much higher correlation would be discovered between diarrhoea and carelessness with regard to disposal of excreta and protection of food from the visitation of flies, than between diarrhoea and fly prevalence.

Many of the facts which I have brought forward merely indicate some form of infective agent and do not necessitate recourse to the hypothesis that carriage by flies dominates the situation. I would point out, however, that—

1. The fly-carrier hypothesis is the only one which offers a satisfactory interpretation of the extraordinary dependence of the epidemic upon the accumulated effect of temperature.

2. That it offers a ready explanation of the spread of infection to neighbouring children who have no direct personal contact with the patient.

3. That the peculiarities of the relation in time between fly prevalence and the epidemic in different localities are not inconsistent with the view that fly-carriage is essential to epidemicity. No other interpretation which is at present forthcoming is nearly so satisfactory, and it is at least worthy to guide in the meantime our efforts at prevention.

Fig. 12.—Diarrhoea mortality and mean monthly temperature, Melbourne, Australia. A, Summer, 1895-6. B, Summer, 1895-7.

the absence of definite quantitative observations I cannot speak dogmatically, but, as far as my memory serves me, I think the number of flies diminishes in Melbourne, as in Washington, during the hotter weather. A monthly mean temperature of 70° in Melbourne indicates that there were a good many days with a maximum shade temperature of over 100° F., which in that locality is associated with extremely dry north winds. Such meteorological conditions are very fatal to flies both in larval and imago stage. On hot-wind days flies have to seek shelter out of the sun, or they rapidly become desiccated. For the same reason they succumb on an exposed window pane, and large numbers of dead flies accumulate on the window frame.

The Relation of Fly Prevalence and Diarrhoea on Space.

No quantitative observations upon the relation between number of flies and the distribution of cases of infantile diarrhoea have, as far as I am aware, been made, but I may mention a few impressions by different observers for what they are worth. Nash (1909), who, whilst medical officer of health for Southend, made, during 1904, spot maps of the epidemic there, says: "The great majority of the deaths from diarrhoea were shown to have occurred in streets in proximity to brickfields, in which were deposited daily some thirty tons of fresh house refuse, which breed incalculable numbers of flies" directly the meteorological or reasonable conditions became favourable for their development.

Dr. Niven (1910, p. 45) is of opinion that the close correspondence between flies and cases of fatal diarrhoea receives a general support from the diarrhoea history of sanitary subdivisions of Manchester, and that the few facts available for the study of correspondence of flies and fatal cases in different subdivisions (Manchester) in the course of the same year also lends support. In his view no other explanation even approximately meets the case.

Peters (1910), in his very exhaustive study of the epidemic in Mansfield in 1908, paid especial attention to the possible part played by flies. From an analysis of his observations, he, I think justly, came to the conclusion that the evidence pointed to the fact that whatever part they might play as carriers from an infected household to a neighbour, flies did not bring infection with them from the manure heaps where they had been bred.

Peters constantly noted that the individual seemed to

The Swiss Society for the Scientific Study of Tuberculosis will hold its first meeting at Lausanne on January 18th and 19th. The society has eighty-eight members.

By way of promoting *esprit de corps* among those who are still nominally serving, or have served, in the civil medical departments of the West African Colonies, two dinners are annually held, one in the summer, one in the winter. The next winter gathering is to take place at the Grand Hotel, Charing Cross, on January 15th, its official title being the dinner of the West African Medical Staff. The honorary secretary is Dr. J. P. Fagan, 27, Scarsdale Villas, Kensington, to whom early application for tickets should be made.

An Address

ON

GALL STONES.

BY

SIR BERKELEY MOYNIHAN, M.S., F.R.C.S.,

PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF LEEDS.

ONE of the most interesting advances made in recent years by the intrepid surgeon into the dim territory of abdominal afflictions was that which disclosed to us the frequency, the symptoms, and the appropriate modes of treatment of cholelithiasis. In this direction, as in so many others, the new vision which has come from a study of the pathology of the living has compelled us to rearrange our ideas and to adjust them in accordance with the different modes of examination which can now be conducted in all the various stages of this disease.

It is now a matter of general acceptance that gall stones are caused by an infection which, having its origin, or at least its refuge, in some part of the alimentary canal, reaches the liver either by way of the blood stream or ascends to it through the common bile duct. Lartigau has shown that the organisms carried to the liver by the portal vein are generally destroyed by the liver's action; but that when from any cause the number or the virulence of the micro-organisms is increased, some may well escape in the bile and find a lodgement within the gall bladder. As soon as any bacteria which have escaped with their lives from the liver reach the gall bladder they begin to act as a menace to the welfare of the patient. The economy, therefore, exerts the protective influence which it seems here also to possess. When a needle intrudes into the knee-joint it is covered over by a plastic exudation and converted into a "loose body." When a bullet is embedded in the soft parts, or in the chest or abdomen, it is wrapped up securely in a coating of fibrous tissue. When a hairpin or a catheter lies in the bladder it is surrounded by salts normally present in the urine, which crystallize out probably in an effort to render the intruder harmless. So in the gall bladder, when germs which have perhaps undergone the process of "clumping" find lodgement there, they are safely immured in a covering of salts, cholesterin in whole or in part, or bilirubin calcium, with the purpose, no doubt, of rendering them inert and of destroying them. Indeed, every gall stone is a tombstone erected to the evil memory of the germ that lies dead within it. Among the organisms which perish in this manner, the bacillus of typhoid, the colon bacillus, and the pneumococcus, which I have on several occasions recovered from the bile, appear to be the most frequent.

It is true that stones, as in cases of cirrhosis of the liver, may be formed within the intrahepatic or hepatic ducts. But such cases are of merely pathological importance. In all cases of cholelithiasis which come for surgical treatment it would appear to be quite certain that the stones have formed within the gall bladder. When calculi are found in the hepatic duct, the common bile duct or the ampulla of Vater, the gall bladder itself may be void of stones. Yet the stones which are removed bear clearly the traces of having been formed within the gall bladder, from which long ago or recently they have migrated. As soon as stones are once formed within the gall bladder symptoms begin to assert themselves. In medicine fallacies die hard, but rarely is one so tenacious of life as that ancient one which expresses the view that in a great majority of cases gall stones do not give rise to symptoms. In all my experience I have only twice met with a case in which an attack of "hepatic colic" was the first indication of the presence of a stone. Indeed, in those rare cases in which the diagnosis admits of doubt, the presence or absence of what I have described as the "inaugural symptoms" of gall-stone disease may nearly decide the question. The description of these symptoms, which I gave some years ago, has been corroborated by other writers—Sherren, Mayo, and more recently by Grube and Graft in their little work on gall-stone disease (see also Rolleston, our first authority, *Diseases of Liver*, etc., second edition).

By the great majority of patients the word "indigestion" is vaguely and variously used to indicate all the several forms of distress which are the forerunners of a crisis of acute biliary colic. The very great majority of medical writers, when dealing with the topic "indigestion" or "dyspepsia," assert that in a large proportion of such cases the symptom owes its origin to "functional" causes, and that it is not dependent upon any structural change in the abdominal organs. Again it is said, when the question of cholelithiasis is considered, that only a very small number of those patients who carry stones in the gall bladder suffer from troubles caused thereby. No one seems to have correlated the two statements, or to have shown how the error in one is explained by the error in the other. The truth is that a very large number of patients—probably, indeed, a large majority—who have suffered for years from "gastric" disorders have no organic disease in the organ impugned, but have a real structural disease in other parts, notably the gall bladder or the appendix. Nothing is more remarkable in connexion with the surgical investigation of dyspepsia than the progressive broadening of the organic bases upon which the clinical symptoms are found to be built. It is the stomach, whose sensibilities are tender, that cries out the warning when other organs are suffering attack.

The symptom "dyspepsia" or "gastralgia" may be due, it is now known, to structural diseases, not in the stomach alone, but also, indeed chiefly, in the gall bladder, duodenum, appendix, or any part of the intestinal canal.

The "inaugural symptoms" of gall stones may very briefly be recapitulated here. The patient complains of a fullness, weight, and distension, or oppression in the epigastrium coming on soon after meals, within half or three quarters of an hour, relieved by belching, and dismissed almost on the instant by vomiting, elicited with remarkable constancy by certain articles of diet, especially those of a "greasy" nature, and dependent rather upon the quality than upon the quantity of the food. There is a sensation of great lightness, which if unrelieved may become acute pain, from which the patient obtains ease by bending the body forwards, by flexing the right thigh on the abdomen, or by loosening all garments which fit tightly to the waist. There is frequently great complaint of "acidity" or heartburn, and in the act of belching there may be sour or acid regurgitation. While the discomfort lasts the patient may notice a "catch" in his breath, and he finds, perhaps, that it is impossible to breathe deeply without feeling an acute stabbing pain at the right costal margin. There may be a feeling of faintness and nausea, and, rarely, vomiting may occur spontaneously. After a more than usually severe attack of "indigestion" the body and side may feel stiff for several days. A frequent and a very characteristic early symptom of cholelithiasis is the occurrence during an attack of indigestion of a slight sensation of chilliness, especially in the evenings after a meal. The patient may shiver for several minutes, and may hasten from the table to huddle over a fire. The sensation of "goose flesh" is often experienced, and several medical men upon whom I have operated have said that in the severer phase it was not unlike a very slight rigor, the chilly stage being quickly followed by one in which the body feels hot and the skin begins to act freely.

Such are the symptoms which may be present for months or even for years before a sudden and dramatic attack of acute pain, perhaps amounting to agony, occurs, as the result of a disarrangement of the stones, or of an attempt on the part of one stone to escape from the gall bladder. The cause of attacks of pain in gall stones is always mainly mechanical: inflammatory attacks, due to infection, are the results of the movements and impactions of the calculi. Among the commonest of all causes of attacks of "biliary colic" is the impaction of a stone in the "pelvis" of the gall bladder, close to or actually at the orifice of the cystic duct. The patency of the cystic duct is all-important. As Keith has said, the valves of Heister, made by an infolding of the mucosa in spiral form, are designed for the purpose of keeping the duct open. The gall bladder acts not as a reservoir of bile—it is too small for that purpose, holding only the amount of bile which can be excreted in an hour and a half or two hours—but as a controller or regulator of the steady supply delivered on demand into the duodenum. It is

very essential, therefore, that the cystic duct should be kept open to the free flow of bile in and out of the gall bladder. So soon as this is arrested, so soon does pain begin. The symptoms caused by the impaction of a stone in the cystic duct are quite characteristic. There is probably a sense of gastric uneasiness, with flatulence, belching, and a sense of distension, as is so often the case in the cholelithic patient after meals. Quite suddenly, however, often with onset as instant as if he were stabbed, the patient is seized with the most acute pain, felt across the epigastrium, often more on one side than the other, and nearly always through to the back, near the tip of the right shoulder. The agony may be terrific, and the patient may reach the very limit of human endurance. He is infinitely restless, and in this differs from the rigid and motionless patient, who has suffered the perforation of a gastric or duodenal ulcer. He is moaning and moving without pause, pressing the body with one hand or both, or bending over a chair or clutching a hot bottle to the abdomen. He sweats and yet feels cold and clammy. He breathes with difficulty, owing to a spasm of the diaphragm, which, like the other abdominal muscles, is tightly contracted to form that firm muscular splint whose purpose it is to keep at rest and free from harm a lesion in need of protection. Nausea, and nearly always vomiting, occur, and vomiting may cause relief, probably by reason of the muscular relaxation which it induces. Very often the pain disappears with absolute abruptness. One moment the patient writhes in agony, the next he smiles in relief. The instant beginning and the instant cessation are characteristic of cystic duct obstruction—they never occur in any other form of gall-stone obstruction with anything like the same precision. The pain is almost always referred to the back, and Boas's sign can often be elicited in and after a seizure. If an attack last for some hours, the distended, tense, and tender gall bladder may be felt. It is often exquisitely sensitive, and may remain so for many days. The importance of tenderness along the lower border of the liver in cholelithiasis was first indicated by Nannyn, who wrote that, in patients who have recently suffered from an attack of colic, "pain is induced when, during a deep inspiration, pressure is made with the hand as far upwards as possible beneath the right costal border. At the moment when the liver impinges upon the tips of the fingers the patient experiences a deep-seated pain."

Dr. J. B. Murphy, one of the greatest of surgeons in a country prolific in the production of surgeons of the first rank, has emphasized the same truth: "The most characteristic and constant sign of gall-bladder hypersensitiveness is the inability of the patient to take a full inspiration when the physician's fingers are hooked up deep beneath the right costal arch below the hepatic margin. The diaphragm forces the liver down until the sensitive gall bladder suddenly reaches the examining fingers, when the inspiration suddenly ceases, as though it had been shut off. I have never found this sign absent in a case of calculus or in infectious cases of gall bladder or duct."

My friend, Mr. Jordan Lloyd, many years ago, called attention to the importance, as a diagnostic sign in cases of renal calculus, of a "jab" suddenly made with the thumb in the ilio-costal space. If a stone lies in the kidney this sudden assault causes a sharp stab of pain. Similarly he has found that a "jab" beneath the costal arch opposite the ninth cartilage, or the striking of the abdominal wall below the ribs with the inner border of the hand, causes a sharp stab of pain when stones lie within the gall bladder.

My own experience does not lead me to attach much importance to these signs unless there has been a quite recent attack of colic. I have repeatedly failed to find any physical evidence of any kind in cases where a day or two later many stones were found in the gall bladder. In the presence of these signs we may therefore safely rely upon their value—their absence signifies nothing.

These symptoms are all doubtless due to the impaction and release of a stone at a point so close to the entrance to the cystic duct as to cause obstruction to the free ebb and flow of bile. If the stone should not fall back into the bladder then it may be tightly and permanently wedged, or it may at last work loose. If it is firmly and immovably fixed in the duct, one of two conditions may develop:

(a) The gall bladder may become distended with clear fluid, with the result that a condition of "hydrops"

develops. So large may a gall bladder be in such circumstances that a diagnosis of ovarian or parovarian cyst may seem well founded. The largest gall bladders recorded contained over five gallons of fluid (Terrier) and three gallons (F. W. Collinson), and even so alert a surgeon as Lawson Tait operated upon a "parovarian" cyst to find that its pedicle was the cystic duct containing a small calculus.

(b) The gall bladder, probably after trivial and temporary distension, begins to contract, and eventually closely embraces the single large stone, or the many stones that lie within it, until all trace of a cavity disappears; the cystic duct remains completely and permanently closed, and the patient has been submitted to what Rutherford Morison calls "Nature's cure" by the rude performance of intraperitoneal cholecystectomy. In such cases the "cure" is not always permanent. Infections arise, new symptoms develop, and an operation has to be performed. It is invariable then to find so large a dilatation of the common duct as to lead to the belief that a stone lies within it.

Whatever the function of the gall bladder may be, its loss results in a considerable distension of the common and hepatic ducts. If the stone which for a time has been closely gripped by the walls of the cystic duct at last works loose, it may lie in a fusiform dilatation of the canal, in a cavity communicating by a niggardly opening on the one side with the gall bladder, and on the other with the common duct. In such cases typical symptoms may be present. There are, briefly, the occurrence of many slight attacks of colic within a brief compass of time. Two or three attacks may appear in one week—attacks beginning quickly, and ending quickly, and of no great degree of severity. The pain is felt in all the upper abdomen, and passes round to the back. There is no chilliness, and no jaundice, and no loss of flesh. The frequent repetition of mild attacks of colic indicates that a stone is loosely impacted, either in the cystic or in the common duct. If in the cystic duct, the symptoms are those indicated above; if in the common duct, the attacks are milder, the pain is restricted to the epigastrium, it occurs more frequently, and is attended by chilliness and possibly a very slight rigour; wasting is almost invariable. Jaundice is commonly absent in both forms. This form of arrest in the progress of a stone is far more frequent in the common than in the cystic duct, so that when many slight attacks of colic occur within a brief space of time, it is very probable that a small stone is loosely impacted in the common bile duct. The absence of jaundice in such a case is of no diagnostic importance, for I find that in almost exactly 25 per cent. of the patients from whose common ducts stones are removed there is not at the time of operation, nor has there ever been in the history of the case, any appearance of jaundice.

When the presence of stones within the gall bladder has been recognized, what is the treatment to be adopted? There is, of course, no medical treatment of gall stones. Nothing that can be wrought by drugs will have any effect in dissolving stones. That is, I suppose, universally admitted. All that is claimed for the treatment at the various spas is that the stones are rendered "latent," and that the patient can bear them for years or months without suffering. Whatever "latency" may be invoked in respect of the clinical declarations of gall stones, there is certainly none attaching to their pathological manifestations. When patients are operated upon after undergoing one or more "cures" extending over several years, it is at once evident that, though symptoms have been kept in subjection, insidious morbid changes have been steadily progressing, changes which may involve the gall bladder, the liver, the duodenum or stomach, or the pancreas; and of these the last is certainly not the least serious. I hold that when once a diagnosis of gall stones has been made operation is always indicated unless there are grave reasons forbidding resort to surgery. Reasons should not be asked to support a plea for operation, but to justify any other course than this. For surgical treatment, all things considered, is far safer than medical treatment; it is curative, not palliative; it is permanent, not temporary. All of us, I hope, read Montaigne's essays, the epitome of human wisdom. Many of the years of Montaigne's life were made wretched by a stone in the bladder, for which in his day nothing but medical treatment could be con-

sidered. No one nowadays treats a vesical calculus by other procedures than operation, preferably lithotomy. Yet one still hears a voice raised against the surgical treatment of stones in the gall bladder, though these can be recognized almost as certainly as vesical calculi, though they give rise to suffering equally terrible, though their consequences are at least as serious, though they can be removed with greater safety, and though the chances of recurrence are far less.

There are few problems that have so vexed the minds of surgeons as that concerned with the relative merits of cholecystotomy and cholecystectomy. In surgical controversy it is often heat that is engendered rather than light. At the moment there seems to be an international diversity of opinion upon this subject. The surgeons of America and of England lean towards cholecystotomy; the surgeons on the Continent of Europe, swayed by the powerful influence of Kehr, incline to the routine removal of the gall bladder and the drainage of the hepatic duct. The ideals are different, I believe, because the material is different. Our view is that the diagnosis of gall stones, after a due study of "inaugural symptoms," can be achieved in an early stage of the disease, that the gall bladder is then but little affected, its musculature is almost or quite unimpaired, and the cystic duct remains patent. We hold that when such a gall bladder is opened, relieved of its stones and deprived of its infection by drainage, it may confidently be expected to return to its normal condition and to perform its functions as well as ever. We hold, too, that there are occasions, fortunately very rare, upon which the presence of the gall bladder is almost essential to life or to health; as for example in cases where, owing to a stricture of the common duct, or to a chronic inflammation of the pancreas, it is necessary to find another passage for the bile to the intestinal canal.

The Continental view seems to be that the early recognition of gall stones is not yet possible, that when a diagnosis of gall stones has been made, operation should be reserved for cases in which the cystic duct is blocked, and a hydrops or empyema has developed; for cases of the recurring cholecystitis; or for cases where there is a chronic occlusion of the common duct. In such cases it is held the gall bladder should be removed and the hepatic duct drained.

If the former view be adopted operations will be more numerous, but each operation will be simpler in character, convalescence will be quicker, the death-rate lower, and the complete and permanent recovery more frequent. I am therefore an advocate of the superior claims of cholecystotomy. But in practice I find that I am compelled still to remove the gall bladder with a frequency far greater than I desire.

It is difficult to give the exact reasons which decide one during the conduct of an operation to remove or to empty and drain the gall bladder. Briefly, it may be said that where the capacity and the musculature of the gall bladder are unimpaired, and the patency of the cystic duct remains, the gall bladder should not be removed. Where the walls of the gall bladder are so modified by disease that neither the storage nor the expulsion of bile is possible, and where the canal through which the bile is emptied is in any degree obstructed, the gall bladder, being always useless and often a source of danger or discomfort, should be taken away.

To this general rule, apparently so simple, there are, however, some exceptions. The most important of these concerns the cases in which a stone, usually a solitary stone, has been for some little time engaged in the orifice of the cystic duct. Such a stone, either by reason of the constant pressure which it exerts, or of the fretting of the mucosa which it may cause, is often responsible for the production of an ulcer. Such ulcers are often seen within the gall bladder, in the pelvis, or at the entrance to the cystic duct, when the parts are examined after the operation of cholecystectomy. If such an ulcer forms it tends to heal after the stone which caused it has been removed. In or after healing there must be some contraction of the scar, and the result is the formation of a stricture in the duct. In such a case there is a "recurrence of symptoms" a few months after the operation, and very great and most natural disappointment. The symptoms and the signs which result from a stenosis of the cystic duct are in most cases hardly to be distinguished

from those aroused by a stone. About 10 per cent. of the operations I perform upon the biliary system are secondary—that is to say, a previous operation has been performed with little or no relief. One of the common causes calling for a second operation is the existence of this tight stricture near the orifice of the duct. It is therefore better at the primary operation to remove a gall bladder when a stone is so tightly driven into the cystic duct that it cannot easily be dislodged. As I have said, such a stone is often solitary, and is made up almost entirely of cholesterol, the crystals of which are arranged along lines radiating from the centre to the circumference. Such stones (radiar cholesterolstein), according to Aschoff and Baumeister, own a different origin from other stones, being the result in aseptic bile of an increased production of cholesterol by the uninfamed mucosa of the gall bladder. There is, accordingly, this additional reason, if their views be correct, for the removal rather than the drainage of a gall bladder whose lining membrane is subject to this primary disorder.

Again, there are certain cases in which, though the walls of the gall bladder appear healthy and the channel through the duct seems quite patent, a few tiny "beads" are so buried in the mucosa of the duct that they cannot be disturbed. In such cases I have several times emptied the gall bladder of two or three hundred little stones, and have had then to take the gall bladder away because, as soon as the duct had been emptied of bile, these tiny little obstacles in the channel were discovered. In the *Annals of Surgery* (1909, I., 1265) I described "a disease of the gall bladder requiring cholecystectomy." This disease may be present with or without stones. The reddened mucosa of the gall bladder presents on examination a series of white or yellow specks due to small, sharply demarcated areas of a fatty degeneration, to fine scars, or to the deposit of tiny crystals of cholesterol. This condition was also described by Dr. McCarty of the Mayo Clinic, Rochester, under the very appropriate title "strawberry gall bladder." In these cases, too, the gall bladder, though it may appear healthy, and though the expulsion of its contents may not be opposed, should be excised. When, however, all the exceptions are considered, it may still be accepted as the readiest rule to remember at the moment of operation that a gall bladder whose muscular power is unimpaired, whose cavity has suffered no appreciable diminution, and whose duct is not obstructed, should be drained, and not removed.

There is no doubt that even now, in the most practised hands, mistakes are still made in this matter. Gall bladders are taken away that were better left behind and some left that it would have been wiser to remove. But the more expert the hand and the more experienced the judgement the fewer the mistakes. If a mistake must be made it is better to err by leaving a gall bladder than by needlessly taking one away.

A LECTURE INTRODUCTORY TO AN ADVANCED COURSE ON TUBERCULOSIS

AT THE PUBLIC HEALTH LABORATORY, MANCHESTER.

BY

SHERIDAN DELÉPINE, M.B. EDIN., M.Sc. MANCHESTER,
PROFESSOR OF PUBLIC HEALTH AND BACTERIOLOGY IN THE
UNIVERSITY OF MANCHESTER.

THE adoption of State-aided systems of insurance in Germany and Great Britain has of late forced upon the attention of statesmen what was previously well known to medical observers—namely, the great importance of tuberculosis as a source of waste of life and energy. Whatever may have been said to the contrary by recent theorists, the voluntary preventive work which has been carried out in the face of much public indifference during the past forty-eight years by the medical profession, under the influence of pathologists, bacteriologists, and hygienists, has resulted in a considerable diminution of mortality from tuberculosis.

It may reasonably be hoped that, with the help now given by the State, greater improvements will be obtained in the

near future. In order, however, that the opportunities now offered should be used to the greatest advantage, it is necessary that medical men engaged in the fight against tuberculosis should be conversant with sound methods, well-ascertained facts, and the few working theories which may serve as guides in the search for more knowledge. Practical acquaintance with facts and methods is needed, not only for the proper discharge of current duties, but also for the purpose of gaining the confidence that is necessary in order to steer the right course and not be constantly tossed to and fro by the various more or less wild hypotheses which gain in rapid succession a short-lived popularity.

The doubts created by these constant changes often lead one to question the value of the best ascertained facts, and may cause a sceptical state of the mind which prepares it for laxity or eccentricities of thought and practice.

Thus an attempt which has been made of late years to apply very accurate mathematical methods to the interpretation of data of doubtful value has disturbed scientific opinion to such an extent that facts capable of clear experimental proof are now doubted.

Heredity, which had ceased to be considered as having more than a secondary share in the spread of tuberculosis, is once more brought forward as a factor of first importance.

The very wide distribution of the *Bacillus tuberculosis*, and the fact that the great majority of people have at one time or another been harbouring the tubercle bacillus and yet have recovered, as well as the analysis of returns of very unequal values, have led some statisticians, Karl Pearson for instance, to doubt whether tuberculosis should be considered as an infectious disease in the ordinary sense.

Such views, if correct, would strike at the root of all modern methods of prevention of tuberculosis.

The importance of predisposing factors is often so great that not a few clinicians and administrators have given but scant attention to the essential cause. It must be acknowledged that in many cases it is possible to obtain excellent results by dealing thoroughly with predisposing causes, and often there is no other course open to us. It is, however, never safe to disregard, even temporarily or partially, the *causa causans*, because it is liable to variations and may, under the influence of circumstances, acquire infective powers exceeding the average. Neither is it safe to trust entirely to the action of natural or artificial curative agencies. Recoveries from infectious diseases may be apparent or real, and do not invariably result in so great a reduction in the number of infective centres as might be expected. Recoveries brought about by natural processes introduce an additional element of complexity in our estimates of the incidence of various infectious diseases.

In studying the conditions which influence the prevalence of any infectious disease we must, therefore, take account of the possible action of a great number of factors, which may roughly be grouped into the following categories:

1. Distribution and habits of the infecting parasite.
2. Conditions influencing the quantity of the parasite.
3. Conditions influencing the virulence of the parasite.
4. Opportunities and channels of infection.
5. Conditions influencing the resistance of the possible host.
6. Proportion and completeness of recoveries.

Even with regard to clinical observations and experimental investigations great divergences of opinion have occurred of late.

Infection through the alimentary canal was ten years ago considered of little importance by the majority, but now there are observers who believe it to be of paramount importance.

Bovine tuberculosis, which was on apparently good grounds considered a variety of the disease observed in man, is supposed now by some to be a different disease.

These difficulties and others indicate the basis upon which has been framed the advanced course on tuberculosis which has begun this winter in connexion with the Public Health Department of the University of Manchester.

[After these introductory remarks, Professor Delépine gave a demonstration of the results of infection through

the skin, the alimentary canal, and the lungs, and discussed, among other matters, von Behring's and Calmette's views.]

THE CULT OF IODINE AND THE DREAD OF SKIN.

By J. LYNN THOMAS, C.B., F.R.C.S.,
SURGEON TO KING EDWARD VII HOSPITAL, CARDIFF.

THE many papers which have lately appeared upon the action of iodine preparations upon skin in the practice of surgeons seem to me to be a reincarnation of the old dread of skin. I have not yet seen evidence that other surgeons have carried the ritual of iodine into the regions which it has invaded in my practice for many years. The end of another year prompts me to record my faith in the cult of iodine evolved unconsciously from the days when "Bryant's sherry," otherwise "diluted tincture of iodine," was in general use with me instead of carbolic acid—1 in 20—which played havoc with my skin, and more than once produced carboluria.

It is over twenty years ago that a German sailor was brought to the Cardiff Infirmary about midnight with a "huge bark" of his shin, caused by the crank-shaft of an engine. The damage had received "first aid" treatment, for "the bark" had been plugged with waste wrung out of oil. The skin of the shin for a few inches below the knee had been stripped up, carrying with it periosteum and ligamentum patellae. The knee-joint had been freely opened, and into it the "first aid" dressing had been introduced.

A large bucketful of "Bryant's sherry" was prepared, and the patient was anaesthetized and turned on his face in order to get the fully flexed knee-joint into the lotion. After thorough cleansing by immersion and mopping, the parts were replaced and the joint put at rest by splinting. Next morning by daylight I was alarmed to find that my hands were discoloured by iodine, showing that the "sherry" was stronger than was usual in my practice: the patient's skin was stained in the same way, and this caused me some anxiety, for I feared "irritation." My fears turned out to be groundless, for the case did well, and my dread of an overdose of the iodine preparation vanished. The man returned some months afterwards with the compliments of a German professor upon the good result obtained by the treatment.

Slowly and by cautious steps I got into the practice of applying the undiluted tincture by means of the eye end of a needle to the redness which often resulted in suture holes before the use of gloves was introduced into my practice in 1898. An account of this appeared in the BRITISH MEDICAL JOURNAL in January, 1899, the first paper, I believe, to be published in this country on the subject.

I well remember that in one of the first cases in which I used screws, a case of fractured tibia with displacement due to oblique injury, in private practice in 1896, redness and signs of "irritation" were observed a few days after operation: removal of all sutures with free swabbing of the wound with the tincture gave a happy result, for all went well. From that time until the present tincture of iodine has on and off played an important part in my routine practice in almost every region upon which operations are done, and I will indicate briefly the conditions in which I think it is of great use, because it has a strong action as an antiseptic, and there is little or no tendency to absorption through the lymphatics.

In the Nursery.

In order to minimize the risks of infection during accidents in childhood I kept a stock bottle of tincture of iodine in the nursery in order to have it promptly applied to bruises, "gravel rashes," etc. I gave up carbolic fifteen years ago, because on returning home I often found that there was no visible evidence of its having been applied to the required spot. I therefore substituted the tell-tale iodine, and was often amused to find that in such a case as that of a small scratch upon the front of the knee, iodine had been diligently applied half way up the thigh and down nearly to the ankle—ritual run riot. During the last few years, when visiting many home and foreign clinics, I have been amazed to find that those who

know better than a nursemaid do very much the same thing when they paint mahogany colour the whole of the front of the abdomen and part of the chest in cases of appendectomy!

I will now leave the subject of iodine and skin, and will give illustrations of cases in regional surgery where I feel the use of iodine is indicated, either on account of pre-existing sepsis, or because I feel that there is a possibility of infection in a clean wound—in such cases, for instance, as an accidental tear in a rubber glove, or those in which during an operation upon quiet gall-bladder and appendix troubles septic conditions are found.

Brain Surgery.

In cases of abscess of the brain I always fill the cavity with the pure tincture, and plug with gauze soaked in it. I may cite a case from my friend Mr. Naunton Morgan, F.R.C.S.E., of a large abscess of the frontal lobe which would not heal up satisfactorily until I removed the hernia cerebri with the cantery, and then dealt with the cavity by swabbing it with iodine.

Cerebellar Tumour.

In a case of a large tuberculous tumour which was removed successfully, the cloth which had been in contact with the skin came accidentally in contact with the damaged cerebellum, and in order to render the area less suitable for the growth of organisms, I painted freely with iodine.

Cerebral Tumour.

Last year I removed successfully an extraordinary tumour—a large calcified parathelioma, or endothelioma, from the left lateral ventricle. As I had removed the tumour with a naked finger and thumb dipped in iodine, I afterwards gently swabbed the damaged area of the cortex cerebri with iodine. The wound healed up promptly.

Abdominal Surgery.

In all cases of abscess due to appendicitis I always and immediately apply iodine freely to the surfaces that have been exposed by incision and mopping up of the pus: the result, in my opinion, has been more satisfactory than it used to be before its introduction.

Suppuration of Right and Left Ovarian Cysts.

A woman, who had been very ill with pain and pyrexia for over a week, had a fixed hard tumour occupying the abdomen from about 2 in. above the umbilicus downwards to the pelvis, where on vaginal examination I found an immovable hard vault. The operation had to be done expeditiously, and whilst placing the gauze roll above the tumour to isolate the intestines many ounces of offensive pus welled out through two gangrenous patches on the posterior surface of the cyst right into contact with them. After much serious trouble and difficulty in dissecting the left tumour from Douglas's pouch, uterus and bladder, I was compelled to leave three long haemostatic clamps upon big vessels at the bottom of Douglas's pouch. I then found that there existed a second small suppurating cyst in the right ovary, the size of my fist, attached to the appendix and ascending colon, and this also during its removal burst through one gangrenous patch in the cyst wall. As the peritoneum had been packed, only the pelvis and parietal peritoneum were flooded; after careful and forcible mopping the whole surface and the intestines were dealt with by pouring in about two ounces of iodine and swabbing. The forceps were removed on the second day, and after a little oozing through the opening left the case did well.

Urogenital Surgery.

In several cases of pyonephrosis, some large with putrescent material in the calyces, and extending down a dilated ureter, I have been able to get the damaged kidney restored to function without a fistula in the loin. I am much more conservative as regards the removal of kidneys damaged by tubercle or calculus than the majority of surgeons whose practice I have had the privilege of witnessing; I was led to adopt this conservative attitude by two incidents. The one occurred in my practice many years ago: a lady had a large pyonephrosis with creamy contents; when the patient was convalescent with a drain in her side, I told her husband that, in my opinion, it was advisable to remove the kidney. Afterwards he told his wife of my views and we had a further consultation. They

did not accept my advice, which at that time I believe was in accordance with the view of the majority of urogenital surgeons, and perhaps now. The wound in the side healed up firmly, and the patient has remained quite well and has borne several children. This is a significant example of the curability of tubercle in organs which are easily removable, and perhaps too often removed. The other case was that of a practitioner, who removed a kidney that he thought had been irretrievably damaged by calculi; it turned out to be the only kidney the patient possessed.

In all the kidney cases of the above nature I thoroughly and forcibly mop the removable material from the interior of the cavity and wash with iodine.

Urethrotomy.

Since I introduced into my practice the method of injecting tincture of iodine forcibly by a glass syringe half full of air, both before and immediately after performing urethrotomy, I have not been worried with "urethral fever" or other symptoms of septic absorption from the wounded urethral canal.

Prostatectomy.

At the annual meeting of the British Medical Association in Toronto (1906) I advocated the plan of performing prostatectomy in two stages in cases where patients suffered severely from toxæmia, partly on account of the fact that an operation created additional raw surface, through which an additional dose of septic matter took place at once; this, in my opinion, too frequently turned the balance against the patient. Since that time I have given up the operation in two stages (*à deux temps*), because I have improved the technique in the direction of prevention against the immediate absorption from the raw surfaces made at the operation. This is done in the first place by a preliminary injection of an ounce of tincture of iodine into the bladder before distending it with air; by my combined method of performing prostatectomy, which usually takes only a few minutes, I have been able to save several moribund patients since the introduction of the free use of iodine—one was an octogenarian with calcified arteries, which showed almost like stems of "churchwarden" pipes upon the radiographic plate.

Rectal Operations.

After thoroughly mopping the mucous membrane—for example, in operating for hæmorrhoids—I swab the mucous membrane with iodine, and then pass an anchored iodine-soaked mop up the rectum for about six inches. This prevents a possible infection of the field of operation; when the operation is finished the mop is pulled out.

Psoas and Iliac Abscess.

Lastly, I should like to draw attention to the following method of treating psoas or iliac abscesses which have not been previously incised nor broken down spontaneously. After opening the abscess in one or more places, according to the requirements laid down by Treves many years ago, I complete the evacuation of the pus and of the lining membrane in the thorough manner which he advocated. I then flood the whole of the interior of the cavity with tincture of iodine, and then mop it dry; afterwards the whole cavity is plugged firmly with a roll of sterile gauze, and the wound closed by mass sutures. The patient is then swathed in cotton-wool, and bandaged firmly in order to keep pressure from without upon the dressing within. On the second day the mass sutures and the gauze are removed from the cavity, and the wound is closed "in tiers," as in the ordinary operation for hernia.

I have twice performed this operation with success upon double psoas abscesses, but not at one sitting.

Every surgeon suffers more or less from what may be called "the dread of skin," and in my case the cult of iodine has developed to such a degree that I venture to record the way it has almost imperceptibly evolved.

THE Research Defence Society has opened a bureau at 171, Piccadilly (opposite Burlington House), for the exhibition of pictures and specimens and the distribution of literature.

ABERRANT AND RECURRENT OSTEO-MYELITIS.

BY

R. CLARK MCGUIRE, M.B., CH.B. GLASG.,
BISHOPTON, HENFREWSHIRE.

UNDER the heading of "Acute Epiphysitis," a very instructive article appeared in the *JOURNAL* of July 20th, 1912, by Mr. Charles M. Kennedy, F.R.C.S., and I venture to publish the notes of three cases occurring in my practice, which support and partly supplement the conclusions arrived at by him. Mr. Kennedy applies the term "acute epiphysitis" to that acute destructive inflammation of the growing end of bones usually due to virulent infection by the staphylococcus. He dislikes the term "osteomyelitis" as applied to that disease, because it is vague, and though admitting that "epiphysitis" is a misnomer, he prefers it on account of its convenience. I prefer the term "osteomyelitis," which, although it covers conditions other than the disease above mentioned, has the merit of being a more exact description of the actual pathological condition. It is the name used by the Glasgow school of surgeons, and favoured particularly by Sir William Macewen, whose work in connexion with the disease is well known. In my opinion "epiphysitis" holds the same relation to "osteomyelitis" that "typhilitis" did to "appendicitis." Both are misnomers, are incorrect, and ought not to be used; the names of medical and surgical diseases should be made to indicate, as nearly as possible, the exact anatomic-pathological condition of the structures involved.

CASE I.

H. M., a boy aged 14 years, came under my notice on February 28th, 1911. He had a rigor two days before, and complained of pain at the upper part of the right thigh, made worse by walking or standing. His temperature was 103° and pulse 120. His face was flushed, the eyes bright, and tongue coated with a dirty white fur. The urine was distinctly albuminous. Physical examination revealed a spot of definite tenderness at the upper part of the thigh just below the middle of Poupard's ligament. Percussion of the outer side of the right trochanter also caused pain in this part. The hip-joint moved freely and without pain in all directions, except for slight adductor spasm when the thigh was abducted. There was no swelling or discoloration of the skin over the painful area. None of the other joints were swollen or painful, and apart from headache he made no complaint of pain in any other part of the body. The heart sounds were quite clear. On the face, chest, and back brownish stains and flat adherent scabs, due to impetigo contagiosa, were discovered. I suspected he was suffering from acute osteomyelitis of the upper part of the right femur, and asked a surgeon to see him in consultation. The latter concurred in my opinion, but, as the local signs were somewhat abating, it was considered advisable to wait and watch how the symptoms progressed. The following day, as the boy's general condition had not improved, the temperature being still 102°, I sent him to the Royal Alexandra Infirmary, Paisley. Owing to the doubtful nature of local signs at the upper part of the right femur, operation was again deferred, but two days after I received a note from the surgeon saying that he had been obliged to operate on the left tibia, where he found about a pint of pus under the periosteum, which was completely stripped from the shaft. No complaint of pain in that region had been made by the boy either before or after entering the hospital, and the condition was only discovered by the surgeon himself in course of his examination. After operation, slight pain continued in the upper part of the thigh, but no further advance of symptoms took place here. The temperature remained at 102°, pulse 112, and signs of pyæmic infection of the lungs occurred, from which death took place about three weeks after admission to hospital.

Mr. Kennedy, in his paper, mentions cases which are admitted to hospital with pyrexial symptoms and a tender spot. These are entered as "? epiphysitis," and if they recover, as sometimes happens in a few days without operation, they are then most probably ascribed to mono-articular rheumatism. The case above reported, no doubt, would have been classed as "? osteomyelitis" of the upper part of the right femur, but the occurrence of definite symptoms of acute osteomyelitis of the tibia of the opposite leg makes it more than probable that there was a primary focus of osteomyelitis in the upper part of the right femur, which although it, in a manner, abated or retrogressed, was undoubtedly responsible for the subsequent infection of the tibia. The simultaneous occurrence of impetigo contagiosa on the skin, when the bone symptoms developed, is a striking illustration of the theory that skin lesions are the chief sites of entry for the organisms (staphylococci) of acute osteomyelitis, and

the subsequent development of the disease in the left tibia, at a situation far removed from the primary focus in the femur, is strong evidence of the extreme vulnerability of growing bone tissue to staphylococcal infection without previous trauma. The case above reported is of an unusual and aberrant type, but Sir Hector Cameron has described a case still more unusual: a man, aged 25 years, developed an abscess in the left leg, due to staphylococcal osteitis of the left tibia, eight years after having had his right leg amputated for acute osteomyelitis and necrosis of the right tibia.

Acute osteomyelitis is one of the most formidable diseases of childhood, and entails considerable loss of life and limb. The suffering during the acute stage is very great and the convalescence after operations on affected limbs is very tedious. Much deformity as a rule results in those cases in which bone loss has been great as a result of necrosis, and it is in cases such as these that a successful bone-grafting operation gives excellent results. The operation of transplanting bone removed from tibias on which osteotomy had been performed was first performed by Sir William Macewen in the case of a boy who had lost the shaft of his humerus by necrosis due to acute osteomyelitis. This operation was attended by brilliant results, and although Macewen's conclusions—namely, that bone forms bone and the periosteum has little to do with the process of repair—have not been accepted by all surgeons, others have followed his teaching, and many cases of successful bone transplantation have now been recorded. In a case of necrosis of the whole diaphysis of the tibia, due to acute osteomyelitis, I have seen the fibula split longitudinally and a portion laid in a bed of granulations springing from the tibial epiphysis, with the result that a large portion of the lost tibia was regenerated. Unfortunately, the sufferings of those afflicted with osteomyelitis do not always end when the acute disease has been successfully combated. Sir Hector Cameron says:

Few patients pass through a serious illness of this kind, especially with necrosis and formation of sinuses in such important bones as the femur, tibia, or humerus, without having relapses, sometimes numerous, and often very severe in character.

These relapses may take place years after, with intervals of good health between them, and they may persist, off and on, till a very advanced age. I give below the notes of two cases of recurrent osteomyelitis, which illustrate the relapsing nature of the disease.

CASE II.

J. L., aged 38, a shepherd, came to me on July 15th, 1908, complaining of pain and stiffness of the right leg on walking. On examination I found that the lower third of the right femur was markedly thickened; there was a depressed adherent scar, 2 in. long, situated on the inner side of the lower third of the thigh. The skin around this was thickened and stained a brownish-red colour; deep pressure over the scar region revealed a spot of distinct tenderness; there was no fluctuation, although the skin and underlying tissues were much swollen, and he had no fever; his general health was apparently good. He stated that he had suffered from bone disease in the part complained of when he was 10 years old, and that "little bits of dead bone had come away" then. Six years before I saw him he had an abscess in the part complained of, which was treated in the Royal Infirmary, Glasgow, but no bone was removed. I diagnosed his condition as chronic osteomyelitis with an acute exacerbation, and ordered him to lie up and rest his leg for a week or two. Hot antiseptic fomentations were applied to the inner side of the thigh over the painful area. He did not improve; his temperature, previously normal, rose to 101° F., and the area of redness and tenderness increased. A large bulla formed over the scar area; this was opened and dressed antiseptically; it contained only clear serum. I expected to find an abscess form and point at any time, and at every visit I went prepared to have to open it. His condition remained unchanged for three weeks, when I tried, under Sir Anthony Bowlby's recommendation, the effect of 15 grain doses of potassium iodide t.i.d. and mercurial ointment applied on flannel to the painful part. He began to improve shortly after, and the pain and tenderness subsided, so that he was able to resume his occupation. The swelling also diminished, but the area round the scar remained firmly indurated.

The slow progress of this case meant a period of over twelve weeks' disablement for the patient, and though his painful symptoms subsided without requiring operation, I have no doubt that his leg will again prove a source of trouble to him. Sir Anthony Bowlby, who happened to be resident on holiday in the district at the time, very kindly offered me his opinion on the case. I had been

rather puzzled owing to its rebellious nature, and feared that a sequestrum was forming and the inflammatory symptoms had developed in the process of separation. I remember Sir Anthony Bowlby then informed me that old-standing cases of osteomyelitis frequently gave trouble in after-life, and his opinion was that the periosteum at the seat of the old disease was in a spongy, hypervascular condition, which readily gave rise to subperiosteal haemorrhages, as a result of slight injuries. Suppuration did not always ensue, although the parts frequently appeared on the point of breaking down. He related the case of a patient on whom, when a boy at Eton, he had operated for acute osteomyelitis of the humerus, and who had frequent relapses in later life, when the parts around the seat of the old disease assumed a very threatening appearance. I am much indebted to Sir Anthony Bowlby for his kind assistance in the case above mentioned, as well as in other cases in which he favoured me with his advice.

CASE III.

J. W., aged 24 years, a law clerk, came to me on February 8th, 1912, complaining of weakness of the right arm and hand and pain and tenderness at the upper and inner side of the right humerus. On examination I found the right arm about 3 in. shorter than the left. The muscles of the arm and forearm were atrophied, and the limb looked very much stunted, and was carried in a limplike condition at the side of the body. There was a scar about $\frac{1}{2}$ in. long situated on the upper third of the right arm at its inner side, and pressure over this revealed a spot of tenderness. The movements of the shoulder-joint were quite free, but caused some pain at the seat of the scar. He said that when he was 12 years old his arm first began to trouble him, causing him great pain, and that the scar on the inner side was the result of the opening of an abscess in that situation by the doctor who attended him. Previous to the onset of this trouble his right arm was the same length and as strong as the left. His present condition was unaccompanied by fever, although the skin around the old scar was reddened and tender. He had been lifting some heavy ledgers the week before he came to me, and blamed that as the exciting cause of his condition. Two years before he came to me he had been in the Paisley Infirmary under the care of a surgeon there. He said that his arm was x-rayed, but no operation was performed, and he was discharged without any improvement. I advised him to rest the arm in a sling, and, by the use of potassium iodide internally and mercurial ointment applied locally on a piece of flannel, the inflammatory symptoms subsided, but the weakness of the arm and hand still remained.

This was another instance of recurrent osteomyelitis. The shortened arm was, no doubt, the result of injury to the upper epiphysis of the humerus at the time of his first attack. No operation on the bone was done on that occasion, and it is just possible that, if the bone had been trophied and the medulla curetted, his epiphysis would have been saved. The disastrous results to the arm in this case are a serious lesson that periostitis with abscess, in the limb of a growing boy, should always be regarded as strongly suspicious of accompanying osteomyelitis, and treatment ought not to end in simply evacuating the abscess, but search should be thoroughly made for a primary focus of osteomyelitis in the bone shaft on the diaphyseal side of the epiphysis.

The two cases reported above serve to show that in bones previously affected with pyogenic organisms the organisms may still persist in the parts, and give trouble years after the primary disease has subsided and the patient thinks himself quite free. In a lecture entitled *Clinical Illustrations of the Persistence of Disease Germs in the Human Body*, Sir Hector C. Cameron says:

I do not think it is sufficiently appreciated what a lifelong trouble this infantile infective disease of bone often proves itself, laying a man aside from business time after time during his life. Twice I have seen men over 70 years of age laid up by most serious and painful abscesses, occurring in each case in connexion with a tibia from which in early life numerous and large sequestra had separated and been removed after long-continued suppuration. In each the tibia was greatly deformed and showed the depressed scars of many old sinuses, and more than one relapse had occurred during the long life of both men. But recurrence is not always confined to the part in which the primary infection takes place. It may occur years afterwards in another part of the body.

I have never used any antistaphylococcal serum in the treatment of relapsing osteomyelitis. In acute cases it is said by those who have tried it to be of no value. It certainly could not take the place of incision with the knife, but in the recurrent type of case, such as the last two described above, it would probably have some value and would be well worth a trial.

PRIMARY SARCOMA OF BOTH BICEPS MUSCLES.

By E. SCOTT-CARMICHAEL, M.B., F.R.C.S.,

ASSISTANT SURGEON TO THE ROYAL INFIRMARY AND HOSPITAL FOR WOMEN, EDINBURGH.

The condition found in the following case seems sufficiently rare to justify its publication; I have not been able to find in the literature a record of this pathological condition affecting the biceps muscle.

The interest of the case lies in the nature of the tumour, the fact that it was bilateral, and situated in identical positions in the biceps muscles.

A working man, aged 56, was sent to hospital on July 27th, 1912, complaining of a swelling in the right upper arm, with a smaller and similar swelling on the left upper arm. He first noticed the swelling on the right side in April, that on the left side being noticed about a week before he came to hospital. They caused him no pain or inconvenience, but he thought his

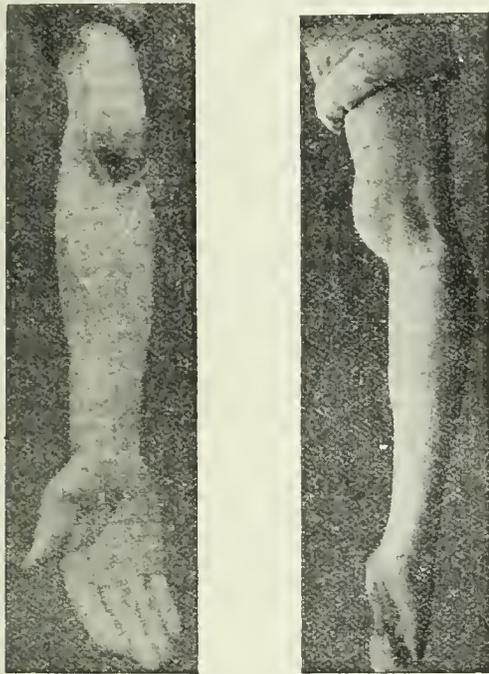

Fig. 1.

biceps muscle was more prominent than it ought to be, and therefore came for advice.

Condition on Examination.

The patient had symmetrical swellings in the lower part of both biceps muscles. They were painless, rather firm and elastic, and of the consistence of muscle in contraction. The swelling in the right muscle was about the size of a large hen's egg, that in the left of a small marble. There was no discoloration of the skin over them, and the swelling was limited to the biceps muscle, except that on the right side there was a small pea-like nodule in the brachialis anticus muscle. The patient denied any syphilitic history, and there was no history of an injury.

The general appearance and characters of the swelling in spite of the history led me to make a provisional diagnosis of gummata in both biceps muscles, and the patient was put upon antisyphilitic treatment for a fortnight.

Operations.

It was thought advisable, however, to explore the smaller swelling on the left side under a local anaesthetic. This was done, and a semisolid tumour was shelled out of a fairly well-defined capsule. The tumour had a yellowish-grey appearance, but showed dark areas, obviously haemorrhages, throughout its substance. The pathological report was that the tumour was of a sarcomatous nature, consisting of mixed round cells.

The patient was therefore admitted for operation for the tumour in the right biceps muscle, which was performed on August 5th.

The tumour was removed along with a large portion of the lower half of the biceps muscle, a small slip being preserved posteriorly behind the musculo-cutaneous nerve. The nodule in the brachialis anticus was also removed.

PATHOLOGICAL REPORT BY DR. JAMES MILLER, PATHOLOGIST, ROYAL INFIRMARY.

The tumour in the biceps measured 3 by 1½ in. It was grey in colour, with numerous small haemorrhages, especially at the margins and some opaque white areas of necrosis in the centre.

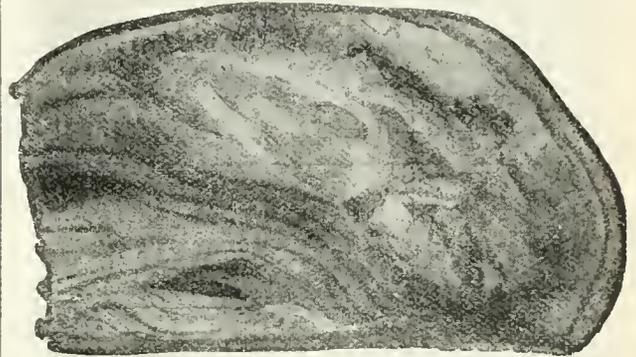

The tumour in the brachialis anticus measured 1½ by ½ in. It was more haemorrhagic and less well defined.

Microscopic Report.—The tumour was uniformly cellular except for bands of well-developed tissue running through it. The cells were rounded or polygonal, moderately large, but varying considerably in size. The nuclei were large, rather pale, staining with a wide-meshed chromatin network. Mitotic figures were fairly frequent. Occasionally larger cells were met with containing six, eight or more nuclei. There was very little stroma between the cells. Many of the vessels were fairly well developed, but some were thin walled. No haemorrhage or necrosis was found in the portion examined. Summing up the histological characters of the tumour, it may be called a medium-sized round-cell sarcoma.

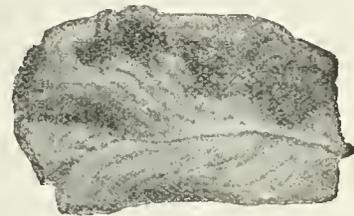

After-History.

The patient since the operation has been under treatment with Coley's fluid. He reported himself on November 2nd,

Naked-eye Appearance of Tumours.

Right biceps muscle with tumour.

Right brachialis anticus muscle with tumour.

Fig. 2.—Drawings to show sarcomatous growth in right biceps and brachialis anticus muscles.

when the actions of the biceps at the elbow and superior radioulnar joints were normal, except that they were slightly weaker than the left; he expressed himself highly satisfied with the power and use of his arm.

There was no sign of any recurrence of the growths.

DR. WALTER HUNTER, M.O.H. for the West Bridgford Urban District, has been appointed to the Commission of the Peace for Nottingham.

The annual report of the Surgeon-General of the United States Navy, published on December 11th, states that while contagious diseases have markedly diminished among the men in the navy, mental affections have increased. About 28 per cent. of men enlisted from the Southern States are infected with hookworm; 50 per cent. of these come from South Carolina and Alabama.

ON December 17th a circular was sent to the medical practitioners of New York informing them that in future they would be expected to report promptly all cases of venereal disease coming under their notice. The name and address of the patient are not to be given, but the sex, age, and the character and stage of infection, with any other relevant information, must be stated. A supply of cards to be used for the reports will be furnished by the Health Department on application. The Wassermann test is made free of charge by the Department, which also provides facilities for gratuitous bacteriological examinations in cases of suspected gonorrhoea.

COCAINE POISONING.

BY

CHUNILAL BOSE, M.B., F.C.S.

A CHEMICAL EXAMINER TO THE GOVERNMENT OF BENGAL; FELLOW OF
THE CALCUTTA UNIVERSITY.

Not many years ago cocaine was a drug hardly known to the people of India outside the medical profession, and now, sad to reflect, it has taken a vigorous hold of a certain class of people in this country both in town and village. In Calcutta, despite the vigilance of the excise authorities, and notwithstanding the stringent measures directed by the Government against the possession and the sale of this substance by unlicensed persons, there is reason to believe that the cocaine habit has much increased and is rapidly spreading. Moreover, it is perhaps safe to say that a considerable proportion of the crimes committed in this city may be traced to the utter moral depravity which follows the habitual use of cocaine. The daily papers are full of the reports of raids on cocaine dens and of cocaine seizures, and the references made to the Chemical Examiner in connexion with the illicit import and the unlawful possession of cocaine are rapidly and progressively on the increase, as may be seen from the figures given below, compiled from the annual reports of the Chemical Examiner's Department, Bengal, for the last four years:

| Year. | | | | Number of Samples of Cocaine Seized and Sent for Examination. |
|-------|-----|-----|-----|--|
| 1908 | ... | ... | ... | 125 |
| 1909 | ... | ... | ... | 243 |
| 1910 | ... | ... | ... | 621 |
| 1911 | ... | ... | ... | 2,138 |

Although the cocaine habit has been described by Erlenmeyer as the third scourge of humanity, the two first being alcohol and opium, yet in some respects cocaineomania is more disastrous in its effect on the moral, intellectual, and the physical well-being of the subject. Professor Berkeley, of the Johns Hopkins University, has observed that he would trust a cocaine debauchee even less than he would a morphinomania, stating as his reason that the moral rectitude and the will power of a cocaine eater always suffer more severely. In Taylor's *Principles and Practice of Medical Jurisprudence*, it is said, referring to chronic cases, that,

like morphia, the habit of cocaine seems to sap the moral fibre of its devotees, so that they become reckless of everything in their efforts to obtain their dose—lying, cheating, stealing, nothing comes amiss to them, so that their craving is satisfied.

Dr. A. H. Brundage, Professor of Toxicology in the Brooklyn College of Pharmacy, remarks that the cocaine habit

is the most seductive, dangerous and mentally, physically and morally destructive of all the drug habits. Cocaine fascinates by the promptness with which it relieves all sense of exhaustion, dispels gloom, and exhilarates, producing a sense of happiness and well-being which transports at once to a longed-for Elysium. Primarily the after-effects are scarcely perceptible, but through continual indulgence an intense craving for the drug or its effects is produced.

It is the utter banishment of gloom and the delightful sense of *bien-être*, which together are directly responsible for the intense craving, characteristic of the habit and productive of the physical, mental and moral degradation and depravity which ensue.

Professor Berkeley reports that the body weight sinks rapidly, even one-fifth to one-third of it being lost within a few weeks.

Dr. Kailas Chandra Bose, Rai Bahadur, C.I.E., in the March number of the *Indian Medical Gazette*, 1902, recorded several cases of the habitual use of cocaine, and summarized the principal symptoms noticed. These were headache, anorexia, emaciation, insomnia, a blackening of the tongue and teeth, dilated pupils, rapid and feeble, sometimes irregular or intermittent pulse, fainting attacks,

hallucinations, incoherent speech and convulsions. In one case there was obstinate diarrhoea, and in another there were symptoms of acute mania.

Prognosis.

Professor Berkeley observes that the prognosis is "most gloomy," for,

even though the patient recover from one attack, he very frequently relapses into his evil habits. In the most favourable cases there remains an extraordinary weakness of the will power, with accentuated tendency to relieve the physical and psychical languor by substituting for the cocaine alcohol, morphine, and other nervines in large quantities.

Dose.

The medicinal dose of the hydrochlorate of cocaine is $\frac{1}{4}$ to $\frac{1}{2}$ grain. The minimum fatal quantities on record are $\frac{1}{10}$ grain hypodermically, 12 to 15 grains by the mouth, and 22 grains by rectal injection.

A few cases have been recorded in European practice in which the drug either proved fatal or produced very severe symptoms when it was injected hypodermically or passed into the natural cavities prior to a surgical operation or administered internally. In one case the injection of $3\frac{1}{2}$ grains into the breast of an adult woman was immediately followed by epileptiform convulsions, and in twenty minutes by death. In another instance, the hypodermic use of $\frac{3}{4}$ grain in a woman, aged 71, proved fatal in five hours. In the *Pharmaceutical Journal*, 1886 (iii, 16, 721), a case is recorded in which the hypodermic injection of $\frac{1}{20}$ grain caused dangerous symptoms in a girl aged 12 years. On November 2nd, 1895, a case was reported in the *Lancet*, in which 2 drachms of a 10 per cent. solution of cocaine (representing 12 grains of the drug) taken internally for the relief of a toothache caused death in twenty minutes, with epileptiform convulsions. In another case $\frac{1}{10}$ grain applied locally to the conjunctiva gave rise to dangerous symptoms: while in still another instance acute manifestations followed the injection of half a drachm of a 10 per cent. solution—that is, grains iij—into the urethra. A rectal injection of 22 grains of cocaine has been productive of death.

The prominent symptoms in all these acute cases of poisoning consisted of dryness and numbness of the mouth and throat, vertigo, dyspnoea, failure of the special senses of sight, hearing, and smell, numbness of the extremities, rapid and feeble, sometimes irregular or intermittent pulse, muscular tremors, a staggering gait, dilated pupils, epileptiform, sometimes tetanoid convulsions, cyanosis, and insensibility.

The practical lesson to be learnt from cases like these is the extreme care which is necessary in administering the drug for the production of local anaesthesia in dental practice and surgical cases.

No case has yet been recorded in Indian medical practice, so far as I have been able to ascertain, of acute cocaine poisoning with a fatal result. In the twenty-seven years during which I have been connected with the Chemical Examiner's Department in Bengal, I have not had a single case of fatal cocaine poisoning referred to me, except the three which I am about to recount, all of which occurred within the past six months. Not only does this fact appear to indicate that the drug is very easily procurable by the common people, in spite of the strict regulations against it, but it also seems reasonable to infer that the people are getting to be more familiar with the uses to which the substance can be put.

CASE I.

B. D., a Hindu male, aged about 25 years, a resident of Calcutta, and by occupation a pressman, was addicted to alcohol and to cocaine. On May 28th, 1912, he played cards with his friends up to a late hour of the night and distributed pan betely with cocaine to his companions, taking the largest share himself. He left the place soon after, and at 2.30 a.m. on May 29th, he was found lying unconscious and groaning at a neighbour's doorway. Medical aid was summoned, the man was removed to hospital, but died on the way there.

Post-mortem Appearances.

Body poorly nourished; rigor mortis present; pupils normal. The lungs, the kidneys, the brain and its membranes and the mucous membrane of the stomach were found congested. The stomach contained about 2 oz. of recently taken food without any special odour.

Chemical Analysis.

The viscera of the deceased, and a small quantity of urine found in his bladder were forwarded to me for chemical analysis, and I detected cocaine in both. I could detect no other poison in the viscera. The dose taken by the deceased could not be ascertained.

CASE II.

K., a Hindu female, aged about 23 years, a woman of the town, was in the habit of taking cocaine. She left home at about 1.30 a.m. on August 29th, 1912, and returned at 6.30 a.m. a few hours later. She was seen to be staggering while washing her mouth at a hydrant hard by. Very soon afterwards she lay down, became unconscious, and in a few minutes she died.

Post-mortem Appearances.

Body fairly nourished; rigor mortis present; pupils slightly contracted; there were no marks of violence on the body. The brain and its membranes, the liver, the spleen, the kidneys, the ovaries, the bladder, and the mucous membrane of the stomach were found congested. The right heart was dilated, and contained dark fluid blood. The stomach contained about 3 oz. of recently taken vegetable food without special odour.

Chemical Analysis.

The viscera in the case were sent to me for chemical analysis, and I detected a marked quantity of cocaine in them. I detected no other poison in the viscera. Neither the dose taken nor the fatal period could be ascertained in this case.

CASE III.

M. K., a Hindu female, aged about 20 years, lived with her husband in Calcutta. On October 17th, 1912, she visited her sister-in-law, L. K., and at about 7 p.m. on the following day she offered L. some white powder which she believed to be a specific remedy for acidity and indigestion. They each took some of the powder, and within half an hour they became ill and then unconscious. M. died soon after, but L. regained consciousness about four hours later, and recovered at the Medical College Hospital.

Post-mortem Appearances.

Rigor mortis present; body well-nourished; pupils slightly contracted; there were no external marks of violence visible. The brain, the meninges, and the lungs were highly congested. The liver, the spleen, the kidneys, the larynx, and the trachea were also found congested. The stomach contained about 9 oz. of sour-smelling food.

Chemical Analysis.

The viscera were forwarded to me for chemical analysis and I detected cocaine in them. There was no other poison present in the viscera. The dose taken by the deceased could not be ascertained, but death took place in this case in about half an hour.

CASE IV.

The case of L. K., sister-in-law of victim No. III, constitutes a fourth case, but it did not terminate fatally. The dose taken rendered the patient unconscious in half an hour, and kept her so for four hours. Her pulse and respiration are said to have been normal during her stay in hospital and her pupils slightly dilated.

The stomach washings were sent to me for chemical analysis, and I detected cocaine in them but no other poison.

Method of Detection.

In all these cases I extracted cocaine by Stas's process. The ethereal extract, on being applied to the tongue, produced very marked anaesthesia. When this was dissolved in dilute hydrochloric acid and evaporated to dryness in a water bath it left a residue which gave well-marked reactions with the principal alkaloidal reagents.

The hydrochlorate thus obtained, when treated with a solution of picric acid, gave a copious precipitate which under the microscope showed the usual long needles arranged in star-shaped bundles.

A fresh portion of the residue treated with a drop of a strong solution of alum and next with a drop of potassium permanganate solution yielded a deep reddish-brown precipitate. The latter, under the microscope, showed the characteristic rectangular plates.

Another portion of the residue was treated with strong nitric acid and evaporated to dryness. The addition to it at this stage of a few drops of an alcoholic solution of potash caused the characteristic peppermint-like odour of ethyl benzoate to evolve.

A 5 per cent. solution of chromic acid added to a solution of the hydrochlorate produced an abundant precipitate which disappeared on shaking. The subsequent addition of a drop of strong hydrochloric acid caused a copious yellow precipitate.

Treatment.

In acute cases the stomach pump should be used, as the anaesthetic effect of the drug on the mucous membrane of the stomach might interfere with the action of an emetic. Hot coffee and stimulants, such as brandy, ether, and ammonia, should be freely given, and hypodermic injections of ether, strychnine, and digitalis might be desirable. In convulsions I may say that chloroform is useful. Morphine appears to possess an antidotal action against cocaine, and

it might be used hypodermically. Inhalation of amyl nitrite has also been recommended. Perfect rest in a lying position should be enjoined in all cases.

My best thanks are due to Captain St. John Moses, M.D., D.Sc., F.R.C.S., F.R.S.E., I.M.S., police surgeon of Calcutta, for kindly supplying me with the notes of the *post-mortem* examination of the three fatal cases and for generally revising this paper.

AN EXPERIMENT TO ILLUSTRATE THE EFFECT OF SIZE OF POPULATION ON THE RATE OF SELECTION OF NEW BACTERIAL RACES.

By W. J. PENFOLD,

ASSISTANT BACTERIOLOGIST, LISTER INSTITUTE, LONDON.

IN the course of a research into the question of the selection of a variant of *B. typhosus* in respect of dulcitate-fermenting power, the following experiment was designed with the view of ascertaining whether the bulk of the fluid medium in which the organism was grown had any marked influence on the rate of selection of the new race.

A set of nine beakers, each beaker being 5½ cm. in diameter, and a set of nine test tubes, each tube being 1 cm. in diameter, were filled to the depth of 1 in. with the same sample of dulcitate peptone water of the following composition, and containing litmus as indicator :

| | |
|------------------------|----------|
| Peptone (Witte) | 20 grams |
| Dulcitate | 5 " |
| Salt | 5 " |
| Water | 1 litre |

The dulcitate-peptone water was rendered faintly alkaline to litmus and sterilized by steaming on three successive days. The tubes and beakers were of the same height, so that the condition of aeration of the medium was strictly similar in each series. This precaution is necessary, as it is well known that alkali formation from the peptone is greatly favoured by free access of air. Each member of these two series was inoculated with the same quantity of *B. typhosus* broth. The strain selected for this purpose was one which, from previous testing, was known to acquire the power of fermenting dulcitate more slowly than the majority of strains. All the cultures were incubated at 37° C.

The time taken to produce acidity in the original beakers and tubes is given in Table I, and it will be noted that no test-tube culture became acid during the period of observation (twenty-six days).

After eight days' growth subcultures were made from each tube and each beaker into 6 c.cm. quantities of dulcitate-peptone water contained in ordinary test tubes. The times taken to produce acidity in these subcultures are given in Table II. Again no subculture from the original test tubes became acid.

After a further period of seven days—that is, fifteen days from the commencement of the experiment—subcultures were again made from the original beakers and tubes into ordinary 6 c.cm. quantities of dulcitate broth. The times required for appearance of acidity are indicated in Table III.

These various tables show that a fermenting race is much more quickly produced by growth of the organism in large quantities of culture medium than in small quantities. If the original small tubes be inoculated with small doses of *B. typhosus* broth and the beakers with large doses, the sizes of these doses being related to each other as the volumes of the dulcitate broths to be inoculated, the fermenting race is again found to arise more quickly in the large quantities.

The original small tubes never developed an acid reaction, and their subcultures likewise did not, within the limits of observation. The large cultures in beakers developed an acid reaction in every case by the fifteenth day. Their first subcultures showed three with a full acid reaction by the tenth day. In the second subcultures from the original beakers nine became fully acid in reaction by the sixth day.

The experiment above detailed was led up to by a preliminary experiment performed with a *B. typhosus* strain which was known to acquire the power of fermenting

dulcitate more quickly than the above-mentioned strain. The details of this earlier experiment were as follows: 50 c.cm., 20 c.cm., and 5 c.cm. quantities of dulcitate-peptone water were put up in three series. In each series there were ten such quantities. Every member of the different series was inoculated with the same dose of *B. typhosus* broth. On the tenth day after inoculation all the broths were subcultured into ordinary test tubes containing 6 c.cm. quantities of dulcitate broth, and the times required

to produce acidity were noted. The results are given in Table IV.

It will be observed that all the subcultures from the initial cultures of 50 c.cm. showed full acidity by the second day. The subcultures from the 20 c.cm. quantities showed four with a full acid reaction on the second day. In the case of the subcultures from the 5 c.cm. tubes not one showed a full acid reaction on the same day.

We conclude, therefore, that, other things being equal,

the larger the culture the sooner will a new race be selected out. This more effective selection from a large population is mainly due to there being more extreme variants from the mean in the large population. The explanation is not chiefly to be sought in the fact that in the larger cultures a few more generations are required to produce the same population per cubic centimetre. By inoculating into constant volumes of dulcete broth seedings of *B. typhosus* of different size the number of generations required to produce the same population per cubic centimetre is altered, but the tubes with small seedings do not give regularly earlier acidity than the tubes with large seedings.¹

Since bacterial selection can be conducted more efficiently from a large population, it would appear probable that the selection of variants by animal passage would, other things being equal, be more successful in a large rather than in a small animal.

CONCLUSION.

The rate of selection of dulcete variants of *B. typhosus* varies directly with the size of the population from which the selection is made.

MEDICAL, SURGICAL, OBSTETRICAL.

TOXIC SYMPTOMS AFTER TAKING A PROPRIETARY PILL.

IN the *JOURNAL* for May 11th, 1912, and in subsequent numbers correspondence took place on green urine due to a proprietary pill, and while in two cases it was stated that those who took the pills showed symptoms of illness which might be referable to the pills, the majority of the cases seemed mainly interesting from the fact that green urine was passed. The correspondents at that time all wrote from parts of England. The proprietors of the pills are now evidently transferring their energies to Scotland, for besides the following case, which is of interest, a practitioner in the town has informed me that one of his patients has been taking the pills without, however, showing any symptoms except the green urine.

J. M., a mason, had for some time felt a pain in the back on rising in the morning, but this passed off soon after starting work. He thought his kidneys were affected, and when a sample of kidney and bladder pills was handed in at his house he thought he would give them a trial. On October 14th he took one pill before dinner, one before tea, and two before going to bed, as directed on the box. That evening on passing urine he noticed that it was greenish, but as the instructions informed him to expect this he was in no way alarmed. On October 15th he took one pill before breakfast, and now noticed small round spots like "heat spots" appearing on the front and back of the neck. Another pill was taken before dinner, and by this time the spots had greatly increased, appearing now on the face, and the neck had become so swollen that he had to take off his collar and put on a muffler before he could go out to his work. He began to think that the pills might be the cause of his condition, as previously he had been in good health except for the slight backache. He had taken six pills in twenty-four hours, and now ceased taking them. By evening the eyelids were swollen and felt stiff and heavy, the right eye being almost closed. The spots were still present on the face, neck, and upper part of the chest, and felt hot and itchy. A poultice with vinegar and water added was applied to the neck and diminished the swelling, but on October 16th his face had such a blotchy and puffy appearance that he could not go to work. He called to see me on the evening of October 17th, and the red papular eruption was very marked on the face and neck, while below both the lower eyelids there was marked oedema, the skin pitting on pressure. Several of the papules were scaly on top, while in various places on the face and neck there was a fine desquamation. Since he had left off taking the pills his condition had improved, and by October 19th all trace of the eruption or oedema had disappeared. The urine two days after

ceasing to take the pills had lost its greenish colour, and was in no way abnormal.

Dunfermline.

MARTIN SMITH.

THE RISK OF ECLAMPSIA RECURRING IN A SUBSEQUENT CONFINEMENT.

A VERY personal interest concerning the above impels me to sound a note of warning to those of the profession who are especially concerned in obstetric practice, and who may be called upon to express an opinion in the matter. For myself, I can never again give a hopeful prognostication, for the following reasons, as exemplified in two recent cases.

CASE I.—Four years ago a lady, aged 36, the wife of a major in the Indian Medical Service, came home to be delivered of her first child. She was advised to fortify herself for the event, somewhere in Scotland for preference, and, accompanied by her husband, she proceeded thither, a sheltered seaside resort being selected as the temporary home. Analyses of the urine were made from time to time, and all went well until early in the seventh month, when eclampsia gripped her with great suddenness and violence. Thanks to a most excellent village doctor—one of God's good men—and to his promptness in securing the best of skill from Edinburgh, she was spared on this occasion, though convalescence was very protracted. Eighteen months later she was back in Bengal, and in a year, becoming pregnant once more, she was again sent home. Every precaution was taken, nothing apparently overlooked; but, despite every attention and treatment, including Caesarean section, she died in an eclamptic state (at about the end of the seventh month of pregnancy).

CASE II.—A lady, aged 30, daughter of a noted surgeon in a Canadian city, and therefore, as in the case of the former patient, able to secure the best attention, had the same experience exactly as regards the incidence of eclampsia in each of her two confinements, with this exception, that Providence spared her life and that of her infants. Albuminuria in her case was transient during the sixth month of her second pregnancy and absent in her first, save at the crisis. Labour in each instance was, of course, induced and at about the eighth month.

As both the foregoing cases occurred in my family circle, is it any wonder that for the future I shall not have much use for the actuary, nor time for his statistics, and that I shall, should the occasion arise, feel it to be my duty to urge on those interested that there is indeed a very grave danger of a repetition of what might easily lead to irreparable disaster?

Putney.

ATHELSTANE NOBBS, M.D.

ATTEMPTED SUICIDE BY DRINKING LYSOL.

ON October 18th I received an urgent call to a patient, aged 63 years, suffering from melancholia, who had swallowed an unknown quantity of lysol. Two days previously I had seen her for this nervous breakdown, and had warned the family to be careful and watchful, as she would probably try to take her life. It never occurred to them that she would drink the lysol, which was used for disinfectant purposes, and was placed upon the washstand.

I found her sitting upon the bed, coughing and hawking up frothy, thick mucus: her voice was rough and hoarse, as if some of the fluid had gone into the larynx. The mouth inside was whitish, and the lips excoriated; the characteristic odour of phenol was present. Upon swallowing she made a wry face, and held her hand to her chest as if the act was painful; she was excited and talkative between the spasms of retching and spitting, and informed me that the devil was inside her; nothing I could give her would do her any good—God had given her up, and she could not die whatever she took. She drank the lysol at 3 p.m. The family discovered it at once owing to the smell and the convulsive coughing, and immediately gave her three glasses of milk. This was vomited soon after she drank it, the vomit smelling strongly of lysol.

It was 4.30 p.m. when I first saw her, and, taking into consideration her general condition, the fact that she had vomited the contents of the stomach soon after taking the poison, and the length of time since the act occurred, I did not wash out the stomach, but contented myself with giving her a solution of magnesium sulphate, which she

took after a little persuasion, and evidently with great pain. As her general condition was fair, I left with instructions to call me if there was any change for the worse, and sent round a stimulant mixture to be taken if required.

Next morning I saw her again. She had slept well during the night, and, apart from her mental symptoms, was apparently very little the worse for her escapade. The tongue had a distinct bluish tint, but was not excoriated. I think she had pain in the alimentary tract, but everything was accredited to snakes, devils, and what not by the patient.

The relatives could not be certain of the amount of lysol in the bottle, but apparently the amount taken was about half an ounce. Martindale mentions that lysol is supposed to be less poisonous than carbolic acid. The early and copious vomiting after taking the milk seems to have been the saving clause in this case.

Bayville, S. Africa.

EMPHYEMA IN AN INFANT.

ON March 24th, 1912, I was called to see a baby aged four months who had suffered from repeated attacks of bronchitis.

The symptoms resembled those of abdominal colic, and rales and rhonchi were present in the chest. The temperature was 101°. On March 25th the child was still in great pain and a rectal enema was given. On the following day dullness appeared over the base of the right lung with lessened breathing. The area of dullness gradually increased, and on using an exploratory needle pus was found. Paracentesis was performed, and about 2 oz. of pus drawn off. The next day it was necessary to do a thoracotomy, which the little patient stood well, and a drainage tube was left in the opening.

The baby gradually improved, so that on the tenth day the tube was removed, and the wound healed in a few days.

Since then the child has had an attack of whooping-cough, but is now strong and healthy.

The following are the points of interest in the case:

The age of the patient, the absence of any history of pneumonia, that the symptoms pointed to colic, and that thoracotomy proved efficient.

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

JENNY LIND INFIRMARY FOR CHILDREN, NORWICH.

A CASE OF STRANGULATED INGUINAL HERNIA IN A CHILD OF 18 MONTHS, CONTAINING THE CÆCUM AND VERMIFORM APPENDIX.

(By B. P. RIVIERE, F.R.C.S. Eng., Assistant Surgeon.)

As several cases of strangulated hernia in young children have recently been reported in the *BRITISH MEDICAL JOURNAL*, the notes of the following case, which came under my care, may be of interest:

S. E., a male child aged 18 months, was admitted on July 9th, 1912, the history being that he had had a rupture on the right side since birth, which had now been down for four days. During these four days the bowels had not been open, and for the last twelve hours the child had been vomiting.

On admission the child looked ill, with somewhat sunken eyes and distended and rather rigid abdomen. In the right groin was a tense swelling in the position of an inguinal hernia, irreducible, and with no impulse on coughing.

Two hours after admission the child was anaesthetized, and as the swelling was still found to be irreducible, it was cut down upon. On opening the sac it was found to contain the cæcum and vermiform appendix, which were

somewhat congested in appearance and tightly constricted by the neck of the sac. The bowel could not be reduced, nor could any more bowel be pulled down until the neck of the sac had been divided. This was done, and the bowel returned to the peritoneal cavity. The sac was then ligatured and removed, the aponeurosis of the external oblique sutured, and the wound closed.

The child made an uninterrupted recovery, and was discharged on August 1st.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

STAFFORDSHIRE BRANCH.

Stoke-on-Trent, November 21st, 1912.

Dr. J. A. COBB, Vice-President, in the Chair.

Cases.

DR. ALLARDICE showed (1) a boy whom he had operated upon for *Chronic middle-ear disease with abscess in the temporo-sphenoidal lobe*; (2) a girl whom he had operated upon for *Lateral sinus thrombosis due to middle-ear disease*, the internal jugular vein having been ligatured in the neck. Dr. Allardice read short notes of the cases, with interesting details of the technique employed, and it was seen that both patients had made a rapid and most satisfactory recovery.

Tuberculin: When and When Not to Use it.

DR. E. C. MYOTT read a paper on this subject, and showed eight patients whom he had treated with tuberculin. He also gave a lantern demonstration. He said tuberculin should not be given without a clear week's genuine temperatures, taken four-hourly. Three to ten minutes' retention in the mouth might be necessary for an efficient record. If the patient had not sufficient perseverance for this treatment should not be begun. The practitioner should learn to catch the temperature fake, for instance, registering successively the same. Patients should be divided into febrile and afebrile. The afebrile might be passed for treatment. Afebrility did not, however, betoken the absence of a mixed infection. There might be a tox-immunity to the mixed germ which might enter upon a phase of renewed activity during a negative tuberculo-opsonic period. Where febrile, if the patient were only recently ill or worse, rest in bed should materially modify the purely tuberculous infection. If the temperature were satisfactorily falling one could afford to wait until the excessive autoinoculation had ceased before commencing the injections. These should then be of a mild type, B.E. or T.R., of small calibre $\frac{1}{100}$ to $\frac{1}{200}$ c.cm., of sufficient interval, five to ten days. If the pyrexia were persistent it should be noted whether continuous or intermittent in type, or both. The sputum should be examined for complicating bacteria in lung cases. Where present, a secondary vaccine should be prepared. A few cases did well with the exhibition of tuberculin alone. The specificity of the secondary vaccine should be verified before starting the tuberculin. It should be remembered that tuberculin would not cleanse the mouth, empty the rectum, or drain pus pockets. Therefore one should avail oneself of hygienic measures—mouth, lung, and intestinal antiseptics—also prompt surgical assistance. Where treatment had been begun already, it should be suspended upon the advent of a concomitant affection—for instance, acute tonsillitis, influenza. Although hypersensitiveness and immunity were both specific, yet they drew upon the one general fund or treasury of the natural resistance. The patient's interpretation for a reaction, "Caught a cold," should not be accepted unless other members of the household had had one. Every result was not due to tuberculin; one boy had hæmaturia and lost 5 lb. whilst preliminarily taking his temperatures. Too long a gap should not be allowed between the injections, especially where employing the soluble form; the patient might become hypersensitive. Slight hæmorrhage was not an indication for cessation, only

for caution, unless backed up by other signs, subjective or objective. Subjective signs might be the only indications to go upon in chest cases. Objective signs were well to the fore in all surgical types—marked skin reaction and induration, ready temperature response. Tuberculin should not be given to a patient who had got up from bed to come to the doctor's surgery. One could not differentiate the effects of the unwounded autoinoculation and the injection. Febrile cases of all sorts were best started on the treatment in bed at home, hospital or sanatorium. Patients should be treated "socially"; the old ones balanced up the young, and prevented the raw recruits from stampeding in the early stages. One should not allow oneself or the patient to be discouraged by an initial loss of weight. An afebrile should not be turned into a febrile case by overdosage; it was better to run the risk of producing a hypersensitiveness, which sometimes followed the employment of too small doses. One should not attempt the bold finesse of one's teacher when one first began. Dr. Myott's paper was discussed by Drs. RIDLEY BAILEY and FORTUNE, and Dr. MYOTT replied.

Prophylaxis in Eye Work.

Mr. S. McMURRAY read a paper on this subject. He strongly recommended that endeavours should be made to find the cause of eye troubles. If the exciting cause were found many eye diseases could be prevented or at least limited.

Ophthalmia Neonatorum.—He suggested the use of 1 per cent. AgNO₃ in the eyes of all children at birth.

Toxic Amblyopia.—Limitation of the amount of tobacco and alcohol consumed after the age of 40, especially in the case of persons suffering from Bright's disease or diabetes and when the occupation becomes more sedentary.

Cataract.—Prevention should aim at delaying the development of arterio-sclerosis.

Glaucoma.—Prophylaxis should aim at a quiet life, freedom from worry, and an antiarthritic régime.

Eczematous Ophthalmia.—Fresh air, good food, and cleanliness.

Trade Injuries.—The tear passages should be examined in all cases of corneal abrasion, and, if found to be diseased, should be washed out.

Miners' Nystagmus.—Periodic examination would allow of early recognition and so shorten the time of incapacity.

He also recommended the correction of all errors of refraction in these cases.

Mr. McMurray's paper was discussed by Drs. RIDLEY BAILEY, DICKSON, KING, ALLOCK, and FULTON, and Mr. McMurray replied.

Specimens.

Dr. HIND showed a bullet and radiogram from a case in which he had successfully removed a *Bullet from the brain of a dog*. Dr. F. N. COOKSON showed an *Enlarged prostate removed during an emergency operation in a case of profuse haematuria associated also with vesical calculi*. Mr. R. H. DICKSON showed a specimen of *Glioma of the retina* with a section under the microscope.

THE Babies' Welfare Association, which has done good work in New York during the past few months, was permanently organized at a meeting of the Academy of Medicine held on December 12th, 1912. The Association (says the *Medical Record*) is made up of seventy different philanthropic and medical societies, and has for its aim the lessening of infant mortality. Health Commissioner Ernst J. Lederle has been elected honorary president.

THE Carlsbad Medical Society offers a prize for the best essay on the treatment of diabetes mellitus, with special reference to balneotherapy. The judges are Hofrat Dr. Bitter v. Jakseh, of Prague; Dr. Luethje, of Kiel; Dr. Ortner, of Vienna; Dr. Schmidt, of Innsbruck; and Dr. Edgar Ganz, president of the society. The judges may, as they think fit, award either one prize of 5,000 kronen, or two prizes of 3,500 kronen and 1,500 kronen, or three prizes of 2,500 kronen, 1,500 kronen, and 1,000 kronen. The competition is open to medical practitioners of all countries. The essays, which may be written in any language, should be sent in before December 31st, 1913, to the Society of Carlsbad Physicians, Carlsbad, from which any further information may be obtained.

Dr. J. O'CARROLL, President, in the Chair.

Specific Treatment of Pulmonary Tuberculosis.

Dr. CROFTON described the treatment of pulmonary tuberculosis by intravenous injections of iodoform dissolved in ether. When, in exceptional cases, this could not be carried out the combination should be given intramuscularly or by the mouth. He thought Szendefly's formula—namely, iodized peptone, menthol, and radium—was less effective, but was useful sometimes for its tonic effect, and could be usefully used to supplement tuberculin. No treatment of pulmonary tuberculosis was complete unless a course of tuberculin were given to increase the patient's resistance. The best preparation was made by dissolving tubercle bacilli in benzoyl chloride. This was given combined with iodoform by intramuscular injection. The results so far had been very good. Dr. MARY STRANGMAN (Waterford) said that since Dr. Crofton's previous paper had been published she had tried the treatment in two of her cases. The first was one that might have been looked on as a forlorn hope. There were cavities in the left apex, and the right base was the only part of the lungs that could be looked upon as sound. There was loss of appetite, wasting, high temperature, and night sweats and extreme weakness. When the treatment was started she was much struck with the improvement within the first few days—the night sweats were practically stopped and the sputum very much diminished; but, unfortunately, at this stage, in giving one dose very quickly, a cough was brought on, which started a haemorrhage which frightened the patient so much that he would not allow another injection for a week. After this the injections were resumed, and have been kept up since. The sputum has now very much diminished, being about 1½ oz. in the twenty-four hours, the temperature has fallen, and all the other symptoms improved. The treatment was carried on for ten weeks. The second case was that of a young girl. The patient consulted her last May for an attack of pneumonia, which was found difficult to treat. A slow recovery was made, and the patient was sent to the country. When she returned she had reduced in weight, had night sweats, loss of appetite, and a few tubercle bacilli were found in the sputum. Iodoform injections were immediately started. For the first three weeks there was no very marked improvement. This was attributed to a low blood pressure. Her sputum, from being profuse, had now diminished to less than a drachm in the day. Cough was very slight. She still suffered from emphysema, but her case was a very hopeful one. Dr. MURPHY had tried the treatment in four cases; in each case the temperature came down, the cough lessened, and the patients appeared much better. The treatment appeared to be efficacious, and in one case he considered the result very good. Dr. NESBITT said he had tried the treatment in one case, and found it did well. The case was one of massive consolidation of the left base in a man aged 30. He was taken into hospital and given thirty-one injections of iodoform, and after three months' treatment his temperature had returned to normal, and had remained so since September last. He increased in weight, lost his cough, and the sputum (which had contained numerous tubercle bacilli) disappeared entirely, although the pulse did not react as he would have wished. He would not go so far as to claim this as the one and only form of treatment, but there was little doubt that iodoform did benefit his patient. Half-grain doses were given in plain solution of ether, and the patient found no bad symptoms, nor did he object to it. Other methods might, he thought, do as much good, but he felt quite justified in trying the iodoform injections in further cases. Dr. MOONHEAD said Dr. Nesbitt touched one very important point—that is, in judging any treatment one should have some idea of the history of the disease. It would, he thought, be admitted that in the natural course all cases

on any form of treatment, and even those not being treated, were subject to considerable variation, and it was only by very careful comparison with a very large number of cases one could form an opinion of the value of a particular form of treatment. He could not help feeling surprised that phthisis was in existence at all, so many remedies had been put forward. He was very much struck with the series of drugs employed in the cases reported, and he was at a loss to know which of them, if any, had a beneficial effect. Iodoform appeared to have a very good effect if any of the three forms of administration suited. He would like to know if a patient who had an opportunity of having first-class sanatorium and climatic treatment consulted Dr. Crofton which form of treatment would be select for him—the sanatorium or the treatment just now advocated. Dr. HAYES said, as his name had been mentioned as having x-rayed Dr. Crofton's patients, he would like to make clear his conclusions. The first was a case of enlarged mediastinal glands, and the patient had been previously operated upon for tuberculous glands in the neck. Nothing else could be detected but these enlarged mediastinal glands. After a course of treatment Dr. Crofton had her examined again, and there was a distinct diminution in the extent of the glands. Dr. COLEMAN said he thought the cases narrated could be taken to prove little. The great difficulty was that Dr. Crofton had not mentioned the number of cases in which the treatment was tried; he had not mentioned any bad or fatal results, nor had he said anything about controls. In order to derive any conclusions from the effect of iodoform treatment it would certainly be necessary to have a large number of cases fully set out and the same number of controls, and if the treatment with iodoform then showed marked improvement by comparison something could be said for iodoform. Dr. CROFTON, in replying, said that every one who had used the treatment was pleased with the results. Iodoform had been used in hundreds of cases without any fatal result. The cases reported were not specially picked ones, but were ones which would have been considered suitable for sanatorium treatment. He wanted to emphasize that the combination of iodoform and specific immunization was the ideal to be aimed at. With regard to the selection of sanatorium treatment under climatic conditions or the home treatment as indicated, he would prefer the latter. He did not think he would use controls even had he an opportunity of doing so, as he considered the cases turned out by sanatoriums were quite sufficient for comparative purposes. The hope of the future was in the prevention of the disease and not in cure, and to bring the resistance up to or above normal would be the best preventive.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

At a clinical meeting on December 18th, 1912, Mr. J. M. COTTEFRILL, President, in the chair, the following were among the exhibits:—Mr. DENIS COTTEFRILL: A case of *Congenital subspinous dislocation of the shoulder* in a boy, simulating an Erb's paralysis, and possibly due to some injury at birth. Dr. GEORGE MACKAY: A *haematoma of posterior orbit* in a man, caused by a blow, and cured by a modified Krönlein's operation. Mr. J. W. STRUTHERS: (1) A woman, aged 50, after removal of a segment of the cervical oesophagus for *Squamous carcinoma*, causing isolated stricture behind the larynx. (2) Female, aged 39, after removal of the right kidney for acute suppurative pyelonephritis. Mr. SCOT SKIRVING: Two men, illustrating rapid improvement from severe *Tertiary syphilitic lesions* with neo-salvarsan. In one of these mercurial treatment had produced little benefit, and had been badly borne. Mr. G. CHENE: A case of *Recurrent pyomyositis* in a woman, aged 35, treated in the first instance by operation, and followed by the development of stone, which had since been removed. Mr. H. WADE: Two patients illustrating *Plastic surgery*; one of an extensive skin graft on the hand, derived from a "pocket" of the abdominal skin; the other of transplantation of portion of the palmaris longus and cephalic vein to restore the function of the divided extensor longus pollicis. Dr. GULLAND: (1) A case of *Senile chorea* in a woman, aged 51, developing within four months, but preceded by delusions and affection of speech for two years. There was a marked rheumatic history. (2) A

case of *Pulmonary abscess* in a man, aged 64; it began as a cold which was followed by pneumonia of the left base. Dr. R. FLEMING: A case of acute *Toxic polyneuritis* in a sailor, aged 24, apparently due to ten days' working with naphtha paint. There was paralysis of extensors of arms and legs, with muscular hyperaesthesia, reaction of degeneration, and delayed sensory conduction. Dr. BOYD: (1) Two cases of *Syphilitic spinal paralysis*, both treated with mercury, and one also with salvarsan, and both still giving a positive Wassermann reaction. (2) A case of *Purpura haemorrhagica* in a man, with haemorrhage from gums, stomach, and intestine; severe attacks of colic, marked joint pains, interstitial haemorrhagic nephritis, and purpuric rash on skin. Dr. JOHN THOMSON: (1) *Oxycephaly* in a girl, aged 14, showing the typical features of exophthalmos, large oblique orbital cavities, defect of cranial ridges, peaked vertex; but without deformities of extremities or mental defect. (2) A case of mild *Cretinism* in a child, aged 9, showing extraordinary growth of thyroid, the weight being doubled in four months, and trebled in thirteen months. Dr. J. S. FOWLER: A case of *Sarcoma of the liver* in a child, aged 9. Dr. E. BRAMWELL: Three brothers, aged 33, 31, and 27, the youngest living members of a family of twelve, showing *Myotonia atrophica*; the leading features were indistinct articulation, bilateral facial weakness, atrophy of sterno-mastoids, weakness of hand movements, the relaxation of grasp being slow and difficult, but carried out more promptly after repetition, weakness of dorsiflexors of foot, no marked atrophy of limbs nor hypertrophy, no fibrillary tremors, tendon jerks diminished. Dr. RAINY and Mr. DOWDEX: A man, aged 47, with *Intestinal haemorrhages* of some weeks' duration, with melancholic and slightly suicidal symptoms. The bleeding was shown by the sigmoidoscope to be from the colon. Lavage with 2 per cent. protargol, followed by saline, brought about complete recovery.

ROYAL SOCIETY OF MEDICINE.

SECTION OF BALNEOLOGY AND CLIMATOLOGY.

At a meeting on December 12th, 1912, Dr. PERCY LEWIS, President, in the chair, Dr. BAIN, in a paper on *Cholelithiasis*, said the successful medical treatment depended, first, on accurate diagnosis, and, secondly, on clear recognition of the causes operating in each individual case. The possible predisposing causes included bile stagnation, anxiety, worry, and indigestion. Besides microbial infection an additional causative factor must be assumed. Recent work tended to show that gall stones were formed independently of infection. Apart from mechanical effects, such as the passage of a calculus, gall stones did not give rise to pronounced symptoms unless there were an accompanying cholecystitis. The early symptoms varied considerably, and did not usually suggest involvement of the gall bladder, consequently the affection very often escaped recognition. Flatulent dyspepsia was one of the commonest. Others were fullness, distension, and discomfort in the stomach; acidity, heartburn, a slightly furred tongue, occasional pain in the epigastrium coming on from thirty minutes to an hour after meals, induced by special kinds of food; lassitude, heaviness, drowsiness, disinclination for work, and occasionally a feeling of weight or a dull heavy sensation in the right hypochondrium. Often symptoms of intestinal indigestion predominated. Depression of a fleeting character was a frequent symptom, and might be the only one. The true nature of the case was revealed by examination of the liver. That organ might or might not be slightly enlarged, but there was invariably tenderness on pressure in the region of the gall bladder. This tenderness, due to cholecystitis, either preceded the formation of biliary calculi, or was associated with their presence. A normal gall bladder would dissolve any gall stone that was introduced into it under aseptic conditions; hence the principles of treatment were to improve the digestion by adapting the diet to the patient's digestive powers, to foster nutritional efficiency by suitable forms of exercise, to disinfect the biliary passages, and to correct any injurious habits. The rational treatment of a case in the first instance should be symptomatic. When the digestion became fairly normal colalin and nrotropin should be administered for several months. The PRESIDENT drew

attention to the fact that nearly all the items of treatment advocated by Dr. Bain acted on the general lines of improving the resistance of the tissues to microbial invasion. The ordering of an annual visit to a spa was a reproach to the efficiency of the treatment there carried out. Dr. SOLLY (Harrogate) said that he considered that once the diagnosis of gall stones was established surgical treatment was the only satisfactory cure. Dr. ACKERLEY (Llandrindod Wells) said that some recent inquiries he had made confirmed the statements of Thudichum and Brockbank as to the rarity of gall stones in animals other than man. In 1,400 necropsies since 1908 made on mammals at the London Zoological Gardens gall stones were found in only 5 cases—twice in ajoutis, once in a spotted cavy, once in a musquash (all four rodents), and once in a wild swine. This evidence tended to show that not bacterial infections, but the artificial habits, especially the food habits, of civilized man were much the more potent factors in the etiology of cholelithiasis. Mr. CAIRNS (Porsyth) regarded the treatment of cholelithiasis as entirely surgical. No doubt cure sometimes resulted from escape of the calculi into the bowel, and temporary relief might be obtained by medical treatment, but the dangers of delay were great. To postpone operative interference until complications arose was a procedure which was unfair to both patient and surgeon. Dr. KEAY said that as one who had himself suffered from an aggravated form of the complaint he regarded the description of symptoms given by Dr. Bain as decidedly superior to that found in most medical, and especially surgical, textbooks. The disease was eminently adapted to medical treatment, but there was no universal remedy, and each patient must be treated individually, and in that treatment less consideration should be given to its supposed microbial origin and more to the avoidance of worry, the improvement of digestion, and consequent character of the bile. If proper treatment were adopted his patients entirely recovered, and it was only in very rare cases that operation was called for. Since undergoing treatment in Karlsbad a number of years ago he had been entirely free from all symptoms of the disease. Dr. BAIN, in reply, said that urotropin was excreted in the bile. The reason why he advocated a yearly visit to a suitable health resort was that the causes which lead to the development of gall stones were in most cases not removed by operation. He agreed with Dr. Ackерley that highly-spiced foods and most condiments should be avoided in gall-stone disease. He agreed with Dr. Edgecombe that when a patient obtained complete relief from his symptoms it was impossible to say, without an abdominal section, if the calculi had broken up and disappeared. Regarding the criticism of the surgeons, his point was that they rarely saw the mild cases, consequently their dogmatic statements were based upon the manifestations of the disease in its advanced stage. They surely could not expect every case of cholecystitis, however mild, to submit to an operation.

LIVERPOOL MEDICAL INSTITUTION.

At a meeting on December 19th, 1912, Dr. LLOYD ROBERTS, Vice-President, in the chair, Dr. THURSTAN HOLLAND, in a note on *X-ray diagnosis of gall stone*, said that in three recent cases he had been able to recognize shadows as those of gall stones. Owing to the composition of the stones their greater part was transparent, but they had a crust of lime salts which gave a marked shadow with a transparent centre. He subsequently showed on the screen that the ring of shadow differed from that of a calcareous gland, which resembled a blackberry, and from a renal calculus, which gave a clear, sharp, homogeneous shadow. Dr. T. R. BRADSHAW showed a clerk, aged 17, with *Paralysis of the motor portion of the fifth nerve*, with complications. The earliest trouble was in February, 1912, when he had some weakness of the right leg. In May he was thrown from his bicycle. He had a slight accident bicycling directly after this. His sight was impaired and he had headache. Next day he had diplopia and difficulty in swallowing, with regurgitation of fluids through the nose. When admitted for treatment in June there was paralysis of the right external pterygoid muscle, and the masseter and temporal were weak. There was also lateral nystagmus, especially on look-

ing to the right, diplopia, and the right palpebral fissure was narrower than the left. The right leg, which the patient said was weak, showed absence of knee-jerk. The grasp of the right hand was impaired. There was no pain or interference with sensibility. The palate was unaffected. The pupils and discs were normal. In the past six months there had been slight improvement. The nystagmus was no longer apparent, and there was no regurgitation through the nose. Dr. Bradshaw could give no satisfactory explanation of the lesion. Dr. WARRINGTON thought the lesion might be a vascular lesion in the medulla or pons. Dr. R. J. M. BUCHANAN suggested an early cerebellar tumour, probably medullary. Dr. W. PERMEWAN thought it important that a thorough examination should be made of the condition of laryngeal muscles. In reply, Dr. BRADSHAW said it was difficult to correlate the lesions with the condition of the right arm and leg. Dr. JOHN HAY, in a paper on vagaries of the auricles, said that normally the auricles contracted at regular intervals about seventy times per minute, and each systole of the auricles was followed by a systole of the ventricles. In some cases extra-systoles arose in some portion of the auricular muscle, causing a premature beat of the heart. In another class of case there was paroxysmal tachycardia, the auricle contracted 200 or more times per minute, each auricular systole being followed by a systole of the ventricle. The stimulus to which the auricle contracted was abnormal in site of origin. The onset and cessation of these auricles were sudden; the rate was uninfluenced by emotion or movement. Dilatation was the result and not the cause of the rapid heart action. In a third class of cases there was a condition of auricular flutter; there was greater acceleration of the auricles—the rate was from 250–330 per minute. The stimulus here also arose in an abnormal site. The ventricular rate was 1 to 2, 1 to 3, 1 to 4 of that of the auricles.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

At a meeting on December 11th, 1912, Dr. WALTER SWAYNE, President, in the chair, Mr. HENRY GROVES showed a number of specimens and skiagrams illustrating the operative treatment of both simple, comminuted, and compound fractures in experimental work. He also demonstrated some of the practical applications of these experimental results, namely: (1) Various intramedullary pegs, including those which could be removed after healing of the fracture. (2) Apparatus for the treatment of compound and comminuted fractures. Illustrative cases in which these methods had been used were shown. Mr. A. L. FLEMING demonstrated the use of intravenous ether anaesthesia with the apparatuses of Rood and Schlesinger, and stated that the latter had the advantages of greater simplicity while giving a more certain drop. Dr. WAYSON-WILLIAMS and Mr. A. J. WRIGHT gave demonstrations of upper bronchoscopy, and also of the use of the naso-pharyngoscope, showing cases to illustrate the normal and stenosed appearances of the orifice of the Eustachian tube. Mr. F. G. BERGIN demonstrated the appearances seen in the fluorescent screen in a normal individual after a bisulph meal. Mr. STACK demonstrated the use of the gastro-scope of Hill and Hirschell upon an oesophagus and stomach removed *post mortem*. Dr. J. A. NIXON and Dr. H. W. BYWATERS demonstrated the use of the polariscope in the estimation of sugars. Dr. A. RENDLE SHORT demonstrated a method of estimating the CO₂ content of the blood. Dr. R. S. S. STATHAM showed the method of performing a urinary acidosis estimation, and emphasized its importance in such toxic conditions as eclampsia. Dr. JAMES TAYLOR showed skiagrams illustrating the condition found at varying periods after the administration of a bismuth meal to cases of intestinal stenosis. Professor WALKER HALL and Dr. KAY-MOGAT showed specimens illustrating the internal secretions of the thyroid, thymus, pancreas, and other glands; also some naked-eye specimens of hearts and lungs with blood vessels injected and the tissues afterwards made transparent. They also demonstrated the action of the blood of pregnant women upon placental protein, with the necessary controls, as a test for pregnancy and eclampsia, upon the lines recently suggested by Abderhalden.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

At a meeting on December 13th, 1912, Professor E. W. Hope in the chair, a paper on temperatures of school children as an aid to early diagnosis was read by Dr. F. E. Wynne. It was based on observations made by him with respect to the temperatures of 1,000 school children. The observations were made in the anticipation that they would enable an early diagnosis of cases of measles to be made. About an equal number of boys and girls were examined and they were all considered to be in a normal state of health. About 8 per cent. had subnormal temperatures and about 25 per cent. had temperatures of 99° or above. Of the latter, 6 subsequently developed measles and 3 scarlet fever. Dr. Wynne thought that the systematic taking of temperatures in schools might have an important bearing in connexion with the discovery of tuberculous children. Among the children whose temperatures were above normal nearly one-fourth were found to react to the tuberculin test. In discovering early cases of tuberculosis among school children weight should therefore be attached to the occurrence of even transitory rises in temperature, and temperature observations should be useful in sorting out cases for the application of the more troublesome methods of tuberculin diagnosis. He came to the conclusion that the systematic taking of temperatures in day schools was not likely to be of much assistance in preventing epidemics, but that it might very usefully be carried out with good results in institutions.

Reviews.

BRIGIT'S DISEASE.

In other departments of medicine, observers are sensible that many older conceptions have had to be revised and on occasions entirely replaced by new ones. The study of bacteriology has brought with it ideas concerning the significance of disease which are effecting a revolution in the outlook of the physician. It is not, therefore, surprising that during recent years very real interest has been taken in the group of cases which constitute Bright's disease and its allies. Judging by a recent book on Bright's disease by a London physician, there is a spirit of unrest abroad due to a fundamental dissatisfaction with the theories held for so many years concerning the mechanism of the various processes which accompany diseases of the kidney. The volume on *Nephritis*,¹ by Professor FISCHER, of Cincinnati, founded on his Cartwright Prize Essay for 1911, demands careful attention, and we feel it a duty to our readers to briefly refer to the important problems raised by Dr. Fischer and to the ingenuity and learning which he has brought to bear upon them. Bright's disease may be due to a number of agents reaching the kidney through the blood stream and leading to alteration of the renal parenchyma; the alteration of the parenchyma leads to a loss of the proteins of the plasma, and albuminuria results. This, however, does not explain how the poisonous agents affect the parenchyma nor why it is that though albuminuria results there may be also dropsy, cardiac hypertrophy, anaemia, etc. Nor do we know the exact nature of the toxins which operate on the kidney, although of late years Ascoli and others have been at pains to bring them into line with Ehrlich's lysins. Dr. Fischer believes that the harmful agents which bring about so many of the changes with which we are familiar in kidney disease are acid bodies; his views are supported by experiments made with acids such as hydrochloric, but he does not assume that ultimately it will be shown that the acid agent is of this nature; it may, for instance, be some acid body such as is developed in the katabolism of protein. Interesting as is this theory of the harmful effect of acid bodies, even more striking is Dr. Fischer's contention that the albumen escaping by the urinary tract in this disease is not derived from the blood at all, at any rate directly, but from the renal parenchyma. The experiments described certainly support Dr. Fischer's

thesis. He gives details of the experiments which show how important is the presence of acids or various salts in determining whether such bodies as gelatine or fibrin when placed in water will merely swell up (that is, assume the "gel" state) or actually become dissolved (that is, assume the "sol" state). Then follow ingenious experiments on animals showing the effect of the same acids and salts upon the renal epithelium, and how this tissue, existing naturally in the "gel" state, is as a result of the experiments made to assume the "sol" state, and as such is responsible for albuminuria. An important conclusion from the experiments is that the "sol" state of the renal epithelium is remediable; it can be made to reassume the "gel" state, and the albuminuria then ceases. This principle established experimentally suggests a line of treatment the details of which we commend to the reader's notice. If Dr. Fischer's views are correct, then the theories of French workers elaborated during recent years, which have led to the belief that sodium chloride is a cause of the dropsy met with in kidney disease, can no longer be maintained. Dr. Fischer is quite well aware of these views, and meets them with arguments which are reasonable. Whatever the ultimate fate of Dr. Fischer's theory as to the possibility of albuminuria being really due to actual loss of parenchyma protein instead of plasma protein, he has brought forward a view which deserves attention and consideration; it is in harmony with views developed in this country which have attributed the changes met with in renal disease to the absorption (not extrusion) of the renal cells into the system.

Dr. HORST OERTEL's lectures on the morbid histology of Bright's disease,² delivered in the Russell Sage Institute of Pathology, are published in a handsome and well illustrated volume. The author states in the preface that he has attempted to emphasize the relations of the histological facts, and to reconstruct the whole as a unit of interwoven processes, a method of treatment which, so far as his knowledge goes, does not exist in English literature. We cannot follow him here, for in the London schools, at all events, morbid anatomy, macroscopic and microscopic, has never been divorced from pathology and clinical medicine. There are other remarks in the preface which would come with more grace from some one else; for example, "a spirit of anatomical renaissance, therefore, permeates these lectures." This leaves so little to the reviewer. One more grumble about the adjectival terminations. Words such as "pathologic," "anatomic," and the like we understand, and there is much to be said for them. But when, in the same sentence, "pathologic" is used once, "pathological" twice, and "anatomical" twice, whilst in another "anatomic" is used, we venture to suggest that these little points are not beneath the notice of a microscopist. The first lecture contains an interesting historical summary ranging from Aëtius, who concluded, between 300 and 400 A.D., that certain cases of oedema and anasarca were associated with hardened kidneys, to the classical observations of Richard Bright. The minute anatomy of Bright's disease may be said to have been put on a sound basis by Henle in 1841 to 1847. Then, as now, the gaps in the knowledge of the histology and physiology of the healthy organ gave the chief opportunities for wrong conclusions as to pathology. No one can deny that the nomenclature of nephritis has been far from satisfactory. The author has no qualms in breaking with many old terms, such as "parenchymatous," "interstitial," "diffuse," which have been used in differing senses. When he also discards "acute" and "chronic" on the ground that they do not precisely describe the time limit of a nephritis, we feel, whilst appreciating their want of significance in the laboratory, that at the bedside these terms mean much. He asks, When does an acute nephritis become chronic? We may ask in reply, When does East become West? There is no precise answer; yet the expressions are full of practical meaning. The author classifies the chief forms of nephritis as simple, degenerative, exudative, haemorrhagic, proliferative, degenerative and productive, and atrophic. The simple nephritis occurs in fevers and toxic states. When desquamation and proliferation of the epithelium are marked, and turbid fluid can be squeezed

¹ *Nephritis, an Experimental and Critical Study of its Nature, Cause, and the Principles of its Relief*. By Dr. Martin H. Fischer, Fischberg Professor of Physiology in the University of Cincinnati. First Edition. New York: John Wiley and Sons; London: Chapman and Hall, Ltd. 1912. (Demy 8vo, pp. 212; figs. 31. Price 10s. 6d., net.)

² *The Anatomical and Histological Processes of Bright's Disease, and their Relation to the Functional Changes*. By Horst Oertel. Philadelphia and London: W. B. Saunders Company, 1910. (Roy. 8vo, pp. 227; 46 illustrations. 21s.)

out of the medulla, the nephritis is described as "proliferative." This is Virchow's catarrhal nephritis. The degenerative and exudative nephritis are the result of intense general intoxications and infections, including the septicaemias and pyemias. The degenerative changes are regarded as the passive features of the inflammation, and are contrasted with the reactive, proliferative, and exudative phenomena. In the fourth lecture, which may be read with much interest and profit, the productive changes following degenerative and exudative nephritis are described. The significance of recent work on autolysis and on the chemistry of the lipoids or phospholipines is made clear. The last lecture treats of productive nephritis, which is usually spoken of as "chronic interstitial nephritis." Wilks and Grainger Stewart, leaving Bright's uniform view of the whole nephritic process, regarded the large white and the small granular kidneys as independent affections. The modern tendency has perhaps been toward the older view. The author believes that there is no essential anatomical difference between any of the changes in productive nephritis and those observed in the other forms; but that contracted kidneys differ from one another, chiefly as regards the mode of origin and development of the change, either, for example, from a diffuse inflammation or from one of a circumscribed patchy, creeping type. Hence, the kidney of productive nephritis offers the greatest variety of pictures. The histological features of each type of disease are clearly described and beautifully illustrated. Nevertheless the author fulfils his promise to treat of the pathological processes as a whole, and does not confine himself to microscopic detail. These are good lectures, full of information, clearly written, and we can recommend them.

The monograph on the morphology of renal secretion³ by Dr. SUZUKI, of Japan, is introduced by a few words by Professor L. Aschoff, in whose laboratory the work has been done. Its novelty consists in the combination of "vital staining" by intravenous injection of carmine solution during life with the use of various methods by which the structure or function of the kidney is affected. We found descriptions of effects on the kidneys of uranium, corrosive sublimate, cantharidin, arsenic, and potassium bichromate; in haemoglobinuria, in hunger and thirst, after injection of urea and uric acid; after administration of lactose, caffeine, potassium chlorate and oxalic acid; after clamping the renal artery, and after unilateral extirpation of the kidney. The changes observed are described in minute detail, and the descriptive sections are followed by summaries of the conclusions to be drawn from the facts disclosed. The highest praise should be given to the plates, which give twenty-one beautifully coloured drawings of the microscopical appearances. We commend Dr. Suzuki's book to the attention of all interested in the minute anatomy and physiology of the kidney as observed in various small rodents under normal conditions and as altered by the various agencies already mentioned. The method of staining *intra vitam* appears to be most successful.

FOOD AND DIETETICS.

DR. WILLIAM TIBBLES'S work on *Foods: Their Origin, Composition, and Manufacture*,⁴ gathers together into one volume a large amount of information on this important subject from a variety of sources, including a good deal of matter from recent issues of technical and scientific journals. The point of view throughout is mainly that of the dietician—that is to say, the composition and food value of the various alimentary substances dealt with are most fully described, the source and manufacture being as fully stated as is necessary for a discussion of the composition; food analysis is only touched on incidentally. The author has not confined himself to the foods in most common use in European countries, but has made a comprehensive compilation of

facts; due balance, however, is maintained between the more and less important matter, so that valuable information is not smothered under a mass of statistics, as sometimes happens. The book is divided into five parts. The first contains some seventy pages, and deals with the chemistry of first the elements, and then the proximate principles of which foods are composed. This preliminary matter disposed of, the other four parts are devoted respectively to foods derived from the animal kingdom and from the vegetable kingdom, condiments and spices, and beverages. The first part of the book necessarily presupposes a fair amount of general chemical knowledge on the part of the reader, and it is, perhaps, easier to find statements to which exception might be taken here than in the main part of the work. For example, the author repeatedly uses the term "ion" as though synonymous with "radical," speaking of methylene $\text{CH}_2=$, methine $\text{CH}=$, and the imino group $\text{NH}=$, etc., as ions; "ethyl alcohol would be reduced to an aldehyde" occurs; the term "protein" is defined as including all the nitrogenous compounds of animal or vegetable bodies except the meat bases and amino-compounds such as leucine or asparagin, although in subsequent pages proteoses, peptones, etc., are excluded from the group of proteins. Such faults as these, however, are not sufficient to mar the clearness of the text to a serious extent. The subsequent parts of the book, dealing with foods under the headings mentioned above, deserve high praise for the large amount of valuable information brought together. On controversial matters the author avoids dogmatism and presents both sides. In regard to the so-called "standard bread," after fairly stating the advantages claimed for it, he adds:

The presence of the cereal and germ in the flour really increases the total percentage of nitrogen and phosphorus very little. Adequate reasons have been given for their exclusion. It remains for the advocates for their inclusion to show good reasons for doing so, such as will be in keeping with modern physiological knowledge. But at present such reasons are not forthcoming.

The experiments of Hill and Flack on feeding rats with white flour and flour containing germ and cereal, which were recorded in our columns, are deconvicted, and the view is expressed that a diet almost devoid of cellulose, like fine white flour, is unsuitable for rats, and that this would account for the inferior nutritive properties shown by it in these tests. Dr. Tibbles's book will certainly take a high place among works of reference on the subject of diet.

We have several times suggested that a small manual to assist practitioners in the calculation of food values and construction of dietaries would be useful. In supplying this want our colleagues in the United States have taken the lead, for not long ago we had the pleasure of drawing attention to the little book on food values published by Dr. E. A. Locke of the Harvard Medical School, and now we welcome a *Laboratory Handbook for Dietetics*,⁵ written by Dr. MARY SWARTZ ROSE of Columbia University. In the preface she says:

It is the purpose of this little book to explain problems involved in the calculation of food values and food requirements and the construction of dietaries, and to furnish reference tables which will minimize the labour involved in such work without limiting dietary study to a few food materials. . . . Tables are included giving the food value for the hundred-calorie portion which is taken as the standard portion in the sense that it serves as a convenient unit in building up a day's ration to yield a stated number of calories; for the gram, which is the unit of weight for all scientific workers; for the ounce, the common unit of the small family group; and for the pound, the unit of the large family or institutional group. These tables have been in practical use for several years in the author's classes, and their value in relieving the student of monotonous clerical labour has been demonstrated.

As may be expected from this description, the book consists very largely of tables, giving analyses of all the ordinary articles of food used in the United States, showing the proportions of protein, fat, and carbohydrate and their fuel value in calories. In addition there are many other useful tables, such as those of height and weight for men and women, boys and girls at different

³ *Zur Morphologie der Nierensekretion unter physiologischen und pathologischen Bedingungen.* Von Dr. T. Suzuki, Arzt in Japan. Mit einem Vorwort von L. Aschoff. Freiburg i. B. Jena: Gustav Fischer, 1912. (Roy. 8vo, pp. 252; Abtn. 6, Tfn. 6. M. 15.)

⁴ *Foods: Their Origin, Composition, and Manufacture.* By William Tibbles, LL.D., M.D. (Hon. Causa) Chicago, L.R.C.P. Edin., M.R.C.S. Eng., L.S.A. Lond. 1912. London: Baillière, Tindall, and Cox. (Demy 8vo, pp. 950. 13s. net.)

⁵ *Laboratory Handbook for Dietetics.* By Mary Swartz Rose, Ph.D., Assistant Professor, Department of Nutrition, Teachers' College, Columbia University. New York and London: Macmillan and Co. 1912. (Demy 8vo, pp. 135. 6s.)

ages. Any moderately intelligent person should find no difficulty in constructing, with the assistance of this book, a dietary containing the required number of calories. It should be mentioned that a table is given of the approximate amount of refuse in common food materials as purchased, showing the percentage loss in these, but we miss a good feature of Dr. Locke's book—namely, the effect of cooking, which is often very large, and, unless taken into account, may seriously modify the results of calculation, especially in the case of meat, which may lose a considerable proportion of its fat, and a less, but by no means insignificant, amount of its protein. Undoubtedly if the broth and dripping are eaten as well as the meat there is no loss, but in many cases they are not. Subject to this omission we have nothing but praise for the manner in which Dr. Mary Rose has performed her task.

The Principles of Human Nutrition,⁶ a Study in Practical Dietetics, is the title of a useful book by WHITMAN H. JORDAN, the Director of the New York Agricultural Experiment Station and author of a previous work on *The Feeding of Animals*. The author writes in a clear, popular style, and his aim is to show the adjustment of physiological knowledge to a rational system of nutrition "without insisting upon adherence to technical details that are not feasible in the ordinary administration of the family dietary." He makes no claim to write on his own authority, but has digested and served up a readable and useful survey of the conclusions "of those authorities and investigators whose sound scholarship in this field of knowledge is unquestioned." He deals with the plant as the source of human sustenance, the chemical elements and compounds of human nutrition, the digestion of food, the distribution and transformations of the digested food, and the functions of food compounds and laws of nutrition; he then passes on to practical dietetics, the selection and regulation of diet, its relation to varying conditions of life, food economics, special dietetic methods such as vegetarianism and eating of raw foods, the nutrition of the child, the character and food value of such commercial articles as meat extracts, breakfast foods, alcohol, and the preparation, sanitation, and preservation of food. Tables are added giving the chemical composition of all the common American foodstuffs. The lay reader will find much sound information on all these points, and those who have control of the feeding of children, etc., cannot fail to gain much insight into the proper execution of their vocation from the perusal of Mr. Jordan's book. The practical application to daily life is shown by a table contrasting the worth of a meal of bread and honey with one of bread and milk. The uncontrolled child will, of course, prefer the former, while the latter has fourteen times as much fat, three times the mineral matter, over twice the protein, and as much food energy. Those children who are allowed to partake freely of sweets, especially between meals, must not be expected to develop with maximum vigour. Such foods not only are incomplete in themselves, but spoil the appetite for the plainer and more nutritious articles of diet. "Farm animals could not be developed to their best estate in so irrational a system of feeding." Discussing the cost of food, the author says, "certainly the groceryman and the baker contribute to the ease and comfort of housekeeping, but those purveyors of prepared foods must be paid for their services, and heavy cash payments are in this way substituted for home labour. Many families do not realize how much is paid for the distribution and preparation of food before it comes into the house." The enormous waste of food is undoubted, he says, in the United States. "The people probably waste enough raw food materials to properly feed half their number." We should doubt whether the waste is really so very great, for much of it must find its way to the fowl-run or pig-trough. A large part of the population, he says, lives at an expense that is a great drain upon individual and social energy. A simple breakfast at a high class hotel costs as much as the raw material required to feed a man for three days. The nation "is expending an undue proportion of its activities in paying for expensively compounded and expensively

served foods, with a corresponding limitation of the means which might secure larger individual and social values."

THE THEORY OF SCHIZOPHRENIC NEGATIVISM.

In a paper which two years ago ran through four numbers of the *Psychiatrisch-Neurologische Wochenschrift*,⁷ under the title of *Zur Theorie des schizophrenen Negativismus*, Professor BLEULER, of Zürich University, discussed the several explanations which had been advanced of the various symptoms collected under the name "negativism." Having found all these theories—psychological and other—either incorrect or unsatisfactory, Professor Bleuler gave the grounds for their rejection, and expounded his own admittedly incomplete explanation. His essay has now been translated into somewhat American English by Dr. WILLIAM A. WHITE,⁸ the Superintendent of the Government Hospital for the Insane at Washington, and the author of the admirable *Outlines of Psychiatry*, which forms No. 1 of the same series. The predisposing cause of negativistic phenomena Professor Bleuler finds in: (a) *ambitendency*, which sets free with every tendency a counter-tendency; (b) *ambivalency*, which gives to the same idea two contrary "feeling-tones"; (c) "the schizophrenic splitting of the psyche," which hinders the proper balancing of the co-operating psychisms; and (d) a "lack of clearness and imperfect logic of the schizophrenic thoughts in general, which make a theoretical and practical adaptation to reality difficult or impossible."

On the basis of these predisposing causes, as Professor Bleuler considers them, either external or internal negativism may develop. External negativism consists in the negation of external influences, or what one would normally expect the subject to do, internal negativism being the negation in the patient's own mind of his own will, intention, or idea. As to the direct causes, "the autistic withdrawing of the patient into his phantasies, which makes every influence acting from without comparatively an intolerable nuisance," is given as the most important factor, though the "existence of a hurt (negative complex, unfulfilled wish) which must be protected from contact" is given also among other causes of external negativism.

Obviously these do not furnish any exhaustive explanation of negativistic phenomena. Even granting that "ambitendency" and "ambivalency" are distinctive and necessary predisposing causes of negativism—an entirely unwarranted assumption—the cause of the "schizophrenic splitting of the psyche" (surely an unnecessary tautological phrase!) remains unexplained. Perhaps the true explanation is given when Professor Bleuler says, "On close examination the same grounds will be found as causes of pathological negativism as for the negative attitude in health," and later, "with this conduct the patients exaggerate and caricature only one of the usual manifestations of the normal."

By the "negative attitude in health" Professor Bleuler means the resistance and perhaps resentment which the normal man opposes to what he does not wish, either to do, or it may be to disclose. The ordinary man does not wear his heart upon his sleeve, and quickly repels too curious probing of old wounds. This negative attitude may be maintained with full consciousness of its *raison d'être*; or it may depend upon the existence of some deeply buried and long forgotten "hurt"—to use Dr. White's translation—which may yet be laid bare by psycho-analytic methods. In pathological negativism this "hurt" may be imagined and delusional, as, for example, in a case related by Professor Bleuler, when the patient reacted negatively to nearly every request or command, under the delusion that it was desired to hypnotize her. But if this be so, should not the explanation of negativistic phenomena be sought in the source of the delusional frame of mind rather than, or at any rate as much as, in "ambitendency," "ambivalency," and "the schizophrenic splitting of the psyche?"

⁷ E. Bleuler, "Zur Theorie des schizophrenen Negativismus," *Psychiatrisch-Neurologische Wochenschrift*, vol. 12. 1910-11. Nos. 18, 19, 20, 21.

⁸ *The Theory of Schizophrenic Negativism*. By Professor E. Bleuler, Zürich. Translated by William A. White, M.D., Washington. Nervous and Mental Disease Monograph Series, No. 11. New York: The Journal of Nervous and Mental Disease Publishing Co. 1912. (Med. 8vo, pp. 56. Price 0.60 dol.)

⁶ *The Principles of Human Nutrition*. By Whitman H. Jordan, New York. London: The Macmillan Company. 1912. (Demy 8vo, pp. 471; figs. 15. 7s. 6d. net.)

Some departments of science are characterized by the tendency to create neologisms, quite apart from necessary technical terms, shibboleths which must be acquired before entering that particular camp. Modern pathological psychology appears to be one of these, and in no recent essay has this tendency been more marked than in this translation. The difficulty of comprehension is increased by a bizarre and entirely original punctuation.

The English reader who desires to become acquainted with Professor Bleuler's views, but does not read German, is advised to purchase a grammar and dictionary and read the original. He will find this the easier way.

THE CLINICAL ASPECTS OF HEART DISEASE.

The study of heart disease presents a double fascination. To the laboratory worker the interpretation of graphic indications is of absorbing interest, and becomes constantly more so as new forms of delicate mechanism are devised to demonstrate them. To the clinical worker, on the other hand, the evidences of cardiac disorder are constantly presenting new features, which have to be studied as a whole. The interpretation of cardiographic and electro-cardiographic tracings, interesting and enlightening as they are, cannot as yet take the place of clinical experience when treatment and prognosis are under consideration. A purely clinical work has its place therefore alongside of some of the recent records of scientific research, and a small work by Dr. R. O. Moon,⁹ dealing with heart disease as it appears to the average practitioner, will be found interesting. As a careful student of all the cardiac literature of modern times his account presents a faithful reflex of the best clinical thought and experience, and his own observations have been sufficiently extended to warrant him in offering them to the profession.

Writing in an easy conversational style, each subject is dealt with in turn by the author, who keeps steadily to his themes of prognosis and treatment.

Recognizing, in common with all experienced clinicians, that cardiac abnormality does not by any means imply cardiac insufficiency, he proves the need for care in prognosis, and the importance of watching the efficiency of the heart's action as shown by the results upon other organs rather than by the way in which the heart is doing the work. Murmurs, abnormal areas of dullness, and even irregular action are not of themselves of importance so long as efficient circulation is maintained. They may serve to put the clinical observer on his guard against possible failure in the future, but they do not prove that present function is imperfect.

In almost every case of heart failure the first line of treatment should be to relieve the cause rather than to strengthen the failing power. The instant use of some form of diffusible stimulant may be necessary, but of far more importance is it to discover and to counteract the functional disorder of circulation which is putting the strain upon the central pump.

Dr. Moon's work brings out all these points into strong relief and, although arranged in book form, it conveys all the interest of bedside teaching, the introduction of illustrative cases and apt quotations combining to form an excellent picture of heart disease from the purely clinical point of view.

AÉRIAL CONVECTION OF SMALL-POX.

DR. ALEXANDER COLLIE'S essay on *Small-pox and its Diffusion*¹⁰ deals almost exclusively with the hypothesis of aerial convection. This hypothesis, it will be remembered, was first propounded by Mr. (now Sir William) Power in 1881, as a result of his inquiry into the alleged prevalence of small-pox round the Western Hospital at Fulham; and it supposes that the virus of small-pox can, under certain conditions, be diffused through the air round a hospital so as to infect susceptible persons. During the last few years little has been heard of this hypothesis, because small-pox has not been prevalent to any notable

extent. But from 1881 to 1903 it was not infrequently under discussion. In April, 1903, there was a full-dress debate on the subject at the Epidemiological Society; and if the reader will turn to the published account of that debate he will find all that can be said in favour of the hypothesis and most that can be brought against it. We say "most" and not "all," because we have a shrewd suspicion that all the adverse evidence has not been forthcoming, partly because it is by no means easy to obtain, and partly because, when obtained, it may be held (though often unjustly) to reflect on the administration of this or that particular hospital. Consequently we range ourselves with those who hold that the distal transmission of small-pox through the air is not proven, though we are far from thinking it is not possible. Dr. Collie is evidently of the opinion that the evidence he sets out in his book is sufficient to dispose of the hypothesis; but he confines his attention, so far as details are concerned, to the instance of the Eastern Hospital, Homerton, up to the year 1885, when it ceased to be used for small-pox. The evidence he brings forward is concerned almost entirely with the subject of the transmission of infection from the small-pox to the fever and other patients who were under treatment on the same site. But no writer on aerial convection can afford to neglect the evidence which has been gathered since 1885. Moreover, Dr. Collie, though ostensibly arguing against the possibility of aerial convection, is really arguing against, we will not say the possibility, but the probability of the spread of small-pox round a hospital at all. We do not think that he will find many to follow him in this view. In the discussion to which we referred above most of the leading epidemiologists took part; and the majority of them, whatever were their views on aerial convection, were unanimous in the belief that a small-pox hospital is a source of danger to its neighbourhood unless certain rules, affecting the staff especially, are rigidly and invariably enforced. We have little doubt that the question will sooner or later be settled, but we do not think that Dr. Collie's book materially helps us to attain that desired end.

PRACTICAL PHYSIOLOGICAL CHEMISTRY.

THE last few years have seen much progress in the direction of placing the study of physiological chemistry in its true position as a branch of organic chemistry as well as of physiology. Dr. ADERS PLIMMER, in his *Practical Physiological Chemistry*,¹¹ has aimed at producing a complete handbook of practical work, for which the need had certainly arisen. It is hardly fair to compare older textbooks with it, but it will be seen how great the difference is when we mention the scope of the leading sections. The chief groups of organic substances which are the constituents of living matter, or are concerned in vital processes, are first treated. The student begins by separating benzoic acid and purifying it by recrystallization, by the separation of certain mixtures, the determination of boiling-points, melting-points, and molecular weights, by tests for the elements and the quantitative estimation of them. We agree strongly with the author in preferring copper sulphate to potassium sulphate as an aid to oxidation in the Kjeldahl process. As a matter of small detail it might be worth while to say that the crystal should be about the size of a pea; in class work it will be found that the term "small crystal" is not quite definite for men who may not have a teacher at hand at the moment. This section of the book is succeeded by elementary practical studies of the hydrocarbons and their halogen derivatives, of alcohols, esters, ethers, aldehydes, ketones, fatty acids, fats, and carbohydrates; of the action of enzymes, of the cyanogen compounds, amines, amino-acids, amides, purins, aromatic compounds, and the proteins. A short study—perhaps too short—of the common foodstuffs comes next, followed by carefully arranged experiments in the study of digestion, blood, urine, and metabolism. In each section sound practical exercises are given, with pictures of the essential apparatus, every group of experiments being preceded by an explanatory summary of the points involved. The summaries are packed with information, much of which

⁹ *The Prognosis and Treatment of Diseases of the Heart.* By R. O. Moon, M.A., M.D., Oxon., F.R.C.P., Physician to the National Hospital for Diseases of the Heart, &c. London: Longmans, Green and Co. 1912. (Cr. 8vo, pp. 121. Price 3s. 6d. net.)

¹⁰ *Small-pox and its Diffusion.* By Alexander Collie, M.D., Abert. Bristol: John Wright and Sons, Ltd. London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd. 1912. (Demy 8vo, pp. 58. 2s. net.)

¹¹ *Practical Physiological Chemistry.* By R. H. Aders Plimmer, D.Sc. London: Longmans, Green, and Co. 1910. (Roy. 8vo, pp. 278; illustrated. 6s.)

has not hitherto been given in works of this class, and are freely illustrated with chemical formulae. A good list of reagents and their strengths and a full index complete this workmanlike volume. Dr. Plimmer's experience as a teacher is a sufficient guarantee for the accuracy of the experimental part of the book. We have no doubt that this is, and will become still more, the book for class work in the subject. We can imagine no better introduction to the study of physiological chemistry.

ENDOSCOPY OF OESOPHAGUS AND STOMACH.

IN a handy little volume of about 100 pages, Dr. CAVAZZA¹² gives a clear account of recent work in connexion with endoscopic inspection of the oesophagus and stomach, with a passing reference to the sigmoidoscope. The illustrations which accompany the text show various endoscopic instruments, and foreign bodies add considerably to the value of the book. As the author points out, in view of the antiquity of the practice of certain jugglers in swallowing swords and other rigid bodies, it was curious that a rigid instrument for passage into, and inspection of, the oesophagus should have been so long in coming as it was. In choosing amongst the various instruments on the market, reference is made with approval to a saying of Professor Moure that the best instrument is the one already in your possession; it is not so much the tool as the man using it. Probably the Brüning instrument is the most generally useful for inspecting the oesophagus. For the very necessary anaesthesia of the pharynx the author prefers cocaine to the newer preparations. Retrograde oesophagoscopy, that is, looking up the oesophagus from an opening in the stomach, may sometimes reveal lesions not otherwise seen. Foreign bodies not giving a shadow to *x* rays may still be detected by the aid of bismuth, if they are in the oesophagus. A brief reference is made to the existence of those imaginary foreign bodies which are so real to patients of a certain type. Gastro-diaphanoscopy and gastroscopy are also discussed, and there are two rather uncomfortable looking sketches of the passage of Moure's gastroscope. The author does not suggest that the oesophagus and the stomach should be rashly and at once explored by endoscopy, and in any case it is well to get the oesophagus fully accustomed to the passage of sounds, bougies, etc., and as far as possible to exclude the existence of aneurysm, ulceration, and other dangerous conditions before going on to the use of the more formidable instruments. Put as to the value of skilful endoscopy in suitable cases this book gives sufficient evidence. There is a bibliography at the end.

NOTES ON BOOKS.

MR. W. HARRISON MARTINDALE, Ph.D., has printed in a small volume entitled *Digitalis Assay*¹³ the full text of the paper on the subject which he read at a recent meeting of the Pharmaceutical Society. It opens with a comparison of physiological and chemical results, and contains full details, illustrated by a coloured plate, of the colorimetric method of assay which the author has devised. It is claimed for it that it shows whether a tincture is above or below standard, and with certainty an excessively strong or a weak preparation. He finds that selected leaves recently dried will, as a general rule, produce tinctures up to standard, but that in practice variations are so great that one pharmacy may supply a preparation twice as strong as another. The author considers that the ideal conditions for growing digitalis have not yet been ascertained. He found that the most potent leaves were those of second year's plants grown in a sunny exposed situation, and showing no flower spikes.

Professor SCHÄFFER has reprinted in a pamphlet the address on *Life: its Nature, Origin, and Maintenance*,¹⁴ which he delivered as President of the British Association

¹² *L'Endoscopia del Sistema Digerente*. By E. Cavazza. Bologna: N. Zanichelli. 1912. (Roy. 8vo, pp. 92, figs. 35.)

¹³ *Digitalis Assay*. By W. H. Martindale, Ph.D. Marburg, F.C.S. London: H. K. Lewis. 1913. (Demy 8vo, pp. 47.)

¹⁴ *Life: its Nature, Origin, and Maintenance*. By E. A. Schäfer, LL.D., F.R.S., M.D., F.R.S., Professor of Physiology in Edinburgh. London: Longmans, Green and Co. 1912. (Med. 8vo, pp. 36. Price 1s. net.)

last September. The address excited much interest and some controversy at the time, and many of those who then read it in our columns will be glad to have it in this convenient form. Not a little of the controversy was due to a misapprehension of the point of view from which it was written. Its intention, as is expressed in the preface the author has written for this reissue, was to indicate in clear language the general trend of bio-chemical inquiry regarding the nature and origin of living material and the manner in which the life of multicellular organisms, especially that of the higher animals and man, is maintained. It is obvious that life as we know it must have originated at some time; and almost certainly it must have originated on this globe and was not carried to it by some chance meteorite or intraplanetary dust. The statement seems to have excited some opposition, but, as the author says, there can be "no difference of opinion upon this point among scientific thinkers."

Second editions have appeared both of *Primary Studies for Nurses*¹⁵ and *Clinical Studies for Nurses*,¹⁶ the authoress in each case being Miss CHARLOTTE AIKENS, a lady who was formerly Superintendent of the Columbia Hospital, Pittsburg, and other like institutions. The second of the books mentioned we reviewed in detail on its first appearance. In effect it is a heterogeneous collection of papers dealing with pretty nearly every kind of medical and surgical disorder, and the companion volume is of much the same kind, anatomy and physiology, hygiene, bacteriology, therapeutics, dietetics, and cooking being the main subjects. The object in view would appear to be to bring within a comparatively brief compass the information which a nurse might conceivably wish to possess in regard to the strictly medical and surgical sides of her work; but the impression is left that what nurses need to know on the subjects dealt with would be much better acquired by attendance at lectures, supplemented, in the case of the more enterprising, by study of ordinary textbooks.

The fifth edition of *A Handbook for Nurses*,¹⁷ by Dr. J. K. WATSON, contains eighty-six pages more than the original volume, and is stated to have been completely revised, but otherwise it is not materially altered. The first edition we reviewed in detail, and regret to be unable to take any more favourable view of the publication than was then indicated. It is an attempt to supply in one volume an account of anatomy, physiology, emergency and other surgery, midwifery, gynaecology, and pretty nearly the whole range of medical disorders. In the circumstances it is quite natural that the information supplied, though at times surprisingly full, should usually be very brief and often unduly sketchy.

The contents of the thirty-seventh volume of *The Transactions of the Edinburgh Obstetrical Society*¹⁸ are about equally divided between gynaecological and obstetric papers. Included among the former is an elaborate account by Dr. E. J. McCann of the technique of the more extensive abdominal operations for uterine cancer, and among the latter is a record of an attempt by Sir Halliday Croom to determine similar points regarding eclampsia, and more especially whether it exhibits any true seasonal variation. The investigation was based upon the records of the Edinburgh Maternity Hospital; the general conclusion was that eclampsia showed a tendency to increase in prevalence but to be less fatal in its results, and that the factors which have led to a suggestion of seasonal variations are dependent not truly on season but on sudden alterations in temperature and rainfall. The volume contains an account of a conjoint meeting with the Glasgow Obstetrical and Gynaecological Society for the purpose of discussing the effect of the maternity benefit clauses of the National Insurance Act on obstetrical teaching and practice in Scotland.

BRIGHTON SUSPENSION PIER (ABOUT 1820).

EIGHTY-FIRST ANNUAL MEETING
OF THE
British Medical Association,
BRIGHTON, JULY, 1913.

HISTORY OF BRIGHTON.

(Continued from p. 1624, vol. ii, 1912.)

IMPRESSIONS OF A VISITOR IN 1778.

SIR JOHN CORBY BURROWS,
M.P., M.D.
Three times Mayor of Brighton.

AN amusing account of Brighton as seen in 1778 through the eyes of a discontented visitor is given in *A Sentimental Diary*, by one J. Ryall.¹ Writing under date August 27th, 1778, he says he left Littlehampton and arrived in the evening at the Crown and Anchor in Brightelmstone for the first time in his life. "All was confusion and consequence here. The building of Babel and Vanity Fair." On Friday, the 23th, he chronicles that he walked on the Steyne and saw the Assembly Rooms:

The new one near the Steine is extremely grand, though the cicling and ornaments are by no means so elegant and high finished as those in the buildings called Portland Place in London. . . . Lay at the Crown and Anchor again. Mem. They charge two shillings a night for lodging, too much at least

when one lives at the same house. Will remove to a private lodging to-morrow.

On Sunday, 30th, he writes:

Have surveyed this town thoroughly; like the place well enough, but abominate both townsmen and visitors. The townsmen look upon all strangers as lawful prize, a sort of god-sends as the Cornishmen call wrecks. . . . The townsmen seem to have forgot that the ocean encircles an island; another such season as the present, however, may clear up this mystery, tho' not perhaps to their entire satisfaction. The people who come to bath appear reserved and sullen. Of course unsociable as if the principal complaint laboured under was pride. . . . The principal business going on among the great vulgar is gaming; after

all as many shepers undoubtedly resort to these places, reservedness in general may be somewhat excusable; and yet, must remark, this makes Brightelmstone a very disagreeable place to me; to select parties it may be pleasurable, but not belonging to any such, am sincerely sorry I left Little Hampton. This town is built on spots in patches, and for want of regularity does not appear to advantage; every one as to building seems to have done what appeared right in his own eyes. Here is no magistracy; if there is an affray the parties must go as far as Lewis, which is much the prettier town to have it settled. Upon recollection this town may be the quieter for having no trading justices resident on the spot. Am since informed a gentleman in the commission of the peace attends here occasionally from Lewis. There can be no antiquities for Brightelmstone was only a small obscure village, occupied by fishermen till silken folly and bloated disease under the auspices of a Dr. Russel deemed it necessary to crowd one shore and fill the inhabitants with contempt for their visitors.

Johnson, the Thrales, and Fanny Burney.

Samuel Johnson's name is associated with Brighton, for in the later years of his life he went there pretty frequently. In 1769 Boswell came to London in the autumn, and found that his illustrious friend was at Brightelmstone with Mr. and Mrs. Thrale. From that place we find Johnson writing to Boswell on September 9th:

I do not find that I am likely to come back very soon from this place. I shall, perhaps, stay a fortnight longer, and a fortnight is a long time to a lover absent from his mistress. Would a fortnight ever have an end?

On October 21st, 1776, he writes to Levett as follows:

Dear Sir,—Having spent about six weeks at this place we have at length resolved upon returning. I expect to see you all in Fleet Street on the 30th of this month. I did not go into the sea till last Friday, but think to go most of this week, though I know not that it does me any good. My nights are very restless and tiresome, but I am otherwise well.

Robert Levett was, according to Boswell, "an obscure practitioner of physic amongst the lower people; his fees being sometimes very small sums, sometimes whatever provisions his patients could afford him; but of such extensive practice in that way that Mrs. Williams has told me that his walk was from Houndsditch to Marylebone." Johnson's acquaintance with Levett began about the year 1746, and so high was the great man's opinion of his sagacity that he declared he would not be satisfied though attended by the whole College of Physicians unless he had Levett with him. Levett had a room in Johnson's house, and his death in 1782 was the occasion for some of the best verses the author of *The Vanity of Human Wishes* ever wrote. Every one who knowe

¹ *A Sentimental Diary, kept in an Excursion to Little Hampton, near Arundel, and to Brightelmstone, in Sussex.* London: Printed for J. Ryall, in Union Street, Westminster; and sold by W. Lee, Printer, in Lewes, and all the Booksellers and News-Carriers in Town and Country. 1778

anything of the literature of the eighteenth century remembers the poem in which the following lines occur:

Well try'd through many a varying year
See Lovett to the grave descend;
Officious, innocent, sincere,
Of every friendless name the friend.

When fainting Nature call'd for aid
And heaving Death prepar'd the blow
His vigorous remedy display'd
The power of art without the show.

In Misery's darkest caverns known,
His ready help was ever nigh
While hopeless Anguish pour'd his groan
And lonely Want retir'd to die.

No summons mock'd by chill delay,
No petty gains disdain'd by pride,
The modest wants of every day
The toil of every day supply'd.

His virtues walk'd their narrow round
Nor made a pause nor left a void;
And sure the eternal Master found
His single talent well employ'd.

On July 29th, 1775, we find Johnson writing to Mrs. Thrale:²

I am very desirous that Mr. ——— should be sent for a few weeks to Brighthelmstone. Air and vacancy and novelty, and the consciousness of his own value and pride of such distinction and delight in Mr. Thrale's kindness would, as Cheney [Cheyne] phrases it, afford all the relief that human art can give or human nature receive. Do not read this slightly. You may prolong a very useful life.

Dr. Birkbeck Hill adds the following note:

The learned, philosophical, and pious Dr. Cheyne, as Boswell calls him, whose books on health and English malady were recommended to him by Johnson. The English malady was melancholy or hypochondria. There is some comfort in knowing that so long ago as 1755 Cheyne pointed out that the conditions of modern life "have brought distempers with atrocious and frightful symptoms scarce known to our ancestors. These nervous disorders are computed to make almost one-third of the complaints of the people of condition in England." (*The English Malady*, ed. 1755, preface, p. 2.)

On August 29th, 1775, we find Johnson writing again to Mrs. Thrale from London:

This sorry foot! and this sorry Dr. Lawrence, who says it is the gout! But then he thinks everything the gout: and so I will try not to believe him. Into the sea I suppose you will send it, and into the sea I design it shall go.

On November 29th, 1777, he writes again to Boswell:

I was not well when he left me at the Doctor's, and I grew worse. Yet I stayed on, and at Lichfield was very ill. Traveling, however, did not make me worse, and when I came to London I complied with a summons to go to Brighthelmstone, where I saw Beauclerk, and stayed three days.

In another letter to Boswell, dated December 7th, 1782, he says:

Having passed almost this whole year in a succession of disorders, I went in October to Brighthelmstone, whither I came in a state of so much weakness that I rested four times in walking between the Inn and the lodging. By physic and abstinence I grew better, and am now reasonably easy, though at a great distance from health. I am afraid, however, that health begins after seventy and long before to have a meaning different from that which it had at thirty. But it is culpable to murmur at the established order of the creation as it is vain to oppose it; he that lives must grow old; and he that would rather grow old than die has God to thank for the infirmities of old age.

Johnson did not admire the Downs at the back of Brighton. He said a man would soon be so overcome by their dismal character that he would hang himself if he could find a tree strong enough to bear the rope, but that this he would fail to do.

Fanny Burney visited Brighton several times in company with Mrs. Thrale, who was evidently fond of the place, and other friends. The Thrales lived at 75, West Street. On her first visit in 1779 the author of *Evelina* was much annoyed by her own celebrity. She was stared at every time she entered the Assembly Rooms or walked on the Stoyne. She went to a big dinner at the Ship Tavern, given by the officers of the garrison, who had their mess there. "It was situated," she writes (in May): "exactly

¹ *Letters of Samuel Johnson Collected and Edited by George Birkbeck Hill*. Oxford, 1892.

opposite to the inn in which Charles II hid himself after the battle of Worcester, previously to his escaping from the kingdom. So I fail not to look at it with loyal satisfaction; and his black-wigged Majesty had from the time of the Restoration been its sign." In the autumn of the same year she was back again at Brighton, when she writes:

We left Tunbridge Wells, and got by dinner time to our first stage—Uckfield. . . . Our next stage brought us to Brighthelmstone, where . . . the morning after our arrival our first visit was from Mr. Kipping, the apothecary, a character so curious that Foote designed him for his next piece before he knew he had already written his last. He is a prating good humoured old gossip, who runs on in as incoherent and unconnected a style of discourse as Rose Fuller, though not so tonish.

A note to this passage says that Foote had spent his last summer at Brighton. There was a Kipping, a surgeon, at 28, West Street, in 1800, and it was a Dr. Kipping who in 1775 attended Single-Speech Hamilton when he had a serious horse accident on Brighton downs. During this visit Miss Burney met Lady Diana Beauclerk and Mrs. Masters, mother of the man who married Byron's first love, Mary Chaworth. In a letter to Miss Burney, dated Brighthelmstone, Wednesday, July 19th, 1780, Mrs. Thrale describes her life there as follows:

I write now from Bowen's shop where he has been settled about three days I think, and here comes in one a man Hopping and asks for "Russell on Sea water" another tripping, and begs to have the last new novel sent him home tonight; one lady tumbles the ballads about, and fingers the harpsichord which stands at every blockhead's mercy; and another looks over the Lilliputian library and purchases polly sugar cake for her long-legged missy. My master is gone out riding and we are to drink tea with Lady Rother. After which the Stoyne hours begin, and we cluster round Thomas's shop and contend for the attention of Lord John Clinton, a man who could I think be of consequence in no other place upon earth, though a very well informed and modest mannered boy. . . . The players this year are rather better than the last, but the theatre is no better than a band box which is a proper precaution I think as here are not folks to fill even that. The shops are all shut still and a dearth of money complained of that is lamentable. But we have taken some Spanish snips it seems and Lavenacreise besides.

In October, 1782, Miss Burney was again in Brighton with the Thrales and Dr. Johnson. On Monday, October 28th, she writes:

At dinner we had Dr. Delap and Mr. Selwyn, who accompanied us in the evening to a ball, as did also Dr. Johnson, to the universal amazement of all who saw him there; but he said he found it so dull being quite alone the preceding evening that he determined upon going with us, for he said it cannot be worse than being alone.

On Saturday, November 2nd, she writes:

We went to Lady Shelley's, Dr. Johnson again excepted in the invitation. He is almost constantly omitted either from too much respect or too much fear. I am sorry for it, as he hates being alone, and as, though he scolds the others, he is well enough satisfied himself; and having given vent to all his own occasional anger or ill humour, he is ready to begin again, and is never aware that those who had been so "downed" by him never can much covet so triumphant a visitor.

Brighton air or society, or the two together, appear to have been too much for Dr. Johnson's temper, for on Thursday, November 7th, Miss Burney writes:

Mr. Metcalf called upon Dr. Johnson and took him out an airing. Mr. Hamilton is gone, and Mr. Metcalf is now the only person out of this house that voluntarily communicates with the doctor. He has been in a terrible severe humour of late, and has really frightened all the people till they almost ran from him. To me only I think he is now kind, for Mrs. Thrale fares worse than anybody. 'Tis very strange and very melancholy that he will not a little more accommodate his manners and language to those of other people.

The only mention of bathing occurs on the last day of the 1782 visit, which was passed, according to Miss Burney, in the following manner:

Wednesday, November 20th. Mr. and the three Miss Thrales and myself all arose at six o'clock in the morning and "by the pale blink of the moon" we went to the seaside where we had bespoke the bathing women to be ready for us, and into the ocean we plunged. It was cold but pleasant. I have bathed so often as to lose my dread of the operation which now gives me nothing but animation and vigour. We then returned home and dressed by candlelight, and as soon as we could get Dr. Johnson ready we set out upon our journey in a coach and a chaise and arrived in Argyl street at dinner time.

It was at Brighton that Mrs. Thrale met Piozzi, whom she afterwards married, to the indignation of society, but

apparently to her own satisfaction. In her *Autobiography*⁴ she gives an account of her first meeting with the Italian singing master:

I was at Brightelmstone in August, 1780, or thereabout, when the rioters at Bath had driven my sick husband and myself and Miss Thrale (Fanny Burney went home to her father) into Sussex for change of place. I had been in the sea early one morning and was walking with my eldest daughter on the cliff, when seeing Mr. Piozzi stand at the library door I accosted him in Italian, and asked him if he would like to give that lady a lesson or two whilst at Brighton that she might not be losing her time. He replied coldly that he was come thither himself merely to recover his voice, which he feared was wholly lost, that he was composing some music and lived in great retirement. So I took my leave and we continued our walk, Miss Thrale regretting she had lost such an opportunity; but on our returning home the same day, Mr. Piozzi started out of the shop, begged my pardon for not knowing me before, protested his readiness to do anything to oblige me and his concern for not being able to contribute to our amusement, but that I should command everything in his now limited power. We parted, and at breakfast the post brought me a letter from the present Madame d'Arblay (Fanny Burney), saying that her father's friend, Mr. Piozzi, was gone to Brightelmstone where she hoped we should meet. . . . And that I should find him a companion likely to lighten the burden of life to me as he was just a man to my natural taste. . . . Mr. Thrale found his performance on the forte-piano so superior to everything heard in England and in short took such a fancy to his society that we were seldom apart except while Mr. Piozzi was studying to compose. . . . His voice strengthened by sea bathing, but never recovered the astonishing powers he brought with him first from Italy.

Royalty at Brighton.

The true begetter of Brighton in a social sense was George IV, but he was not the first royal personage whose name is associated with the place. As mentioned by Fanny Burney in one of the passages quoted, it was from Brighton on the night of October 14th, 1651, that Charles II escaped from England after the battle of Worcester. He lodged or, as our ancestors used to say, lay at a small inn called The George, which stood in West Street. It has since been known as the King's Head. He was taken across to Fécamp in a collier by Nicholas Tettercell. Unlike too many of those who befriended the Merry Monarch in his adversity, Tettercell received a valuable ring and an annuity of £100 for himself and his descendants. His craft is said to have been fitted up and admitted into the Royal Navy under the name of the *Royal Escape*. She mouldered quietly away at Deptford till 1791, when the little that was left of her was broken up for firewood. Tettercell was constable of Brightelmstone in 1670 and died in 1674. He is buried in the churchyard of St. Nicholas, where there is a tomb with inscriptions in prose and verse.

It was in 1782 that George IV, then Prince of Wales, first visited Brighton. He was the guest of his uncle, the Duke of Cumberland, and was so pleased with the air and with the town that he went there frequently, and for years was almost a resident. Thackeray says:

It is the fashion to run down George IV, but what myriads of Londoners ought to thank him for inventing Brighton. One of the best physicians our city has ever known is kind, cheerful, merry Doctor Brighton.

There the First Gentleman of Europe built his famous Pavilion, aptly described by Hare as "a foolish Chinese palace." The number of minarets made Sydney Smith say it seemed as if the dome of St. Paul's had come down to Brighton and pupped. William Wilberforce said, even more happily: "It looks very much as if St. Paul's had come down to the sea and left a litter of cupolas." Charles Lamb, in his essay on Baramness of the Imaginative Faculty in the Productions of Modern Art, tells the following story:

The Court historians of the day record that at the first dinner given by the late King, then Prince Regent, at the Pavilion, the following characteristic frolic was played off. The guests were select and admiring, the banquet profuse and admirable, the lights lustrous and oriental, the eye was perfectly dazzled with the display of plate, among which the great gold salt cellar brought from the regalia in the Tower for this especial purpose, itself a Tower! stood conspicuous for its magnitude. And now the Rev. . . . the then admired court chaplain was proceeding with the grace when at a signal given the lights were suddenly

overcast and a huge transparency was discovered in which glittered in gold letters— "BRIGHTON EARTHQUAKE— SWALLOW-UP ALIVE!"

Imagine the confusion of the guests, the Georges and Garters, jewels, bracelets, molten upon the occasion! The fans dropped and picked up the next morning by the sly court pages! Mrs. Fitz—what's her name, fainting, and the Countess of * * * holding the smelling bottle till the good-humoured Prince caused harmony to be restored by calling in fresh candles and declaring that the whole was nothing more than a *pantomime hour*, got up by the ingenious Mr. Farley, of Covent Garden, from hints which his royal highness himself had furnished! Then imagine the infinite applause that followed, the mutual rallyings, the declarations that "they were not much frightened" of the assembled galaxy.

This joke was in questionable taste, but later the Pavilion acquired an evil reputation which shocked the most loyal among the respectable inhabitants. Moralists shook their heads and said they were happier before Brighton was captured by fashion and the vices which followed in its train. But it was very lively. There were,⁵ says an anonymous author, grand reviews on the downs, sham boat fights out at sea, gala nights at the grove, balls and feasts at the castle, fireworks in the Steyn, and raffling at Gregory's library. Gregory often had a thousand names on his lists for half-guinea and guinea tickets. George was called "Brighton's support," but though his presence was profitable to the natives it was very costly to visitors. Some moralist of the time recorded his impressions of the costliness of Brighton in the following epigram:

Say why on Brighton's church we see
A golden shark displayed.
But that was aptly meant to be
An emblem of its trade.
Nor could the thing so well be told
In any other way.
The town's a shark that lives on gold,
The company its prey.

Thackeray, in his *Four Georges*, gives us a specimen of the orgies at the Pavilion:

And now I have one more story of the Bacchanalian sort, in which Clarence and York and the very highest personage of the realm, the great Prince Regent, took part. The feast took place at the Pavilion at Brighton, and was described to me by a gentleman who was present at the scene. In Gilray's caricatures, and amongst Fox's *Jolly Associates*, there figures a great nobleman, the Duke of Norfolk, called Jockey of Norfolk⁶ in his time, was celebrated for his table exploits. He had quarrelled with the Prince, like the rest of the Whigs, but a sort of reconciliation had taken place, and now, being a very old man, the Prince invited him to dine and sleep at the Pavilion, and the old duke drove over from his castle of Arundel with his famous equipage of grey horses still remembered in Sussex. The Prince of Wales had concocted with his royal brothers a notable scheme for making the old man drunk. Every person at table was enjoined to drink wine with the Duke—a challenge which the old toper did not refuse. He soon began to see that there was a conspiracy against him. He drank glass for glass, he overthrew many of the brave. At last the First Gentleman of Europe proposed bumpers of brandy. One of the royal brothers filled a great glass for the Duke. He stood up and tossed off the drink. Now, says he, I will have my carriage and go home. The Prince urged upon him his previous promise to sleep under the roof where he had been so generously entertained. No, he said, he had had enough of such hospitality. A trap had been set for him. He would leave the place at once and never enter its doors more. The carriage was called and came, but in the half-hour's interval the liquor had proved too potent for the old man. His host's generous purpose was answered, and the Duke's old grey head lay stupefied on the table. Nevertheless, when his postchaise was announced he staggered to it as well as he could, and stumbling in bade the postillions drive to Arundel. They drove him for half an hour round and round the Pavilion lawn. When he awoke that morning he was in bed at the Prince's hideous house at Brighton. You may see the house now for sixpence. They have fiddlers there every day, and sometimes buffoons and mountebanks hire the riding horse and do their tricks and tumbling there. The trees are still there, and the gravel walks round which the poor old sinner was trotted. I can fancy the flushed faces of the royal princes as they support themselves at the portico pillars, and look on at old Norfolk's disgrace, but I can't fancy how the man who perpetrated it continued to be called a gentleman.

With Brighton, too, is connected the name of Mrs. Fitzherbert, who was really married to George, as is proved

⁴ *Brighton: The Road, the Place, the People.* London: Published (for the proprietors) by J. H. Thomson, 49, Fleet Street, 1862.

⁵ This is the same duke of whom it is recorded that he would say: "Next Saturday, with the help of Providence, I intend to be drunk." He attended the funeral of Lord Brougham's mother, and the party was so drunk that the coffin was dropped over a bridge into a river on the way, the loss not being discovered till the party arrived at the churchyard.

⁴ *Dr. Johnson's Mrs. Thrale. Autobiography, Letters, and Literary Remains of Mrs. Piozzi.* Edited by A. Hayward, O.C. Newly selected and edited, with introduction and notes by J. H. Lobban. Published by F. N. Spon, Edinburgh and London, 1910.

by the documents published by the late Mr. Wilkin in his book, *Mrs. Fitzherbert and George IV.*

William IV did little for Brighton beyond building the Norman entrance to the Pavilion, and Queen Victoria is said to have turned her back upon it for ever because when she walked on the Chain Pier butchers would insist upon following her and kissing the hem of her garment. From that time the Pavilion ceased to be a royal palace and became the property of the town. The building which had cost a million was sold for £54,000.

The "Queen of Watering Places."

Brighton has been called the "Queen of Watering Places," and its social attractions are very great. It has many rivals, but none with the special advantage it possesses of being at the point of the south coast nearest to the capital. It is so accessible by railway that a large number of busy toilers in the City and other metropolitan centres of work, make it their residence; hence it is appropriately styled "London-on-Sea." The air is bracing, and it is a favourite place for the completion of the recovery of convalescents and the recuperation of the overworked. A full account of the geology of the soil, and of the meteorology, vital statistics, climatic qualities, and of the indications and contraindications of Brighton as a health resort is given in the *Climates and Baths of Great Britain, being the Report of a Committee of the Royal Medical and Chirurgical Society of London* (Macmillan and Co., London, 1895, p. 363). It may be noted that the mineral spring at Furze Hill to which Bellian attributed such therapeutic virtue, and which was more accurately analysed by Maveet, receives only a passing mention in that work.

In this discursive sketch we have traced the growth of Brighton from a fishing village, the life of which for many centuries was a struggle against the encroachments of the sea, the visitations of storm and flood, and the depredations of foreign foes, to a large and prosperous city. On another occasion we may supply some omissions and describe more in detail its claims to the interest of the visitor who goes thither for pleasure, and its advantages as a health resort.

THE MEDICAL INSTITUTIONS OF BRIGHTON.

The medical institutions of Brighton comprise the Royal Sussex County Hospital, the Royal Alexandra Hospital for

In addition there are two medical societies—the Brighton and Sussex Medico-Chirurgical Society, and the Brighton Division of the British Medical Association.

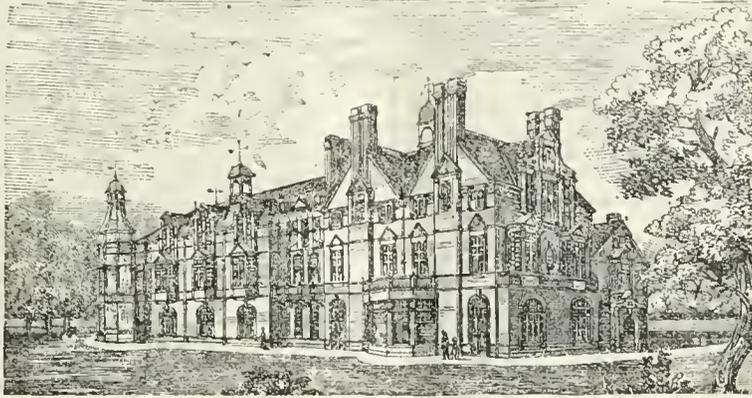

The Royal Sussex County Hospital.

The Royal Sussex County Hospital, which is the chief hospital in the county, is situated in the eastern part of the town, and is a very old-established institution, dating, in fact, from early in the nineteenth century. Prior to 1813, a small hospital known by the same name existed in Middle Street, and in its day did much good work. During the year mentioned, however, the Earl of Egremont, then Lord Lieutenant of the county, called a meeting with a view to discussing the advisability of organizing a medical

institution with a broader and more comprehensive basis than the one already in operation. This proposition did not meet with immediate favour, and it was not till 1824 that any definite scheme was arrived at. Lord Egremont gave £1,000 towards the first building fund, and Mr. Thomas Read Kemp presented the site and £1,000 towards the building. Lord Egremont laid the foundation stone on March 15th, 1826, and the hospital was opened with three in-patients admitted on the very day of the inauguration on June 28th, 1828. The in-patients for the ensuing twelve months numbered 224, the accidents 13, and the out-patients 72. These figures were more than doubled in two years, and quadrupled within twelve years, the figures for 1840 showing 874 in-patients, 254 accidents, 60 urgent cases, and 1,208 out-patients. In 1839 the Victoria wing was added, and named after Her Majesty the Queen; the Adelaide wing, named after the Consort of William IV., was opened in 1841; the east and west wings in 1855, the chapel in 1856, the enlargement of the west wing in 1867, the museum in 1870, the new library and museum and the Lady Grant block in 1887, and the York building in 1893. This building was so called in honour of the Duke and Duchess of York, whose wedding took place about the time the wing was opened. Since then many improvements have been added to the hospital, such as a home for nurses, a new out-patient department, and a new operating theatre.

The foundation stone of the new out-patient department was laid by the late King (then Prince of Wales) in 1896, and has now, of course, been completed many years. His Royal Highness was not the only member of the Royal Family who has shown an active practical interest in the work of the hospital, as various tablets and inscriptions about the interior bear witness. George IV., William IV., Queen Adelaide, and Queen Victoria have all been among its patrons, Queen Victoria having given £1,000

At the present time the hospital has 195 beds. In 1911 2,507 cases were admitted, 1,389 operations were performed in the theatre, and 628 in the surgery; 10,340 out-patients were admitted, 7,083 casualties treated, and 119 patients sent to the convalescent home belonging to the hospital at Ditchling. The staff consists of three consulting physicians, including Dr. Ainslie Hollis, President elect of the Association, three consulting surgeons, including Mr. T. Jenner Verrall, whose work in connexion with the Association is so well known, a consulting gynaecologist, and a consulting dental surgeon. There are three physicians and three surgeons, with a corresponding number of assistant physicians and assistant surgeons. In addition there are physicians or surgeons in charge of the special departments of ophthalmology, dermatology, electrical and x-ray work, and dentistry, as well as two anaesthetists and a medical and a surgical clinical assistant. The hospital serves a very large district indeed, and is one of the largest and most important in the South of England.

Royal Alexandra Hospital for Sick Children, Brighton.

The fact that on an average 186 of the available 195 beds are occupied is sufficient to prove that the institution is appreciated by those for whom it is intended.

The Royal Alexandra Hospital for Sick Children.

The Royal Alexandra Hospital for Sick Children is situated in the centre of the town, in the Dyke Road. It was founded in 1868, and was the concurrent and simultaneous work of several benevolent ladies and gentlemen. The patients were at first treated at a house in Western Road, with only three or four small rooms for the accommodation of the inmates. The hospital was attended with immediate and great success, thus showing that the originators were correct in their estimate that such a place was wanted in a town as populous as Brighton. The medical profession was enthusiastic, and such men as Sir William Jenner and Dr. Charles West were warm in its praises. H.R.H. the Duchess of Cambridge and H.R.H. the Duchess of Teck were the first royal patronesses. The number of patients increased to such an extent that it was deemed necessary to enlarge the hospital, and premises were taken which stood on the site of the present building. After being occupied for some time they were found to be insanitary and ill-adapted for hospital purposes, and it was therefore decided, in 1875, to discontinue repairing and patching them, and in 1880 the foundation stone of the present building was laid, with Masonic rites, by the Right Worshipful Brother Sir Walter W. Burrell, M.P., Provincial Grand Master of the Freemasons of Sussex. In July, 1881, the present hospital, consisting of three spacious wards, each containing twenty beds, and the necessary household accommodation, was opened by their Royal Highnesses the Prince and Princess of Wales. The Princess of Wales graciously acceded to the request that the hospital should be called the Royal Alexandra Hospital for Sick Children. In 1887 the hospital work increased so much that an assistant physician was appointed, and later

on an assistant surgeon. Later an orthopaedic surgeon and a skiagraphist were appointed, and the operating theatre was enlarged and improved. In May, 1896, H.R.H. Princess Louise, Duchess of Fife, laid the foundation stone of the Nurses' Dormitory, a detached building approached from the hospital by a covered way. In the same year the hospital was visited by the Prince of Wales, who inspected all the wards, and wrote as follows in the visitors' book: "Found the hospital in excellent order.—Albert Edward." In the same month the Princess of Wales also honoured the hospital with a visit. The Princess was accompanied by her three daughters and Prince Charles of Denmark. Noticing the entry made by the Prince of Wales in the visitors' book, the Princess remarked to the matron that she was thoroughly prepared to endorse the Prince's gratifying comment. During the year 1902 the new laundry was built at a cost of over £900, and plans for the new out-patient department were prepared and passed. This building has since been opened and contains, in addition

to the usual rooms, a small theatre for minor operations and a well-fitted x-ray and electrical room. There is also a room fitted with the appropriate apparatus for the treatment of lateral curvature and other deformities.

At the present time the hospital consists of three wards, with 61 beds, with an isolation ward, an operating theatre, an x-ray department, and a well-organized out-patient department. The staff consists of two physicians, two surgeons, an assistant surgeon, a dermatologist, a dentist, and a skiagraphist. The number of patients admitted in 1911 was 814, and out-patients and casualties numbered 4,332. The number of operations performed was 351. It is interesting to note, as showing the advance in surgery, that in 1870 ten operations only were performed as follows: 1 tracheotomy, 1 excision of joint, 1 amputation of finger, 2 tenotomies, and 5 operations for removal of bone.

Out-patients' Department and Isolation Block, Royal Alexandra Children's Hospital, Brighton.

The Throat and Ear Hospital.

The Throat and Ear Hospital, situated in Church Street, Queen's Road, near the railway station, was founded in 1878 by Mr. Cresswell Baber and Dr. Scatliff. It was first started in two small rooms in Grenville Place. It was soon transferred to a house in Queen's Road, and, finally, the present spacious building was opened by the Duke

of Norfolk in 1898. The staff consists of four acting surgeons with a dental surgeon. There are twenty beds in the hospital, which are always more or less full. In 1911 the number of out-patients was 1,524, and of in-patients 322. The operations performed under general anaesthesia numbered 622.

The Sussex Eye Hospital.

The Sussex Eye Hospital, situated in Queen's Road, was founded in 1832. The present building was built in 1847, and rebuilt in 1882. At first out-patients only were attended, the number in the year of foundation being 397. In 1911 there were 219 in-patients and 4,926 out-patients. The

staff consists of three surgeons and three assistant surgeons.

The Hospital for Women.

The Hospital for Women, West Street, is a hospital for the treatment of diseases peculiar to women and for attending women in their confinements. The present building contains eight beds, and 176 in-patients were admitted, and 468 out-patients seen in 1911. In addition 1,161 midwifery cases were attended. There is a branch for midwifery patients in Hove. Attached to the hospital are four acting members of the staff, and nurses are trained there for midwifery work. It is intended, as soon as the necessary funds can be raised, to obtain a more suitable site and building for the hospital.

The Dispensary.

The Brighton, Hove and Preston Dispensary is the oldest medical institution in the town. It was founded in 1809, and the following extract from a letter written in 1849 by Mr. Thomas Attree, the first Honorary Secretary of the institution, is of interest in connexion with its origin:

About forty years ago, in the year 1809, when I was Vestry Clerk to the Commissioners of the town and to the Directors and Guardians of the Poor, and conducting a large practice as a solicitor, was Honorary Secretary to the various fresh schemes for the improvement of Brighton, then in the first blush of its prosperity, and thinking of becoming a town of itself and not an adjunct of Lewes. At this time when I was overworked with business, a stranger, a new client (as I thought) was shown into my office. He was dressed as a quaker, with a ready smile heightened to a short laugh as he noticed my manner in asking his business.

" 'Tis not business, friend, and yet it is, for 'tis the business of charity Richard Phillips comes about. I'll tell thee. For the benefit of the sick poor of this town thee must have a dispensary. Thou canst help. Thou dost not say no, so Richard Phillips takes it for 'Yes.' " *And so it was.* I found I had taken upon me another, and not a trifling occupation.

The dispensary was then founded, and the first building used was situated in Nile Street, near the market. The work grew rapidly, and in 1811 it moved to larger premises in North Street, and it was at this time that the scheme of the Earl of Chichester to connect it with an infirmary and an accident ward was commenced. Rooms were fitted up to contain 10 beds, and these wards, it was hoped, would eventually expand into a county hospital. For a short time the institution, now termed the "Brighton Dispensary and Sussex County Hospital," had to go into temporary premises in Duke Street, till in 1818 a much larger building in Middle Street, with accommodation for 20 in-patients and more room to deal with out-patients, was purchased. In 1849 the dispensary was transferred to the present site in Queen's Road, and branches were established later on in Hove and Preston. The Hove branch was improved and the present building opened in 1888; it contains 2 wards of 6 beds each for the reception of accident and urgent cases, so that they may not have to be conveyed four miles to the County Hospital. The work of the institution has increased enormously; in 1809 the number of out-patients was 429; in 1911 the number was 9,179. The number of in-patients at the Hove branch in the first year of opening, 1869, was 33; in 1911 it was 195 and 252 operations were performed. In addition to these there were at the three branches 1,216 casualties.

It is interesting to notice that one of the first physicians appointed to the staff of the dispensary was Dr. (afterwards Sir Matthew) Tierney, Physician Extraordinary to His Royal Highness the Prince of Wales, and that during over one hundred years there have been only three honorary secretaries—Mr. Thomas Attree, 1809 to 1835; Mr. Somers Clarke, 1835 to 1889; and Mr. Cecil Somers Clarke, appointed in 1889, the present holder of the office. There is a Samaritan Fund in connexion with the dispensary, which is chiefly used to provide additional nourishment to those patients who, in the opinion of the medical officers, need it to aid their recovery.

The Lady Chichester Hospital.

The Lady Chichester Hospital and Dispensary for Women and Children which is officered by medical women

consists of two portions, the hospital in Brunswick Place with thirty-three beds, and the dispensary in Ditchling Road. The object of this charity is especially to provide early treatment for cases of serious breakdown among poor women and girls, and to afford to poor women of Brighton and the neighbourhood the opportunity of free consultation with doctors of their own sex. That the institution is appreciated is shown in the fact that there were 7,850 attendances during the year 1910 at the dispensary.

The Dental Hospital.

The Dental Hospital is situated in Queen's Road, and has a good staff for the treatment of dental diseases. There is also a Dental Society which meets for the discussion of matters connected with the speciality.

THE BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

The Brighton and Sussex Medico-Chirurgical Society is of old standing, for it was established in 1847. At a meeting of the medical officers of the Brighton Dispensary held at that institution in May, 1847, Dr. King in the chair, it was resolved that it was desirable to establish a Brighton Medical Society. A circular was sent to the members of the profession in the town inviting them to meet and discuss the matter, and as the result of that meeting the Brighton and Sussex Medico-Chirurgical Society was formed, and at the outset forty members joined. It is interesting to note that among them were many men whose sons are now practising in the town. The society was established for the advancement of medical and surgical knowledge among its members, and the first ordinary meeting was held on August 5th, 1847. Dr. King was the first chairman, when Mr. Hingston read the first paper on the sequelae of measles and scarlet fever.

The society gradually increased in numbers, till at the present time it has a membership of 135. The chairman is Dr. E. Hobbouse, who will be the president of the Section of Medicine at the annual meeting at Brighton this year. Meetings of the society are held monthly when cases are shown and papers read, and, in addition, clinical and pathological meetings take place at the various hospitals in the town. The society possesses an excellent library, which is constantly being augmented by the addition of fresh works. The membership in the past has included many names of note—for example, E. L. Ormerod, F.R.S., John Cordy Burrows, M.P., W. Mellitt Hollis, John Jardine Murray, Dr. Withers Moore (the President at the last annual meeting which was held in Brighton twenty-six years ago), Arthur Newsholme, T. Jenner Verrall, and E. Cresswell Baber. The society is in a flourishing condition, with an increasing membership, and its meetings are well attended by the practitioners in the town and neighbourhood.

THE BRIGHTON DIVISION OF THE BRITISH MEDICAL ASSOCIATION.

The Brighton Division of the South-Eastern Branch of the British Medical Association was formed in June, 1903, when Mr. W. J. Stephens was elected first Chairman; Dr. W. Ainslie Hollis, Vice-Chairman; and Mr. T. Jenner Verrall, Honorary Secretary. At the present time the Division is one of the most flourishing in the South of England, the membership now exceeding 200. Dr. Ryding Marsh is the Chairman; Dr. Benham, Secretary; and Mr. Burchell, Assistant Secretary. Meetings are held frequently, and great activity has been displayed in medico-political matters, notably in the matter of the Insurance Act, in connexion with the Brighton and Hove Education Committee's school appointments, and medical appointments under the Board of Guardians.

THE mid-December meeting of the United Services Medical Society was held at the Royal Naval Medical School at Greenwich, this being the first occasion on which the society has met at this new institution. The president of the society, Fleet Surgeon P. W. Bassett-Smith, R.N., presided, and Fleet Surgeon Munday gave an account of the medical work involved by the attempts carried on since 1909 to put down the illicit trade in arms in the Persian Gulf.

LITERARY NOTES.

MR. H. K. LEWIS announces that No. 1 of Volume II (January, 1913) of the *Journal of Vaccine Therapy* was published on January 3rd. Dr. W. D'Este Emery has succeeded Dr. Allen as editor. A feature of the new volume will be a monthly review of progress in vaccine therapeutics. It is intended to devote some pages each month, if there be sufficient matter, to short extracts from articles in current periodical literature bearing on the subject dealt with by this journal. Special attention will also be given to applied bacteriology in relation to vaccine therapy, since success in treatment is dependent upon accuracy in diagnosis of the infecting organism or organisms. Record will be made of such improvements and discoveries in bacteriological science as may conduce to this end, particularly in regard to methods of procedure and general technique likely to be of value to the general practitioner.

The November number of *L'Hygiène* contains, in addition to an interesting record of Dr. Rebreyend's experiences in the French hospital at Adrianople, a short article by Dr. A. Maurice on the re-education of the sense of hearing; an account by Dr. "Horace Bianchon" of the present state of public health in France and the notification of tuberculosis; and some excellent advice by Professor George Vian, of the Dental School of Paris, as to the best means of preserving the teeth. Dr. George Rosenthal discusses the physiological exercise of respiration and breathing gymnastics. The illustrations are, as usual, numerous and on the high level of artistic finish to which we have become accustomed in our excellent contemporary.

In the JOURNAL of December 14th we discussed the value of a well sounding name. The paragraph attracted some notice in the lay press, and from comments that appeared it was evident that the justice of our remarks was recognized by lawyers and men of business as well as doctors. Since then, on looking through the recently published life of G. F. Watts, we were interested to find that the great artist abhorred the surname which he had made so famous, doubtless thinking it too common and bourgeois. One of the "devout female sex," by many members of which he was made the object of an innocent worship, found a solution which gratified him. She called him the "Signor," and by that designation he was always known among his friends.

Jules Lemaitre is fond of the conversations of doctors and especially of surgeons, because they know human nature well, as they see men in the circumstances in which they show most clearly what they are. The continued sight of the worst sufferings combined with this knowledge of mankind inspires them with a melancholy and lofty philosophy sometimes brutal and negative, but with great pity at bottom. In his *Contemporains* Lemaitre tells the following story, which he had from a well-known doctor, who in 1870 was surgeon-major in the army of Metz. The ambulances were full of wounded. There were terrible operations to be performed, and many of them, and the chloroform had run out. A messenger was sent under a flag of truce to ask a supply of the anaesthetic from the Germans. They did not answer for four days, and then the reply was to the effect that under their articles of war they were not allowed to permit chloroform to be sent into a besieged place, that substance being a derivative of alcohol! The surgeon had only one small bottle of chloroform, and was puzzled how to select the cases in which it should be used. The first patient who came under his hands was a little soldier with a shattered hand. Amputation through the forearm was necessary. The soldier begged for an anaesthetic, and although the doctor explained the situation, he still insisted that he was too weak to bear the operation without an anaesthetic. The surgeon finally gave way, but whilst he was getting ready the little soldier suddenly cried out: "There are others in much worse case than I am. It would be beastly to be a coward!" So he declined the anaesthetic. Another patient was an officer with a terrible wound requiring a long operation. When the surgeon said that he was going to give him an

anaesthetic, the captain replied: "Monsieur le Major, you must keep that for those who are not officers."

In the JOURNAL of December 28th, 1912, some account was given of the authority given to bishops under the "Act for the Appointing of Physicians and Surgeons," passed in 1511, of granting licences to practise the art of healing. It may interest some of our readers to learn that the subject was dealt with Dr. Henry Barnes, of Carlisle, in a paper read at Seascale in 1902, which was printed in the Cumberland and Westmorland Antiquarian and Archaeological Society's *Transactions*, Vol. III, New Series, and issued in pamphlet form in 1903. Speaking of the fact that bishops also licensed midwives, he says this was necessary, inasmuch as if there was any danger of the child dying before the priest could be summoned the midwife was bound to baptise it. Before the licence was given, she had to take an oath containing fifteen items. She was to use "pure and clean water only, and not any rose or damask water, or water made of any confection." Dr. Barnes states that in the Norwich Diocese Book there is between 1770 and 1786 a record of licences granted to thirty persons "to perform the office, business, and functions of midwife," and to three persons, two of whom were women, to practise as surgeons, and to others to practise phlebotomy. No licences were granted after 1786. About three years ago, Dr. Pol Gosset of Rheims published in the *Revue Médicale du Nord-Est* an account of the selection of women to act as midwives by the curé of the parish. The following oath was administered to them:

You promise to God, and you pledge yourself by oath, to assist by night and day the women with child, whether rich or poor, who may have recourse to your aid; and to devote yourselves to the preservation of their infants, as much from religion as in accordance with promise, or for presents, or other consideration whatever. You will not do anything, nor agree to anything being done, to hasten delivery by any extraordinary procedures, nor anything which could injure the health of the mother or child.

The curé was enjoined to choose midwives from among the most respectable and virtuous women of the parish. Any one who had ever been suspected of heresy or sorcery must be rejected. Women chosen for the office were instructed in the ritual of baptism, which they were to administer only in case of necessity.

In the JOURNAL of December 28th, 1912, reference was made to the fact that Jean Jacques Rousseau had been sounded for stone by Frère Côme. It may interest some readers to read Rousseau's own account of the matter as given in *Les Confessions*. Rousseau all his life suffered more or less from urinary troubles and he became convinced that he had stone in the bladder. In 1762 his suffering became so acute that Marshal de Luxembourg, who befriended him, insisted on his seeing Frère Côme. He himself brought the Prior-Surgeon to the patient's bedside, and in Rousseau's words had the courage, "certainly rare and meritorious in a great lord," to remain beside him during the operation, which was severe and prolonged. Rousseau proceeds:

Nevertheless it was only a question of being sounded, but I had never been able to have this done even by Morand who tried several times, always without success. Frère Côme, who had a hand of unequalled skill and lightness, succeeded at last in introducing a very fine catheter after making me suffer more than two hours, during which I strove to refrain from groaning so as not to rend the sensitive heart of the kind Marshal. On the first examination Frère Côme believed he had found a large stone and told me so. At the second he found nothing. Having tried again more than once with a care and thoroughness which made me find the time very long he declared there was no stone, but that the prostate was scirrhous and of extraordinary size. He found the bladder large and in good condition and ended by telling me that I would suffer much and live long. If the second prophecy is fulfilled as exactly as the first my sufferings are not near their end. Thus after having been treated successively for so many years for twenty diseases which I had not, I ended by knowing that my disease, incurable without being mortal, would last as long as myself. My imagination held in check by this knowledge, no longer made me see in perspective a cruel death in the pains of calculus. I ceased to fear that the end of a bougie which had broken in the urethra long before had formed the nucleus of a stone. Freed from imaginary fears more cruel for me than real evils I endured the latter with greater equanimity. It is certain that since that time I have suffered much less from my disease than I had till then.

British Medical Journal.

SATURDAY, JANUARY 4TH, 1913.

THE UNDERTAKING AND PLEDGE.

A CONSIDERABLE number of practitioners have written to the central office urging that the Association should relieve them of their Undertaking and Pledge, thus allowing them to accept service on panels. As it is impossible at the present time to answer these letters individually, the following may be taken as a general reply. It is evident that in most cases the request for release was made because of sheer economic pressure, and not because the applicant desired of his own free will to accept service.

The position of the practitioner who is a loyal and devoted member of the Association, and therefore anxious to carry out its policy, but who finds himself faced by the fact that some of his neighbours are going on the panel, is indeed a cruel one, and the State Sickness Insurance Committee, when it considered the matter at its meeting on Monday, December 30th, 1912, would have been glad to find some way out of the difficulty which, while maintaining the policy of the Association, would not penalize the loyal practitioner. In the opinion of the Committee, however, the terms of the Undertaking clearly preclude practitioners who have signed it from either making individual arrangements for service under the Act or entering into any agreement which is not in conformity with the policy of the Association. Those who signed the Undertaking and Pledge can be released from their bond only by the deliberate decision of the Representative Body. Only by ignoring the spirit which underlies the whole conception of the Undertaking and Pledge can the binding nature of these documents be denied. There is no doubt that those who signed them did so with the intention of acting with the profession as a body, and, in conformity with ordinary democratic principles, they agreed to be bound by the ruling of the majority. There is no getting away from the fact that the opinion of the majority of the profession, as expressed in the vote of the recent Divisions and reflected in the findings of the last Special Representative Meeting, was strongly against accepting service under the Act under present conditions. Those who now wish to evade their pledge must remember that the present policy of the Association of refusal to accept service under the Act is the consequence of the vote which has recently been given in the Divisions, and it must be assumed that when that vote was given the Divisions acted with a full sense of the probable consequences. There is no doubt that in any district where the profession remains absolutely or even practically united in refusal to serve, those responsible for the provision of medical attendance will be compelled to allow arrangements to be made outside the Act. The threatened whole-time service would be difficult to form not only on account of the controversy with the profession, but because the idea would be repugnant to

the average insured person. The Government, which is now refusing to allow persons to make their own arrangements, would undoubtedly be glad to do so if it found that in the whole, or the greater part, of the kingdom panels were not likely to be formed.

Another aspect of this question requires special mention. Some practitioners, fortunately very few, seem to imagine that by resigning their membership of the Association they get rid of their responsibility for the present situation and their Undertaking and Pledge. This is, of course, an entirely mistaken idea. It cannot be too strongly urged upon every member of the Association that whatever the result of the present fight may be, the necessity for a strong combination of the profession in order to defend its interests will be greater than ever under the new conditions of medical practice.

GASWORKS PITCH INDUSTRIES AND CANCER.

Two reports on ulceration of the skin and epitheliomatous cancer occurring in workers employed in the manufacture of patent fuel and grease have been published by the Home Office. Apart from the frequency of epithelioma and ulceration of the corneal surface of the eye in men who handle tar and tar products, and the pathological problem raised, their occurrence is of interest to the medical profession, since both of these conditions, as also the scrotal epithelioma of chimney-sweeps, have been added to the third schedule of the Workmen's Compensation Act. Men who handle pitch or are engaged in the manufacture of briquettes occasionally suffer from warty growths which may ulcerate and become the seat of epitheliomatous cancer, or particles of pitch strike the eyes and induce severe inflammation of the conjunctiva and cornea, which may end in loss of vision. In South Wales there are nearly 1,000 persons employed in the manufacture of briquettes. Epithelioma of the skin is not unknown among grease workers in the north of England, but the largest number of cases is reported among the pitch makers of South Wales. The manufacture of patent fuel is an important industry. Of 1,604,000 tons made in this country 1,449,000 tons are made in South Wales. Sooner or later the skin of the men who follow the employment becomes swarthy, the hair follicles and sebaceous glands become blocked with minute plugs of pitch, shotty particles are felt distributed throughout the skin, especially of the forehead, neck, and forearms; or warts develop, and these ulcerating may become epitheliomatous. Of 246 patent fuel workers examined by Dr. T. M. Legge 51 were found to be affected by warts, while 28 showed signs of having been previously affected. Between July 1907 and 1911, 30 cases of epithelioma were reported for compensation under the Workmen's Compensation Act. It was hoped that the adoption of means for the prevention of pitch dust, provision of better washing accommodation in the works, enforcement of washing before each meal, bathing, and the wearing of goggles and overalls, would reduce the number of cases. These recommendations were not favourably received, either by the employers or by the workmen. The latter objected to the bathing on account of the soreness of the skin caused by contact with the pitch.

Mr. Albert Herbert Lush, barrister, in his report to the Home Secretary on the proposed draft regulations, encouraged manufacturers to do all they

could to reduce dust in the factories. He also expressed the hope that the mischievous agent in pitch might be detected and measures employed for its elimination, believing that if this were done without any injury to the product commercially, it would be the most satisfactory solution of the difficulty. It would appear as if the hope expressed by Mr. Lush were about to be fulfilled. In the *BRITISH MEDICAL JOURNAL* of April 15th, 1911, there appeared, under the title of "The Gasworks Pitch Industries and Cancer," a suggestive and helpful paper by H. C. Ross and J. W. Cropper, in which it was shown that the cancerous affections were caused by gasworks pitch and not by blast-furnace pitch. There are certain substances known as auxetics, containing amidines, amines, and amido-acids, which are produced in the human body as the result of injury. These have the power of inducing division of leucocytes. Ross and Cropper expressed the opinion that pitch-workers' cancer might be due to the chemical auxetics and augmentors of cell division found in gasworks tar, and that these substances were not contained in blast-furnace tar. Traumatism has for long been regarded as predisposing to cancer. It is probable, therefore, that in cancer "there must be present primarily in the injured site the auxetics which cause benign cell proliferation *plus* augmentors which cause malignant cell proliferation when mixed with auxetics."¹ Either factor is by itself harmless; it is the mixture which is the causative agent. The fact that only one of the two kinds of pitch alluded to causes cancer is of importance as indicating the possible conjoint play of auxetics and kinetics. Ross and Cropper found that these principles are soluble in water. They can be dissolved out of the pitch by washing, but one very important commercial drawback to the grinding and washing of the pitch is that the "steaming power of the briquettes made from such pitch was found to be lowered when tried in a locomotive; the binding quality of the pitch also was reduced. Washing of the pitch is therefore, from a sales point of view, not practicable. The auxetics and kinetics are present in the tar before it is distilled and run into the moulds to set as pitch. Briquette manufacturers dislike the presence of water in tar. Every effort is made to keep the tar free from water, since it forms with the soot in the tar an emulsion which froths up out of the retorts, making distillation a slow process and one requiring the use of more fuel, as well as the employment of more labour.

There is more cancer among the workmen to-day than formerly, a circumstance which some attribute to the retention of anthracene oils in the pitch. Experiments do not support this supposition. The dangerous principles are not anthracene or anthracene oils, but some substance mixed with those, the exact nature of which is as yet unknown. All that can be said is that pitch is more dangerous than tar, and tar more dangerous than coal. The problem is how to distil out of the tar those harmful principles without injury to the pitch commercially. Washing will accomplish this, but the difficulty is how to have it carried out. The subject is one well worthy not only of further inquiry on the part of the Howard McFadden Research scholars, but of experimentation on a large scale by manufacturers. It is the briquette makers and not the owners of gasworks and tar distilleries who would benefit. Tar distillers might object to the recommendation of washing

the tar on the ground of expense, but if increased cost is incurred it must be met by raising the selling price of the briquettes. From a health point of view, this first charge might be settled by some international agreement. At any rate, washing of the tar on a large commercial scale seems worthy of trial. It would seem as if, through the labours of Messrs. Ross and Cropper, we were on the eve of ascertaining the true cause of cancer in pitch workers, and of a comparatively easy and effective way of preventing it. Should the Government make further investigations into this subject, the above are the lines upon which the inquiry might well be conducted.

TALES OF HIPPOCRATES.

DURING a recent visit to the island of Kos, Professor Meyer-Steinig¹ collected several tales of Hippocrates from the lips of a native guide, Jakobus Zaraftis. Although the name of Hippocrates figures extensively in titles of wells and different localities, even the better educated classes in the island seem to possess only a hazy knowledge of its most illustrious citizen. In the legends concerning the great physician he has been confused with, and included among, the numerous saints of the Greek Church. But though he has thus acquired a spurious halo, his miracles are largely concerned with the arts of healing and diagnosis, and in this respect tradition has preserved his dominant claims to fame. The following tales contain some quaint conceits.

A consumptive, whose appeal to Hippocrates for aid was refused, retired in despair from the town to the mountains, where he intended to die. Here he saw a snake vomiting milk after it had swallowed a cow. Thinking that this milk must be poisonous, the consumptive drank it to hasten his end. He then retired to the shade of a tree where he slept for several hours, after which he awoke, hungry and refreshed. He rapidly recovered. On his way home he met Hippocrates, and told the physician how despair had driven him to the mountains, where he had regained his health; but, before he came to the incident of the snake, the physician exclaimed, "How could I provide you with milk vomited by a snake?" Delighted by this display of wisdom, the consumptive seized Hippocrates by the hand, and hailed him as the world's greatest physician. The refusal of Hippocrates to treat the consumptive tallies with the frequently repeated injunction in the *Corpus Hippocraticum* to abstain from treating the incurable. The snake's contribution to the miraculous recovery is interesting as illustrating the not uncommon part played by this reptile as a healing power both in heathen mythology and in the Old Testament.

One day Hippocrates met a shepherdess on the road, and greeted her with the salutation: "May it be well with thee, maiden!" When he met her again on her way back, he greeted her thus: "May it be well with thee, woman!" Struck by the repeated blushes of the girl, a companion of Hippocrates asked him why within the same day he had first called the girl maiden and then woman. Hippocrates replied: "Because earlier in the day she was a maiden, and now she is a woman." His curiosity aroused, the companion addressed himself to the girl, who, weeping, admitted that she had in truth been merely a maiden in the morning, but that she had been assaulted and seduced by the shepherd's son on her return from the flock. When questioned as to how

¹ *The Problem of the Gasworks Pitch Industries and Cancer. The John Howard McFadden Researches.* London: John Murray, Albemarle Street. 1912. (Price 6d.)

¹ *Archiv für Geschichte der Medizin, May, 1912.*

he had detected that the girl had been violently seduced, Hippocrates replied: "The gait of a maiden differs from that of a woman." Here, again, Hippocrates appears as an acute observer, not as a healer.

A girl who had been bitten by a snake and who was hastening to obtain medical aid, met a man to whom she applied for guidance to one who would give her an antidote. The man, whose identity with Hippocrates was unknown to the girl, replied, "Before seeking the aid of a physician, seek that of God by making offerings unto Aesculapius and Hygieia." He then lighted a piece of sponge which he applied, still blazing, to the wound. The flesh seethed under this treatment, but Hippocrates endowed the patient with courage and superhuman powers to endure the pain. He also comforted her by assuring her that the offerings were accepted, and that she would be healed of her wound by the servant of God. He then retired to a cleft in a mountain where he found a tortoise which he killed; he caused the patient to drink its blood, and applied its flesh to the burnt spot. The patient was then directed to return home, and to repeat the treatment with tortoise blood and flesh twice, after which she would be healed. In this story Hippocrates is incognito, and he combines mysterious rites with the doubtless equally efficacious procedure of cauterization.

A king's daughter, whose illness was incurable, was affianced to a young man who had spent the whole of one night in a chapel in prayer for the invalid. As he was returning in the morning from this place he met a white-bearded old man carrying a rod, on the top of which was a living snake's head. In its mouth was a sweet-smelling clove flower. After exchanging greetings the old man said: "You have prayed to God for the recovery of your beloved. It is right that you do penance, for your erotic songs have brought her to this pass. But God has taken pity on you, and has sent me to tell you that she will recover." The lover would have kissed the old man's hands and feet, but dared not for fear of the snake. Perceiving this the old man said: "I know how thankful you are for what I have said, but I am sent from God. I am the physician Hippocrates, and in the mouth of my snake there is a flower. This is the remedy for the illness, which is jaundice. Take the whole root of this flower, crush it, and squeeze the juice out of it. Give it her so that she breathes it in by the nostrils, and you will see all the poisons streaming out of them, her colour will again bloom, and all her former strength and beauty will return." Saying this, the old man became invisible. The lover did as he was told, and his prayers were granted. There seems to be considerable confusion in this story, for the reference to a chapel places the incident with those of Christian tradition, while the snake perched on the rod is plainly borrowed from tales of Aesculapius. It is interesting to note that the influence of the emotions on the bile was recognized at such an early date.

The following tale closely resembles those told by Grimm and Hans Andersen: A king's daughter had suffered for many years from snakes, which dwelt within her and devoured her. The king, her father, sent heralds throughout his kingdom to proclaim that he who could heal his daughter should receive many and royal gifts. Numerous physicians practised their arts in vain. A young man, hearing of the prizes to be won, prayed God to show him how to gain them and heal the patient. His prayer was heard, for he met an old man, who told him that "God hears everybody, but everybody hears not

God. He has heard you, and has sent me, the physician Hippocrates, to show you the remedy for the patient. Find juicy portulaca, and from its seed press a cupful of oil. Give this to the patient on an empty stomach, and, if she continues to fast till midday, you will see the snakes leave her both from above and from below, and she will recover." The young man seized the old man by the hand, and exclaimed, "I thank God Who has sent thee, O god-like Hippocrates." The old man immediately became invisible, the youth cured the patient, received the promised gifts, and gained thereby the lady of his love. Probably the "snakes" of this tale are not unfamiliar objects with the modern representative of the healing arts.

THE FORTHCOMING REPRESENTATIVE MEETING.

IN response to a requisition in due order according to the regulations of the Association a Special Representative Meeting has been summoned to meet in London on Friday, January 17th. The main business of this meeting will be to consider the situation created by the attitude of the Government towards the decisions of the Representative Body, and whether it is desirable to release practitioners from the pledge and undertaking they have given in connexion with the National Insurance Act. The events of the last fortnight have, we are aware, caused much distress to many members of the profession who are loyally attached to the British Medical Association. The contrast between the voting in the Divisions and the reports published with regard to the resolve of very many practitioners in various parts of the country to join the panels with the intention of working the Act has led to much wild talk of a *débâcle*. It is, however, most unwise to draw any such conclusion. It must be remembered that one of the great parties in the State is committed to getting medical benefit under the Act to work, and that its political organs in the press may not consider it obligatory to show both sides of the picture, or to imitate the caution of Mr. Lloyd George, who on Monday declined to express any opinion on the question whether it was not practically certain that a sufficient number of doctors will come forward to work the Act. Any one who wishes to know how far political rancour and party fears may carry a twentieth century journalist towards rivalling the style of the pamphleteers of the eighteenth should read recent issues of the *London Daily News and Leader*. At the time we are compelled to go to press no authoritative information which even approaches completeness is available, and the discussion which Mr. Worthington Evans desired to raise in the House of Commons on Tuesday evening, which might have enabled the Chancellor of the Exchequer to state his views on the situation, could not then come on owing to a blocking motion on the paper. It is reported that in some parts of the country the applications from medical men are numerous enough to form adequate panels; in others it is asserted that their number is large enough to enable panels to be formed which the Insurance Commission will feel justified in regarding as sufficient. On the other hand, in others there are no applications, or they are so few in number that a sufficient panel cannot be formed. The Insurance Commissioners have this safeguard—that December 31st, 1912, was a date selected by them as conveniently fitting in with their arrangements, but any medical practitioner would be at liberty to apply to go on the local panel or fall in with any other provisional arrangement at a later date. There is no cause for panic, and no wisdom in talking about disruption of the British Medical Association. There are no signs of any such catastrophe and the fear is groundless, if only for

the reason that, as the Association is a democratic organization, its policy can be and is determined by the members themselves. The constitution of the Association does not permit action as hasty as some members at this moment would appear to desire. It is true that those who voted at Divisional meetings did not number more than about half of the total number of practitioners in active practice in the United Kingdom, and it is open to any one to put his own explanation upon the abstentions. Some have assumed that the majority of those who did not attend to vote proved themselves by so abstaining to be in favour of the Act. Others contend that the majority of those who abstained did so because they looked upon the result as a foregone conclusion. Neither deduction rests upon any solid basis. Many letters have been received urging that the Association should take a ballot or poll of the profession by post, the writers believing that in that way a much larger vote, more nearly reflecting the opinion of the majority of the profession, would have been obtained. With regard to this, it may be again pointed out that the Association has no constitutional power to take a postal vote. When the constitution was under discussion there was a considerable volume of opinion in favour of taking this power, but the suggestion did not commend itself to the majority at that time. A Division can at its own cost take a postal vote in its own district, but the result would not be binding and would not be the decision of the Division.

LISTER'S EARLIEST OPERATIONS IN FRACTURE.

THE letter by Dr. Theobald A. Palm, published in the *JOURNAL* of December 21st, 1912, recalling an early case in which Lister operated for badly united fracture—the operation was performed in the Edinburgh Royal Infirmary on December 12th, 1870—and the note appended giving the reference to this *JOURNAL* and the *Collected Papers* has brought us an interesting letter from Dr. Just Lucas-Championnière who, as is well known, was one of the first surgeons to study and adopt the antiseptic system. Our distinguished correspondent recalls that before the date of the operation above mentioned he had published in the number for January, 1869 (p. 18) of the *Journal de Médecine et de Chirurgie Pratiques*, which he conducts with so much success, a note of a case in which in 1868 Lister had, at the Glasgow Royal Infirmary, operated to correct a badly united fracture. The details of the case, Dr. Lucas-Championnière says, made the greater impression on him because he was present at the operation, and the patient was a Frenchman. The following is a translation of the note published in January, 1869: "We have seen a patient cured in whom the operation would never, Mr. Lister said, have been attempted had he not long before acquired the certainty that he could by his method transform a compound fracture, even one involving a joint, into a simple fracture. The case was that of a man in whom fracture of the lower extremity of the tibia and the two malleoli had been followed by a deviation of the foot outwards and forwards accompanied by displacement on to its inner side. The deformity was maintained by a voluminous and shapeless mass of callus. Four months after the accident Mr. Lister, after incising the soft tissues behind the internal malleolus, covering the parts as he went on with carbolic oil, divided the internal malleolus at its base under cover of a compress soaked in carbolic oil, and, opening into the joint, divided also the external malleolus. Traction was made on the foot, the resistance was felt suddenly to give way, and the foot was brought into position. The patient was dressed with carbolic compresses and plaster renewed every day or every other day. There was no suppuration and no complications. Later on Mr. Lister divided the Achilles tendon, and after that the patient did very

well; we have seen him walking in the hospital." In commenting now on this case, Dr. Lucas-Championnière writes: "No record, I think, better shows how Lister attacked the opening up of the site of a fracture, and one moreover involving an articulation," and goes on to express the pride with which he now recalls that he was the first to appreciate and record this case. It may justly be called an epoch-making case, for although there is a discrepancy in the description of the deformity of the foot, his note almost certainly refers to the first case in which Lister cut down on a badly united fracture. As recorded in the address delivered before the Medico-Chirurgical Society of Glasgow and published in sections in the *BRITISH MEDICAL JOURNAL* during 1868 and early in 1869,¹ he operated on April 11th, 1868, on a man, aged 29, who four months previously had sustained a simple fracture into the ankle-joint, the fibula being broken two inches above the joint and the internal malleolus at its base. When the man came under treatment the foot was useless. It was clear that the foot could not be replaced without breaking through the callus, which could be plainly felt in both bones, and there seemed no prospect of doing this without cutting down and adopting means which, in the case of the tibia, "would necessarily involve opening into the articulation, or producing artificially a compound fracture into the ankle-joint. This," Lister continued, "I certainly should not have dreamed of doing without the aid of the antiseptic system, being well aware of the disastrous course such injuries commonly run under ordinary treatment." He had, however, already had experience of the successful result of the antiseptic treatment of recent compound fractures, and he therefore did not hesitate to operate in the manner described by M. Lucas-Championnière. Healing under a scab, the end which was sought, was delayed by the formation of two sores with exuberant granulations, but these were completely healed on June 4th, the bones having been firmly united a fortnight earlier. The tendo Achillis was divided on July 26th, and the plantar fascia also, to correct an exaggerated arching of the foot. When last seen, early in September, 1868, he could walk firmly and well and complained only of some remaining stiffness of the ankle.

FILARIA LOA.

WE have received from the London School of Tropical Medicine a copy of a telegram sent by Dr. R. T. Leiper, Helminthologist to the School, and Interim Wandsworth Scholar, from Calabar, West Coast of Africa, on December 27th, 1912. The telegram was to the following effect: "The metamorphosis of *Filaria loa* has been proved to take place in the salivary glands in a fly belonging to the genus *Chrysops*." According to Sir Patrick Manson² *Filaria loa* has been known for over three hundred years. It is African in origin, but the cases of the affection caused by the parasite first described occurred in the West Indies in negroes who must have been attacked in West Africa before their deportation as slaves to America. The parasite appears to be widely distributed throughout tropical West Africa from Sierra Leone to Benguela. In some parts, as in Old Calabar, Cameroons, and the Ogowé River, a very large proportion of the inhabitants are the hosts of the parasite. *Filaria loa* has been noticed very frequently beneath the skin of the fingers, and has been excised from under the skin of the back, from above the sternum, from the left breast, the frenum of the tongue, the loose skin of the penis, the eyelids, the conjunctiva, and the anterior chamber of the eye. It has been stated that it may

¹ The report of the case was contained in the section of the address published in the *BRITISH MEDICAL JOURNAL* on October 31st, 1858, p. 462. It will be found in the *Collected Papers*, vol. ii, p. 71 et seq.

² *Tropical Disease*. Fourth Edition, p. 677.

wander about under the scalp, but the part most frequently affected is the eye, for which the parasite seems to have a predilection. In the conjunctiva it may produce considerable irritation and congestion; sometimes there is pain with swelling to such a degree as to block up the eye. As a rule, the migrations of the parasite give rise to no serious inconvenience, but they may cause sensations of pricking, itching, creeping, and sometimes produce oedematous tumefaction in different parts of the body. These "Calabar swellings" are the commonest result of the invasion of the parasite. The swellings, which are due to the worm's migrations in the deeper parts of the limbs, in the muscles, and round the tendons, are painful, and impair movement so that the victim may be unable to write or even to use his hands. The swellings rarely last for more than a few days, but often recur in the same or another part of the body. There is some reason to suspect that at times, when travelling inside the skull, the worms cause epileptiform convulsions. It is obvious that if the parasite should wander into the glottis or the urethra the results might be serious. The effects are, however, seldom fatal. The embryos of *Filaria loa* are found in the blood only during the day time, and have therefore been called *Microfilaria diurna* by some, in distinction from *Filaria bancrofti*, the cause of elephantiasis, whose embryos are found in the blood only during the night and are known as *Microfilaria nocturna*. Sir Patrick Manson, many years ago, surmised that this nocturnal periodicity pointed to a nocturnal blood-sucking insect as the intermediate host, and he proved that the intermediate hosts were certain species of mosquitos. The diurnal periodicity of the embryos of *Filaria loa* suggested that the intermediate host was a day-biting insect, a member of the genus *Chrysops*. This, according to the telegram, has now been proved by Dr. Leiper. The importance of the discovery lies in this—that now it will be possible to determine the conditions under which human beings become infected. This gives ground for hope that means of preventing such infection will be found. The members of the genus *Chrysops* are day-biting flies, and are very widely distributed not only in the tropics but also in temperate climates, even in the British Isles. It is expected that Dr. Leiper will now be able to show which species of *Chrysops* are the carriers, as it is known that *Filaria loa* is limited to West Africa.

HEALTH RESORTS OF THE BRITISH ISLANDS.

THE study of British climatology and its application to medical treatment was greatly stimulated by the establishment of the special society which is now the Section of Balneology and Climatology of the Royal Society of Medicine. Under its auspices a descriptive textbook,¹ edited by Dr. Neville Wood, has recently appeared, in which a large amount of useful information is brought together as to the existing facilities for climatological and balneological treatment in the British Isles. Such a work is of course bound to cover, to a certain extent, some of the ground traversed by the account of the climates and baths of Great Britain, published ten years ago by the Royal Medical and Chirurgical Society. Borrowing a hint from the numerous publications relating to spas and health resorts published on the Continent, the editor has arranged the material at his disposal in a form that makes reference easy, and has dealt with individual places rather than with the corresponding features of larger areas. The inland health resorts and those which are commonly known as "watering places" are first described. In alphabetical order Bath heads the list, and the account of its therapeutic advantages is supplied by the Bath Medical Committee.

¹ *Health Resorts of the British Islands*. Edited by Neville Wood, M.D., Member of the Council of the Section of Balneology and Climatology of the Royal Society of Medicine, with the assistance of an Advisory Committee appointed by the Council of the Section. London: University of London Press, 1912. (Med. 8vo, pp. 268; 40 illustrations and 2 maps. 10s. 6d. net.)

A new property has of late years been credited to the waters—namely, radio-activity. The part that radium may play in the elimination of uric acid has not been determined, but the results of treatment by the Bath waters have always been attended with a remarkable measure of success. Efforts have not been wanting at Bath, as at many other British health resorts, to supply all forms of treatment and to render the "cure" as attractive as possible. Many Continental spas owe their popularity to the social amenities which they provide, and the complete change of scene and surrounding are as attractive to the British visitor as the curative reputation of the waters. It is hoped to attract Continental visitors in like manner to British spas, and to that end a French translation of the book is in preparation. The leading features of Scottish and Irish health resorts are included, and the addition of well-selected photographic views of all the more important places adds greatly to the practical usefulness of the volume. It is frankly admitted that in the practice of hydropathy many of our institutions are by no means up to the Continental standard. Some of them are simply comfortable residential hotels with baths attached to them. The average British patient, as a rule, unless he is seriously ill, will not place himself under doctor's orders with the same unquestioning faith displayed at Nauheim. Where faith is lacking, the "cure" is apt to be incomplete. But there are many valuable "hydros" fully described in Dr. Wood's book, where all sorts of treatment, with or without faith, can be carried out under one roof, and the well-equipped mineral water hospitals at Bath, Buxton, and elsewhere, afford relief to a large number of poorer sufferers every year. The coasts of the British Isles teem with health resorts of varying character, and a knowledge of these variations is very necessary before recommending any seaside place to an invalid. Much of the information with regard to them is derived from local medical committees. Some of the individual writers have supplied accounts which fall a little short of completeness. The reader unacquainted with the West of Scotland, for instance, might form the erroneous impression that there is only one hotel at Oban! Information as to the chief sanatoriums for tuberculosis, and a comparative summary of the relative advantages of healthy resorts at home and abroad, conclude a handbook which we can cordially recommend as a most useful addition to the number of works of reference which have become a necessity to the practitioner of modern medicine.

HOSPITAL PATIENTS AT ADRIANOPLE.

AT the present moment, when the eyes of Europe are centred on the Near East, and the name of Adrianople is on every one's lips, it is interesting to find a description of the Thracian capital written by one of the few Europeans who have spent some time within its walls. The November number of *L'Hygiène* contains an article by Dr. P. Rebreyend, at one time surgeon to the French hospital at Adrianople, in which the writer draws a vivid picture of the quaint old city on the banks of the Maritza. His account of the hospital itself is by no means the least interesting part of his narrative. Founded at the time of the Russo-Turkish campaign, it was taken over at the end of the war by the French Assumptionists, who placed it under the care of nuns of the same order; and for some years past this modest little establishment of 45 beds has been a lodestone for the sick poor of every nationality and creed within a radius of many miles. As may be imagined, therefore, Dr. Rebreyend during his stay at Adrianople had ample opportunity for studying at close quarters the mingled elements which go to make up the population of this portion of the Balkan States; and it is both interesting and instructive to note his comments on the strong racial

characteristics which still distinguish one from the other a group of alien peoples who are all equally poor, equally ill-fed, and, with few exceptions, almost equally unhygienic. Dr. Rebreyend confesses that he found his Armenian, Jewish, and even his Greek patients extremely trying. Their hysterical lack of self-control was in striking contrast to the calm endurance of the Bulgars, whom the writer describes as being as fearless as they were dirty. He relates how he found one man waiting for him, seated upright on a chair; a train had passed over his arm, yet he retained his composure even when, on the removal of his vest, the injured limb came away in the doctor's hands. The greatest courage of all, however, was manifested by the Turkish men patients; their womenkind, as a rule, were excessively timid and neurotic. Dr. Rebreyend cites as a proof of the passive endurance of which the Turk is capable the case of one of his own patients, a man upon whom he himself had operated, and who alarmed him by his failure to awaken from the anaesthetic. He lay upon the operating table breathing as calmly and as regularly as a child, and the most vigorous slappings and shakings failed to have any effect upon his unnatural quiet. At length, in despair, after exerting themselves to the utmost for some twenty minutes, the assistants raised him to a sitting posture; and as he continued to pay not the slightest heed to those about him, started flicking him with wet towels. Their feelings may be imagined when the patient suddenly remarked: "It is of no use; you will never send me to sleep." He had been awake for the last half-hour!

THE DISCOVERY OF CHLOROFORM.

DR. PRIDEAUX G. SELBY (of Teynham, Kent) writes: "About the year 1885 Dr. Matthews Duncan, in speaking to me about the discovery of chloroform, told me that on the historic November 4th, 1847, it was he who took the chloroform to Simpson's house, and that he had found it in the chemical laboratory of the late Professor Gregory at Edinburgh. Dr. Matthews Duncan narrated how they were trying every possible form of inhalation in their search for an anaesthetic, and had all made themselves very ill by inhaling ordinary coal gas. The above scarcely agrees with the statements in your issue of December 14th, 1912, but anything bearing on that historic occasion is of intense interest, and Dr. Matthews Duncan's statement seemed worthy of record." We see nothing in the statement here attributed to Dr. Matthews Duncan that conflicts with the account of the first experiments with chloroform given in the JOURNAL. Dr. Matthews Duncan may have taken the bottle to Simpson's house, but it was not he that suggested that a trial should be made of it. On this point we have Simpson's positive statement, quoted in the JOURNAL of December 14th, 1912 (p. 1681). This is confirmed by the independent testimony of David Waldie, whose statement is contained in a paper on chloroform read by him at a meeting of the Liverpool Literary and Philosophical Society on November 29th, 1847. The following quotation from that paper, which we find in the *Chemist and Druggist* of December 21st, 1912, is conclusive. After dealing with the discovery of the chemical substance by Soubeiran in 1831, made again a year later by Liebig, who named it perchloride or terchloride of formyle, and referring to the fact that Dumas gave it the name of chloroform in 1834, Waldie proceeds: "To the best of my knowledge, from the result of many inquiries, it seems to have been introduced into this country as a medicinal agent, first in Liverpool, where, indeed, in the form of a spirituous solution, it has been more known than in any other part of the country, and from which, I believe, the knowledge of its therapeutic properties has extended. About the year 1838 or 1839 a prescription was brought to the Apothecaries' Hall, Colquitt Street, one ingredient of

which was chloric ether. No substance being known there of that name having the properties of that with which the mixture had been previously prepared, Dr. Brett, then the company's chemist, in investigating the subject, found, in the United States Dispensatory, the formula for its preparation which has been noticed above, and prepared some. Its properties pleased some of the medical men, particularly Dr. Formby, by whom it was introduced into practice in this town. After coming to take charge of the company's laboratories, I found that the method of preparation yielded a product which was not of uniform strength, and sometimes of disagreeable flavour. Accordingly, I altered the process by separating and purifying the chloroform and dissolving it in pure spirit, by which a product of uniform strength and sweet flavour was always obtained. The vapour of the so-called chloric ether seems to have been tried as a substitute for sulphuric ether in February or March last, but without very satisfactory results, which, indeed, could scarcely be expected, unless the vapour of alcohol possessed the same properties, it being composed principally of alcohol. When in Scotland, in October last, Dr. Simpson introduced the subject to me, inquiring if I knew of anything likely to answer. Chloric ether was mentioned during the conversation, and being well acquainted with its composition, and with the volatility, agreeable flavour, and medicinal properties of chloroform, I recommended him to try it, promising to prepare some after my return to Liverpool, and send it to him. Other engagements and various impediments prevented me from doing this so soon as I should have wished, and in the meantime Dr. Simpson, having procured some in Edinburgh, the results which he communicated to the Medico-Chirurgical Society of Edinburgh, on November 10th, and which he published in a pamphlet entitled 'Notice of a New Anaesthetic Agent as a Substitute for Sulphuric Ether in Surgery and Midwifery.' Miss Eva Blantyre Simpson, speaking of her father's recklessness in experimenting on himself, says it is not unlikely that he may have made a private trial of chloroform, and laid it aside again "to start fair with his two assistants (Duncan and Keith) who had worked so unfinchingly with him." She adds that some other compounds were tried on that night of November 4th, 1847, "and then chloroform, which was lying in its little phial among some papers, was unearthed." This, as we know, was supplied by Duncan and Flockhart.

A PARASITIC MOULD OF THE HOUSE-FLY.

IN our issue for November 30th, 1912, appeared a letter from Dr. H. de Riemer Moegou, of the Lister Institute, Elstree, recording the fact that he had succeeded in obtaining an artificial cultivation of the *Empusa muscae*. It would appear, however, from information that has reached us that this is not the first time that corresponding success has been obtained. The existence of this parasite of the house-fly was, it is said, first recorded over fifty years ago by a German worker, and in 1910 Dr. Julius Bernstein, who was then engaged in bacteriological investigation on the subject of flies on behalf of the Local Government Board, suggested in one of his reports that an artificial cultivation of the *Empusa muscae*, if it could be obtained, might prove highly valuable in ridding towns of the pest of flies derived from horse-dung. Another person interested in the same subject was Mr. Edgar Hesse, whose regular occupation is that of assistant to a taxidermist in London, and whose hobby it is to study subjects of a bacteriological kind. This gentleman, a year or two ago, began to devote his energies to an investigation of the *Empusa muscae*, and at the beginning of last July submitted to the Local Government Board a sample of what he believed represented a successful attempt to cultivate this organism. The Local Government Board, through Dr. Monckton

Copeman, who is interested in the same subject, had the specimens examined by Dr. Julius Bernstein, who reported that the organism present was, in fact, the *Empusa muscae*. In the same month another experiment by Mr. Hesse proved successful, for he succeeded in killing three species of fly—*Musca domestica*, *Faunia canicularis*, and *Stomoxys calcitrans*—by feeding them on food impregnated with spores derived from one of his own artificial cultivations of the *Empusa muscae*. Mr. Hesse, it appears, placed the first of these facts on record in the issue of *The English Mechanic and World of Science* for July 12th, 1912, and a somewhat inaccurate version of this communication was published shortly afterwards in the American press. Since then Mr. Hesse has carried his experiments, we learn, somewhat further by insinuating manure with artificially-cultivated spores, and then attempting to develop fly larvae therein. The result was encouraging, for though the larvae assumed the chrysalis form, they did not hatch out. Other facts which Mr. Hesse believes he has proved are that the *Empusa muscae* is polymorphic, and by nature a saprophyte, though capable of living a parasitic existence when its spores happen to be swallowed by a fly. In the saprophytic condition it produces gonidia, but forms zygospores and gemmae when its food supply is exhausted. The spores produced persist, he finds, in a torula condition, and by inducing flies to swallow the spores by placing the latter in syrup he has subsequently been able to recultivate the conidia thrown off by them, thus completing the life cycle of the fungus. These observations are of interest because hitherto describers of this fungus have asserted that its spores work their way into the fly through the surface of its abdomen, while Mr. Hesse's experiments would seem to indicate that they are swallowed and probably germinate in the crop.

PELLAGRA IN AMERICA.

THE Pellagra Commission of the New York Post-Graduate Medical School and Hospital has spent four and a-half months in studying pellagra in South Carolina. It is stated that there are at least 50,000 persons in the south suffering from the disease. At first it was confined almost entirely to the poorest class, but is now spreading considerably among the well-to-do. It is proposed to send another expedition in the spring. The Report of the United States Public Health Service issued at Washington on December 14th states that the number of persons who have died of pellagra in the States in the period 1907 to 1911 is 6,205.

BOY NIGHT-WORKERS.

THE Committee on the Night Employment of Male Young Persons in Factories and Workshops,¹ of which Lord Ashton of Hyde was chairman, and which was appointed by the then Home Secretary, was the outcome of a debate in the House of Commons on May 24th, 1911. Objections were raised to the permission granted by an Order, dated April 10th, 1911, to employ boys of 15 years of age and upwards at night in the process of making artificial silk fibre in non-textile factories. There was a feeling against the night employment of boys generally, and it was thought that the Orders had been unduly extended. The Committee visited sixty-eight factories, and as several of the visits were paid during the night-shift period, so that the members of the Committee had the opportunity of seeing for themselves the exact conditions of work. The Factory Acts allow the employment of boys of 14 years of age in certain industries, and when the Acts were first applied in 1867 to some of the chief industries it was thought proper, owing to the continuous nature of some processes, to make special modifica-

tions allowing night employment of boys. Provision was also made for the extension of the same privilege to other trades by means of a Special Order of the Secretary of State. By the Act of 1895, and which was reaffirmed in the Act of 1901, night work was allowed for boys of 14 to 18 years of age at blast furnaces, in iron mills, letterpress printing works, and paper mills; power was also given to the Secretary of State to extend the exception by Special Order to boys employed in non-textile factories provided that the nature of the business required night work and that the processes were not injurious to the health of young persons. Among the industries excepted were certain departments in iron works, sugar refining, the galvanizing of sheet metal and wires, china clay works, electrical stations, and the manufacture of cordite and gun-cotton. No young person can be employed more than twelve hours in any consecutive period of twenty-four hours. The Committee tried to ascertain whether the health of boys employed in night work had suffered. It was difficult to obtain accurate information upon this point. Many of the medical men examined had not observed any injurious effects. Others thought the lads had suffered through want of adequate rest and sleep, deprivation of sunlight, and irregularity of feeding. Some factory surgeons, again, thought that the growth had been retarded, but there was no unanimity of opinion on these points. The conclusions arrived at by the Committee were that night work was unnatural, that the alternation from day to night work in the three-shifts system did not allow sufficient time for the individual to adapt himself to the unnatural conditions, and that night work deprived youths of the beneficial influence of sunlight and of sound continuous sleep. The Committee found, further, that the supervision of boys in the factory at night was not so efficient as during the day, and that the employment deprived the boys of the opportunity of attending evening classes. The Committee is therefore of the opinion that it is undesirable to employ boys under 18 years of age in factories where night work is required. A boy who is earning wages at the age of 14 is usually better fed than a boy who is not occupied at all, and it is better to have boys under some restraint between 14 and 16 years of age than running wild. It has to be remembered that boys of 14 are allowed to work in coal mines. Why, then, it may be asked, refuse to give permission to work in the factories? The Committee expresses its belief in the three-shift system of eight hours per shift with a half an hour interval of rest, in the advisability of boys being periodically medically examined until the age of 18, of employers giving proof of having made all effective provisions, and the Secretary of State only granting exceptions under the most necessitous circumstances.

THE MADNESS OF KINGS.

THE recent death of the aged Regent of Bavaria, and with it the reopening of the whole painful story of this ill-fated house, raises questions of peculiar interest in connexion with the psychiatry of royal personages. It would appear at first sight that, if the moral and intellectual qualities of a sovereign can add to the enrichment and glory of a nation, the contrary should also hold good. It is remarkable to note, however, how little dependent the evolution of a nation really is upon the mental or physical health of its monarch. Moreover, the history of the House of Bavaria shows that a madman clothed in purple can on occasion be an excellent head of the State. The outstanding cases of insanity in reigning monarchs are not numerous. Perhaps one of the earliest to which historical reference is made, is that of Nebuchadnezzar, King of Babylon, who suffered from lycanthropy, a form of insanity of comparative frequency in antiquity as well as in the Middle Ages. Beyond being afflicted with jealousy amounting almost to

¹ London: Wyman. 24d.

monomania. there is no indication that Saul, King of Israel, was insane. More recently Peter III of Russia, grandson of two great kings—Peter I on the maternal side, and Charles XII of Sweden—was a degenerate in the full meaning of the term. Paul I of Russia, his son, was sickly, weak, and epileptic from birth. He it was who proposed that the sovereigns of Europe should settle their differences by mortal combat! Although he imperilled the country by his extravagance and eccentric habits, the pathological history of Paul is interesting in that he was incontestably the superior of his father from a psychological point of view. His death by strangling was defended as a matter of necessity for the welfare of his country. The subject is one of great interest for the physician and the philosopher, and we do not know that students of psychiatry have hitherto given it the attention it deserves.

EPSOM COLLEGE.

ELSEWHERE will be found an appeal by Sir Henry Morris, Honorary Treasurer of Epsom College, on behalf of that most deserving institution. The calls on the profession are so great, and its financial future is at present so shrouded in threatening clouds, that there is some danger lest the appeal should fall on ears deafened by the din of a fight *pro aris et focis*. It need scarcely be pointed out, however, that Epsom is intimately connected with the domestic hearths of doctors. To many of them it is what Byron called

That schoolboy spot
We ne'er forget though there we are forgot.

To others it is the place where their sons are receiving a public school education of the highest class at a moderate cost, and where the sons of some of their less fortunate brethren are boarded, clothed, and maintained free of charge. To others, again, Epsom represents a haven of refuge for men who have been buffeted about by the storms of life, for widows and for orphans of medical men. To meet the cost of all these benefactions a sum of nearly £7,000 a year is required, of which £4,500 must be obtained by annual contributions. More money is urgently needed for general purposes, among which Sir Henry Morris mentions the provision of adequate arrangements for the sick in time of epidemic illness, and other improvements. Full details of the great work done by the foundation will be found at p. 7 of our advertisement columns in last week's issue. The medical profession is by no means rich, and it is highly creditable to the spirit of brotherhood which animates its members that it should, mainly by its own efforts, have raised such a monument of benevolence. We have all reason to be proud of Epsom, and not a few of us owe it a debt of gratitude. We therefore most earnestly commend Sir Henry Morris's appeal to the favourable notice of our readers. We hope that the support which has been so liberally given in the past will not be wanting at this hour of special need.

NEW YEAR HONOURS.

AMONG the honours conferred by the King on the occasion of the New Year is that of knighthood to be received by Dr. R. W. Philip, physician to the Royal Infirmary and senior physician to the Royal Victoria Hospital for Consumption, Edinburgh, in recognition of the pioneer work he has done in the organization of a co-ordinated system for dealing with tuberculosis. The same honour is conferred on Dr. George Turner, formerly medical officer of health for the Transvaal, and medical superintendent of the Pretoria Leper Asylum, whose services in these capacities were conspicuous; and on Dr. David Hardie, of Brisbane, member of

the Medical Board and Central Board of Health, Queensland. Inspector-General Duncan Hilston, R.N., C.B., honorary physician to the King, formerly in charge of the Royal Naval Hospital, Haslar, is promoted to be K.C.B. The Kaiser-i-Hind Gold Medal is conferred on Major H. W. Grattan, R.A.M.C., officer in charge of the enteric fever convalescent depot at Naini Tal; on Dr. J. Andrew Turner, Health Officer to the Bombay Municipality; on Major E. Reinhold Rost, I.M.S., senior civil surgeon, Rangoon, whose name is known for his researches on the morphology of the lepra organism, and the treatment of leprosy; and on Major E. L. Ward, I.M.S., Punjab. The honour of knighthood is accorded also to Mr. Francis Darwin, who, after studying medicine at St. George's Hospital and graduating M.B., became personal assistant to his illustrious father, and has won distinction as a botanist. The same honour is conferred on Mr. Stewart Stockman, Chief Veterinary Officer to the Board of Agriculture. Professor Wyndham Dunstan, formerly lecturer on chemistry in the medical schools of Oxford and St. Thomas's Hospital and at the Pharmaceutical Society, becomes C.M.G.

LADY ALMONERS AND THE AFTER-CARE OF HOSPITAL PATIENTS.

THE institution of the lady almoner as an adjunct to the hospital staff has already proved very effectual as a means of checking actual abuse. The mere fact that such an officer is empowered to inquire into the social status of hospital patients prevents application by those who are not prepared to face her. But the functions of the lady almoner go far beyond those of the inquiry officer. While the medical staff in the casualty or out-patient departments can prescribe treatment and give valuable advice they are quite unable to see to it that either are used intelligently. It is only by knowledge of home conditions and social surroundings that the average patient can be satisfactorily helped to regain his health. The lady almoner and her trained assistants are now at hand to help him, if he be a patient of St. Thomas's Hospital. A system has been in force at that institution for the last three years, started and financed by the trustees of the Cicely Northcote Trust, whereby a large number of the hospital's patients, particularly tuberculous and gynaeceological cases, have been materially assisted in their own homes by the sympathetic aid and advice of a number of lady assistants, trained to the work and acting under the general guidance of the lady almoner. To give such help in strange households without undue interference with established customs, requires no small amount of tact on the part of the visitor, but experience has shown that it is for the most part received with gratitude if offered in a sympathetic way. The Cicely Northcote Trust has recently issued its third annual report, which contains, not only a full account of the work done, but also some interesting statistics as to the social conditions commonly prevailing amongst the patients with whom it has had to do. Such facts as the following, for instance, are somewhat striking. Of 341 consumptive patients visited in their own homes no less than 287 were found to be sleeping with at least one other person, and sometimes with three or four, in the same bed. The help given to gynaeceological patients naturally calls for the exercise of much tact and perseverance to overcome prejudice and rooted habits, but good work appears to have been done particularly amongst unmarried girls and women. In many cases a reference to other charitable agencies has provided the needed help. Such work as this, if it could be extended to all the great hospitals, would greatly increase their practical value to the community. The published accounts of the Trust go to prove that administrative expenses are heavy, but no explanatory details on this point are given in the report. Administrators of

large legacies left for charitable purposes would be well advised in following the example of the Cicely Northcote Trustees.

SIR RONALD ROSS, who intends to reside in future in London, has been appointed Physician for Tropical Diseases to King's College Hospital. On the transference of the hospital in South London in the course of the summer, he will have charge of beds for cases of tropical disease.

DR. ALEX. HILL has been appointed Principal of Hartley University College, Southampton. Local interest in placing the college on a sound footing has been greatly stimulated in recent years. A sum of £32,000 has been raised for the erection of the first block of a new college, and it is believed that Dr. Hill's long experience in educational work will be of great assistance in the development of the institution. In addition to his work in Cambridge, where he was Master of Downing College from 1888 to 1907, and Vice-Chancellor in 1897-99, he served as one of the Commissioners reporting to the Treasury on University Colleges, as a member of the Welsh Colleges Committee, and as President of the Teachers' Guild. He has also held the office of President of the Neurological Society, and was Secretary of the Congress of Universities of the Empire held in London last year.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Medical Benefit.—Mr. F. Hall asked whether, under the National Insurance Act, an insured person will be entitled to be treated by his own medical practitioner; and, if so, whether in the event of a number of doctors refusing to accept service under the Act, any amendment thereof will be sought to meet the situation thus arising. The Chancellor of the Exchequer replied: The insured person is entitled to a free choice amongst the doctors registered on the panel subject to conditions defined by Section 15 (2) of the Insurance Act. If, however, the doctor of his choice declines to go on the panel, the insured person is not entitled to claim as a right that he should be treated by his own medical practitioner at the expense of the insurance fund. Mr. F. Hall: May I ask whether, in the event of private medical practitioners not coming on the panel, the insured person is to be at the mercy of the Insurance Commissioners or the Insurance Committee? and how does that really fit in with Section 15 of the Act and the promises made? Mr. Lloyd George: If the hon. member will take the trouble to read the Act he will see that there is only a right of choice amongst doctors on the panel, and that if any private arrangements are made with doctors outside they must be subject to the allowance of the Insurance Committee and the Insurance Commissioners. Mr. F. Hall: May I ask the right hon. gentleman whether, when he went into that question, he thought so many medical practitioners would not accept service under the Act? Captain Murray: Can the right hon. gentleman say whether it is not practically certain now that sufficient doctors will come forward to work the Act? Mr. Lloyd George: I prefer not to express an opinion. Mr. Worthington Evans: May I ask whether any objection will be made by the Insurance Commissioners to allowing Insurance Committees to permit private practitioners in counties to continue attendance for individual patients under Section 15, Subsection (3), of the Act? Mr. Lloyd George: I think that would depend entirely upon circumstances. Earl Winterton: Will the right hon. gentleman make a general statement as to what he proposes to do in cases of counties where the whole of the doctors have

refused to serve? Mr. Lloyd George: I should first of all have to wait and see whether there are any counties of the kind. Earl Winterton: There are.

There was a desire to raise a discussion on medical benefit with reference especially to the conditions under which insured persons can make "their own arrangements," and on the motion for the adjournment of the House on Tuesday evening Mr. Worthington Evans asked whether the business would be in order in view of a blocking notice put down by Mr. Sherwell (Huddersfield). Mr. Lloyd George said that the Government would not oppose, and he would be happy to answer questions, but the Speaker ruled that a debate would not be in order, and appealed to Mr. Sherwell to withdraw his block so that the matter might be discussed on Wednesday; this suggestion was accepted.

Tuberculosis Prevention in Ireland.—A bill entitled the Tuberculosis Prevention (Ireland) Bill was introduced into the House of Commons on December 16th by the Chief Secretary for Ireland. The memorandum prefixed to the bill states that its main object is to amend the law under which provision is made by local authorities in Ireland for the treatment of tuberculosis. It amends and extends the Tuberculosis Prevention (Ireland) Act, 1908; it is to be construed as one with that Act, and the two Acts are to be cited together as the Tuberculosis Prevention (Ireland) Acts. The first clause of the bill would make the notification of tuberculosis compulsory throughout the whole of Ireland; at present it is only in force in those sanitary districts in which the provisions of Part I of the Act of 1908 have been adopted. The second clause directs that cases of tuberculosis are to be notified to the medical superintendent of the tuberculosis dispensary which may have been established in any county instead of the local medical officer of health. The third clause varies the regulations as to the classification of expenses incurred by county councils in connexion with tuberculosis hospitals and dispensaries, and provides that all such expenses are to fall upon the poor rate. The clause also contains a temporary provision with regard to such expenses during the current financial year. The fourth clause empowers county councils providing a common hospital or dispensary to adjust the proportion of the expenses to be borne by each county. The fifth clause would enable a joint hospital provided by sanitary authorities under the Public Health (Ireland) Act for the treatment of tuberculosis to be transferred to a county council. The sixth clause declares that a person suffering from tuberculosis may be admitted, and maintained and treated in any hospital provided under the Act, notwithstanding that he is not an inhabitant of a county the council of which has provided or joined in providing the hospital. The seventh clause authorizes the Local Government Board to place any land vested in it at the disposal of the county council as a site for a dispensary. The eighth clause repeals certain sections and subsections of the Tuberculosis Prevention (Ireland) Bill.

Tuberculosis Act (Ireland), 1908.—Mr. Hugh Barrie asked the Chancellor of the Exchequer whether he was aware that, until it was definitely known what grant-in-aid was to be provided by the Treasury, Irish county councils were reluctant to adopt Part II of the Tuberculosis Act, 1908, with its financial responsibilities; and whether he would take an early opportunity of intimating the amount of the Treasury grant. Mr. Masterman said that the Irish Local Government Board was now preparing a circular explaining the distribution of the grant, including the additional sum to be provided in connexion with the provision for non-insured persons. In reply to a further question, Mr. Masterman said that he was unable to say whether the circular would be in the hands of the Irish county councils at their next meeting (January 10th), but would communicate with the Irish Office.

AT the meeting of the Medico-Legal Society to be held at 11, Chandos Street, London, W., on Tuesday, January 21st, at 8.30 p.m., Professor Benjamin Moore will read a paper entitled "First Steps towards a State Medical Service."

Scotland.

[FROM OUR SPECIAL CORRESPONDENTS.]

PRACTICAL INSTRUCTION ON TUBERCULOSIS AT EDINBURGH.
The opening of the well-equipped new dispensary buildings at Edinburgh has added much to the teaching facilities in relation to tuberculosis. There are now available for purposes of study the Tuberculosis Dispensary, the Sanatorium (Royal Victoria Hospital), and the Royal Victoria Hospital Farm Colony. These are all linked together closely, and those attending the course have the opportunity of studying the co-ordinated system in operation. In addition, the pathology of the subject is overtaken in the pathological department of the new school and the new pathological museum and laboratory attached to the dispensary.

The next course commences on Monday, January 13th, at the new dispensary. As the numbers attending previous courses have been large, graduates and others proposing to join the present course are advised to make early application. A further announcement regarding the course will be found in this week's advertisement columns.

SCHOOL BOARDS AND MEDICAL TREATMENT.

A good deal of interest has been aroused by the recent decision in the Court of Session with reference to the medical and dental treatment of school children under the Glasgow Board. It may be explained that the Glasgow School Board will get a share of the sum of £7,500 which was set apart by Parliament for the treatment of necessitous school children in Scotland for the year ending February 28th, 1913. This money is available for the purposes of treatment. In Edinburgh premises have been rented by the School Board, although the arrangements for treatment so far as the staff is concerned have been made to February 28th only. The amount which the Edinburgh Board will obtain is £850. Glasgow's share will be much larger. The judgement of the Court of Session does not deal with this money but merely makes it clear that the School Board is not empowered to take money from the rates for the purposes of treatment. That was the view of the board before the raising of the action, but as the Education Department was rather of opinion that the Education Act made it possible to do certain things, a legal decision was necessary to remove any doubt in the matter. Hence the test case. It may be noted that the cost of medical inspection undertaken in the schools of the Glasgow Board amounts to about £5,000, half of which is rated for. The staff consists of a principal medical officer and three full-time medical assistants, together with thirteen part-time medical assistants. There are ten nurses employed. In addition there are specialists for eye and throat diseases and for the mentally defective cases. Under the Govan School Board, also in Glasgow, there are two medical officers devoting their whole time to the work of medical inspection, and ten are engaged part time. The cost is about £1,800. In Aberdeen the School Board works in co-operation with the Public Health Committee of the Town Council. The medical arrangements are in charge of Dr. Rose, who has an assistant and a staff of nurses. Recently the School Board appointed a dentist to give half-time service at a salary of about £250 a year, the cost being defrayed out of the Treasury grant. In Dundee the duties of the school medical officers are confined to inspection and giving advice as to the most common school ailments, especially defective sight, bad teeth, and ringworm.

MILK AND RETURN CASES OF SCARLATINA.

In his usual report to the Health Committee of Glasgow, Dr. A. K. Chalmers, M.O.H. for the City, drew attention in November to an unusual experience in connexion with return cases of scarlatina. Twelve cases in all occurred, affecting eleven households. An interval of sixteen and thirteen days respectively separated the two earlier cases from the others, the dates of sickness being November 2nd, 5th, 18th, 23rd, and 26th (1 case each), November 20th (3 cases), and November 21st (4 cases). All the employees at the dairy of which these families were customers were medically examined without furnishing a history or showing any symptoms suggesting scarlet fever, but when

the farm from which the milk supply of the dairy was obtained was visited and the members of the household examined, it was found that two of the farmer's children had been dismissed from one of the county fever hospitals, one on October 26th and another on November 16th, and that the former was suffering from an acrid nasal discharge so frequently associated with return cases of the disease, while the latter bore evidence of having recently had a similar discharge. This is believed to be the first instance in which milk appears to have become the carrier of infection thus acquired, and the explanation in the present instance would appear to be that the mother attended to the child with the discharge, and was also engaged in milking. The children were at once removed from the farm and the premises disinfected. Since then no further cases have occurred.

OVERCROWDED GLASGOW.

An important pronouncement will shortly be made with regard to the problem of dealing with congested areas in the city of Glasgow. No fewer than five committees of the Corporation are at work, and, with a view to ascertaining the rate of progress and arriving at a common policy, the Lord Provost held an informal meeting a few weeks ago with the principal members of these committees. As a result, proposals for a definite policy on a large scale will shortly be submitted. The financial aspects are large and give rise to controversy, but it is generally recognized that the time has come when some forward step must be taken. The most important of the committees is that on the Housing of the Working Classes Acts, of which Bailie Dr. E. McConnell is convener. It is tackling the question of back lands in slum areas. The tramways surplus of £56,000 handed over to it two years ago is a start. Though the magnitude of the task renders progress slow, several slum areas are to be purchased for demolition and the creation of open spaces in congested districts. The City Improvement Committee, and special subcommittees of the Health, Tramways, and Statute Labour Committees of the Corporation are also dealing with different phases of the problem.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

TUBERCULOSIS SCHEMES.

At its last meeting the Dublin County Council elected Dr. M. J. Cuffe as tuberculosis medical officer at a salary of £500 a year, with £100 additional travelling expenses.

The Cavan County Council proposed to appoint a tuberculosis officer at a salary of £200 per annum, with £50 for travelling expenses. At the last meeting a letter was read from the Local Government Board suggesting that they should fix the proposed salary at £400 and expenses. Letters were also read from the secretaries of the Conjoint Committee and of the co. Cavan Local Medical Committee, stating that any doctor appointed under the terms proposed by the county council would not be in a position to receive the co-operation of the general practitioners of the county, inasmuch as the terms were distinctly at variance with those laid down by the Conjoint Committee. After discussion the matter was adjourned pending the receipt of particulars as to the number of insured persons in the county.

The Insurance Act County Committees' Association, after considering the Local Government Board circular on the scheme for the distribution of the maintenance grant for treating non-insured persons and dependants of insured persons, passed a resolution that, in view of the uncertain cost of the treatment required and the inadequate promises made hitherto by the Exchequer, the committee could not recommend the county councils to undertake for the present institutional treatment of non-insured persons other than such dependants as could be wholly provided for out of the funds of the Insurance Committees.

P. F. COLLIER MEMORIAL DISPENSARY.

At a meeting held at the Mansion House, Dublin, on December 16th, the Countess of Aberdeen, on behalf of the Women's National Health Association, formally handed

over the P. F. Collier Memorial Dispensary for the Prevention of Tuberculosis to the Lord Mayor and Corporation. The first annual report was read by the Medical Superintendent, showing that from July, 1911, to November, 1912, 1,176 patients had been seen and examined, and 547 were diagnosed as suffering from definite pulmonary tuberculosis. Béraueck's tuberculin had been administered to a large number of patients with very satisfactory results. The total number of attendances of patients at the dispensary during the year was 8,400, and an extensive system of home visitation had been carried on. The Honorary Secretary, Sir William Thompson, Registrar-General for Ireland, submitted the balance sheet, which showed that the building, equipment, and initial expenses were £2,519, which with the other expenses, wages, medical appliances, brought the total expenditure to £4,114. The Corporation had agreed to pay £2,000 for the dispensary.

Lady Aberdeen said that when Mr. Robert Collier made his generous offer he expressed the hope that it might be found possible to hand it over to the rightful keepers, the municipality.

BELFAST AND ITS MILK SUPPLY.

Some months ago the City Corporation sought powers from the Local Government Board to inspect dairies outside the borough from which milk was sent into the city. Some 12,000 of the 18,000 gallons consumed come from outside dairies. The councils of some districts objected that no English city had these powers, and that difficulties would arise from the double inspection and the different standards demanded; but it was pointed out that if a dairyman complied with the Act he had nothing to fear. The Local Government Board has come to the conclusion that, while it is right that the city council should satisfy itself of the purity of the milk supply, it would be better for inspection to be a matter of consent on the part of the district councils.

THE DRAFT RULES FOR MIDWIVES IN BELFAST.

The Public Health Committee, on December 19th, 1912, received an objection from the Local Government Board to the draft rules which the committee had drawn up to give effect to the provisions concerning midwives practising in Belfast, contained in Part 8 of the local Act of 1911. These draft rules had been laid before the medical guild in Belfast, and had been discussed. The Board pointed out that the provisions relate to certificates to practise, the midwives' roll, and the notification of intention to practise, but that the corporation was not given any powers to make rules or regulations in respect of the practice of midwifery.

SALARIES OF MEDICAL OFFICERS.

At the last weekly meeting of the Thurst's Board of Guardians the salary of Dr. Thomas Barry, medical officer of Littleton Dispensary District, was raised from £120 to £160, in order to place him on equal terms with the other medical officers in the Thursts Union.

England and Wales.

FROM OUR SPECIAL CORRESPONDENTS.

MANCHESTER AND DISTRICT.

POST-GRADUATE CLASSES.

The course of post-graduate demonstrations given by members of the honorary staff of the Manchester Royal Infirmary will be resumed on Tuesday, January 14th. The demonstrations will be given on Tuesday and Friday of each week during the second half of the winter session, the medical demonstrations being on Tue-days and the surgical on Fridays. Notice of subjects will be published, and will also be found posted in the Oxford Road Lodge of the Royal Infirmary.

COURSE IN TUBERCULOSIS.

An advanced course in tuberculosis commenced on December 17th in the Public Health Laboratory of the University of Manchester, when a laboratory class began

its work under the guidance of Professor Sheridan Delépine, assisted by Drs. Sidebotham and Sellers. This part of the course will be supplemented by lectures and demonstrations, and we publish this week the introductory lecture given by Professor Delépine. The first course of clinical instruction will begin on January 20th at the out-patient department of the consumption hospital, and will be under the direction of Drs. Moritz, Haring, Renshaw, Marsden, and Cunliffe. The first course of instruction on administration will be conducted by Dr. Niven at the Manchester Public Health Office, beginning on April 5th. The whole course extends over a period of not less than six months, and the course of clinical instruction is continued throughout the whole period.

THE MANCHESTER AND SALFORD PROVIDENT DISPENSARY ASSOCIATION.

Some months ago, when the resignations of the clubs were sent in throughout Manchester and Salford, there was evidently some doubt as to whether the resignations applied only to members who would become insured persons or to the whole club. Opinions varied among the medical officers of the provident dispensaries, but in order to arrive at uniform action a meeting was held, and they decided to inform the officials of the Dispensary Association that their resignations must be regarded as applying to the whole of the members, many of whom are women and children. It was also decided that the final decision as to any new terms that might be offered for treatment of the non-insured members should be left to the Joint Committee of the Manchester and Salford Divisions acting as the Provisional Medical Committee. Soon afterwards a communication was received from the Dispensary Association saying that it was prepared to make an increase in the capitation payment to the medical officers. At present there are nine branch dispensaries, whose funds are kept separate, and which have a total membership of over 15,000 on the books, or, reckoning those children of members who are under 14 years of age for whom no subscription is required, the gross number is about 17,000. After the withdrawal of those who will be insured persons under the Act, it is expected that from 8,000 to 10,000 will still remain on the books, and it was for these non-insured that it was proposed to continue the dispensaries. The present contribution is a penny a week, with a provision that the subscription for all children under 14 years of age in any one family shall not exceed twopence a week, children over this age paying as separate members. There is also an entrance fee of 6d. a member or 1s. for a family, and persons actually suffering from illness may join on paying an entrance fee of 5s., provided that the whole of the family of the applicant joins at the same time. A penny is also paid for each bottle of medicine or other article supplied. Members have a free choice among the doctors of the branch they join, and the medical officers receive one half of the ordinary contributions according to the number of members on their lists, and in addition, if there is any balance after defraying expenses, at least two-thirds of it, and sometimes the whole, is distributed to the medical officers in proportion to the amount already received. In 1910 the receipts from subscriptions and entrance fees were £3,187, and the sum paid to the medical officers, who number 32, was £1,695, which does not include fees for special visits nor confinements, for which a special charge is made. There is no fixed income limit, but the dispensaries are understood to be only for those who are unable to pay ordinary fees, and if any question arises on any person applying for admission it is referred to the Charity Organization Society for investigation. Under the new terms offered the contributions would have been raised so as to provide about 50 per cent. increase in the remuneration of the medical officers, who would also have been entitled to control the admission of new members, and membership would also have been open to review at any time if a member's circumstances changed so as to make him reasonably independent of a charitable institution. These conditions were suggested owing to complaints that not a few of the members could well afford to pay ordinary medical fees. The offer of the Dispensary Association was laid before the Joint Committee of the Divisions, which decided to submit it to the medical officers themselves before coming to any decision. A conference was accordingly held,

and after some discussion the medical officers, voting separately, decided to reject the offer not to appoint any committee to negotiate about any fresh arrangements, and expressed the opinion that the dispensaries, at any rate on their present basis, should be ended. These resolutions of the medical officers present at the conference were then confirmed by the Joint Committee, and the following reasons for the decisions were assigned: (1) That the dispensaries cannot be carried on as a satisfactory business undertaking. (2) That the management expenses are extravagant, and cannot be proportionately reduced when insured persons now members are withdrawn. (3) That any medical charity should be solely under the control of the medical profession. It was recognized that this decision will undoubtedly be serious for a few of the medical officers, and it is hardly to be expected that the council of the Dispensary Association will willingly acquiesce in the ending of an institution which has been in existence for upwards of thirty-six years.

NORTHUMBERLAND AND DURHAM.

THE decision of the recent Representative Meeting was awaited with great anxiety by all the members of the medical profession in the industrial districts of Northumberland and Durham. When the decision and the resolutions, with the remedy suggested, were known, great astonishment was expressed that the meeting should have tampered with one of the cardinal points, as it was feared that the attack which has been so successfully carried on by the profession against the National Insurance Act would thus be weakened. The men in this area have been working for years to get rid of friendly society control, and for any legislative body of their profession to ask them to again place themselves in such a position seemed to them most unwise. The loyalty and devotion with which the members of the profession have united in face of a common foe have been most striking. At the many meetings held since the Representative Meeting the great depths to which the roots of this loyalty have penetrated have been proved. It has only been owing to what is regarded as the sheer necessity of the situation, and the impossibility of carrying out the resolution of the Representative Meeting, that the men in so many areas have agreed to work the Act provisionally. They are still heart and soul with the Association; and, so far from there being any ground to fear for the maintenance of the Association, it is certain that it will increase in power, and go on growing upon a foundation even more solid than that on which it has hitherto rested. At one of the largest meetings of the Branch Council ever held, a very long and able discussion took place, and the opinion of an independent legal authority was obtained which stated that, owing to the action of the Representative Meeting, the pledge was no longer binding on the members of the Association; the Branch Council passed a resolution to that effect, and advised the members to accept service provisionally under the Act, and at the same time to renew their demands for the points for which they had been fighting. This line of action has been adopted by all the Divisions in the Branch with the exception of two, and it seems probable that even these two, although they are very strong and their circumstances are unexceptional, will find it impossible to resist accepting service under the Act.

A notice of meeting was sent to all the members and non-members in the area, outside the county boroughs, asking those unable to attend to express their views on the present position in writing. Only some fifteen replies against working the Act were received, as compared with close on a hundred stating that owing to the recent action of the Representative Meeting there was nothing for it but to work the Act provisionally. This is the feeling which prevails generally throughout the Branch; but there is a deep feeling of sorrow and regret that this action has been forced on its members. One and all state that some other and more dignified way out should have been found. There is every indication that the men in this area intend to stick to the Association; but, it is said, men in other areas in the country will have to learn to give and take, and not to ask men to carry out impossibilities and sink their principles, as has recently been demanded of them.

LONDON.

LONDON COUNTY COUNCIL.

Medical Treatment of School Children.

DURING an all-night sitting of the London County Council on December 17th, 1912, Mr. R. A. Bray moved an amendment to a formal report of the Education Committee on the subject of school medical work:

That the Education Committee do consider as to the establishment of one or more school clinics under the direct management of the Council.

He urged that the Council should try various methods of supplying medical treatment and select the one that proved the best. Of the two methods at present in operation, the Board of Education had stated that it could not sanction the arrangements with hospitals as anything more than a temporary expedient. Those in touch with the negotiations knew that the hospitals generally would never conform to the "London Hospital type," as required by the Board of Education. There were also difficulties connected with the other method of providing medical treatment—that of local centres managed by committees of local practitioners. The Board of Education only allowed the Council to make the agreements from year to year, and that made it difficult to obtain premises at a reasonable rent. Furthermore, it would be very convenient to the Council to be able to move its medical men about, and this could not be done with the local medical committees. The local practitioners had undertaken for a fixed rate of pay to provide medical treatment at a certain place, but sometimes the Council was not able to supply the full number of cases agreed upon. If the doctors were in the service of the Council it would be possible to arrange for them to go to another centre and put in the rest of their time there. As to the cost of a clinic, a private house could easily be adapted for the purpose. The second element of expense was the payment to the doctor. He had very good reason for believing that the doctors under the present arrangement had asked to be paid not only time-rates but piece-rates as well. They wanted £50 a year for one half-day a week, and at the same time they would only see a limited number of new cases each time. The experience of Miss McMillan at the Deptford health centre showed that the doctors there could see a great many more new cases each time than those under agreement with the Council saw. The Council had agreed to everything the doctors had asked for, without any sort of bargaining. If the doctors were in the direct employ of the Council their attendance for a definite time to see all the cases that the Council liked to send could be secured. By this means the work could be done much more cheaply. Finally, Mr. Bray urged that the present arrangements with the hospitals were unsatisfactory because a child with more than one ailment might be sent to one hospital for one complaint and to another for a second, while the nursing treatment which followed was provided by a third organization.

Miss Adler, who seconded, called attention to the fact that under the present arrangements in 3,000 cases out of 27,000 the children did not complete the course of treatment. A clinic would be more convenient to parents and would enable inspection and treatment to be co-ordinated.

Mr. F. R. Anderton, chairman of the subcommittee of the Education Committee concerned, claimed that the local treatment centres were practically clinics, and were so described in the report of the medical officer to the Board of Education. In addition to the arrangements now in force at eleven hospitals and eleven treatment centres, schemes were in prospect for treatment at one more hospital and five other centres. These would provide for the treatment of 48,000 defective children. No figures had been adduced by previous speakers to show that local treatment centres were more expensive than would be clinics managed by the Council. One of the advantages of the present arrangements was that the doctors on the rota of the practitioners' centre were known locally; they were the people whom the parents would be most likely to trust, their reputation being known. There was no need for an experiment of the kind suggested.

On a division, the proposal was lost by 55 votes to 40, and the report of the Committee was adopted.

Further Provision for Dental Treatment.

Mr. Bray moved a further amendment:

That the Education Committee do consider and report as to the establishment of additional dental centres which will, with existing centres, make provision for the treatment of not less than 50,000 cases a year.

He pointed out that it was proposed this year to increase the provision only from 13,000 to 19,000, and then only to treat children of three age groups—6, 7, and 8. Nevertheless, of the whole number of London children, a very large proportion required dental treatment.

In reply, Mr. Cyril Cobb, Chairman of the Education Committee, announced that additional schemes were under consideration which he hoped would be thought entirely adequate. There were seven treatment centres at present; four more were about to be established, and seven more in the course of the year. By this time next year the Council would be treating 32,000 children. A sum of £8,500 was included in the estimates to meet the cost.

The amendment was lost, and the Committee's report was then adopted.

Correspondence.

EPSOM COLLEGE: AN APPEAL.

SIR,—Will you allow me to ask your readers to respond to this appeal on behalf of the Royal Medical Foundation of Epsom College? The need of fresh supporters has never been more acutely felt than at present, because, apart from the annual loss of many staunch friends who became attached to the institution in its earliest years, the general increase in taxation, and the uncertainty which is overshadowing future medical practice, are seriously affecting the income derived from annual subscriptions.

As is well known to all your regular readers, the foundation provides annuities of £30 each for fifty aged members, or widows of members, of the medical profession, and gives a first-class education, together with clothing and maintenance, to fifty necessitous sons of medical men. To meet these urgent liabilities a sum of close upon £7,000 a year is required, of which about £4,500 must be obtained by annual contributions.

The applicants far exceed in number those that can be helped, even when the whole of the sum just mentioned is subscribed.

Besides the demands on the foundation funds, the general purposes fund of the college has been well-nigh exhausted in making good the ravages of time and of weather on extensive buildings situated on an elevated and exposed (though very healthy) site, in making such structural alterations as changes in educational methods and in the ordinary requirements of a large institution necessitate, as well as in substituting modern sanitary conditions for those which were in use when the college was built some sixty years ago.

Much still remains to be done in providing adequate and up-to-date arrangements for the sick in times of epidemic illness, in repairing boundaries and roads within the boundaries, in providing increased accommodation in the college chapel, and in making other improvements. The council therefore would welcome contributions specially earmarked "general purposes," as well as donations and fresh annual subscriptions to the Royal Medical Foundation Fund.

In order that this letter may not be too long, full details of the work which is being carried out by the college were given in last week's advertisement columns of the BRITISH MEDICAL JOURNAL.—I am, etc.,

HENRY MORRIS,

Honorary Treasurer.

London, W., Dec. 18th, 1912.

MANIFESTATIONS OF A HEALTHY HEART.

SIR.—While Dr. James Mackenzie's paper (December 21st, 1912, p. 1697) is highly interesting and instructive, yet there are points which appear to me somewhat obscure, and if they could be cleared up it would be of great advantage to the profession.

It is clear that both the mechanical details of the pump as well as the driving power must be in order for the heart to be "normal," and if the first are faulty the second is called upon for more work, and if the first are sufficiently faulty the second cannot supply this work.

In the paragraph, "Significance of Murmurs," Dr. Mackenzie excludes from the discussion "murmurs due to damaged valves," and states that he confines himself to the question of "functional" murmurs, winding up the paragraph with the words: "I am justified in stating that functional murmurs in the young, in the absence of evidence of muscle affection, are signs neither of disease nor of impairment."

This last sentence shows that the term "functional" requires defining before any discussion on the subject can be satisfactory, as, in at any rate the minds of some, the essence of a functional murmur is that it should not be due to "disease or impairment" in the first place.

Again, in respect of the method of teaching complained of: Is it not in the natural order of science to make the regular and murmurless hearts the rule for normality, and to include some with murmurs and irregularities as exceptions to the rule? Yet the author evidently means more than this, but what it is is not plain.

I think it must be held that the examiner for life insurance, who sees the examinee for the first time, is met with the question as to whether a murmur is due to previous disease and malformation or not, and that until a "functional" murmur is defined and methods of proof with statistics are worked out, the verdict can only be given chiefly by means of the clinical experimental method as opposed to scientific demonstration *in toto*, which does not yet exist.

Dr. Mackenzie's paper, however, foreshadows further assistance to the profession in these matters, and I am sure it will be much welcomed when it comes.—I am, etc.,

SHEFFIELD NEAVE, M.R.C.P.

London, W., Dec. 12th, 1912.

TRANSITORY BIGEMINAL PULSE.

SIR.—The disabilities of living so far away from the centre of the medical universe are great, inasmuch as one's opinions are apt to get somewhat stale in transit. In spite of this drawback, may I venture to comment on a case reported in the JOURNAL of October 5th, page 841, by Dr. William Johnstone, under the heading "A Case of Abnormal Pulse Rhythm"? I will ask your permission to go even further. May I have the temerity to criticize the case reported by Sir Lauder Brunton in the issue of October 19th—a case arising directly out of Dr. Johnstone's report?

I would premise my remarks on both these matters by asking why so many medical men ignore the information to be derived from a tracing of the jugular pulse? In both the cases under review a definite conclusion is impossible without such a record.

Failing certain information one can but suggest probabilities: I would like to suggest to Dr. Johnstone that his case is merely one of a regularly recurring "interpolated extra-systole"; the fact that the combined periods of the first two elements of the trigeminy equal in duration the longer periods makes this explanation very probable. I have noticed that when a heterogenetic rhythm tends to persist, there is frequently a reflex acceleration of the sinus rate, the apparent object of which is to anticipate the heterogenetic beat, and the certain result to restore the normal sequence of contraction of the heart's chambers, and eliminate the intrusive irregularity which must obviously interfere with the efficient performance of the cardiac functions—points which explain the subsequent regular pulse at a rate which is, in virtue of the absence of a time record, probably enhanced, if one may judge by the periods themselves. Dr. Johnstone's case is probably quite simple after all.

Sir Lauder Brunton records a case of bigeminy. The description of the albuminuric patient leaves one with the impression that he conforms to the type in which extrasystoles are common, even though his field of cardiac response is not markedly contracted. On examining the

very meagre radial tracing published, one immediately notes that, if the lesser of the two beats is an extra-systole, the pause is not fully compensatory. Since we are not dealing with "ventricular extra-systoles," the mind turns to "auricular extra-systolic bigeminy" as an explanation, and since this is simple and, on *a priori* grounds, probable, one asks why Sir Lauder Brunton does not advance it. If, however, Sir Lauder demands a really erudite explanation of his tracing I can suggest the following:

1. Pulsus alternans is found in conditions in which the contractility of the muscle is impaired. It is probably dependent on an interference with the rate of restoration of the muscle, such interference being attributable to insufficient blood supply.

2. Dr. Thomas Lewis has recorded a case of "alternation of impulse conduction"—a point noted during some experiments to determine whether the phenomena of asphyxiation depended on oxygen deprivation or CO₂ poisoning.

3. Given "alternation of contractility" and "alternation of impulse conduction," why not "alternation of the rate of impulse formation"? I can conceive of a localized arteritis interfering with the nutrition of the sino-auricular node; I can conceive of a localized area of fibrosis in that region bringing about a similar result; I can conceive of a lesion of the vagal termini just sufficient to keep up for some time an alternating series of inhibitory impulses, provided that some outside influence originated a maximal, or nearly maximal, stimulus.

If Sir Lauder scorns "auricular extra-systole" as being too simple an explanation of his case, I feel sure that "alternation of rate of impulse formation" will not fail by virtue of its lack of complexity. Anyway, I would like to suggest a jugular tracing or any electro-cardiographic record as being easily available steps towards elucidation.—I am, etc.,

MACNEILL SIMPSON.

Sydney, New South Wales, Nov. 24th, 1912.

ESSENTIAL CONDITIONS FOR MILK CONTROL.

SIR.—In addition to the important points raised in the leading article of the JOURNAL upon "Essential Conditions for Milk Control" (December 21st, p. 1720), it is desirable to draw immediate attention to a recent decision of the High Court of Justice bearing upon the registration of purveyors of milk (Spiers and Pond, Limited, v. Green). It was decided that a person who occasionally sells milk in connexion with another business, where the selling of milk does not form a substantial part of the business, does not carry on the trade of a purveyor of milk, and therefore does not require to be registered under the provisions of the Dairies, Cowsheds, and Milkshops Order, 1885. This important decision will remove hundreds of small milk vendors from the supervision of sanitary authorities, and experience shows that it is the small dealers that need most supervision, at any rate as far as the condition of the premises is concerned. It is to be hoped that the new bill introduced by the President of the Local Government Board will provide for the supervision of all premises used for the storage and sale of milk, however small the "turnover."—I am, etc.,

THOS. E. FRANCIS, M.D., D.P.H., M.O.H.

Llanelli, Dec. 21st, 1912.

ASSISTANT MEDICAL OFFICERS IN ASYLUMS.

SIR.—I have read with considerable interest the letters in the recent issues of the BRITISH MEDICAL JOURNAL. It is not to be wondered at that there is a difficulty in getting young medical men to fill these appointments. I have had over fifteen years' experience as an assistant medical officer in an asylum, and I consider that there is very great room for improvement in the position of the office. An assistant medical officer is, to my mind, little better than a "glorified house-surgeon and clerk" rolled into one. We have heard a lot of late about the Medico-Psychological Association trying to improve "the status"

(whatever the association may mean by this vague term) of the assistant medical officer. Candidly, I think this association has done very little for the assistant medical officer in trying to better his position, and I am afraid is not likely to do much. I know of several asylums where the assistant medical officer is absolutely nobody—kept in the background by the resident medical superintendent; and as to appealing through the resident medical superintendent to his committee of management for due recognition as to his position, why, it would be rank insubordination. Too often the assistant medical officer does practically all the work but the resident medical superintendent usurps the kudos. This is not as it should be. To the public the term "assistant medical officer" means a very minor official indeed. Would not the title "assistant medical superintendent" tend to elevate the status, at least in the eyes of the man in the street? The assistant medical officer's position is one of great responsibility. He has much real hard work, for which there is too often no recognition whatever. The subordinate staffs of asylums are making strong efforts, and rightly so, to improve their positions by the National Asylum Workers' Union. Why should not the assistant medical officer do likewise? I am sure the Lunacy Commissioners and inspectors would support them in their efforts. I am, etc.,

SENIOR A.M.O.

(Member B.M.A. and Medico-Psychological Association).

December 28th, 1912.

THE REPORT OF THE DEPARTMENTAL COMMITTEE ON SIGHT TESTS.

SIR.—In reference to your article on colour vision at sea in the BRITISH MEDICAL JOURNAL of December 21st I may say that the Board of Trade has suffered through its advisers. For instance, the method of classifying colour blindness recommended by the Committee is absolutely erroneous. The Committee recommends a method of classifying colour blindness by measuring the luminosity of the colour sensations of those examined by the flicker method of photometry. Light sensation and colour sensation are two distinct things. I have examined two bad cases of colour blindness (dichromics who confuse red with green), and their ratios of red to green came out precisely the same as normal on the method recommended by the Committee. I then examined a man in whom I could not detect the least defect of colour perception, and he appeared very colour blind on the Committee's method. Professor A. W. Porter and I examined one of the colour-blind men with very feeble lights from all parts of the spectrum. We could find no defect in his perception of luminosity. As stated in the BRITISH MEDICAL JOURNAL of the time, I offered to demonstrate cases to the Committee, and this offer was refused.—I am, etc.,

London, W., Dec. 22nd, 1912.

F. W. EDRIDGE-GREEN.

Public Health

AND

POOR LAW MEDICAL SERVICES.

EXAMINATION OF ALLEGED LUNATIC.

A CORRESPONDENT writes that he was called in by a relieving officer and magistrate to examine and advise on a case of alleged lunacy, with a view to the committal of the patient to an asylum. After examination he did not feel justified in certifying that the patient was of unsound mind, but directed his removal to the union infirmary. Is he entitled to a fee?

* This depends on the magistrate. If he ordered a fee the guardians are bound to pay it, but under the Lunacy Act he is not bound to make such an order. The fee is due for making the examination and furnishing the certificate, whether the patient proves to be a lunatic or not.

DR. JULES CONSTANTIN, formerly an assistant of Dr. Doyen of Paris, but lately an aviator with the Bulgarian army, was killed while flying in his biplane over the Turkish army at Tchatalja. It is said he had gone up into the air with the object of dropping bombs into the Turkish intrenchments.

Universities and Colleges.

UNIVERSITY OF OXFORD.

THE following candidates have been approved at the under-mentioned examinations:

- FIRST B.M.—*Organic Chemistry*: A. G. East, F. C. Gladstone, W. R. Greenshields, A. Hodgkinson, R. M. Humphreys, R. W. Lush, J. J. Savage, J. Le R. Shibley, D. H. Skinner, C. H. Terry, A. E. Thomas, W. S. Tunbridge, B. E. Wall, K. F. D. Waters. *Human Anatomy and Physiology*: E. W. Bowell, W. Brown, B. A. Bull, J. J. Conybeare, K. M. Dwyer, O. H. Gotch, T. R. Price, S. W. F. Underhill.
- SECOND B.M.—*Materia Medica and Pharmacology*: A. C. Ballance, L. R. Procter, L. G. Brown, F. B. Chavasse, R. C. Fairbairn, R. St. A. Heathcote, R. J. Inman, E. E. Mather, N. A. Spratt, T. O. Thompson, H. A. B. Whiteledge. *Pathology*: F. W. Browne, E. W. Carrington, J. C. Davies, R. St. A. Heathcote, E. W. N. Hobhouse, A. Jackson, M. B. Lawrence, C. W. B. Littlejohn, H. G. Morris, G. S. Robinson, A. H. Southam, G. Stanger, A. B. Thompson, W. W. Waller. *Forensic Medicine and Public Health*: T. B. Batchelor, G. E. Beaumont, R. F. B. Bowes, H. T. Evans, R. A. Fawcus, S. Hibbert, A. Juet, R. C. Ozanne, W. R. Reynell. *Medicine, Surgery, and Midwifery*: G. E. Beaumont, R. A. Fawcus, W. J. Hart, S. Hibbert, A. Juet, E. O'Connor, R. C. Ozanne, W. R. Reynell, J. Sainsbury, L. Scott, G. H. Varley, G. W. Carte.

Degrees.

The following degrees have been conferred:

- D.M.—C. D. H. Corbett.
B.M., B.Ch.—H. T. Evans, G. H. Varley, G. Stanger, R. A. Fawcus, F. Scott, J. Sainsbury.

Radelife Travelling Fellowship.

A competition for a Radelife Travelling Fellowship, of the annual value of £200 and tenable for three years, will commence on February 18th. The names of candidates must be submitted to the Regius Professor of Medicine by February 10th.

UNIVERSITY OF CAMBRIDGE.

THE following candidates have been approved at the examinations indicated:

- FIRST M.B., PART I. *Chemistry*.—E. V. Beale, D. C. Beaumont, W. E. L. Brown, H. Chell, W. L. Dandridge, W. D. Doherty, A. M. Gaslee, H. H. Ginsburg, R. F. S. Gwynne, S. J. Higgs, M. H. Jupp, W. N. Leak, P. C. Livingston, A. G. P. McArthur, J. H. Naumann, J. S. Need, J. W. McK. Nicholl, S. W. Page, E. D. Spackman, M. B. R. Swann, W. E. Vaudrey, S. Waterworth, W. G. Woolrich.
- PART II. *Physics*.—E. V. Beale, W. E. L. Brown, T. A. Collot, R. S. Corbett, W. L. Dandridge, W. D. Doherty, A. W. R. Don, A. M. Gaslee, C. T. C. Gill, H. H. Ginsburg, L. B. Hartley, S. L. Higgs, C. R. Hind, J. S. La Fontaine, W. N. Leak, J. B. S. Lewis, R. Lumsden, G. Lyon Smith, R. Mansell, S. W. Page, F. S. W. Raikes, G. M. Shackel, E. D. Spackman, M. B. R. Swann, W. E. Vaudrey, S. W. Wan, S. Waterworth, W. G. Woolrich.
- PART III. *Biology*.—D. J. Batherham, P. J. Briggs, E. R. Brown, G. W. Brown, T. A. Collot, T. L. Crawhall, W. D. Doherty, A. W. R. Don, W. N. Leak, G. T. Lipschitz, G. Lyon Smith, G. S. Need, M. B. R. Swann, G. D. C. Tracy.
- SECOND M.B., PART I. *Human Anatomy and Physiology*.—C. G. Ainsworth, F. H. R. Altounyan, J. Aydon, E. F. Bailey, O. A. Beaumont, S. B. Bhatia, J. M. Bigger, A. B. Bratton, F. V. Cant, H. Chadwick, Y. M. Contes, A. O. Courlis, D. Crellin, C. S. Dodson, J. S. Ellis, J. S. Eloff, E. T. D. Fletcher, C. Gardner-Hill, C. B. Hawthorne, R. C. Hewitt, E. P. Hicks, L. G. Jacob, M. W. Jones, C. B. Kundersley, J. B. Leather, F. G. Lewis, M. L. Loveless, W. B. Loveless, H. D. McDroy, E. O. Morrison, B. Mountain, E. G. D. Murray, F. P. Nicholas, R. Playfair, R. T. Reine, W. F. R. Schloss, E. P. W. Wedd, W. L. Willett, A. G. P. Wills, C. B. Wilson, W. R. Wilson, G. W. Woodhouse, F. H. Young.
- SECOND M.B., PART II. *Pharmacology and General Pathology*.—J. W. Adams, W. F. Benstead-Smith, J. H. Cumming, R. W. B. Gibson, G. D. Sherwood, G. H. S. Thomas, R. W. Willocks.
- THIRD M.B., PART I. *Pharmacology and General Pathology*.—Examined and Approved: J. W. Adams, W. F. Benstead-Smith, J. H. Cumming, R. W. B. Gibson, G. D. Sherwood, G. R. S. Thomas, R. W. Willocks.
- PART II. *Surgery, Midwifery, and Medicine*.—F. S. Adams, J. W. Adams, H. C. Attwood, T. E. Banister, H. W. Farnes, F. S. Pedale, E. Calverly, W. T. Channing-Peace, D. G. Charrington, A. C. Clifford, B. J. Cochrane, H. G. Earle, J. V. Fiddan, C. Hardwicke, T. H. Hardy, I. W. Jony, W. C. D. Maile, C. G. H. Morse, H. J. S. Morton, T. H. Oliver, T. E. Osmond, G. M. Parker, S. H. Rouquette, L. T. Rutherford, A. S. Seabrooke, P. B. Smith, G. W. Spencer, F. S. Tucker, J. W. Tonks, C. Warner, A. M. Zaporos.
- THIRD M.B., PART I. *Surgery and Midwifery*.—K. B. Aikman, J. Brewer, E. N. Butler, A. M. Humphry, H. Y. Mansfield, S. G. Platts, F. Roberts, D. N. Seth-Smith, W. J. F. Symons.
- PART II. *Medicine, Pathology, and Therapeutics*.—E. Wordley.
- M.D.—J. G. Sauer.

* Under old regulations.

† Under new regulations.

UNIVERSITY OF LEEDS.

Degrees.

THE following degrees have been conferred:

- M.B., Ch.B.—C. Metcalfe, H. Auger, J. H. Blackburn, N. V. Mitton, J. J. Pickles, M. Feto, S. Samuel, W. H. Symons, and B. W. F. Wood.
- First class honours. Second class honours.

Examinations.

The following candidates have been approved at the examinations indicated:

- SECOND M.B., Ch.B., Part I.—H. S. Bhalla, H. Franklin, H. M. Holt, C. E. Leake, H. S. Lockwood, J. Rosenzweig, J. Smith, R. S. Topham, A. Umanski. Part II.—H. S. Bhalla, M. Hutchinson.
- FINAL, Part I.—W. D. Anderton, S. N. Cohen, J. C. Gillies, F. King, H. R. Knowles, W. H. Loun, J. J. Pickles, H. W. Robinson, H. Schochet, H. L. Taylor, C. Wilson, J. Wright.
- D.Psych.Med.—Alice E. M. Babington.
- D.P.H.—H. F. Horne.

LONDON SCHOOL OF TROPICAL MEDICINE.

THE following candidates were approved at the examination held at the end of the fortieth session:

- S. H. Dankes, A. Moore, J. A. Beattie, de V. Condon, Major I.M.S.; G. R. Footner, A. Ismail, E. H. Mayhew, G. Browse, Major I.M.S.; G. L. Johnston, J. L. Pawan, W. C. P. Winter, A. K. Sinha, R. S. Turton, C. H. Marshall, G. E. Dodson, F. D. Bana, F. E. Whitehead, A. C. Swertz, F. Rice, A. F. Wallace, H. G. F. Spurrell, W. A. Lamborn, J. Dalrymple, P. J. Dunn, E. M. Condy, A. da Gama, F. G. Rose, J. M. Benson, H. W. Hayes, J. P. Hoare, C. W. Mason, R. C. Chakraborty, R. A. Murphy, E. T. MacIntyre, W. E. Roberts.

Medical News.

THE second International Congress on Life Saving and the Prevention of Accidents will be held at Vienna in September (9th-13th), 1913. His Imperial Highness Archduke Leopold Salvator is patron of the congress. Communications relative to the Congress should be addressed to the General Secretary, Dr. Heinrich Charas, Radetzkystrasse 1, Vienna 5.

WE are requested to state that a dance under the auspices of the Birmingham School of Medicine will be held in the Edgbaston Assembly Rooms on January 21st, when it is hoped that all past students and other medical men interested in the school will be present. Further information can be obtained from the secretaries, Cyril A. Reason and Mary I. Hemingway, University Club, Birmingham.

THE first of the Friday evening discourses for the coming session of the Royal Institution of Great Britain will be given by Sir J. J. Thomson on January 17th. He will discuss some further applications of the method of positive rays, and on February 28th Mr. C. T. R. Wilson, F.R.S., will describe the photography of the paths of particles ejected from atoms. Other discourses will be given by Sir John Murray on life in the great oceans, and by Professor Andrew Gray on gyroscopes.

THE general meeting of the Roentgen Society will be held, under the presidency of Sir J. Mackenzie Davidson, M.B., on Tuesday next, January 7th, at 8.15 p.m., when a paper on spark photographs at high pressure will be communicated by Professor A. W. Porter, F.R.S., and Mr. W. E. Haines. It has been arranged that the society shall meet on the first Tuesday of each month. Further particulars can be obtained from Dr. Robert Knox, 7, Harley Street, W. The meetings take place at the Institution of Electric Engineers on the Victoria Embankment at the bottom of Savoy Street.

THE eleventh annual dinner of the Royal Free Hospital and London School of Medicine for Women was held at the Trocadero Restaurant on December 11th. Mr. Stanley Boyd, F.R.C.S., who was in the chair, said that progress and increasing prosperity were the signs of the times, and that the present history of the school was a cause of deep satisfaction to those who, like himself, had known it from its early days. He referred to those who had worked so enthusiastically to create a medical school for women, among whom the name of Mrs. Garrett Anderson, the President of the School, stood foremost. For the first time for many years the school stood free of debt, and, in spite of increasing expenditure in all directions, the finances might be said to be satisfactory. The entry in October last of thirty-seven new students, making a total of 180 students in the school, was the largest for many years. The generous gift of a considerable piece of freehold land adjoining the present buildings would enable the hospital to begin a much-needed extension of premises, which would include a new out-patient department and maternity wards. Several valuable scholarships, bursaries and prizes had been endowed during the past year, and many generous gifts for special purposes had been received from friends of the school. Dr. Walter Carr and Dr. May Thorne responded, and the toast of "The Guests" was proposed by Dr. W. d'Este Emery, and responded to by Sir John Rose Bradford and Admiral Pelham Aldrich. Dr. Sainsbury proposed the health of the Chairman, who briefly replied.

Obituary.

PETER REDFERN, M.D. Lond., F.R.C.S. Eng., D.Sc.,
EMERITUS PROFESSOR OF ANATOMY AND PHYSIOLOGY IN THE QUEEN'S
UNIVERSITY, BELFAST.

THE announcement of the death of Professor Redfern was received with great regret throughout the profession in Ulster and by a very large circle of lay friends. On December 17th he celebrated his ninety-first birthday at his seaside home, Templepatrick House, Donaghadee, co. Down. He was then in wonderful health, but caught a cold, which became a bronchial attack, and he died on December 22nd.

Dr. Redfern's was one of the most familiar names for years in the North of Ireland; his outstanding personality, his eloquence, his powers of demonstration, his quickness of thought, his absolute determination to let no preconceived idea influence his observations, his sterling and unflinching honesty, his constant appeal to facts, all constituted him the centre of academic life in the faculty of medicine and a court of appeal in many civic enterprises.

Dr. Redfern was born at Chesterfield in Derbyshire, and received a great part of his education in Scotland. He was a student at the University of Edinburgh, and during his student career there was greatly influenced by the teaching of Dr. Hughes Bennett, Professor of the Institutes of Medicine, and enjoyed the friendship of Dr. Handyside and Mr. James Spence, afterwards Professor of Clinical Surgery in Edinburgh. He was, however, a graduate of the University of London: he took the degree of M.B. in 1844, and that of M.D. in 1847, receiving the gold medal at each examination. He became a Member of the Royal College of Surgeons in England in 1843, and a Fellow by examination in 1851, the year before Lord Lister received that diploma.

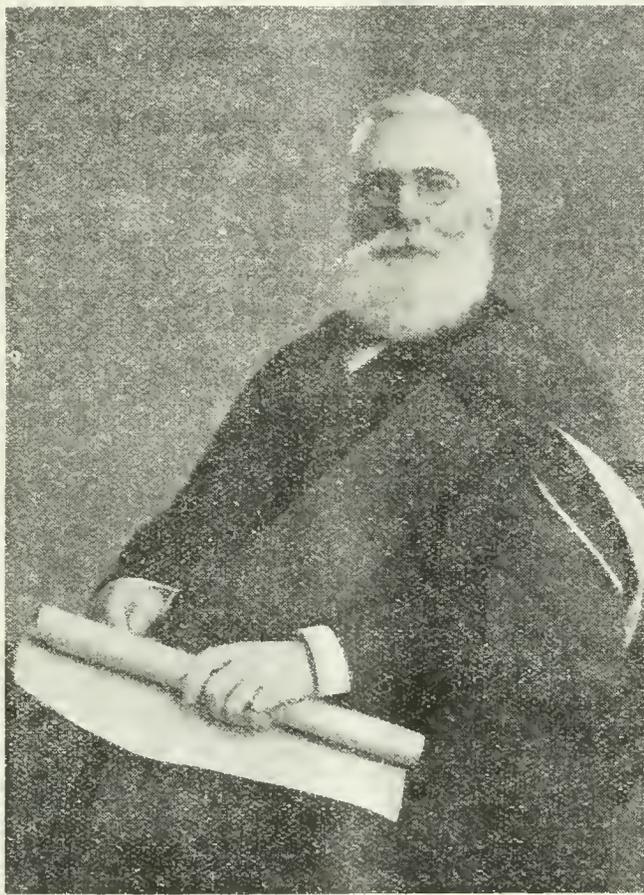

In 1845 Redfern was appointed lecturer in anatomy and physiology in Aberdeen, and subsequently became professor of those subjects and surgeon to the Royal Infirmary. In 1860 he was appointed first professor of anatomy and physiology in the New Queen's College in Belfast; this post he held till his resignation in 1893, so that he was a teacher of these two subjects for forty-eight years, thirty-three of which were in Belfast. In Belfast Dr. Redfern came amongst a number of very able men. Thomas Andrews, who discovered the liquefaction of gases, was professor of chemistry; Wyville Thomson, subsequently the scientific director of the *Challenger* expedition, was professor of natural history; James Thomson, as profound a thinker as his illustrious brother, Lord Kelvin, was professor of engineering; McCosh, subsequently head of the Princetown University in America, was professor of metaphysics. In the original plans of the Queen's College no provision had been made for a faculty of medicine, and

it fell to Dr. Redfern to guide the authorities in the matter; one result was the creation of dissecting-rooms, museums, and lecture-rooms, well up to date in convenience and facilities for work, and much in advance of those of the time. When he entered on his duties the largest class for anatomy and physiology was 79; chiefly attracted by his teaching, the numbers rose to 156 in 1866 and to 325 in 1881-2. When the Royal University was established and trust in the stability of university life in Ireland was lost, Ulster students flocked across the water and the numbers fell. Dr. Redfern foresaw what was about to happen. As a whole-time professor his retiring allowance was based on the average number of students of the last three years, and when the authorities were hesitating he promptly resigned and brought the chief teaching of the medical school to an abrupt termination. Finally he was practically asked

to withdraw his resignation, and, as was understood, on his own terms. His action in this emergency showed his determination, courage, and foresight.

Any reference to the life of this veteran would be incomplete without some mention of him in the lecture-room or dissecting-room. The notice of his death will recall literally to hundreds of medical men scattered throughout the world occasions of sharp, yet kindly, reproof, of terse sentences of condensed wisdom, that are probably, in their universality, a guide in life to them even now. "Oh, you think you see! Cannot you see a body of a red colour, measuring so many inches by so many, without thinking?" "Mr. —, do you know the peritonæum?" "Oh, reduced to hoping you know it; a very poor condition!" "Mr. — did not see what was before him; he saw what he thought; what was in his own mind."

A collection of these sayings, repartees, and aphorisms would furnish no mean guide to public, private, and scientific life. What he had said, what he had

PETER REDFERN.

[W. J. Killalea, Belfast

advised, what he had found, was more frequently quoted from day to day by generations of students than the words of any other teacher in the school. In his earlier days he made several contributions to medical literature on the growth and nutrition of cartilage.

On his retirement in 1893 his colleagues, pupils, and friends presented him with his portrait, which now hangs in the Examination Hall of the Queen's University. The chair which he had filled for so long with distinction was divided; Dr. Symington was appointed professor of anatomy, and, thanks to the munificence of the Davville family, a separate chair of physiology was instituted, to which Dr. W. H. Thomson was appointed. Dr. Redfern acted as examiner for the London University and other boards, and was an original member of the Senate of the Queen's University in Belfast.

He received the honorary degree of D.Sc. from the Queen's University, and was a corresponding member of the Royal Academy of Medicine, Belgium. He was one of the secretaries of the annual meeting of the British Association

in Belfast in 1874, and when the British Medical Association met in that city in 1884 Professor Redfern delivered an address in physiology. After his retirement he continued to take an interest in educational matters, and was a member of the Board of Governors of the Belfast Royal Academical Institution and of Campbell College.

He married in 1860 Miss Youngrove, a member of a distinguished Aberdeenshire family, and is survived by her and by three sons and five daughters. His eldest son is Dr. J. J. Redfern, visiting physician to the Croydon General Hospital; two other sons are in the army; his eldest daughter married Professor W. H. Thompson, now of Trinity College, Dublin.

At a meeting of the Belfast County Borough Local Medical Committee held in the Medical Institute, Belfast, on December 23rd, 1912, when there was a large attendance, Professor Sir John W. Byers, who was in the chair, referred in feeling terms to the great loss sustained by the profession in the recent death of Dr. Redfern. The following resolution was proposed by Dr. R. W. Leslie, LL.D., President of the Ulster Medical Society, and seconded by Sir Peter R. O'Connell, M.D., D.L., and passed in silence, the members standing:

That the members of the Belfast Local Medical Committee desire to take the earliest opportunity to express their sense of the great loss sustained by the medical profession in the recent death of Dr. Redfern, who during the thirty-three years of his professorship at Queen's College, Belfast, did so much to establish and extend the prestige and reputation of the Belfast Medical School. They rejoice to know that in all phases of his pre-eminent career he did everything in his power, both by precept and example, to uphold the scientific position and the dignity and honour of the profession of medicine.

WE regret to record the death of Dr. EDWARD MAZIERE COURTENAY, which occurred on December 20th, 1912, as a result of pneumonia. He was the son of the Rev. D. C. Courtenay, Rector of Glenarm, and a nephew of Sir Maziere Brady, Bart., Lord Chancellor of Ireland. After graduating in Medicine at the University of Dublin, he directed his energies from the first to the study of mental disease. He commenced his practical work in England, but after a few years he was appointed Medical Superintendent of the Limerick District Asylum, a post which he held till 1890, when he became Inspector of Lunatics and Member of the Board of Control of Asylums in Ireland. In this position he did the work of his life. At that time lunatic asylums were abodes of dread; admission to the "madhouse" was regarded not only as a misfortune but as a stigma. Through strenuous and persistent efforts, extending over years, the entire character of these institutions has been altered. The "airing yards," with their hopeless rows of idle patients, have disappeared; tracts of land were acquired, on which even the incurable can be healthily engaged, and work in some form has been found for almost every one. Industries have been fostered, not so much for the sake of economical administration as for the curative influence of employment. A sense of comfort was introduced, and even amusement was not forgotten. As a natural consequence, listlessness gave place to interest, and comparative happiness prevailed in place of an atmosphere of sullen gloom. Cures were effected in increasing numbers. Prejudice was gradually dispelled, and the friends of the inmates came to look upon asylums as real refuges for the mentally afflicted. This was all the more important as the ratio of insanity in Ireland was increasing. In initiating and carrying out these reforms Dr. Courtenay took a leading part, and many a medical superintendent of asylums feels grateful for the assistance perseveringly and successfully rendered in securing better conditions of life and treatment for the most helpless and most pitiable section of our population. The private life of Dr. Courtenay was marked by the same qualities as were manifested in his service to the public. Unassuming and unselfish to a singular degree, he has left behind him in the hearts of many a memory and an ideal of what a friend can be.

Letters, Notes, and Answers.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*.

TELEPHONE (National).—

2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

SPINAL PUNCTURE IN EPILEPSY.

AUDAX asks if the treatment of epilepsy by spinal puncture advocated by Dr. Giacomelli has been adopted by any one else, and, if so, with what result. Further, is there any painful reaction a few hours afterwards?

ANSWERS.

DR. J. S. BOLTON (Nottingham), in reply to "T. H. G." (December 21st, 1912, p. 1740), states that x rays will often cure blind external fistula, and suggests that the same treatment would be suitable in "Delta's" case.

VARICOSE ULCERS.

DR. R. ALLAN (Dumbarton) writes: If "J. H. M." would apply Mead's rubber plaster once every sixth day, the plaster to be applied only 1 in. beyond the edge of the ulcer, and covered with Gangee tissue, then apply elastic bandage 3 in. by 3½ yds., and before renewing dressings clean skin with turpentine, taking care not to touch the granulations with anything, I think he would meet with success.

DR. H. J. THORP (Ipswich) writes: I have found the following ointment most serviceable: R Hyd. ox. rub. benè levigat. gr. x, vaselin. alb. ad ʒi. Ft. ung. Yellow vaseline is too irritating. The varicose vein must be supported by bandaging the limb.

DR. GEORGE PERNET (London) writes: A good method is that recommended by Unna. I dealt with it fully in the BRITISH MEDICAL JOURNAL for 1909, vol. i, p. 463. If carried out on the lines laid down it is very useful in the ambulatory treatment of this obstinate condition.

F. W. writes, in reply to "J. H. M.": Grafting meets with success, after getting ulcers in a healthy state by rest, elevation of limb, boracic lotions, and, of course, treating the cause.

DR. W. ODELL (Torquay) writes, in reply to "J. H. M.," to say that in his opinion calcium iodide given in 3-grain doses, well diluted, thrice daily, will promote permanent healing of varicose ulcers more rapidly than any other drug.

T. H. M. writes: Varicose ulcers will not heal while they are kept in a septic condition with ointments, etc., nor will they heal while the tissues are gorged with venous blood; to get them to heal the thickened edges must be reduced. In favourable cases they can be got to heal by wearing a Martin's bandage while on foot and an antiseptic lotion at night, and I may mention that an old bicycle tube, split and washed, the thickened joint cut away and old patches removed, make the best "Martin's" bandage I have used; the old used tubes are best. If "J. H. M." cannot cure his patient's ulcer by this means, he had better tell him that unless he goes to bed and has his ulcers treated on ordinary surgical lines, including skin grafting if possible, he will have to put up with them. The only place for effectually dealing with these cases is hospital.

LETTERS, NOTES, ETC.

DR. EDWARD COYLE, of Belfast, writes to express his interest in a paper by Dr. Mackenzie published in the JOURNAL of December 14th; after thirty years' experience of cardiac cases he desires heartily to endorse Dr. Mackenzie's attitude with regard to the need for reform in the diagnosis of heart affections.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|----|----|----|
| Eight lines and under | .. | .. | .. |
| Each additional line | .. | .. | .. |
| A whole column | .. | .. | .. |
| A page | .. | .. | .. |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restants* letters addressed either in initials or numbers.

An Address

ON

THE HISTORY AND NATURE OF CERTAIN SPECIMENS ALLEGED TO HAVE BEEN OBTAINED AT THE POST-MORTEM EXAMINATION OF NAPOLEON THE GREAT.*

(WITH SPECIAL PLATE.)

BY ARTHUR KEITH, M.D., F.R.C.S.,

CONSERVATOR OF THE MUSEUM, ROYAL COLLEGE OF SURGEONS, ENGLAND; HUNTERIAN PROFESSOR.

ON May 5th it will be ninety-two years since the great Napoleon died. The physicians who attended him during his exile in St. Helena from October 17th, 1815, until the stormy evening of May 5th, 1821—O'Meara, Stokoe, Antommarchi, Arnott—are all dead long ago. We cannot question them now concerning the Emperor's symptoms and mortal disease. We must form our opinion of the nature of his illness from the letters they wrote and the diaries which they kept. So minutely have these documents been studied and their reliability discussed, that the verdict pronounced by modern writers such as Lord Rosebery¹ and by M. Paul Frémeaux² carries with it an air of finality. Their verdict is (1) that in his last illness Napoleon was attended by a series of incompetent physicians, who formed a wrong opinion of the case and applied disastrous remedies; (2) that Napoleon died of cancer of the stomach, the Emperor himself being the only one to form an approximately accurate diagnosis.† It seems scarcely possible at this distance of time that any new evidence bearing on Napoleon's last illness can be in existence, yet I hope to convince you that the two small specimens from the Museum of the Royal College of Surgeons of England are actually parts of the great Emperor's body, and that they throw a new light on the "drama of St. Helena."

In the history of these specimens John Hunter, the patron saint of this society, is indirectly connected. They have been preserved on the shelves of the museum founded by him; they came to that museum through one of the most famous of Hunter's pupils—Sir Astley Cooper—the dominant surgeon in England at the time of Napoleon's death. They came to Sir Astley Cooper from Napoleon's physician, O'Meara, who had good reason to remember Hunter's existence, for in 1823, when living in the Edgware Road, London, O'Meara married the aged widow of Captain Donellan, whom Hunter tried to save from the hangman's rope in 1781. Soon after Antommarchi took up his post at St. Helena, in succession to his friend O'Meara, Napoleon questioned him regarding the inheritance of disease, fearing then (November, 1819) that he suffered from the malignant condition which carried off his father at the early age of 39—cancer of the stomach. The authority quoted by Antommarchi to convince his august patient that disease is not inherited was John Hunter. "Hunter," said Antommarchi,⁴ "one of the greatest physicians England has produced, was the first to combat that theory (the inheritance of disease), and all the schools have adopted his ideas on the subject" (vol. i, p. 237). A thin thread of Hunter thus runs through the story of Napoleon's last illness.

Before proceeding to relate the history and prove the authenticity of the Napoleonic documents now brought before you, it will be well to give first a brief account of their appearance and nature. They are two small pieces of the human bowel suspended in sealed bottles filled with alcohol. A superficial observer might easily believe that he is looking at two small oblong tags of dusky skin, each

with a curious wart-like raised patch in its centre (Figs. 1 and 2). The largest of the specimens could be covered by six postage stamps; it measures 55 mm. long by 35 mm. wide; the smaller measures 48 by 25 mm. The expert, however, observes that the two surfaces of the specimen are totally different in texture and appearance. One side is covered by the inner or mucous lining of the bowel; this lining membrane is here and there raised up into transverse folds, so shallow and slight that one infers with certainty that the specimens have been cut from the lower part of the small intestine—the ileum. The wart-like plaques are really elevated areas set within the lining membrane of the bowel, and in life it is clear they must have been situated on the free side of the bowel—on the opposite side to that which is attached to the suspending membrane or mesentery of the bowel. While one side of the specimen is thus covered by a shaggy mucous lining, the other, or outer, is smooth, being composed of the peritoneal and muscular coats of the bowel. Even on the outer or smooth surface the wart-like growth on the inner surface is apparent; its outline comes through as a blackish patch or spot (see Fig. 3), but, since the wart-like growth contains some effused blood and dilated vessels, these patches at the *post-mortem* examination must have shown out on the free surface of the bowel as red patches, and must have then been sufficiently prominent to catch the eye of the anatomist. These two small tags of bowel seem very slight documents to throw light on the old and vexed questions relating to Napoleon's death, but they have the advantage over all other available documents that they are facts for all time, whereas diaries and letters are but imperfect reflections of what man's brain believed at one time to be facts.

I shall now proceed to lay before you a series of documents which will explain why this source of evidence has been neglected during these seventy years past. The first document is from the pathological catalogue of the Museum of the Royal College of Surgeons; it was written by Sir James Paget when he was revising a new edition of the catalogue in 1883 and represents the mature opinion of the foremost of surgeon-pathologists of the Victorian period.

No. 2526. A portion of small intestine with a raised, rounded plaque of cancer projecting about one-eighth of an inch above the mucous membrane, and five-eighths of an inch in diameter; its surface is broken and fissured, and its edges overlap the mucous membrane around its base of attachment.

No. 2527. Another portion of small intestine, with a much smaller oval cancerous nodule having a smooth rounded surface.

This and the preceding were in the Museum of Sir Astley Cooper.

The following entry is in the MS. Catalogue of Sir Astley Cooper's Museum.

"Incipient Fungus in the Glands of an Intestine Napoleon. Barry O'Meara to Sir Astley Cooper."

The truth of the statement that these portions of intestine were taken from the body of the Emperor Napoleon I is open to grave doubt. Dr. Antommarchi, Napoleon's personal physician, states, in his very complete account of the *post-mortem* examination, that "the mucous membrane of this canal (intestinal) appeared to be in a sound state"; and in the separate report, drawn up by the English surgeons present at the autopsy, the statement is found that, with the exception of the stomach, "the abdominal viscera were in a healthy condition." It further appears from Dr. Barry O'Meara's memoir (*Napoleon in Exile*, etc.) that he was recalled to England nearly three years before Napoleon's death; and the steps taken by Napoleon's personal attendants to prevent the abstraction of the heart and stomach also show the improbability of these specimens having had the source ascribed to them.—October, 1883.

It is very clear that Sir James Paget did not believe that these specimens represent parts of Napoleon's body. His reasons may be summarized thus: (1) No mention is made of similar appearances in the *post-mortem* report; (2) O'Meara was in England when Napoleon died; (3) Napoleon's body was closely guarded, so that abstraction of parts was impossible.

The next document I produce is from M. Paul Frémeaux, who is rightly regarded as the highest authority in everything pertaining to Napoleon. The letter was addressed to the editor of the *Daily Mail*, and it is by his courtesy that I am enabled to publish it now.

Sir,—The *Daily Mail* has published on 12th of February last (1910) a very favourable review of *The Drama of St. Helena*, the English translation of *Les Derniers Jours de l'Empereur*, which had just come out in London. A few days later, on the 18th, my

* Second Hunterian Lecture of the Hunterian Society; delivered January 8th, 1913.

† After this lecture was prepared for publication, M. H. Barlow called my attention to a work just published, *The Illness and Death of Napoleon Bonaparte*, by Dr. Arnold Chaplin (Hirschfeld Bros., 1913). Dr. Chaplin does not accept the specimens here described as authentic, and regards the Emperor's death as due to cancer of the stomach secondary to an ulcer of the stomach. See also BRITISH MEDICAL JOURNAL, December 28th, 1912, p. 1761.

name and beek were again kindly alluded to in your columns. I feel so much indebted to the *Daily Mail* that I beg to be allowed to elucidate for its readers, if I can, the question you have raised as to the authenticity of a Napoleonic relic preserved at the Royal College of Surgeons. "There," according to your statement, "in a small upper room, are two bottles, each containing a section of intestinal membrane. The label says: *Two portions of small intestine with cancerous growths projecting above the mucous membrane. They came from the museum of Sir Astley Cooper, with the following description: Incipient fungus in the glands of an intestine. Napoleon. Barry O'Meara to Sir Astley Cooper. It is almost certain that these specimens were not taken from the body of Napoleon.*" The label does wisely, I think, in expressing such a doubt. To realize this it is only necessary to examine two points. First, is it possible that any part of the Emperor's corpse can ever have been abstracted and have become an anatomical relic? Be it said at once that it is possible, but highly improbable. Secondly, admitting that portions of intestine were ever abstracted from the Emperor's corpse, can the specimens in the museum of the Royal College of Surgeons be those portions? This time the answer will be No!!! it is not possible.

Napoleon expired on the evening of the 5th of May, 1821. His autopsy took place on the following day, the 6th of May, at 2 p.m., as related in *The Drama of St. Helena*. The work of dissection was undertaken in a green painted and crudely lighted room of Longwood House by the Emperor's own physician, Dr. Antommarchi, under the eyes of five English Surgeons, the Doctors Short, Arnett, Mitchell, Burton and Livingstone, and of two assistant surgeons, Doctors Rutledge and Henry. Lieutenant-Colonel Thomas Reade, Major Harrison and Captain Crokat represented the Governor, Sir Hudson Lowe; Grand Marshal Bertrand, Count de Montholon, and the Abbé Vignali, the French Colony at St. Helena. Three servants of Napoleon, Marchand, St. Denis, and Picheron, who had brought in the corpse and laid it on a large table covered with a sheet, were also present.

Dr. Antommarchi opened the body.

The cavity of the thorax was first exposed to view, and the lungs and the heart detached from it; the liver, the stomach, and the intestines were next taken out of the abdomen. When the several organs had been duly examined, they were, with the exception of the heart, which was to be offered to the ex-Empress Marie Louise, and of the stomach, which had been found the seat of the mortal disease, restored to their places, and still under the eyes of all the spectators, the closing of the body by means of a suture was made by Dr. Antommarchi.

Napoleon's remains were then dressed for interment in the uniform of a colonel of Chasseurs of the Old Guard, and Assistant Surgeon Rutledge was ordered to take charge of them. He has left a memorandum of his watch in which he says: "The heart and stomach were put in a silver case by me, and I was directed by Sir Thomas Reade not to lose sight of the body or the vase, to take care and not to permit of the cavities being opened a second time for the purpose of the removal of any part of the body, and not to allow the contents of the vase to be disturbed without an order from him to that effect. . . ."

On the evening of the seventh, Dr. Rutledge saw the corpse and the vase containing the stomach and the heart, placed and soldered up in a leaden coffin, and on the ninth, Napoleon was carried to his grave in Geranium Valley.

This short account is sufficient to show, I think, how unlikely is the supposition that any part of Napoleon's body may have been clandestinely removed, either during the process of autopsy, or later on, during Dr. Rutledge's watch. During the autopsy, the abstraction could hardly have escaped the notice of a rather numerous party; during Dr. Rutledge's watch, the complicity of this surgeon would have been required in order to commit a most criminal and a most downright sacrilege—the undressing and secret reopening of the corpse.

But, admitting, as I said before, the possibility of portions of the small intestines having been taken from the body of Napoleon, the specimens on view at the Royal College of Surgeons and described as infected with incipient fungus, cannot be those identical portions. The impossibility is clearly shown by the *post-mortem* observations made on the 6th of May at St. Helena. There exist two reports of the autopsy: an official report established by Drs. Short, Arnett, Mitchell, Burton, and Livingstone, and the private report of Antommarchi. According to the official report, the only abdominal viscera presenting unhealthy appearances were the liver, which suffered from

abnormal adhesions, and the stomach, which was perforated by an ulcer and had become a mere mass of cancerous disease. In the private report of Antommarchi, where the state of all the organs is described at fuller length, it is a question of the intestines, but the remark made on them is "that the large intestines were covered with a substance of a blackish colour and extremely visceous." This blackish substance must have been simply an exudation of matter coming from the stomach; for in a note written to Count de Montholon previous to his report, Antommarchi says that:—"all the intestines were sound." Dr. Henry, who was, as it has been seen, one of the persons present at the autopsy, states also, in an unpublished letter to Sir Hudson Lowe I have in my possession, that the intestines were in a healthy condition.

The Napoleonic relic on view to the public at the Royal College of Surgeons is consequently a more than dubious one. The distinguished Curator of this Museum, Dr. Keith, interviewed by one of your representatives, pointed out to him that a man of the social standing and medical reputation of Sir Astley Cooper, who was President of the College of Surgeons in 1827, and at one time made £30,000 a year in fees, would hardly have left the statement inscribed on the label above referred to unless he had been convinced of the genuineness of the specimen. But this statement does not seem indeed as explicit as it ought to be for such an exceptional specimen. Instead of "Incipient fungus in the glands of an intestine: Napoleon," one would like a somewhat longer and more precise mention, such for instance, as: "Incipient fungus in the glands of an intestine: two affected portions of small intestine taken from the body of Napoleon." Further, is it not surprising that Sir Astley Cooper did not take the trouble to write out and

commit to some separate and special paper a full story of so precious an anatomical relic, and to tell among other things, how Barry O'Meara, who was not at St. Helena at the time of the Emperor's death, had been able to procure it? If the divulgation would present, about 1840, any danger for anybody, nothing was so easy for Sir Astley as to state that the paper would be kept sealed up and remain secret for a given number of years after this date.

The reasons which led M. Frémeaux to reject the specimens before you as authentic Napoleonic relics are Paget's reasons amplified and emphasized. When I produce the third document, by my esteemed colleague Mr. Shattock, Pathological Curator of the College of Surgeons' Museum, you will have lost faith both in the specimens and in myself. Sir Astley Cooper described

the intestine as showing incipient fungus, which, in our terms, may be translated as an early stage of cancer; Sir James Paget unhesitatingly said the intestinal outgrowths were "rounded plaques of cancer." Soon after Sir James Paget wrote the description printed above, Sir Frederic Eve,* when acting as Pathological Curator to the Museum, examined sections of the outgrowths under the microscope—a method unused in diagnosis until long after Napoleon's time—and found they were not cancerous in nature. There the matter rested until recently, when a part was cut from each tumeur, and a continuous series of sections were cut, stained by various methods to bring out the nature of the tissues, and examined microscopically. The results of that examination will be seen in Mr. Shattock's report, which is as follows:

HISTOLOGICAL REPORT UPON SECTIONS OF THE TWO
INTESTINAL LESIONS STATED TO HAVE BEEN
OBTAINED FROM THE BODY OF
NAPOLEON I.

I.

The smaller lesion, the edge only of which was histologically examined, is a somewhat prominent hemi-

* Mr. Shattock and I were unaware of Sir Frederic Eve's examination until after our own investigations were completed. It will be thus seen that two independent examinations have been made.

DESCRIPTION OF SPECIAL PLATE.

Fig. 1.—The larger piece of bowel, showing the plaque-like outgrowth on the surface of the mucous coat. (From a photograph; natural size.)

Fig. 2.—The same specimen viewed on its peritoneal or outer surface. The plaque-like growth is also apparent on this surface; the serous coat over it is frayed and ragged. (Natural size.)

Fig. 3.—The second piece of bowel with a similar but smaller outgrowth in the mucous coat. (Natural size.)

(Figs. 1, 2, and 3 are from blocks prepared by Mr. Frank Butterworth for new edition of the Guide to the Museum of the College.)

Fig. 4.—Section across the edge of the larger plaque (Fig. 1), showing its relation to the coats of the bowel. The mucous coat ascends on the edge of the plaque but ceases there. The lymphoid tissue comes to the surface and is breaking down, especially towards the centre. The submucous coat splits at the edge of the plaque so as to enclose the cellular mass. Strands derived from the submucous coat (represented by black lines) are seen to be scattered in the mass, as in a Peyer's patch. The inner or circular muscular coat is very thin and beneath the plaque becomes partially opened out by intrusions of the small round-celled tissue. The outer longitudinal and serous coats have become detached from the inner circular coat—a rupture which may have been caused during manipulation of the specimen. (Magnification $\times 20$.)

Fig. 5.—Section across the edge of the smaller plaque. The same coats are seen as in Fig. 4; the lymphoid mass is enclosed in the submucous coat. The mucous coat passes on to the summit. Ulceration seen in the last is absent. There is no infiltration of the inner muscular coat. (Magnification $\times 20$.)

PROFESSOR A. KEITH: ON CERTAIN SPECIMENS ALLEGED TO HAVE BEEN OBTAINED AT THE POST-MORTEM EXAMINATION OF NAPOLEON THE GREAT.

FIG. 1.

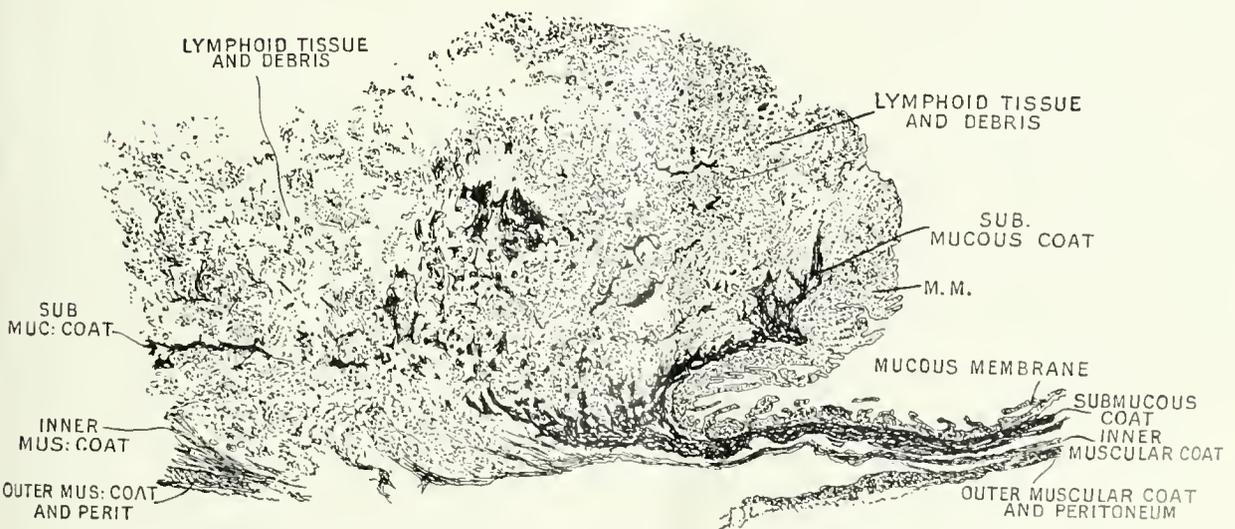

FIG. 4.

spherical eminence 6 mm. in diameter, overhanging its base of attachment, and projecting from the mucosa into the lumen of the bowel, the outer surface of which is smooth and flat.

The sections include portion of the normal intestine beyond the eminence, and were cut vertically to the free surface; they were stained by Van Gieson's method. Although the several histological elements have stained with very little differentiation (with the exception of the fibrous tissue), the general structure is readily traceable; the glandular epithelium is fairly preserved, and the columnar form of the individual cells, patches of which remain in certain of the crypts, is quite distinct, although the nuclei are undifferentiated.

In the unaffected portion of intestine beyond the lesion the several coats are easily to be recognized: the villi are intact, but their investing epithelium is wanting. Over the edge of the swelling the villi are likewise entire; there is no ulceration or necrosis. The swelling itself is confined to the submucosa, and is sharply limited both laterally and on the deep aspect. It consists of small cells lying in a stroma of connective tissue.

There are in it certain denser collections or blocks which at first suggest an epithelial origin, but these do not lie in proper alveoli of their own, but in the midst of the other tissue; and all gradations between such and the general mass of cells occur. In no instance are such collections furnished with a lumen (which in the crypts is well pronounced), and in none can they be resolved into columnar cells, although in the proper crypts such cells are quite distinct.

The examination of a second series of sections, made so as to include the whole extent of the lesion, shows that the nodule is strictly confined to the submucous tissue, that it is circumscribed, and that it consists of a uniform collection of cells supported in the meshes of a somewhat scanty stroma of connective tissue. There is no indication of a second epithelial structure in its midst.

Although badly preserved and in consequence indifferently stained, the mass can, under one-sixth objective, be resolved in favourable spots into small round cells arranged in the meshes of a delicate stroma, the whole of the appearances corresponding with those of a "solitary gland."

In places the tissue is strewn with brownish pigment, as though it had been the seat of past hæmorrhage.

II.

The larger lesion takes the form of a low, discoidal elevation, slightly overhanging its base, and measuring 15 mm. in diameter. The peritoneal surface of the gut is smooth and flat. The microscopic sections include the edge of the lesion, with the adjoining piece of the bowel.

The lesion is practically limited to the submucosa, and is sharply circumscribed both laterally and on its deep aspect. The deeper coats of the intestine are intact beneath it. The mucosa ceases over the summit of the eminence.

Structurally it consists of a uniform mass of small cells, with little stroma.

A considerable amount of brown, spheroidal pigment is scattered throughout the lesion, indicative of past hæmorrhage.

Remarks upon the Histological Data.

There can be no doubt that the two lesions represent a solitary and an agminated gland of the lesser size.

Their limitation to the submucosa, their circumscription, and the extension of the mucosa over them all combine to show this. In form and size they resemble such glands when enlarged from inflammatory or hyperplastic conditions. There is no indication that either is the seat of a carcinomatous inroad from the epithelium.

Into both glands hæmorrhage appears to have occurred. In sections stained with Cresylecht violet the presence of bacteria, chiefly short, stout bacilli (probably *B. coli*), is very obvious.

S. G. SHARROCK.

It will thus be seen that these pieces of bowel do not show secondary cancerous growths at all, but enlargements of those areas of lymphoid tissue which are normally present in the lower part of the small bowel,

known as Peyer's patches, the use of which—be it spoken for our encouragement—we do not even yet know. We do know, however, that such patches become enlarged in many chronic diseases which are endemic in the tropics, and the clinical notes made by Napoleon's physicians leave not a shadow of doubt, as I shall show presently, that the Emperor suffered from a disease in which the lymphoid tissue of the body was subject to enlargement.

My faith that these specimens might prove genuine—at least, that their history was worth investigating—rested on my belief in Sir Astley Cooper. He had John Hunter's passion for collecting specimens, especially such as illustrated the diseases of distinguished patients. When a puzzling case had ended in death he summoned his assistant, Mr. Lewis, and addressed him thus: "Mr. — is dead; I must have an inspection of that tumour." When the tumour was obtained a small label was attached, and it was dropped into a big tank with many others. Sir Astley, like all busy men, expected leisure days to come in the eve of his life when the specimens could be arranged, catalogued and described—but when the time came the will and desire had abated. Hence, when his collection—comprising 1,500 specimens—was acquired by the Royal College of Surgeons after his death in 1841, at the age of 73, my predecessor, Mr. Cliff, reported to the Council of the College that Sir Astley had attached only the briefest of descriptions to his specimens, and that full histories could be obtained only by a search through his private papers—a search that was never carried out. Hence the description attached to the Napoleonic specimens—"Napoleon, Barry O'Meara, to Sir Astley Cooper"—is perfectly in order. Two preparations obtained at the *post-mortem* examination of royal personages have even briefer labels—merely the name of the distinguished patient and the date. There can be no doubt, then, that the two specimens were in the possession of Astley Cooper, and that he believed they were genuine, and, we may be certain, had good reason for this belief.

Sir Astley Cooper had peculiar opportunities of acquiring anything of particular medical interest. He was recognized as the leading, learned, and popular surgeon of his time. He was surgeon to King George IV and to King William IV. He was the trusted medical adviser of Lord Liverpool, the Tory Prime Minister during the exile, illness and death of Napoleon; he was well acquainted with Lord Bathurst, Secretary for War and for the Colonies, who had the care and keeping of Napoleon. He must have been consulted often by these two men about the Emperor's case. If any one in England could possibly command or obtain any first-hand evidence from the *post-mortem* examination, Sir Astley Cooper was that man. We know, too, he was an alert man of the world—a shrewd judge of men, and the very last person to deceive himself or to wilfully mislead others when in the quest of truth. Hence, when he attached the brief label to the Napoleonic relics we may be certain that he knew how O'Meara obtained them.

I have said that it was my faith in the judgement and honesty of Sir Astley Cooper that induced me to investigate the history of these specimens. It was a study of Antommarchi's account of the *post-mortem* examination which brought the conviction that they must be authentic. Paget and Frémcaux appeared to have overlooked the passage which I now quote from Antommarchi's report:

The digestive canal was distended by a great quantity of gas. In the peritoneal surface and in the folds of peritoneum (mesentery) I observed small spots and patches of a pale red colour (*petites taches et de petites plaques rouge, d'une nuance très légère*) of various dimensions and scattered at some distance from each other. The mucous membrane of this canal appeared to be in a sound state. The large intestine (that is, its lining membrane) was covered by a blackish, very viscous matter.

I have mentioned that the raised lymphoid plaques in the two Napoleonic specimens contain effused blood and dilated vessels. They must have appeared, therefore, as red patches scattered along the intestine, giving rise to the exact condition described by Antommarchi. We have to suppose, therefore, if these two specimens are not genuine, that O'Meara, having read Antommarchi's report, obtained by some miracle similar specimens from another *post-mortem* examination, and foisted them on a shrewd man like Sir Astley Cooper as genuine Napoleonic remains.

We have seen that Sir James Paget quotes the second sentence of the above extract from Antommarchi's report, "The mucous membrane appeared to be in a sound state." Could an intestine showing raised plaques be described as apparently in a sound state? The explanation is to be found in the conditions under which the *post-mortem* examination was carried out. In a modern *post-mortem* room with large sinks and ample supply of water the viscous matter which coated the lining membrane of the bowel could be thoroughly cleansed away and the plaques would then become apparent. But at Longwood there were neither sinks nor a sufficient supply of water; the lay representatives of Napoleon's staff and of Sir Hudson Lowe's establishment were looking on; a satisfactory cause of death had been discovered before the bowels came to be examined. Even if he had so desired, it would have been impossible for Antommarchi to carry out the tedious and disagreeable duty of examining the lining membrane of the bowel from end to end. That his examination was cursory is apparent from his words—"The mucous membrane appeared to be in a sound state."

The question may well be asked here: Why is it, then, that the official report, drawn up by the five medical officers who looked on while Antommarchi made the examination of Napoleon's body, contains no mention of these red spots and plaques on the intestine? The official report simply states that the stomach was the seat of an extensive cancer and that the rest of the body was healthy, except that the upper surface of the liver was bound to the dome of the diaphragm by adhesions. Every medical man knows that the official report cannot be true; a cancer so extensive as that of Napoleon's must have spread and there must have been secondary growths along the lymph streams leading from the stomach. That there were such secondary deposits we learn from Antommarchi's report. He records that:

The gastro-hepatic omentum was contracted, swollen and very much hardened and broken down. The lymphatic glands in this fold of peritoneum and those situated along the curvatures of the stomach, as well as those situated over the pillars of the diaphragm were in part enlarged, scirrhous and some were even in a state of disruption. . . . Many of the glands of the air passages of the lungs (bronchiæ) and in the space between the lungs (mediastinum) were somewhat enlarged, almost breaking down and undergoing suppuration. . . . The left lung was slightly compressed by a pleural effusion and had numerous strands of adhesion to the posterior and lateral parts of the chest and to the pericardium. I carefully dissected the lung and found the superior lobe strewn with tubercles (nodular masses) and some small tuberculous excavations.

It is clear from Antommarchi's description that the cancer had spread, and that the appearances described by him are exactly those which we expect to find in the later stages of a case where death has resulted from cancer of the stomach. The English surgeons simply say "trailing adhesions of the left pleura were found; the lungs were quite sound." Why is it that we have to refer always to Antommarchi's account to obtain the details relating to the marks of disease in Napoleon's body? There are two reasons: (1) As I shall show, Antommarchi was a skilled anatomist and pathologist, trained under and assistant to Paul Mascagni, the very ablest anatomist and pathologist in Europe at the beginning of the nineteenth century; the English naval and army surgeons had no special training in such investigations. (2) The official report was a political, not a medical, document; it had to convince the opponents of Lord Liverpool's Government, the enemies of the Governor of St. Helena—Sir Hudson Lowe—and the partisans of Napoleon, that the Emperor died, not from a disease caused by his confinement in St. Helena, but by one which, at that time, was regarded as a dispensation of Providence. It is true that Antommarchi wished to prove that his patient had died from a "chronic gastro-hepatitis," but he sets the facts down which he observed as he made the examination, and they are twisted in no manner whatsoever to support the theory he was so desirous of proving—namely, that Napoleon was killed by his confinement in St. Helena. There is really only one report of Napoleon's *post-mortem* examination; that is Antommarchi's, and in that document we find described the appearances which agree with those to be seen in the two specimens preserved in the Museum of the Royal College of Surgeons.

We have thus traced the history of these specimens at two points in their history. We have Sir Astley Cooper's word for it that they came into the possession of Dr. Barry O'Meara. We have an authentic document showing that Antommarchi saw morbid appearances of the same kind as those shown by the two specimens when he performed the *post-mortem* examination on May 6th, 1821, twenty hours after the Emperor's death. Only Antommarchi thought them worth mention and therefore worth acquiring or investigating. How and why did they pass from Antommarchi to O'Meara? We shall see that neither the opportunity of acquiring them, the means of transferring them, nor a good reason why they should have been given by the Corsican to the Irishman are wanting.

Those two men being the centre figures of my story must be surveyed at close quarters and their movements and motives followed. Modern writers have formed a very indifferent opinion of them. Lord Rosebery¹ says of O'Meara: "Least of all, perhaps, to be depended on is O'Meara." And as to Antommarchi his lordship writes: "No one of the chroniclers is less reliable. . . . We must take the Antommarchian narrative for what it is worth, and that is very little." M. Frémeaux² says of him: "In spite of his incompetency, he succeeded at first in giving the impression of being a good doctor." As regards O'Meara, Colonel Knollys sums up his character thus (*Diet. Nat. Biography*): "There seems no doubt that his conduct throughout was that of an indiscreet person or rather a puppet of Napoleon. His diagnosis of his patient's case as one of liver disease, induced by the malignity of the climate, was falsified by Napoleon's subsequent death from a disease which is not affected by climate." O'Meara and Antommarchi, if we accept the verdicts just quoted, seem to be the very last persons on whom we can place any reliance. We shall see how far they deserve to be thus maligned.

When Napoleon stepped on board the *Bellerophon* on July 15th, 1815, O'Meara was one of the surgeons on board. The Emperor was in his forty-sixth year, the surgeon in his twenty-ninth; O'Meara's knowledge of the Italian tongue became a bond between them; the young Irishman of Trinity College, Dublin, was chosen to accompany the Emperor to St. Helena as personal medical attendant. His services were not seriously required until the summer of 1816, when the Emperor had his first attack of a peculiar fever which recurred again and again until death occurred on May 5th, 1821. The attacks were recurrent and lasted for irregular periods; their average duration was about three weeks; they were always most severe in the closing months of each year; they became more frequent and more severe as the case progressed. The attacks were ushered in by rigor, fever, and headache; usually the first symptoms of each onset was an attack of colic attended by diarrhoea or intestinal disturbance; usually the throat and air passages became inflamed and catarrhal; the gums became swollen, ulcerous, and bleeding. The tonsils enlarged; so did the lymphatic glands in the groin; we may safely infer that the lymphoid tissues of the whole body, including Peyer's patches in the intestine, were also involved. The feet and legs became swollen and remained swollen until the attack had passed away, leaving the Emperor weak in body and depressed in mind. In the attack at the close of 1816 no symptoms of a special affection of the liver were observed. During the attacks of fever which commenced towards the end of 1817, however, all the characteristic symptoms of an inflammatory condition of the liver became manifest, and in every recurring bout of fever these symptoms became more and more prominent. There is no kind of cancer of the stomach, nor of ulcer of the stomach, unless that ulcer is part of a general infection, that can give rise to such attacks of fever as Napoleon suffered from in the first three years of his illness. On the other hand, we do know that many forms of fever endemic to tropical countries may first attack the bowel, or enter the body by the bowel, and at a subsequent date give rise to disturbance or inflammation of the liver.

O'Meara formed the opinion—he could not have done otherwise—that Napoleon was suffering from a form of inflammation of the liver, or hepatitis, which is endemic to, and then prevalent in, St. Helena. It is very easy for

us now to see, with our modern knowledge of tropical diseases, that Napoleon was the unfortunate victim of a general infection—one affecting particularly the alimentary tract and secondarily the lymphoid tissues of the body—a form of infection in which the liver often becomes the seat of disease. No wonder if Napoleon did become infected with the diseases endemic to St. Helena; sources of infection abounded. Mosquitos buzzed round him; the water which he drank was carried from a distance and stored in open vessels. We know that some of the water sources of St. Helena were infected. In November, 1817, the convict ship *Friendship* came into the harbour of Jamestown, all on board being well on her arrival. She took water on board, and in ten days over 100 of the convicts were prostrate with attacks of diarrhoea and fever, similar to those which overtook Napoleon.⁵ There were goats on the island, which, in the Mediterranean region at least, are the transmitters of Malta fever; rats also abounded at Longwood.

O'Meara's position in St. Helena was one of great difficulty; he had to serve two masters—Napoleon and the Governor, Sir Hudson Lowe. He stuck manfully by his patient, with the result that he was sent home on July 25th, 1818. On November 2nd of that year his name was ordered to be erased from the list of naval surgeons. He then settled in London, took up the cause of Queen Charlotte, and later became an ardent follower of O'Connell and an advocate of the first Reform Bill. In January, 1819, Napoleon was for three days in the medical charge of Surgeon Stokoe, of H.M.S. *Conqueror*. He saw Napoleon in one of the attacks of the recurrent fever, diagnosed inflammation of the liver with impending abscess. He was court-martialled and dismissed the navy. Sir Hudson Lowe had forbidden the diagnosis of any endemic disease of the liver—at least, in the island under his charge.

Before Antommarchi enters our narrative it will be well to again refer to the condition found in Napoleon's body after death. We have seen that the English surgeons admitted there was some pathological adhesions between the liver and the diaphragm. For fuller information we turn to Antommarchi's report:

The spleen and liver were *indurated, enlarged, and distended* with blood. The texture of the liver, which was of a brownish-red colour, did not, however, exhibit any remarkable alteration in structure. The gall bladder was filled and distended with very thick and clotted bile. The liver, which was affected by chronic hepatitis, closely adhered by its convex surface to the diaphragm; the adhesions occupied the whole extent of that organ, and were strong, cellular, and of old formation.

We see, then, that not only did Napoleon manifest in his illness all the symptoms which indicate an inflammatory infection of the liver, but that at his death the clearest evidence was found that the liver had been the seat of an inflammation so acute that the diseased tissue which had formed round the liver had become converted into tough bands of adhesion.⁶ Yet O'Meara and Stokoe were dismissed from the navy by ignorant laymen because they were competent and truthful physicians. In Napoleon's case the presence of cancer was masked by the severity of the original disease, an endemic tropical fever, one of a family of diseases the nature and cause of which are only now becoming understood. It will also be perceived how anxious O'Meara must have been when the Emperor's death occurred to obtain some evidence that the diagnosis he made of the case was well founded and right. We shall see that Antommarchi had every reason to supply him with such evidence.

We now turn to Antommarchi, the much misunderstood Malvolio of the drama of St. Helena. At the time of O'Meara's dismissal, near the end of the summer of 1818, Antommarchi was in Florence attached to the hospital of St. Mary's as assistant or prosector in anatomy and pathology—the two subjects were not then separated. He was at that time a man of 29—three years younger than

Clause probably inserted by Antommarchi subsequent to the original draft of his report.

⁵ Dr. Arnold Chaplin regards the widespread adhesions between the liver and diaphragm as the result of the ulceration of the stomach, the condition which he supposes preceded cancer. Such adhesions are always the result of an inflammation round the liver, and usually follow inflammation of the liver—never, so far as I know, an ulcer of the stomach. There was no adhesion of any part of the stomach to the diaphragm; the adhesion of the cancerous area of the stomach to the liver was not a strong one; when separated the peritoneal coat of the stomach was unbroken.

O'Meara—a Corsican by birth, a Frenchman by nationality, an Italian by education, and the most excitable mortal ever caged within the walls of a laboratory. In 1812 he became assistant to Mascagni; in 1815 that great master of anatomy died, leaving his magnificent illustrations and discoveries unpublished. In 1818 Antommarchi was busily preparing Mascagni's plates for publication, on behalf of a committee which had raised money for this purpose. O'Meara, on reaching England in 1818, dispatched two letters to Italy, one from Napoleon requesting "Madame Mère" to get him a physician, another giving a full description of Napoleon's case to guide the physician chosen as his successor at St. Helena. Cardinal Fesch chose two men—Abbe Vignali, a cleric, who had acquired a smattering of medicine, and Antommarchi, who, late in the autumn of 1818, sat in the dissecting room at Florence preparing Mascagni's plates for publication. The winter 1818-19 was spent in preparing to depart; in February, 1819, Antommarchi went to Rome, where Napoleon's case, as set out by O'Meara, was discussed at a sederunt of physicians. He reached London on April 15th, 1819, on his way to St. Helena; he left London on July 9th. During his stay of nearly three months in London he saw O'Meara almost every day, consulting and receiving advice about Napoleon's case. The Corsican had more in his head than Napoleon's case; he carried Mascagni's plates under his arm, and showed them to everybody and everywhere. At first the authorities refused him permission to take these plates to St. Helena; they suspected that these drawings of the lymph vessels of the human body might cover a Napoleonic plot in hieroglyphics. Antommarchi overcame their prejudices; before he left he was able to inform his colleagues in Florence that he had obtained permission to dedicate the preliminary volume of Mascagni to the Prince Regent of Great Britain and Ireland.⁶ He reached St. Helena on September 20th, 1819—fourteen months after O'Meara had left—and was in charge of Napoleon—except for the occasions in which he was in disgrace—for a period of nineteen months. During that period the feverish attacks already described, except for an interval in the spring and summer of 1820, kept recurring with greater virulence, and as we now know, became intensified by the disturbances due to the onset of cancer.

No wonder Antommarchi has been misunderstood by distinguished writers like Lord Rosebery and M. Frémeaux! He belongs to a peculiar genus of humanity, the product of our research laboratories and of enthusiasm for science. Outside the laboratories those men seem unbalanced in their judgements and actions when measured by that conventional standard known as common sense. Inside the laboratories they are at home; their eyes are open and accurate then; their brains seek out puzzles which to the mind of the mere layman seem matters unworthy of attention. Napoleon knew the species of man Cardinal Fesch had sent him at once: "A kind of Cuvier," said the Emperor, "to whom he would give his horse for dissection, but not trust the cure of his own foot." In short, the Cardinal had selected the right man to work out the botany of St. Helena and to perform the autopsy on Napoleon, but altogether the wrong man to treat skillfully what in its event proved to be a most difficult, puzzling, and fatal case of illness. Those curious red spots which he saw on the intestine, as he carried out the final examination, were exactly the kind of thing which would arrest his attention; they were anomalous appearances which were at least worth keeping, perhaps worth investigation and explanation. They might confirm the diagnosis which O'Meara and he had made—namely, that the Emperor died of a disease endemic to St. Helena.

The question now remains to be answered: Could Antommarchi have abstracted such specimens unobserved either during or after the autopsy? M. Frémeaux answers very decidedly, No, it was impossible. Medical men will be less dogmatic in their answer. Centuries of a struggle to elucidate the problems of human disease against the obstacles raised by prejudice on the part of the public at large have compelled the best medical men to carry out the behests of science and human well-being by underhand and crafty means. I have known cases where great parts of the body were removed under the most strict surveillance. Antommarchi was an expert at annexation; he stole and smuggled out of St. Helena that fine death mask of Napoleon, which I

have no doubt we owe chiefly to the Irish surgeon, Burton, a cousin of the great Dublin physician Graves.⁷ We know, however, that Antommarchi had the opportunity of obtaining such specimens as those at the College of Surgeons. The *post-mortem* examination began a little after 2 o'clock on the afternoon of the day following Napoleon's death; by 5.45 the examination was finished; Antommarchi had cut out the heart and the stomach (it would have been easy to take some parts of the bowel too—the English surgeons did not think them worthy of attention) and placed them in a silver vessel filled with spirits of wine. Does any one believe that the laymen and doctors stood by and watched until Antommarchi put the last stitch in Napoleon's final toilet? The atmosphere, the absence of water, the excitement at finding cancer, gave an opportunity to a man like Antommarchi, if he were inclined to use it. His friend, Dr. Arnott—Arnott always speaks of *Professor* Antommarchi—was placed on watch; M. Lebeau states that Surgeon Rutledge was placed as custodian; no doubt Arnott and Rutledge relieved each other, for twenty-four hours elapsed between the time of the autopsy and the arrival of the four-fold coffin. During that period the silver vessel stood open to Antommarchi, who was "at home" at Longwood; the other surgeons were strangers there. When the coffin came Antommarchi was ordered—he was most reluctant—to place the heart and the stomach in the coffin. He prayed to be allowed to take them home with him. He took the stomach out and placed it in a silver sponge box removed from Napoleon's dressing-table; he left the heart in the original vessel, and makes the statement that he soldered down the lid of that vessel. That was the last opportunity Antommarchi had of retaining any of the relics he may have wished to carry away.

We have shown, then, that specimens of the kind now in the Museum of the Royal College of Surgeons were seen at the *post-mortem* examination of Napoleon and that the man who saw them had the opportunity and the will to obtain them. We must now follow Antommarchi's movements back to London. He left St. Helena on May 27th, 1821; by August 5th he was in London. O'Meara was there then: so was Sir Astley Cooper. The coronation of George IV was just over; Queen Charlotte lay on her death-bed—events in which both Cooper and O'Meara were interested. Like the rest of England they wanted to know the details of Napoleon's death. The first news of that event reached England on July 4th; on July 8th O'Meara wrote a letter to the *Morning Chronicle*, pointing out that the cause of Napoleon's death given in the official report must be received with reserve and scepticism; he drew attention to the fact that the official report was not signed by Antommarchi—the man best qualified to express an opinion had refused to sign the document; that the symptoms and history of Napoleon's case were incompatible with death from cancer; that the adhesions of the liver to surrounding parts indicated hepatitis and confirmed his diagnosis; that the official report of the *post-mortem* examination was, what we now know to be the truth—a political document. We have no record of the meeting of Antommarchi and O'Meara; we simply know they were both in London in August, 1821, but does any one doubt that those two men, who met so often two years before in the most friendly manner, who spoke a common language, whose reputations were at stake over the same case, would meet and see if they could retrieve their position and convince the public that they were right in their diagnosis and that the Hudson Lowe faction was in the wrong? It is likely that Antommarchi gave those relics of the examination at St. Helena to O'Meara as mere relics to be added to his Napoleonic collection, or it may have been with the view of having a final verdict as to their nature and their bearing on Napoleon's illness. They came, at least, from O'Meara to Sir Astley Cooper, and when the famous surgeon saw them he pronounced them cancerous growths, the very diagnosis which O'Meara, at least, wished to disprove. We have seen that Sir James Paget also regarded them as cancer, but did not substantiate his diagnosis by the more precise modern methods. And now, long years after, when all the actors are dead and gone, these specimens are submitted to modern and accurate methods and they prove to be not cancer but diseased lymphoid

patches, probably manifestations of the infection of the body by one of those diseases which are still endemic to tropical or semi-tropical countries—a diagnosis which ought to give the disturbed ghosts of O'Meara and Antommarchi nights of blissful rest. Micro-organisms are still to be seen in the lymphoid plaques. Antommarchi, it may be added, returned to Italy, and led a life of continuous quarrel; then to Paris, where he tried to publish copies of Mascagni's plates as his own;⁸ and then went abroad and died at Santiago in 1838, at the age of 49. Dr. Barry O'Meara, after marrying Captain Donellan's widow in 1823, died in the Edgware Road on June 3rd, 1836, at the age of 50, a result of attending one of O'Connell's (the Liberator) meetings.⁹ At the sale of his effects the tooth (third molar) he extracted from Napoleon was sold for 7½ guineas; the tooth forceps then employed, 3 guineas; a lock of the Emperor's hair, £2 10s.* It will be thus seen O'Meara would naturally desire to add to his Napoleonic collection, and we may reasonably suppose one so much indebted to him as Antommarchi would like, if possible, to gratify his desire.

It will be seen that this narrative deals with two problems: (1) The history of two specimens in the Museum of the Royal College of Surgeons of England; (2) with the nature of Napoleon's illness during the last four and a half years of his life. The evidence which I have produced here has convinced me of the authenticity of the specimens. Such specimens were observed at the *post-mortem* examination; Antommarchi had opportunities of taking them; there were inducements for him to take them, and reasons why he should give them to O'Meara; we know O'Meara gave them to Sir Astley Cooper; we know that he was a keen collector of such specimens; we know they were transferred from Sir Astley Cooper's museum to their present abode.

The two specimens show a diseased enlargement of the lymphoid tissue of the bowel; we know that in his attacks, four and a half years before his death and probably two years before Napoleon became the subject of cancer, the lymphoid system of the body—the tonsils—the lymphatic glands became enlarged. Sir William Leishman informs me that all the symptoms manifested in the attacks of fever "are very similar to those of a chronic form of Malta fever, or, as we are now told to call it, undulant fever."

No one who has tabulated from the records left by O'Meara, Stokoe, and Antommarchi the symptoms manifested month after month by Napoleon during the first three years of his illness can doubt the recurrent febrile nature of his original disease. The symptoms are neither those of gastric ulcer nor gastric cancer, but of a nature which shows he suffered from a form of Malta fever, or of an infection nearly akin to Malta fever. The following letter from Sir William Leishman throws an important light on this point:

Royal Army Medical College
(University of London),
Grosvenor Road,
London, S. W.,

December 5th, 1912.

Dear Professor Keith,

What you tell me is extremely interesting. From the details you give I think it very probable that Napoleon must have suffered from a chronic form of Malta fever—or, as we are now told to call it, undulant fever. There is nothing in your account inconsistent with this; the recurrent febrile attacks with occasional jaundice and hepatic pain are well known in this disease, and a chronic hypertrophy of the lymphoid tissues is well marked in some cases, especially in connexion with the spleen, and various groups of lymphatic glands, such as the mesenteric, inguinal, axillary and others. My assistant, Major Kennedy, who was one of the Malta Fever Commission and had a considerable experience of *post-mortems* on these cases, also tells me that Peyer's patches are frequently enlarged in chronic cases and sometimes even ulcerated, and this in cases in which enteric fever could be definitely excluded. Such cases also show at times distinct scorbutic symptoms and bleeding from the gums.

Malta fever was probably widespread over the Mediterranean long before it was identified as a clinical entity, but I cannot say anything about St. Helena, though I think if you were able to find that goats' milk was in use in the island in Napoleon's time, and especially if they imported Maltese goats as they did at Gibraltar and elsewhere, there would be a reasonable suspicion that he might have been reinfected there too.

Very truly yours,

W. B. LEISHMAN.

* I have been unable to trace the further history of these relics. A description of Napoleon's third molar would be of interest.

Three years before Napoleon's death we may reasonably suppose that the inflammation of the liver which frequently appears in cases of fever endemic to tropical countries had brought about adhesions to the diaphragm and stomach. Hence it was impossible to feel any tumour in a stomach thus bound down beneath the liver. Skilled physicians like Héreau (1829)⁵ and Boudouin (1901)¹⁰ have supposed the great ulcer found in the stomach at death to have been caused not by cancer, but by inflammation. I do not think that their opinion can be upheld; it is altogether in opposition to the appearances and characters described by Antommarchi—the only account worthy of a moment's thought. Nor do I think that the view adopted by Dr. Chaplin—that the earlier symptoms were solely due to an ulcer of the stomach—can be accepted as a full and satisfactory explanation.

It is plain, then, that Napoleon suffered originally from an endemic fever in which the liver was severely affected, and that in the course of the illness cancer of the stomach—his father's ailment—supervened, but the symptoms of the supraced disease were entirely masked by the original disease. When that interpretation is applied, Napoleon's case becomes clear, definite, and understandable. It was a condition which might well have baffled and misled the most skilful physicians in Europe, until the terminal illness in the spring of 1821, when Dr. Arnott¹¹ alleges he began to suspect that the stomach was the seat of Napoleon's trouble. The discovery of cancer at the autopsy was a revelation to all; the Emperor alone anticipated the result. Poor O'Meara, Stokoe, and Antommarchi! Dismissed, court-martialled, and maligned by the laymen in authority and by modern lay writers because they did not solve a problem which only was capable of a full solution after death. In the main they were right in their diagnosis; most unfortunate in their treatment. It is an open question whether it was the fever or the cancer which actually killed Napoleon; the best that can be said is that, whether in St. Helena or out of it, cancer would have ended the career of the great Emperor.

The German Gynaecological Society will hold its fifteenth annual meeting at Halle in May (14th-17th). The principal subject proposed for discussion is the relation between diseases of the heart and kidneys as well as disturbances of internal secretion with pregnancy.

The Department of Health of the city of New York has authorized the performance by its inspectors of anti-typhoid vaccination under conditions similar to those governing the free administration of diphtheria antitoxin. The vaccine will also be supplied free to medical practitioners for their own use.

The January issue of the journal entitled *Concrete and Constructional Engineering* contains some striking statements with reference to the safety of various buildings in London in regard to fire. Seven years ago a very large number of buildings had been officially recognized as not meeting the requirements of the London County Council in regard to general construction, the provision of escapes, and other measures designed to diminish the annual number of deaths from fire. It is stated that there are now over 90,000 buildings within the metropolitan area which are officially "unsafe." Suggestions as to how the evil might be remedied without undue delay are also put forward in the journal in question. The other articles, though mainly technical, contain nevertheless a good deal that is of general interest. A subject worthy of discussion in its pages would seem to be the truth or otherwise of a popular impression to the effect that "fireproof" buildings burn up quite as quickly, or quite as effectively so far as destruction of life is concerned, as buildings which claim no such title.

UNIVERSITY OF LONDON.

LECTURE II.

THE TRANSMISSION OF PLAGUE BY FLEAS.

MAY I remind you that bubonic plague is not an infectious disease? The patient is a negligible source of danger to his surroundings, provided he does not develop a secondary pneumonia. The reason is that, even if the excreta do contain some plague bacilli, there is no mechanism available to convey them into a second human being, as pest is not easily contracted by feeding. From an epidemiological point of view bubonic plague must be regarded as a disease of rats, in which, under suitable conditions, the infection spreads from rats to man.

It would be impossible for me to put before you this afternoon the mass of evidence for the above statements. I have already surveyed it in opening the discussion on the "Spread of Plague" at the meeting of the British Medical Association at Birmingham in 1911 (Martin, 1911), and, moreover, it is now well known.

It was difficult to explain how the bacillus was transferred to man from the rat, especially as man-to-man infection had been shown to be negligible. On epidemiological grounds, Ogata (1897), Simond (1898), and Ashburton Thompson (1900) came to the conclusion that the agent must be some form of insect, and for various reasons choice fell upon the flea.

You will naturally inquire why, if the flea is to be considered an agent of transmission from rat to man, does it not transmit from man to man? The answer is quite satisfactory, but I will, with your permission, postpone it until we have considered the case for carriage from rat to man.

If the blood of the animal contain a sufficiency of plague bacilli, some will obviously be taken in by a flea whilst feeding, and Ogata (1897) found that crushed fleas taken from a plague-infected rat produced the disease when injected into mice. This experiment was repeated with success by Simond (1898) and Tidswell (1900).

*The Mechanism by Means of which the Flea might Infect a Healthy Animal.**

The blood is sucked up from the wound made by the pricker. This structure is composed of three parts—the pharynx and the two mandibles (Fig. 14). The apposition of the three forms a fine tube (Fig. 15), up which the blood is drawn, and passed down the gullet into the stomach by successive waves of contraction from before backwards of the muscles actuating the chitinous pharynx. The stomach is a pear-shaped organ occupying a considerable part of the abdomen of the insect. The internal economy of a flea and the arrangements of the mouth parts may be gleaned from the diagrams (Figs. 13, 14, and 15), which are borrowed from the Reports of the Commission.

The average capacity of a rat-flea's stomach was found by the Commission for the Investigation of Plague in India (Report, 1907, p. 397) to be 0.5 cmm., and the number of bacilli in the blood of a plague-infected rat before death anything up to 100,000,000 bacilli per cubic centimetre. If, therefore, a rat-flea imbibed the blood of such a rat, it would receive into its stomach 5,000 germs.

* In dealing with the agency of fleas in the spread of plague I shall draw largely upon the work accomplished during the last few years by the Commission for the Investigation of Plague in India, with which I have had the honour to be associated. The Reports of the Commission have been published as special numbers of the *Journal of Hygiene*, 1906 to 1912.

Evidence of Multiplication of Bacilli in the Stomach of the Flea.

The Commission fed fleas on plague-infected rats until the death of the latter and afterwards on healthy animals, a fresh animal being supplied each day. Each day a number of the fleas was dissected and the stomach contents examined as to the presence or absence of plague bacilli. In 5 to 30 per cent., according to the time of year, plague germs were found up to the sixth day, and in one instance on the twentieth day (Reports, 1907, pp. 398-405). The bacilli were often present in immense numbers, far more numerous than ever seen in blood, and massed together as in culture. We have good evidence in this observation that multiplication of plague bacilli may take place in the flea's stomach. During the season of the year when the epidemic occurs the proportion of infected fleas for the first four days after removal from the plague rat was 43 per cent., on the sixth day there were 15 per cent., on the eighth day 16 per cent., and on the twelfth day 9 per cent. In the non-epidemic season only 5.2 per cent. were infected during the first six days.

The Distribution of Plague Bacilli in the Body of the Flea.

The blood on completion of the digestive process in the stomach passes into the rectum of the flea as a thick, slimy, dark-red mass, and appears at the anus as minute, dark-red or black, tarry droplets. It was demonstrated by cultural and microscopical examination that the rectal contents were often crowded with plague bacilli.

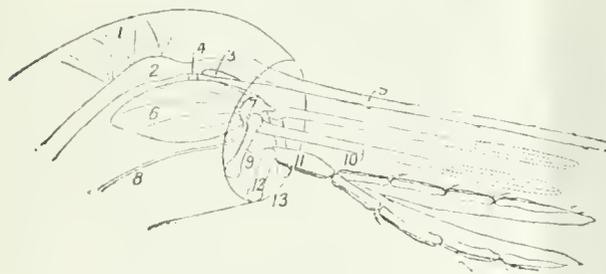

Fig. 14. Diagram of the mouth parts of the flea. 1, Muscles operating aspiratory pharynx; 2, aspiratory pharynx; 3, mouth; 4, ligament; 5, epipharynx; 6, hypopharynx and muscles operating salivary pump; 7, salivary pump; 8, salivary duct; 9, basal element of mandible; 10, mandible; 11, labium; 12, basal element of labium; 13, peritrial ring.

Fleas, taken from plague rats at intervals varying from a few hours to several days, were dissected, and the various parts of the body examined for the presence of bacilli. In not a single instance were plague bacilli observed outside the organs already mentioned. No infection of the body cavity was seen, and although particular attention was paid to the salivary glands, nothing at all resembling a plague bacillus was ever detected in them.

How the Flea may Transmit its Infection to the Healthy Animal.

Several methods of transmission are possible, such as (a) the animal eating the infected fleas; (b) the mechanical conveyance of the bacilli by the pricker; (c) the regurgitation of the stomach contents down the pricker; (d) the deposition of the faeces on the skin, the bacilli being subsequently rubbed in by scratching.

This last method is the only one which has been proved capable of bringing about infection. A well-fed flea deposits a considerable amount of faeces in a surprisingly short time, and it was proved by both the Commission for the Investigation of Plague in India (Report, 1907, p. 418) and Verbit-ki (1904) that wounds made by the pricker might afford a sufficient avenue for the entrance of bacilli when liquid containing them was gently applied to recent bites.

Whilst, however, experiments have shown that infection may be brought about in this way, the possibility of infection by a regurgitation from

the stomach preliminary to sucking blood cannot be excluded.

Proof that Plague is Carried from Animal to Animal by Fleas.

Simond (1893) infected one rat from another by placing them in a bottle together with twenty fleas. The second, uninfected rat, was enclosed in an iron box with a grating, so that the two animals could not come into contact. Gauthier and Raynaud (1902, 1903) repeated Simond's experiments under better controlled experimental conditions. They employed a cage divided in the middle by two wire grills 2 cm. apart, placed in a glass jar. In one compartment was placed an inoculated white rat on which had been deposited a dozen fleas captured upon rats from ships in the harbour at Marseilles. When the inoculated animal died a healthy rat was placed in the second compartment, and after some hours had elapsed, during which the fleas transferred themselves from the dead to the living animal, the cadaver was removed. Gauthier and Raynaud succeeded five times in conveying the infection from one rat to another; the number of negative experiments is not stated. An examination of the stomachs of the fleas found upon the septicæmic animals showed the presence of *B. pestis*. The fleas used in their early experiments were not identified. Tidswell (1903) made further attempts to convey plague from rat to rat by the agency of fleas, but was unable to do this.

Verjbitski (1904) carried out an extensive series of experiments on the flea-transmission of plague in St. Petersburg. He showed that the plague bacilli could be recovered from the stomach contents of fleas six days after they had fed on plague rats, and that the faeces of such fleas contained the *B. pestis* for about the same time. He succeeded in infecting rats with fleas from diseased rats fifteen times in seventy-six experiments. In each experiment ten possibly infected fleas were allowed to feed on the rat. Verjbitski also made experiments similar to those of Gauthier and Raynaud described above, and out of forty experiments, using ten fleas apiece, infection was conveyed in four.

Liston (1905) pointed out that the common flea infesting rats in India was not *Ceratophyllus fasciatus* or *Typhlopsylla musculi*, as in Europe, but a non-pectinated flea identified by Rothschild as *Xenopsylla cheopis*. Liston observed multiplication of the plague bacillus in the stomach of this flea. Although his experiments on transmission, which were made by allowing fleas to bite first an animal suffering from plague and subsequently a healthy animal, were not successful, he brought forward much interesting and valuable circumstantial evidence in favour of the view that plague is epidemiologically thus spread. He showed that *X. cheopis* takes readily to another host, for example, guinea-pigs and man, when rats are not available.

The possibility of the rat-flea carrying plague from one rat to another was demonstrated in a considerable series of experiments by the Commission for Investigation of Plague in India (Report, 1906, pp. 435-450). A glass case was used containing two wire cages side by side, each standing in a tin tray which collected the urine. Both trays were filled with sand in order to provide dryness and shelter for the fleas. Each cage was furnished with a lid through which the rats were introduced and food and water given to them, and the whole apparatus was covered in with fine muslin to prevent the escape of the fleas. A rat placed in one of these wire cages could not come in contact with a rat in the other cage, nor with its urine or faeces.

The method of experiment was as follows: A plague-infected rat and a number of rat-fleas were placed in one of the wire cages. After the rat died, a fresh healthy rat was put into the other cage, the corpse of the infected rat being left in for twenty-four hours longer.

Sixty-six experiments with English white rats and with Bombay wild rats were done in this way, with the result that 30 healthy rats contracted plague; fleas formed the only apparent means of transmission of the bacilli from rat to rat.

In order to exclude aerial infection a second series of experiments was carried out, in which fleas were taken from a rat which had died of plague and placed on a fresh rat in a clean flea-proof cage of similar construction to that already described, but containing only one wire cage. Out of 38 experiments 21 successful transmissions were obtained in this way.

The Importance of Flea-Transmission in Epizootics.

The following experiments, which had as their object the determination of the relative importance of the Indian rat-flea, *X. cheopis*, and of actual close contact in the absence of fleas in the dissemination of plague from animal to animal, were carried out by the Commission (Reports, 1906, pp. 450-467; 1907, pp. 421-436; 1910, pp. 315-335) in a series of small cabins, which were built especially for this purpose. In these animal houses plague-infected animals, rats or guinea-pigs, were kept in close contact with healthy animals. They ran about together in a confined space and ate out of the same dishes.

The plague-infected animals were allowed to die, and the corpses were not removed until some time after death. In some instances the concentration of infection was very great, in one case 21 infected animals being at one time in contact with 25 healthy ones. The cabins were never cleaned out, so that the animals ate food contaminated with the faeces and urine of their infected companions. In the experiments with rats, the healthy frequently ate the carcasses of the infected ones introduced.

Sixty-six series of experiments were carried out, each involving about 40 to 70 animals. In 35 experiments fleas were present, and 31 were control experiments in which no fleas were introduced. In all the control experiments

not one of the healthy animals contracted plague, whereas in those cases where fleas were present an epizootic occurred, varying in extent and rate of spread according to the number of fleas present.

Some interesting experiments (Reports, 1906, p. 461) were also carried out in the animal houses that had been used for some of the previous experiments. Guinea-pigs and monkeys were introduced into them for one night. Some of the animals were in cages placed on the floor, and others in cages covered by fine muslin, gauze, or surrounded by a layer of sticky fly-paper, 6 in. wide—that is the simplest precautions were taken to exclude fleas.

Of 15 unprotected monkeys, 6 died; of protected, none. Of 24 unprotected guinea-pigs, 18 died; of protected, none. The animal houses remained infective three weeks after the last animal had died of plague. This period corresponds with the maximum time fleas fed on a plague rat have been shown to remain infective when placed on a series of healthy animals.

Experiments in Plague Houses.

The Commission subsequently (Reports, 1906, pp. 467-482, and 1907, pp. 436-446) repeated similar experiments in plague houses in Bombay. The infectivity of 142 houses where cases had occurred or rats had died was tested by placing a guinea-pig there overnight. The guinea-pig was subsequently segregated, and in 31 cases it died of plague.

Ninety-two experiments were made in which two similar animals—monkeys, guinea-pigs, or rats, the one protected by gauze or sticky paper, the other not protected—were placed in suspected houses; 15 unprotected animals died; none of the protected.

On ninety-six occasions fleas taken off guinea-pigs which had spent the night in a suspected house were transferred to a healthy animal. In 26 cases the second animal died of plague, although not infrequently the guinea-pig from which they had been removed escaped infection. The conclusion that in a plague-infected house the infection is due to infected rat-fleas, and not to an infection of the soil or the air, seems to me abundantly justified.

Fleas as the Agents of Transmission from Rat to Man.

In considering how far the results just detailed can be applied to man, we enter at once upon less secure territory, because it is impossible to put conclusions to the test of experiment. The only measure of the correctness of such an interpretation is its adequacy to interpret all the known epidemiological facts concerning the spread of plague.

The justice of applying the results of these animal experiments has been severely criticized in several quarters, and particularly by Galli-Valerio (1907), on the ground that rat-fleas do not bite man. It is true that, speaking generally, different animals harbour specific parasites; but the more we learn upon this subject the clearer it becomes that such specificity is not so sharply defined as was imagined, and that a particular flea, although commonly confined to a few hosts of allied species, may frequently be found in considerable numbers upon quite different animals. Moreover, it has become abundantly clear that a flea, although exhibiting a decided preference for one species, will, if hungry, betake himself to animals of widely different type in the absence of its proper host.

The common flea found on rats in India and other warm parts of the world* is *X. cheopis*. This flea is a non-combed species, and not unlike the human flea, *Pulex irritans*, in appearance. That *X. cheopis* readily feeds on man was observed by Tidswell (1903), Gauthier and Raynaud (1903), and Liston (1905). The Commission for the Investigation of Plague in India kept *X. cheopis* alive for four weeks upon an exclusively human diet, and my colleague Mr. Bacot has bred them for years on the same regimen.

With regard to the readiness with which *Ceratophyllus fasciatus*, the common rat-flea in Europe, attacks man, considerable divergence of opinion has hitherto existed. According to Wagner (quoted by Tiraboschi, 1904, p. 180), Tiraboschi (1904, p. 266), and Galli-Valerio (1907), this

* The distribution of rat-fleas has recently been dealt with by Dr. Chick and myself in the *Journal of Hygiene*, vol. ii. p. 129 (1911).

Table showing Results of Feeding Experiments with *Ceratophyllus fasciatus*.

flea does not bite man. On the other hand, Gauthier and Raybaud (1903 and 1909) and McCoy and Mitzmain (1909) found that when hungry it fed on man with readiness.

Dr. Harriette Chick and I (1911) have made some hundreds of experiments on this question, and are at a loss to understand the negative conclusions arrived at by Tiraboschi and Galli-Valerio. Under the conditions of our experiments *Ceratophyllus fasciatus* fed upon man as readily as upon a rat. Nevertheless, it is doubtful whether *Ceratophyllus fasciatus* is attracted to man as readily as is *X. cheopis*. Compared with the latter, it is a poor jumper.

We also made 107 experiments with *Ctenophthalmus agyrtus*, a flea common on *Mus decumanus* in this country, when living in fields, ricks, or barns, and 122 experiments with the mouse-flea, *Ctenopsylla musculi*. Under the conditions of the experiment the former would not bite man at all, and the latter only very occasionally. This latter experiment is interesting, because mice, although dying of plague, have not been found to be associated in the same way as rats with the origin of plague epidemics.

The Capability of Flea Transmission to Interpret the Epidemiological Facts regarding Bubonic Plague.

(1) Poverty, dirt, storage of grain in the bedroom, accumulation of refuse, and insanitary conditions generally, have been shown to be effective in so far as they lead to the support of a large rat population in close association with human beings. All these conditions also increase the population of rat-fleas, and man's accessibility to them.

(2) In 75 per cent. of cases the situation of the bubo is such that the bacillus must have obtained entry at some superficial area of the body. This is also consistent with infection by fleas.

(3) A number of instances have occurred during the last ten years in India in which the introduction into a distant village of the effects of a person dead of plague has been followed after an interval of about a week by mortality amongst the rats, and subsequently by an epidemic of plague. The same sequence has also taken place after the visit of an individual who had worked or resided in a house where some of the inmates had suffered from plague, although the stranger himself did not suffer from the disease.

These observations are better explained on the assumption that the infection was transported in the bodies of fleas contained in the clothing or upon the person of the stranger than by any other suggestion that has been put forward, for at the earliest opportunity rat-fleas would betake themselves to the rats, and could thereby start an epizootic. That such transmission of rat-fleas does actually happen has been proved by the Commission for the Investigation of Plague in India, members of which frequently carried away rat-fleas upon their persons and clothing when visiting native quarters in the course of their scientific duties.

(4) Perhaps the most striking feature of epidemics of bubonic plague is the marked seasonal prevalence of the disease amongst rats and amongst men. In places where it is endemic the epizootic, followed by the epidemic, starts at or about the same time each year, grows, declines, and more or less disappears. As one passes away from the Equator the plague season becomes later. In Bombay the height of the epidemic is in March, in Lahore in April, in Jhelum in May, in Rawal Pindi in June, and further north in July, August, and September. The epidemics of London in 1665, and of Marseilles in 1720, reached their maximum in September. The effect of latitude in determining the season when plague flourishes is analogous to that upon the flowering and seeding of a

plant, and indicates dependence upon some biological factor. Within the tropics, where temperature variation is less and the seasons are determined by the prevailing winds and rainfall, the epidemic season is also well defined, but varies in different localities.

The seasonal incidence of plague is not due to any periodicity in the breeding of rats. In India, in localities where the latter was investigated, it bore no relation to the season when plague occurred. It was found by the Commission (Reports 1908, p. 266; and 1910, pp. 446 and 483), however, that the epidemic season coincided with the

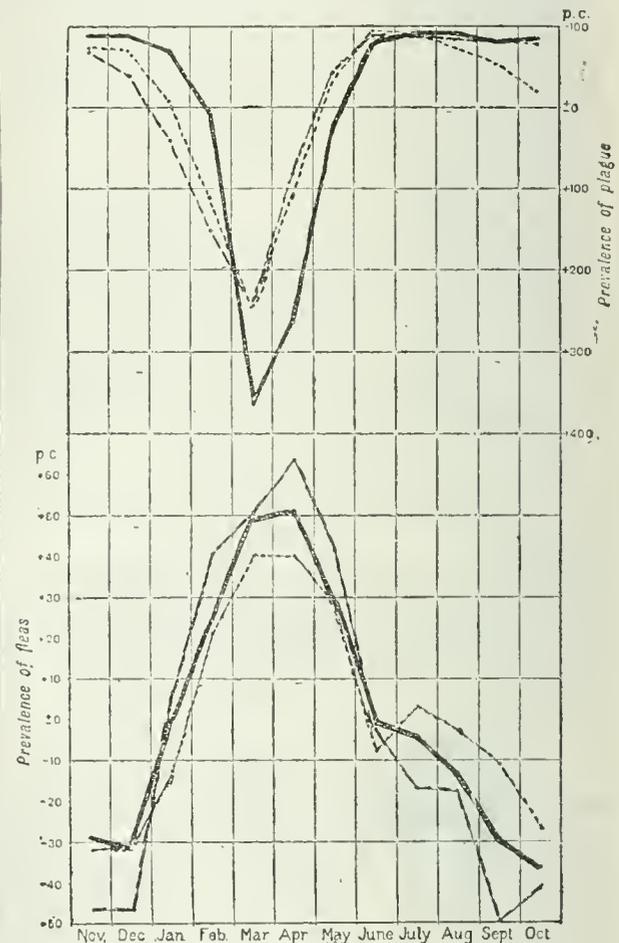

Fig. 16.—Prevalence of fleas in Bombay

— Human plague. — Fleas on all rats.
 - - - Plague in *M. decumanus*. - - - Fleas on *M. decumanus*.
 . . . Plague in *M. rattus*. . . . Fleas on *M. rattus*.

period of greatest flea prevalence. In Bombay, Belgaum, Poona, and two Punjab villages the Commission undertook a census of rat-fleas upon captured rats, in the course of which the fleas on 150,000 rats were recorded. In each case the observations extended over more than one year.

The analysis of the figures showed a seasonal variation in the number of rat-fleas in all the localities. The average number per rat varied in Bombay between 3 and 7, in Poona between 2 and 11, in the Punjab between 2 and 12, and in Belgaum between 1 and 17. The interesting point is that

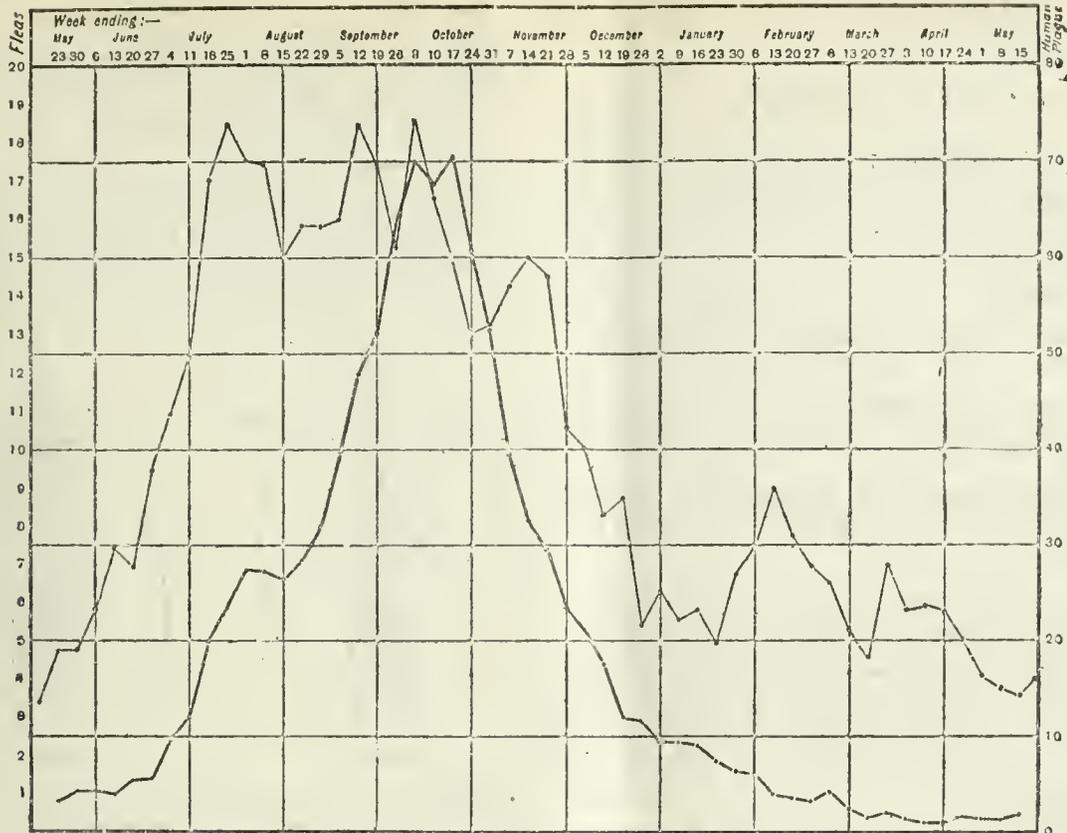

Fig. 17.—BELGAUM. ——— Average number of fleas per *Mus rattus*: weekly figures: observations made in 1908-1909. ——— Average number of deaths from plague, calculated for each week of the year, from May, 1897, to May, 1909 (twelve years), in Belgaum city.

in all the places examined plague is epidemic when the average number of fleas is well above the mean, and the height of the epidemic corresponds fairly closely with the season of maximal flea prevalence. This coincidence is brought out in the attached charts (Figs. 16 and 17) borrowed from the reports, which show the variations in the number of fleas per rat and number of deaths from plague each week for Bombay and Belgaum respectively.

A similar seasonal variation in the prevalence of *X. cheopis* and correspondence between the maximum of these fleas and the epidemic period has been observed by Kitasato (1909) in Japan, Tidswell (1910) in Sydney, and by Gauthier and Raybaud (1910-11) at Marseilles, and by Andrew (1911) in Tongschang in Northern China. The incidence of the epidemic period in the season of greatest flea prevalence under such different climatic conditions as obtain in Bombay, the Punjab, Poona, Tongschang, and Marseilles, is in itself suggestive, and, in view of the results of animal experiments already referred to, one is justified in believing that the most favourable time for the epidemic is largely determined by the seasonal prevalence of rat-fleas.

(5) The rat-flea hypothesis also affords an interpretation of the fact that epidemics decline when the mean daily temperature passes 85° F. A mean temperature of 85° F. in India means also dry weather. Fleas, whether in the larval, pupal, or imago state, are rapidly killed off at this temperature unless associated with a high degree of humidity.

The Commission for the Investigation of Plague in India found that in Bombay the proportion of fleas which became infected, the time they remained infected, and the number of successful experiments on flea transmission was greatest during the winter months (Reports, 1907, pp. 197-204; 1908, pp. 510-515 and 529-538). An analysis of their results showed 67 per cent. successful transmissions when the temperature was 73° to 78° F., against 14 per cent. successes when the temperature was 82° to 85° F. Transmission experiments were therefore carried out simultaneously at 70° and 85° F. in suitable chambers both upon rats and guinea-pigs. The results were consistent with previous experience. The possibility that the virulence of

the bacillus might undergo some variation if grown at one or other temperature was examined by the Commission and excluded.

The claims of flea transmission to be the predominating mechanism of spread from rat to man may be briefly summarized as follows:

1. The experimental evidence that plague is easily transmitted from animal to animal by rat-fleas.
2. That in presence of fleas, the epizootic, if started, varies as regards severity and rate of progress with the number of fleas present and the season of the year, whereas all attempts to induce epizootics in the absence of fleas have failed.
3. That under natural conditions (experiments in plague-houses, etc.) an animal can be protected from infection by any simple procedure which will exclude the visits of fleas.
4. The only discovered infection in plague-houses resides in plague-infected fleas.
5. Rat-fleas *X. cheopis* and *Ceratophyllus fasciatus* readily bite man.
6. The conclusions drawn from animal experiments, when applied to the problem of the spread of plague amongst human beings, afford a reasonable interpretation of every cardinal epidemiological fact.

The Part taken by the Human Flea.

It is possible to transmit plague experimentally by means of *P. irritans*. Nevertheless the direct transmission of the disease from man to man cannot, at the present time, be of frequent occurrence, or we should have evidence of direct infection instead of dependence upon the epizootic.

The reason why the human flea is ineffective is because in human cases the average degree of septicaemia before death is so much less than in rats that the chance of a flea imbibing even a single bacillus is small.

A variation of the plague bacillus in the direction of greater infectivity, with perhaps diminished toxicity leading to a higher degree of septicaemia in man, would permit of direct transmission by human fleas. Bubonic plague would then be independent of the rat, and spread

directly from man to man. For several reasons it seems to me not improbable that this may have happened in the plague of the Middle Ages.

SOME OTHER DISEASES TRANSMITTED BY INSECTS.

Three other diseases which can be transmitted by insects—typhus, relapsing fever, and poliomyelitis—must be mentioned, although I am not sure that I am justified in including any of them under the heading "bacterial." The infective agent in typhus has, so far, not been isolated, but it is ascertained that it is an organism capable of propagation, for Nicolle (1910) and Wilder (1911) have succeeded in carrying the disease through a number of generations of monkeys by inoculating them with 1 c.cm. to 5 c.cm. of blood or serum from an infected animal. The organism is held back by Berkefeld and porcelain filters. It is, therefore, free in the blood and of some considerable size.

Relapsing fever is caused by a spirochaete, and there is considerable difference of opinion as to whether spirochaetes should be classed amongst the bacteria or protozoa.

The infective agent of poliomyelitis is a minute invisible organism, which passes readily through a porcelain filter, so that it escapes the clutches of the systematist altogether.

THE TRANSMISSION OF TYPHUS FEVER BY LICE.

Typhus is a disease associated with poverty and dirtiness. It occurs in temperate climates, and mostly in the winter and spring. In warm climates it is uncommon. In Mexico, where it still flourishes amongst the poor Indians and half-caste population, it is confined to the central plateau 4,000 to 10,000 feet above the level of the sea, and does not affect the population of the lower hot country, although cases are frequently introduced from the higher lands.

Typhus has been shown to be capable of transmission by the agency of body lice (*Pediculus vestimentii*) by Nicolle, Compté, and Conseil (1909), and by Ricketts and Wilder (Wilder, 1911).

THE BIOLOGICS OF LICE AND THE MECHANISM BY MEANS OF WHICH THEY MIGHT CARRY INFECTION.

Life-History of the Body Louse.

The life-history of the body louse has recently been studied by Warburton (1909), to whom and to my colleague, Mr. Bacot, I am indebted for most of the following facts on the subject. Unlike fleas, lice have no grub stage. The eggs take one to five weeks or longer to incubate, according to temperature. The young louse when just hatched is a small edition of the parent, and sucks blood at the earliest opportunity. It is, however, not sexually mature; three moults occur, and in about fourteen days its growth is complete and the insect is sexually mature. The females lay 100-200 eggs. Lice, especially when young, are delicate creatures. They are voracious feeders, and must be fed at frequent intervals. They, as a rule, are unable to stand starvation for more than two days. They are very sensitive to heat and drying, and soon succumb at temperatures above 25 C. unless the air be kept nearly saturated with moisture. They live in clothing and bedding, and feed several times

Fig. 18—Alimentary canal and mouth parts of louse (*Pediculus vestimentii*).

The general arrangement of the alimentary canal may be seen in Fig. 18, which also shows the sac in the floor of the mouth which contains the piercing organ. The four salivary ducts (two only of which are shown) open into the base of this sac. The pharynx is a chitinous organ which collapses by its elasticity, and suction is produced by the contraction of the muscles (*m*) attached to its dorsal surface and the chitinous skeleton of the cranium. The blood is forced into the stomach by the relaxation of these muscles in order from before backwards.

The stomach or crop is a capacious organ with two later diverticuli from its anterior end.

The body louse obtains its nourishment entirely by sucking blood. It is provided with penetrating instruments the apposition of which forms a canal through which the blood is pumped into the stomach by a pharyngeal pump similar to that of the flea. These piercing instruments are not permanently exterior to the head and carried tucked away in a labium as in fleas and bugs, but, as described by Pawlovsky (1906), the apparatus is retractile and contained in a special pocket in the floor of the mouth (Fig. 18, *p*). The anterior part of the mouth is provided with a ring of hooklets, which is everted when the pricker is thrust out (Fig. 19 *A*, *h*).

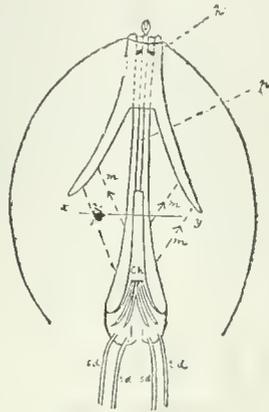

Fig. 19 A¹.

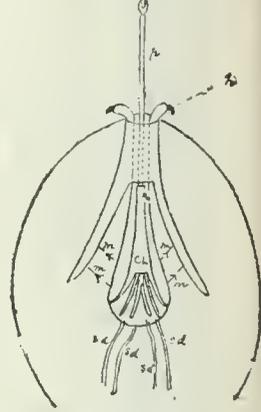

Fig. 19 A².

When the insect feeds, the tubular "pricker" (*p*) is protruded through the mouth and penetrates the skin of the host, and the hooklets serve to attach the mouth to the skin. The exact way in which the sucking tube is built up is not quite clear, but from preparations made by my colleagues Mr. Bacot and Dr. Rowland* the arrangement of these parts appears to be as follows.

Three elements enter into the formation of the "pricker," each of which is bifurcated at its base (see Fig. 19 *A*). From the dorsal and ventral aspects of two of these parts, just anterior to their bifurcation, a chitinous expansion is given off which runs forward and embraces the finer piercing organs (Fig. 19 *A* and Fig. 19 *B*, *Ch*). The two together form a sheath round the basal portions of the piercing organs.

The relation of the three elements to one another and how the sucking tube is formed may be seen from Fig. 19 *B*, which represents a transverse section in the neighbourhood of the line *xy* in Fig. 19 *A*¹; *Ch* is the chitinous sheath, *a* the dorsal element which we may call the stylet, *b* the median, and *c* the ventral element. The interlocking of the lateral chitinous expansion of *b* and *c* forms the canal *s.t.* up which blood is sucked.

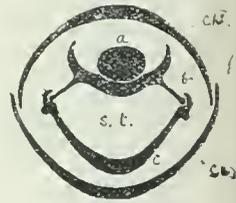

Fig. 19 B.

Fig. 19 *A*¹ is a diagrammatic representation of the head of a louse with the pricker retracted, *A*² with the pricker extruded; *p* is the "pricker" made up by the apposition of the three parts mentioned above. Anteriorly these pass through a tunnel in the substantial chitinous piece shaped like an inverted Y, which apparently also forms a skeletal framework for the attachment of the muscles (*m*, Fig. 19 *A*) which pull the whole organ forward.

Ch is the sheath covering the basal portion of the piercing parts. At the base the bifurcation of the three elements is seen, and also the four salivary ducts (*sd*)

* I am greatly indebted to Mr. Bacot and Dr. Rowland not only for lending me specimens of the mouth parts of the louse, but also for their kindness in making fresh dissections for the purpose of this lecture. The mechanism of the sucking apparatus of the louse is much more difficult to comprehend than that of the flea or bug, and the description given merely represents the conclusions I have been able to arrive at without a prolonged study of the intricate arrangement of the organ.

which enter there, but the precise connexion of which has not yet been made out.

When the whole organ is pulled forwards it not only drives out the "pricker," but evaginates the lining membrane of the sac and everts the ring of hooklets (*h*) whereby the head is anchored to the epidermis.

Summary of the Position with regard to the Transmission of Typhus by Lice.

1. The infection of typhus circulates in the blood during and for some time after the febrile period.
2. It is taken up by lice when they feed upon a patient, and may be transmitted to monkeys by them.
3. As in the case of fleas and plague, a considerable number of insects—ten or more—are required to give a reasonable chance of infection to a monkey, an animal which is probably much less sensitive than man.
4. There is reason to believe that the virus proliferates inside the insect; for, in order to produce infection by means of blood taken from a patient, the volume required is much larger than could possibly be contained in the lice employed (Wilder).
5. The infectivity of lice endures seven days, and seems to be greater some days after feeding on a typhus patient than immediately (Nicolle and Wilder), but the number of experiments so far performed is not adequate to establish this.
6. There is reason to believe that the infection may be transmissible to a second generation of lice (Wilder).
7. The present limitation of outbreaks of typhus to the most vermin-infested section of the population, its occurrence at a period of the year when the clothing is rarely removed from such persons, and washing of either takes place at considerable intervals, and the practical limitation of the disease to cold climates, all receive ready interpretation on the assumption that lice are essentially the porters of infection.
8. Further support is provided by the non-infectivity of typhus under modern hospital conditions, and the success attending prophylaxis directed towards the extermination of insect parasites: and I am unaware of any epidemiological fact inconsistent with the view that lice carry the infection.

THE TRANSMISSION OF AFRICAN RELAPSING FEVER BY THE TICK.

Relapsing fever is widely distributed about the world, and was at one time very common in this country. In 1868 Obermeyer discovered the presence of spirochaetes in great abundance in the blood of patients during the febrile attacks. These were subsequently shown to be the cause of the disease.

In 1905 Dutton and Todd (1905), in the Congo, and Koch (1905) in German East Africa, discovered that the tick-fever of Africa was relapsing fever, and that the spirochaete was conveyed from patient to patient by the tick *Ornithodoros moubata*.

Bionomics of Ornithodoros moubata.

These ticks are common in the native caravan routes. The adult feeds several times and lives a long time. They are very hardy insects, and can endure many months without food both in the larval and adult stages. In their habits they more resemble the bed-bug than the majority of the Ixodes; during the day they hide in the earth of the floors or in crevices in the walls and roofs, and at night emerge to feed upon the occupants. The female lays several broods of some hundreds of eggs in crevices of the ground. Incubation lasts from eight days to two months, according to temperature. The first moult occurs within the egg. The young larval *Ornithodoros* somewhat resembles its parent, has four legs but undeveloped sexual organs. It feeds upon blood and moults a few times, after which it is a sexually mature insect.

The number of infected ticks along the caravan routes of German East Africa is considerable. Koch (1905, 1906) found 5 to 15 per cent. contained spirochaetes, and in one instance 50 per cent. of the ticks collected from a particular locality contained spirochaetes.

Ticks, once infected, may retain the infection and transmit it to their progeny, for Dutton and Todd (1905) and Koch (1905-06) found that young ticks raised from the egg were infective. Möllers (1908) further discovered that

the second generation from infected ticks were also capable of giving rise to relapsing fever. The same fact was demonstrated by Hindle (1912) for *Spirochaeta gallinarum* and *Argas persicus*, the fowl tick. These facts, no doubt, account for the large proportion which harbour the infection.

The precise mechanism of transmission in relapsing fever is still uncertain. For a few days after feeding on an infected animal Dutton and Todd (1905) and Koch (1905) found the spirochaetes in the alimentary canal of the tick. Subsequently they disappeared from the stomach and gut, but were found by these observers in some of the internal organs, ovaries, Malpighian tubes, and salivary glands.

Leishman (1909), working in London upon a number of ticks sent from Africa, failed to find spirochaetes, although the ticks were capable of infecting monkeys. He noticed, however, that the cells lining the Malpighian tubes contained large numbers of minute chromatin-containing granules, and that similar granules were present in the ovary, and eggs of ticks, which subsequently gave rise to infective individuals. Ticks in which he failed to find these granules did not give rise to infection.

From these and other observations Leishman was led to the conclusion that the chromatin granules represent a stage in the development of the parasite. These interesting observations have been confirmed by Balfour (1911) in Khartoum in the analogous case of *Argas persicus* and fowl spirochaetes. Some experiments by Hindle (1911) also have a bearing upon this point. Hindle failed to find any spirochaetes in infected ticks kept some time at 21° C., but similar ticks warmed up to 35° C. for a few days showed spirochaetes throughout the body, and all the organs were infective, when injected into suitable animals.

The Structure and Arrangement of the Mouth Parts and Alimentary Canal of Ornithodoros moubata.

The general arrangement of the mouth will be seen from the diagram Fig. 20. The boring instrument or rostrum

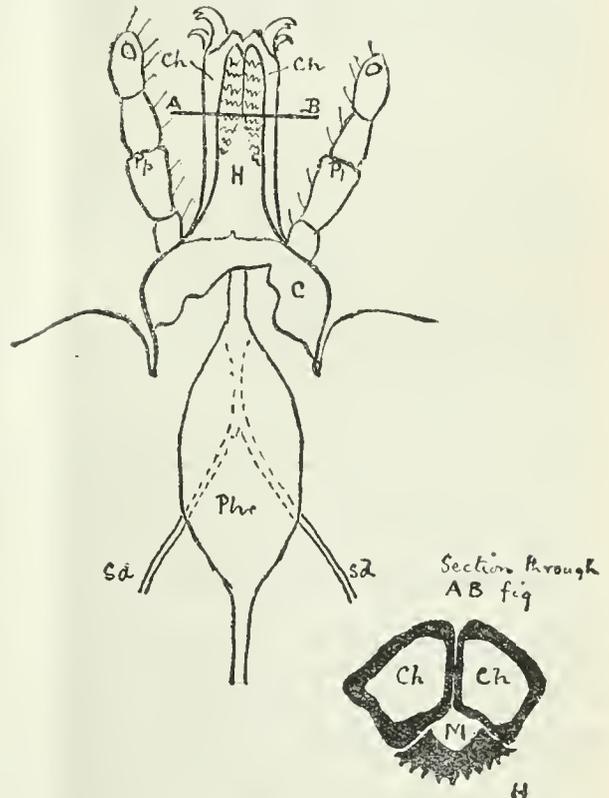

Fig. 20.—Mouth parts of tick (*Ornithodoros moubata*).

consists of three parts, two chelicerae (*ch*) and a ventral hypostome (*h*). The chelicerae are hollow chitinous organs inside which are muscles which operate the terminal claws; the hypostome is barbed. In the act of boring the claws are straightened and the three parts of which the rostrum is

composed are advanced a little further. The claws are again advanced for a further pull, and the barbed hypostome prevents any slipping back. By a succession of these efforts the rostrum is buried in the skin.

The three instruments of the rostrum, when apposed, form a canal, at the base of which is the mouth. This widens into a pharynx, which is alternately compressed and expanded by a co-ordinated contraction of the individual muscle fibres attached to it. The blood is driven by the pump through the narrow oesophagus into the crop or stomach (*st*). The stomach is a capacious pouch (Fig. 21),

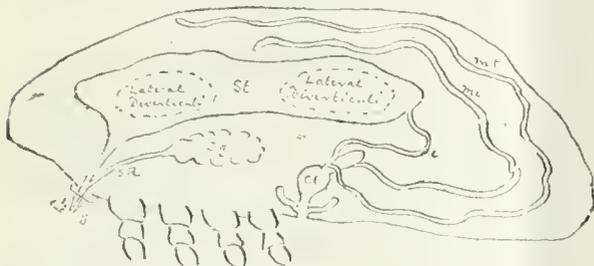

FIG. 21.—Alimentary canal and mouth parts of tick (*Ornithodoros moubata*)

having extensive lateral diverticula, which themselves branch so that after a full meal the organ distends the insect. The intestine is a very narrow tube connecting the stomach to the cloaca (*c*). The anus is not terminal, but opens in the mid-line just behind the last pair of legs.

The salivary glands (*sg*) are of the compound racemose type, each with one duct (*sd*) passing forward to the mouth.

Koch was of opinion that the spirochaetes passed from the salivary glands during the act of sucking, but both Leishman and Hinde consider that the infection is not transmitted by this channel, but that the infective excrement from the Malpighian glands passes out per rectum, and is washed into the puncture made by the insect by means of the coxal secretion which is deposited during the latter stages of feeding.

THE TRANSMISSION OF THE RELAPSING FEVERS OF EUROPE, AMERICA, AND INDIA.

Whether the spirochaetes which are responsible for relapsing fever in various parts of the world represent distinct species (Novy and Knapp, 1906; Uhlenhuth and Haendel, 1907), or merely varieties, does not seem to me proven in view of the observations of Darling (1909), and Manteufel (1908). Anyhow, they are very similar, and can all be transmitted by the tick *Ornithodoros moubata* (Manteufel, 1908, and Neumann, 1909). It is, however, clear that this tick was not the transmitting agent in Ireland and England, where relapsing fever was common fifty years ago, nor is it so in Russia, America, or India, at the present time.

The epidemiology of the disease in these countries is not yet clear. Spirochaetes are such obligatory parasites that the agency of an insect transmitter seems almost necessary. The only certain way of producing the disease is by inoculating a minute quantity of the blood of a patient during the febrile stage. Spirochaetes have been found in the urine, but no one has succeeded in producing infection by this means. It must also be remembered that they can find their way through the unbroken skin.

The distribution of relapsing fever among the population is consistent with the view that insects are necessary, for, like typhus, this disease is in Europe almost confined to the poorest and dirtiest members of the community. It has been frequently suggested that bugs might disseminate the disease. Tietim (1897) and Karlinski (1902) found that the stomach contents of the bed-bug remained infective for two or three days after feeding on the blood of a patient, and Kladrnitsky (1908) observed appearances strongly suggestive of multiplication of the spirochaetes in the stomach of the bug. With one exception, however, all the numerous attempts to transmit the disease by the bed-bug have been unsuccessful. Experiments have also been made with fleas by Sergeant and Foley (1908) and others. The results were negative. A further reason for doubting the importance of either of these insects is that the disease is not more prevalent at the time of year

these insects abound, but rather the contrary. In Europe the disease occurred in epidemic form throughout the year, the greatest prevalence being usually during winter and spring.

The only remaining ectoparasites are lice—*Pediculus capitis* and *Pediculus vestimenti*. The general bionomics of these insects has been dealt with, and it only remains to point out that their prevalence is not confined to the warmer months, but is greatest during the winter (Hamev, 1910), when clothes are least changed and washed.

Mackie (1907), in an investigation of an outbreak of relapsing fever in a mission school in India, brought forward some rather striking epidemiological facts pointing to lice, rather than bugs, as being concerned with the epidemic. He found spirochaetes in 14 per cent. of the lice taken off the boys. They were present in the alimentary canal, ovary, and Malpighian tubes of these insects. From his observations he came to the conclusion that spirochaetes multiplied greatly in the stomach of the insect, reaching their maximum on the third day. Mackie fed lice from the patients upon monkeys, but he failed to transmit the disease. In two experiments by Sergeant and Foley (1910) relapsing fever followed the infection of the clothing by lice from patients.

The spirochaetes of relapsing fever infect rats, and Manteufel (1908) made some observations on the capacity of the rat-lice (*Haematopinus*) to transmit the disease. He first ascertained by forty experiments that, when free from lice, sick and healthy rats could be caged together without the latter contracting the disease, and then repeated the experiments with the addition of lice. Two infected rats were caged together with seven healthy ones. The sick animals were killed by ether at the height of the disease, and then put back into the cage in order that the lice might crawl off the cadavers and attach themselves to the living animals. Three of the seven became infected. In another similar experiment with *Spirochaeta duttoni*, one out of eight rats became infected. Manteufel could not find spirochaetes in the louse outside the alimentary canal, nor in the eggs.

These experiments were confirmed by Neumann (1909), so that it seems highly probable that relapsing fever is spread by lice as well as by the tick *Ornithodoros moubata*. Although the former agent may not be nearly so efficient as the latter, it may make up by its greater numbers and persistency.

The details of transmission by lice are still unknown, but, from the habits of these insects to freely discharge the contents of their alimentary canal during feeding, and the readiness with which spirochaetes can penetrate uninjured epithelium, it is not difficult to imagine how this may happen, even supposing the salivary secretion does not contain the infection.

TRANSMISSION OF POLIOMYELITIS BY STOMOXYS CALCTRANS.

At the International Congress on Hygiene, held in Washington last September, Rosenan announced that he had succeeded in conveying poliomyelitis from an infected monkey to several other monkeys by means of the bites of *Stomoxys calcitrans*, the small biting stable-fly.

This observation has recently been confirmed by Anderson and Frost (1912). Three monkeys exposed daily to the bites of 300 *Stomoxys* which had previously fed on two infected monkeys during the whole course of their illness all developed the disease seven to nine days after their first exposure. The observation is of particular interest because hitherto the transmission of poliomyelitis by the subcutaneous inoculation of blood from an infected monkey has been very uncertain even when large quantities of blood have been transferred. It suggests that either the previous experiments have been made at the wrong stage of the disease, or else that the virus multiplies or intensifies in the body of the fly. The seasonal incidence of the disease being summer and autumn is consistent with insect transmission, but the continuance of the epidemic in Sweden after flies have disappeared indicates that there are other means of spread.

BED-BUGS (CIMEX LECTULARIUS) AS PORTERS OF INFECTION.

The general career of the bed-bug is more or less familiar to most people, but it may not be unnecessary to

point out that, unlike fleas, there are no larval or pupal stages, but the insect emerges from the egg as a little bug. For the following facts I am indebted to my colleague, Mr. Bacot, who has made observations on this subject.

The young bug sucks blood on the earliest opportunity, grows and moults, and feeds again. After five moults it is a sexually mature and adult insect. Bugs only visit their hosts for food, and then preferably at night; they strongly resent light, and during the day hide themselves in some cranny of the room or furniture. They are very hardy and do not require the constant feeding which is so troublesome in breeding lice and fleas. They can survive without food for six months or more.

A bug which has imbibed a good meal retires to some secluded spot and slowly digests it. It is some days before he develops a fresh appetite and sallies forth again in search of prey.

The Arrangement of the Alimentary Canal and Mouth Parts of the Bed-Bug.

The general scheme of the alimentary canal will be sufficiently clear from the diagram (Fig. 22). There are

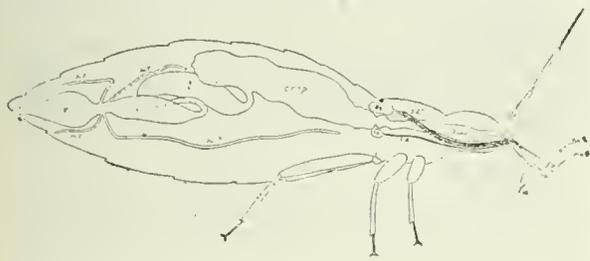

Fig. 22.—Alimentary canal and mouth parts of bug (*Cimex lectularius*).

two pairs of salivary glands (*sg* and *sg*¹) and the duct of the larger of the dorsal pair (*sg*¹) bifurcates shortly after it emerges from the gland and both tubes run forward to the base of the piercing organ. The exact way in which the three salivary ducts on each side terminate has not yet been determined. The mouth parts also differ from those of the flea in that the sucking tube is made up by the apposition of four elements instead of three. These are two maxillae (*mc*) and two mandibles (*mi*). When not in use these delicate piercing instruments are carried in a groove on the dorsal aspect of the three-jointed labium (*lab*). Whilst feeding this support is folded backwards under the head.

Experiments on the Transmission of Relapsing Fever, Typhus, and Plague by Means of Bed-Bugs.

The observations of Tietin have already been referred to. Although these show that the spirochaetes of relapsing fever may live from some hours to many days, according to circumstances, in the stomach of the insect, they give no information as to whether the bed-bug can in a natural way transmit the disease.

Christy (1902) and M. Rabinowitch (1907) and Shellack (1909) tried the experiment on themselves without success. Their attempts were very thorough: Shellack, for instance, fed 168 bugs, which had been previously nourished on a diet of rat-blood infected with *Spirochaeta recurrentis*, upon himself. The experiment lasted a month, and was so arranged that a variety of intervals elapsed between the ingestion of infected blood and the second meal.

Breinl, Kinghorn and Todd (1906), and Rabinowitch (1907), and Sergent and Foley (1910) have also tried to transmit relapsing fever to monkeys by means of bugs. Large numbers of insects were employed by the former observers, sometimes as many as 590 to one monkey.

Their experiments were carried on over two or three months. Bugs which had fed upon an infected monkey at all stages of the disease were used, and the interval between feeding upon the infected and healthy animal varied. Nevertheless, no transmission of the disease occurred.

The only case of a successful transmission was one experiment by Nuttall (1907), who removed a bug shortly after it had commenced to feed upon an infected mouse, and allowed it to complete its meal upon a normal mouse.

Bed-bugs were excluded from consideration as trans-

mitters of typhus by Nicolle (1910) and by Wilder (1911), as the distribution of these insects both in time and space does not coincide with that of typhus. Wilder, however, tried experimentally to convey the disease from monkey to monkey by bugs, but without success.

Verbitski (1904) made a number of experiments on the transmission of plague by the bed-bug. He showed that plague bacilli multiply in the stomach of bugs, as they do in that of fleas, and that their virulence was unimpaired. He succeeded in conveying plague to guinea-pigs by the bites of bugs, but only up to four days after they had fed on an infected animal.

There is really no evidence to incriminate the bed-bug in the case of either typhus or relapsing fever. It is possible to transmit plague experimentally by means of bugs, but there is no epidemiological reason for supposing this takes place to any extent in nature.

There are two differences in the habits of bugs and those of fleas and lice which may possess epidemiological significance. The first concerns their customary intervals between their meals. Bugs show no disposition to feed for a day or two after a full meal, whereas fleas and lice will suck blood several times during the twenty-four hours. The second is in respect to the time the insects retain a meal and the extent to which it is digested before being excreted. Fleas and lice, if constantly fed, freely empty their alimentary canals, and the nature of their faeces indicates that the blood has undergone but little digestion.

Both these insects evacuate such undigested, or half digested, blood per rectum during the act of feeding, and the remnants of the previous meal are thus deposited in the immediate vicinity of a fresh puncture. It is not unlikely that, should the alimentary canal of the insect be infected with plague bacilli, spirochaetes, or the organism responsible for typhus fever, these may be inoculated by rubbing or scratching.

Bugs have not this habit, and in all the cases I have examined their dejections were fully digested, almost free from protein, and consisted mostly of alkaline haematin.

This is, however, probably not the whole explanation, and there is, I believe, much yet to learn as to the mechanisms of insect transmission, and why one blood-sucking parasite is an effective porter and another not, even in the cases of bacterial infection where no stage in the life-cycles of the organism takes place within the insect host.

An Address

ON

MEDICINE AND LIBERTY.

GIVEN AT A MEETING OF THE DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY ON JANUARY 9TH, 1913.

BY WILLIAM GORDON, M.D., F.R.C.P.,

EXETER.

It is, however, certain that men who begin by losing their independence, will end by losing their energy.—Buckle, *History of Civilization in England*, vol. ii, p. 186.

I HAVE to thank this society for allowing me to discuss within its tranquil, scientific atmosphere a question vital to the future of English medicine, needing the calmest and clearest deliberation, yet now forced by circumstance into the arena of political conflict. It is unfortunate that no attempt has hitherto been made, so far as I am aware, to deal philosophically with this question, and in making the attempt I must make large claims upon your indulgence.

The demand has just been made upon English medicine, in the National Insurance Act, to part with a great measure of its independence, and, in considering this demand, there are four questions which we are bound to put to ourselves:

- I. What is it that we are asked to part with?
- II. To whom are we asked to hand it over?
- III. Why has the demand arisen? and
- IV. What must be the consequences of our acquiescence?

I. WHAT IS IT WE ARE ASKED TO PART WITH?

It is now the independence of much of our practice, soon of most of it, ultimately perhaps of all of it; and here we have to consider two points.

- (a) What is the value of independence to medicine? and
- (b) What is the present value to this country of its medical profession?

I propose to show that for the fullest expansion towards perfection of medicine, liberty is essential, and that English medicine at the present time is foremost in the world.

MEDICINE AND LIBERTY IN HISTORY.

If we look back over the history of medicine, as far as it is traceable, we shall have no difficulty in recognizing that there have been four great periods of pre-eminent progress. The first was coincident with the golden age of Greek culture and culminated in the lifetime of Hippocrates, about the second half of the fifth and the beginning of the fourth centuries before Christ. The second occurred rather late in the Renaissance, and its activities centred round Padua in the sixteenth century of our era. The third followed close on the second, reaching from the seventeenth century onwards to culminate in the nineteenth, its activities centering round England. The last, which is but the expansion of the third, began within the nineteenth century, and its activities reach throughout the civilized world.

Now if we examine these periods attentively we shall find that all of them have this salient characteristic in common, a remarkable development of intellectual and personal liberty. The first period corresponds to that wonderful epoch in which human intelligence suddenly attained to heights not since surpassed, and in which admittedly one chief cause of so great a growth was the unexampled intellectual freedom which then permeated the Hellenic world. The second period formed part of that great European revival of learning which followed the flight of Greek scholars to Italy and the invention of printing. As its activities centred around Padua, it was associated with the greatest intellectual freedom of the time, for Venice was then mistress of Padua, and in every way fostered its university, that it might worthily advance the new learning. It was under the protection of the enlightened Venetian Senate that Vesalius enjoyed

As already announced in the JOURNAL, the second International Congress on life-saving and precautions against accidents will be held at Vienna in September (9th to 15th). The Permanent Secretary of the British Section of the Congress is Mr. Samuel Osborn, F.R.C.S., Constitutional Club, Northumberland Avenue, W.C.

The fourth congress on the hygiene of the dwelling will be held at Antwerp this year from August 31st to September 7th. The following is the programme of subjects proposed for discussion: (1) Hygiene of the emigrant; (2) colonial hygiene; (3) hygiene of ports and ships; (4) the extension of towns. Further information may be obtained on application to the General Secretary, Hotel de Ville, Antwerp.

The Roboral Company, 23, Cloth Fair, E.C., has recently issued a catalogue relating almost entirely to diagnostic appliances and instruments other than clinical thermometers and stethoscopes. A special feature is the number of means provided for enabling practitioners to make use themselves of methods of diagnosis for the assistance of which they are commonly dependent on the co-operation of laboratory workers.

those unique opportunities for the study of anatomy which enabled him, in 1543, to publish his work on the *Structure of the Human Body*—a work that broke the medical slumber of more than a thousand years, shattered the fabric of Galenical authority, and, by founding modern anatomy, made possible the construction of a new physiology and a new medicine. The third period opened with the work of another Paduan—our own William Harvey—who, after four years' study under Fabricius, the discoverer of the valves in the veins, took his degree in 1602, and twenty-seven years later published his immortal work on the circulation of the blood. It was in post-Elizabethan England, then practically working out an ideal of popular liberty unknown elsewhere, that he completed his investigations, and that, untroubled by Government interference, there followed him the succession of illustrious medical observers who may be said to have culminated in Lister.

Significant that round sea-going, liberty-loving Greece, sea-going, liberty-loving Venice, and sea-going, liberty-loving England should have centred the achievements of these three great periods of medical history.

But the third period extended also to countries close to England, and these illustrate the same relations between medicine and liberty. In Holland, freed at the end of the sixteenth century from Spanish tyranny, Boerhaave taught and Haller began his work. In France at a later time, freed from the oppression of the Bourbons by its revolution, Bichat published his great work on anatomy and Laënnec discovered auscultation.

The fourth period is, as I have said, but the world-wide expansion of the third, and in it may be discerned a clear relation between national liberty of thought and exceptional medical progress.

Thus, in all these periods of pre-eminent medical achievement liberty has been pre-eminent also.

To complete our survey, however, of the historical relations of medicine and liberty, we must also look at those periods of history in which freedom was restricted, and try to discover what effect this restriction of liberty produced upon the development of medicine.

After the fall of Hellenic freedom, amidst the decline of Hellenic literature and art, medicine declined also. Even the anatomical revival under the early Ptolemies at Alexandria about 300 B.C. produced no such genius as Hippocrates, although the influence of enlightened rulers seems to be reflected in the work of Hierophilus.

At Rome, to which Greek medicine extended its practice, the influence of enlightened governments, with relative freedom of thought, seems connected especially with medical advance. Aesclepiades flourished in the last days of the Republic, the friend of Cicero and of Mark Antony; Celsus wrote just after the end of the Augustan period; Soranus, Rufus, and perhaps Aretæus, adorned the golden age of Trajan and the Antonines, constituting a series which terminated in Galen. Galen forms one of the most conspicuous figures in medical history, and was contemporary with Marcus Aurelius, whom he attended; but, remarkable as he was, the spirit of Hippocrates was not his, and his fatal formalism petrified medical knowledge for many succeeding centuries. "If a man were called to fix the period in the history of the world," wrote Gibbon, "during which the condition of the human race was most happy and prosperous, he would, without hesitation, name that which elapsed from the death of Domitian to the accession of Commodus. The vast extent of the Roman Empire was governed by absolute power, under the guidance of virtue and wisdom." And of the two Antonines: "Their united reigns are possibly the only period in history in which the happiness of a great people was the sole object of government."

After Galen, medical attainment rapidly fell away, and no great name broke the long slumber of thirteen hundred years which stretched to the coming of Vesalius. The dogmatic rule of the Church, admirable as it was for its time and its peculiar task, made medical advance impossible. At the same time, in the Eastern empire, medicine was merely mechanically preserved, though it is interesting to note that Alexander of Tralles, whose work has been called a refreshing oasis in the desert of Byzantine literature, was the contemporary of Justinian.

Turning from these regions of the Eastern and Western

empires, thus become sterile, to the extraordinary outburst of Saracenic civilization, we come again upon medical work of no mean order. Rhazes, the most notable of the Arabic physicians, followed on the most splendid era of the Caliphs of Bagdad. As in Moslem Spain, Avenzoar followed on the golden age of Cordova; on the other hand, Avicenna, born nearly a century and a half later than Rhazes, and in a beginning period of decline when dogma was in the ascendant, was little but a brilliant commentator and highly endowed compiler. It seems to be a singular fact noticeable in successive ages of enlightenment that medicine takes a longer time to mature than other arts and sciences. Yet, in spite of the encouragement of princes who encouraged every form of art and science, of well-equipped hospitals, and innumerable translators of Greek medicine, Arabic medical achievement, so far as we can discover, is curiously disappointing. Anatomy was forbidden, and the rule of intellectual dogmatism in all subjects was practically supreme. Thus liberty was restricted. Only Rhazes and Avenzoar seem to have ventured, in great measure, to think and observe for themselves. Similarly, rather later, in Italy, Salerno, fostered by Frederick II, who drew his culture from the Arabs but partook of their spirit of autocracy and intolerance, produced no work of enduring value.

Coming to later times, whilst medicine was flourishing in free England, in France, under the tyranny of Louis XIV, conditions were widely different. "His age cannot boast," says Buckle, "of a single medical writer whose name is now known as having made any specific addition to our knowledge. In Paris the practice of medicine was notoriously inferior to that in the capitals of Germany, Italy, and England, whilst in the French provinces the ignorance, even of the best physicians, was scandalous."

In Spain, even so late as the end of the eighteenth century, whilst intolerance of opinion still reigned supreme, the science and practice of medicine are described as having been at the lowest ebb.

Thus the lesson of history, however tested, reads the same—that for pre-eminence in medical progress pre-eminence in liberty is essential.

MEDICINE AND LIBERTY IN OUR TIME IN ENGLAND.

Turning next to the survey of our own experience of the influence of lay control, we have a fair field of observation; for there are certain departments of medicine which can scarcely be otherwise than under some measure of lay control, yet in all of them we may observe that the tendency of progress is more and more to yield to medicine the utmost possible measure of independence.

The Army Medical Service.

In the latter part of the last century, following the medical breakdown of the Crimean war, great pains were spent on the improvement of the Army Medical Service. The old regimental system, socially popular as it was, was found unsuitable for modern requirements, since the entire subordination of a medical officer to the military commandant, however able a soldier and amiable a man he might be, was often incompatible with progress. A medical service was therefore established independent of regimental military control, and a certain amount of advantage was thereby undoubtedly gained for the army. Wanting, however, the requisite military rank and title to secure a sufficiency of authority, this service was still found defective in efficiency. In the year 1893 the public necessity for the grant of military rank and title was recognized, and these were conceded by Lord Lansdowne, whilst at the same time a most important administrative change constituted a civilian medical advisory committee to aid in controlling the new corps. How vast has been the effect of these successive relative enfranchisements every one who has watched the progress of the Army Medical Service must be well aware.

The Public Health Service.

Taking next the public health service of this country. This has long been under the rule of local and personally interested authorities possessing an undue amount of power over the tenure of office of their medical officers, and the consequence has been a serious embarrassment to the promotion of sanitary improvement. Gradually,

however, by improved terms of service, by greater powers given to the Local Government Board and its medical advisers, this branch of medicine also has been working towards fuller enfranchisement. The results on the national health have been such as cannot be mistaken. Now, moderate and far-sighted thinkers are already urging the establishment of a Ministry of Public Health, with an adequate staff of medical administrators, which, by still further freeing medical science from unintelligent control, will, it is held, still further advance the well-being of the nation.

The Medical Charities.

Turning to our medical charities, I can give an interesting personal experience extending over more than twenty years. Eighteen years ago I was on the staff of three important medical institutions. In one of these the entire staff was *ex officio* on the governing committee. Scientifically and financially this institution was, and has remained since, extremely flourishing, and has admirably maintained its position in the forefront of modern work. In the second charity only two members of a large staff represented their colleagues upon the board. It was then fairly flourishing, though definitely behind the times, and since then, through friction and short-sighted administration, it has fallen hopelessly behind. The third charity had then no representation whatever upon the weekly committee, and matters were in a truly deplorable state. The charity was financially discredited, backward scientifically, and the scene of constant unnecessary friction. A few years later the entire staff were placed upon the board. Immediately a remarkable change took place in the progress of the institution. Not only did its scientific development go forward by leaps and bounds, but, owing largely to the staff, its finances were put upon a flourishing basis; and friction absolutely ceased.

Thus what history indicates, the experience of our own time in our own country corroborates.

Foreign Experience.

But we may be told to look abroad where Government interference with medicine is producing, it is claimed by some of us, beneficial results. But is this really the case? In the first place, the experiment has not yet lasted long enough for reliable deductions to be drawn. The progress of medical decline has seldom been sudden, and its beginnings are open to question. Already there are some observations which appear to be worth making. It does not seem to me, from what I and others have seen abroad, that the average general practitioner in these Government-controlled medical professions is as capable as he is in this country. It is perfectly obvious that the sanitation is behind our own, and that the nursing is not equal to English nursing. The tables given illustrate the superior progress in the country where medicine has hitherto been freest—that is, in this country.

General Death-rate All Ages per 1,000 Living.

| 1910. | | 1910. | |
|-----------------------|------|---------------|------|
| England and Wales ... | 13.5 | London | 13.7 |
| German Empire 1909... | 17.2 | Berlin | 14.7 |
| France | 18.0 | Paris | 16.7 |
| Austria | 21.2 | Vienna | 16.6 |
| Switzerland | 15.1 | Berne | 13.2 |

Phthisis Death-rate per 1,000 Living.

| 1910. | | 1910. | |
|-----------------------|------|---------------|------|
| England and Wales ... | 1.02 | London | 1.23 |
| German Empire... | 1.44 | Berlin | 1.76 |
| France | 1.80 | Paris | 3.66 |
| | | Vienna | 2.61 |
| Switzerland | 1.61 | Berne | 1.95 |

Far be it from me to speak disparagingly of my foreign friends, to forget many kindnesses, many invaluable privileges and priceless instruction received at their hands. I have been filled with admiration at the teaching of these men, and gladly recognize those particulars in which they are definitely ahead of my own countrymen, but here it is a matter of immediate vital importance to English medicine to compare foreign conditions with our own, and I am certain that the foreign conditions, taken as a whole, show nothing which is in favour of a fuller Government control.

I have heard a distinguished surgeon abroad point to the miserable conditions under which he worked and say, "Whilst money is required by Government for other purposes the medical department will have to wait."

Mr. J. G. Gibbon, B.A., D.Sc., in his work on medical benefit, founded on the experience of Germany and Denmark, who has no reason to approach the subject in any other spirit than that of disinterested scientific inquiry, lays it down that "detailed control in expert matters should be exercised through the organization of the doctors themselves" (p. 126). "The work of an expert can," he says, "only be properly criticized in matters of detail by another expert"—the layman's "control will prove clumsy and ineffective."

In short, however we look at the question, wherever we turn for information, we find nothing to support a claim that undue lay interference with medicine is for its advantage. *The fullest possible liberty is, everywhere and always, clearly the accompaniment of the fullest medical efficiency.*

THE VALUE TO ENGLAND OF ITS EXISTING MEDICAL PROFESSION.

Coming now to the exact standing of English medicine at the present time—on which, indeed, I have already touched—I may briefly summarize matters thus: No branch of modern medicine since Harvey can show so splendid an array of productive genius as the English. Sydenham, Hunter, Edward Jenner, James Simpson, Lister, Spencer Wells, Horsley, Manson and Ross, Wright, Bruce bring the records continuously down to our own day. The discoveries of Horsley, Ross, Wright, and Bruce are affairs, so to speak, of yesterday. English preventive medicine is admittedly unequalled in the world. Our hospitals are superbly equipped, our teaching is admirable, and its arrangements are such as to afford the greatest possible individual training to the largest number of medical students, not only in the science and art of their calling, but in the priceless sense of responsibility and of duty to humanity, making, as I have just said, the English general practitioner the best in the world. It is only in respect of where we come in contact with undue lay control, as in our public health appointments governed by interested local bodies, in our public services where lay control is excessive, in such hospitals as do not give their staffs adequate representation on their committees, above all, in club practice, where the medical man has been placed under the control of the insufficiently educated, do we discern serious necessity for reform, reform which is admittedly in every case the grant of greater liberty for the medical officers.

To sum up, we are asked to part with the freedom of the finest branch of the medical profession in the world, a demand which is not merely novel and unjustifiable, but obviously retrograde and evil.

II. TO WHOM ARE WE ASKED TO PART WITH IT?

If this vast, intricate, highly technical, intellectual, responsible body of knowledge were to be controlled by correspondingly intellectual and responsible persons, such as would probably constitute a great, all-embracing Ministry of Medicine, we might not, perhaps, expect a greater falling off in the standard of English medicine than Greek medicine undoubtedly suffered under the successors of Alexander the Great or under the Antonines at Rome. But the proposal made is very different. What we are asked to do is so amazing that I refrain from here characterizing it as I might. We are asked to place the control of medicine in the hands of committees whose majorities are drawn from the less educated strata of the community. Bear this well in mind. It is the fundamental fact in the greatest crisis through which modern medicine has been called to pass. Financial details, details of administration, are relatively immaterial. What we are asked to do is to sell our freedom to inferior intelligences, to place knowledge under the control of ignorance. In saying this I should be sorry to hurt the feelings of those whom circumstance has denied advantages which have been given to us, of many who with equal good fortune might have proved my own intellectual betters. I am one of those who would rejoice to see equal opportunity at the outset for all. But we are dealing with things as they actually are, and the

issues at stake are so tremendous that we must face facts and state them plainly.

III. WHY IS THE DEMAND MADE OF US?

The ostensible reason is to improve the medical attendance on the poor. On this subject I venture to assert that a vast amount of malevolent nonsense has been written and spoken. As a medical consultant, with a considerable experience extending for more than twenty years, I am in a position to appraise the value of the much abused club doctor. When I recall the self-forgetful, tireless good work done by him under conditions so altogether disgraceful, not to him, but to the community at large, I am filled with admiration. Defects there have been, grave defects, but how, under the circumstances, were they to be avoided? The grant of State aid to enable the poorer classes to properly remunerate their medical men so as to enable them to devote the time they desire to their cases is altogether right. But if this had been the real reason for the proposals now put forward, there would have been no necessity for keeping the preparation of the National Insurance Bill a close secret from the medical profession—a short-sighted policy which, by excluding expert advice, ensured the measure being unworkable; for the refusal to hand to the profession advance copies of the bill when its completion was announced; for the attempt to rush it through Parliament with no adequate discussion; and now to force it upon the medical profession, by methods which I will not characterize, in spite of protests from every authoritative quarter.

The National Insurance Act, when dispassionately examined in the history of its construction, the defective details of its design, and the startling mendacity of its advocates, is clearly aimed not chiefly at the improvement of the medical treatment of the poor, which it will impair and not improve, but at the advancement of a political party and the establishment of a personal predominance.

IV. WHAT WILL BE THE CONSEQUENCES IF WE ACQUIESCE IN THESE ARRANGEMENTS?

I shall consider very briefly and carefully not what the results may be, but what they must be. Medical men are, by the Act, required to place themselves under the control of committees armed with punitive powers, chiefly composed (by a majority of three-fifths of their number) of representatives of men of less culture and training than the medical man—by men, in fact, drawn from the very group which has already proved to the hilt its utter unfitness for such duties. They will be charged with work which will occupy them too fully to permit of reasonable recreation, and leaving no time for the professional reading which is necessary to prevent their falling behind the current standard of knowledge, and will be liable to punishment in their professional capacity by a body wholly incompetent to pronounce an opinion on such matters. Under such circumstances we have to ask ourselves if an adequate supply of efficient medical men can be maintained for the national needs?

The experience of the Army Medical Service affords us a test of what is likely to happen. Twenty years ago the Army Medical Service was reasonably well paid, only moderately badly treated, was at least under the control of well-educated, cultured men, and afforded interesting opportunities of travel and a share in the distinctions of military life. Yet there was a serious shortage of candidates for it and efficiency fell off. Why? Because its conditions were officially and socially unpleasant, and the pursuit of knowledge was hindered.

But the conditions of the Army Medical Service twenty years ago were paradise to what the conditions of the "panel" will be now. These conditions will be so degrading to self-respect and pride of work that energy, professional enthusiasm, and knowledge must fall off, and the question faces us, Will educated and self-respecting men enter such a service or put their sons into it? It is unimaginable that a sufficient supply can be maintained. Already the supply has fallen to an alarming degree. In the two-year period, 1911 and 1912—the period affected by the introduction of the National Insurance Bill—the entry of medical students in the United Kingdom has been about 450 fewer than in the two-year period 1909–10. And since, in the inevitable

degradation of medicine, all its branches will share alike—for any one who enters medicine must run the risk of the "panel"; no boy beginning his hospital work, can be certain of better fortune—general practitioners, consultants, surgeons, specialists, public servants either in army, navy, or public health, medical teachers and medical investigators all must clearly degrade in efficiency together. How is it possible to think otherwise? And as medical teaching begins to suffer, the profession must obviously take a further long step down.

Whatever, therefore, may be our views with regard to the control of medicine by Government under the auspices of the highest intelligences in the community, there cannot be a moment's hesitation in condemning as highly dangerous to the national welfare the present proposals. We may, I submit, only too confidently draw the following conclusions:

CONCLUSIONS.

1. There is sound historical and contemporary evidence that the progress of medicine is intimately related with liberty of thought and action.
2. That wherever lay control exceeds what is necessary, the progress and practice of medicine are impaired.
3. That the proposals now made in the National Insurance Act are so pernicious that it is the duty of the medical profession to resist them by every legitimate means in its power.

SALVARSAN IN PERNICIOUS ANAEMIA.

BY
E. F. MAYNARD, M.D., M.R.C.P.,
PHYSICIAN, SUSSEX COUNTY HOSPITAL.

EVERY ONE reading the notes of the case reported in your issue of December 14th last by Dr. Hobhouse will congratulate him on the happy result of his treatment; the case taken with those reported by Dr. Byrom Bramwell might lead one to suppose that in salvarsan we had possibly a specific in pernicious anaemia; that such, however, is not the case is unfortunately borne out by the total failure of this drug in the following instance, which is still under my care in the Sussex County Hospital. Why in one case the drug should bring about an apparent, if temporary, cure, and in another totally fail to produce any improvement remains for the future to elucidate.

C. H., aged 61, stated that he had not been fit to work for two years; that he had had indigestion and jaundice, had lost weight considerably, and had vomiting and diarrhoea, headache and drowsiness. His skin was bronzed on face and hands, but there was no pigmentation of mucous surfaces, nor around the nipples. The heart and lungs were normal.

He was at first thought to be the subject of Addison's disease, but a blood examination negativated this diagnosis, and showed the condition to be pernicious anaemia. The temperature was never as high as 100 F., but invariably at night ranged between 99 and 100°; on the night following the first injection of salvarsan it was somewhat higher, but ever afterwards distinctly lower, never reaching above 99°. He was admitted on October 3rd, 1912, and the following are the blood counts:

| Date. | Red Cells. | White Cells. | Haemoglobin. | Colour Index. |
|----------------------|------------|--------------|--------------|---------------|
| October 6th | 1,184,000 | 3,050 | 40 | 1.6 |
| October 11th | 1,108,000 | 3,250 | 45 | 2 |
| October 22nd | 1,243,000 | 4,750 | 50 | 2.08 |
| October 28th | 1,332,000 | 4,350 | 35 | 1.4 |
| November 5th | 1,016,000 | 2,850 | 35 | — |
| November 15th | 1,088,000 | 2,800 | 40 | 1.9 |
| November 27th | 1,344,000 | — | 35 | 1.3 |
| December 9th | 1,152,000 | 4,800 | 35 | 1.7 |
| December 18th | 1,272,000 | 3,150 | 40 | 1.6 |

The first dose of 0.3 gram of salvarsan was given intramuscularly on October 13th, after which there was a

definite increase in the number of red cells for a fortnight, when a second dose of the drug was given (October 29th). Examination of the blood a week later revealed a diminution in the red cells; the treatment was therefore stopped. The patient has since November 30th been treated with an autogenous vaccine of pure culture of streptococci obtained from the gums, and the latest report shows some improvement in the number of red cells, and the colour index, and fewer normoblasts and megaloblasts. The following notes were made by the pathologist:

October 6th. One normoblast on film: cells irregular, but stain well.

October 11th. Megaloblasts and normoblasts present; cells stain badly.

October 22nd. Several megaloblasts; poikilocytosis and anisocytosis marked.

October 28th. One megaloblast.

November 5th. Megaloblasts and normoblasts present; staining irregular.

November 27th. Nucleated cells; megaloblasts and normoblasts.

December 18th. One normoblast and one megaloblast; marked poikilocytosis.

My thanks are due to Mr. Cheves, the house physician, for the notes of the case, and to Dr. Galt and Mr. Healey, pathologists, for their careful reports on the blood.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

EXTERNAL MYIASIS IN A MONKEY.

On June 25th, 1912, two small groups of dipterous larvae were noticed on a specimen of *Cercopithecus callitrichus*. The monkey was suffering from acute tuberculosis, and died the day following the observance and removal of the parasites. One batch of these larvae were taken from the nose and region of the face surrounding the mouth, the other from the right side of the body near the groin. In both cases the larvae were in various stages of development, some of them having apparently only recently hatched. Altogether twenty-one of these parasites were removed from the host, and were subsequently placed in petri dishes containing raw flesh and sand.

It became evident that at least two species of diptera were inculturated, sixteen specimens being of the typical *Muscid* type and the remainder larvae of *Fannia canicularis*. Two examples of the latter were allowed to complete their development, the adult emerging on July 27th and August 5th. The majority of the remaining larvae pupated by June 29th, but four specimens remained in the larval stage until July 5th, 6th, and 7th respectively. The four specimens referred to were separated, and subsequently on July 15th, 18th, and 19th three specimens of the blow-fly, *Calliphora erythrocephala*, emerged, the remaining example having shrivelled up. From the remaining puparia seven specimens of *Muscina stabulans*¹ were obtained, the period spent in this stage varying from eleven to nineteen days.

The above records are of some interest, as neither *Fannia canicularis* nor *Muscina stabulans* can be classed among the "flesh flies," although both, but more especially the former, have been known to occur in the alimentary tract of human beings. The natural breeding places of the so called lesser house-fly (*Fannia*) are human excrement and decaying vegetable matter, but records are in existence of its having been reared from the larvae of a lepidopterous insect (*Epischnia carilla*) and of its occurrence in the nest of the common bumble-bee (*Bombus*). It is possible, therefore, that the larvae in question may have been derived from an external source, as, for example, the food of the monkey at the bottom of the cage; but, however this may be, they were found by us on the animal itself. In this connexion also it is worth noticing that the monkey was taken a considerable distance from the cage before the larvae were removed. The larvae of *Muscina stabulans* also feed on decaying vegetable substances and dung; they sometimes, however, attack growing plants, but in these cases have probably been introduced with the manure. The fly has also been reared from human

¹ The identification of this species was kindly confirmed by Mr. E. E. Austen.

excrement and from the pupae of certain insects, notably those of the gipsy moth, although there appears to be some doubt whether the pupae attacked were healthy or not.

THE CAUSATION OF THE CRESCENDO CHARACTER OF THE PRESYSTOLIC MURMUR IN MITRAL STENOSIS.

I HAVE frequently in former communications called attention to the physical fact that the auricle, as it contracts, can exert a rapidly increasing pressure on its contents. The ventricle could do the same were it not that as soon as the pressure on its contained blood rises above that in the aorta it escapes into that vessel, which acts as a safety valve to the ventricle, preventing its pressure ever rising further.

When, however, in mitral stenosis the escape of blood from the auricle into the ventricle is hindered, the auricle can probably increase the pressure on its contents to an extent far greater than is commonly supposed. It can, apparently, force it with ever-increasing pressure into the ventricle as its contraction progresses, even without the necessity of hypertrophy of the auricular walls to aid it.

This follows as a simple consequence of certain physical principles, which must apply to a greater or lesser extent to the contractions of such hollow viscerae as the heart chambers, uterus, bladder, etc.

Let AB and CD be two thin, hollow contracting spheres (elastic or muscular), the larger CD being double the diameter of the smaller AB. If they be equally thick, it can be shown that CD has four times the quantity of material in its walls than AB has; and if they are contracting on their contents with equal force per unit of material, it can also be shown that the pressure within the smaller sphere will be double that in the larger. The smaller sphere has, therefore, an eightfold mechanical advantage over the larger, in that with one-quarter the contractile material it can produce double the pressure on its contents.

If the smaller sphere were one-third the diameter of the larger it would, by the same reasoning, produce three times the pressure on its contents with one-ninth of the contractile material in its walls; that is, it would have a mechanical advantage over the larger of 27 to 1.

Supposing, then, that the larger sphere were to contract to half its diameter, it could, if its force of contraction remained constant, increase the pressure on its residual contents eightfold; and if it contracted to one-third its diameter it could, theoretically, raise the pressure on its residual contents twenty sevenfold.

In fact, the pressure which a thin, spherical, contractile wall can exert on its contents varies inversely as the cube of its diameter.

I do not mean these figures to be taken as mathematically precise as applied to the auricle, uterus, bladder, or other hollow viscera. They, however, indicate the immense mechanical advantage which these organs must have as their contraction on their contents progresses, and partial expulsion of these contents takes place; for the same physical principles apply necessarily to them.

I have little doubt that it is largely due to this fact that the presystolic murmur is crescendo in character. As the contents of the auricle are expelled through the stenosed

mitral orifice, and the auricle becomes itself smaller and contracted, the pressure the auricle can exert on its residual contents can enormously increase, from merely physical principles, without any additional effort on the part of the auricle. The murmur would, therefore, go up to, or even into, the first sound, as a crescendo murmur; in consequence of and in accord with the rising pressure under which its blood is expelled into the ventricle.

Mentone.

DIABETES MELLITUS AND LIFE ASSURANCE EXAMINATIONS.

It is well known that not every case in whom sugar is discovered in the urine should be refused for life assurance; but I do not intend here to discuss the various glycosuric cases which, after careful examination, may be accepted at special rates. I shall merely, as have many others, refer to the possibility of temporary absence of sugar from the urine of diabetic patients, when undergoing medical treatment, becoming a source of serious error from the assurance point of view. Every one knows that in slight cases the sugar in the urine may be got rid of by suitable diet; and the use of certain drugs, such as aspirin and calcium iodide, has been said occasionally to have a similar effect. But it is not quite so generally well known that in grave cases of diabetic mellitus, in which sugar cannot be completely got rid of from the urine by ordinary dietetic methods, it may occasionally be temporarily banished by the employment for a day or two of (more or less disguised) starvation methods.

Thus, in a young woman, aged 23 years, under my care in 1909 at the German Hospital, the sugar in the urine was reduced by careful dieting to about 70 grams for the twenty-four hours. On September 10th the diet was temporarily limited to 200 to 300 grams of olive oil in the day, with as much water as was wished for, and a codcin-phosphate pill (which the patient had been taking three times a day) was continued. As a result of this disguised starvation method sugar completely disappeared from the urine on September 12th and on September 13th I ordered a return to the special diet for her diabetes. On the next day the urine contained 4.5 per cent. sugar again. During the days of exclusive olive oil diet the patient did not feel hungry or as if she was being starved. Once or twice she felt a little sick, owing to the oil, but she looked well and had her usual somewhat florid complexion. She lost only about 4 lb. in body weight. She was not emaciated, and on the whole gained weight whilst she was in the hospital. This case was one of grave diabetes mellitus, but surely a life assurance examiner, had he examined her when the sugar disappeared, might have been deceived. The reaction for diacetic acid ("Gerhardt's reaction") was indeed positive, but in the absence of sugar the examiner would hardly have tested the urine for diacetic acid. I should not repeat this dietetic trial in a similar case, for I think that it might conceivably favour the onset of diabetic coma, from which indeed I heard that this patient, like so many young diabetics, afterwards died.

Other "hunger cures" or "starvation cures" can similarly temporarily remove the glycosuria. Thus, at the Edinburgh Medico-Chirurgical Society on December 15th, 1909, Dr. F. D. Boyd brought forward a case of severe diabetes mellitus in which a single "hunger day" caused complete disappearance of glycosuria for twenty-four hours, the sugar reappearing afterwards in only small amount. Dr. G. Guelpa of Paris, on page 57 of the English translation of his *Fasting in Diabetes* (London, 1912) refers to the case of a man who was refused for life assurance on account of diabetes. The result of Dr. Guelpa's treatment by starvation and purgation was that on the evening of the second day of treatment the urine no longer reduced Fehling's solution. On the third day the man presented himself for life assurance examination, and no obstacle to his acceptance could be found. In grave cases sugar may sometimes vanish from the urine on a trial of von Noorden's "oatmeal diet."

Reports of Societies.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

Friday, December 13th, 1912.

Dr. A. J. HORNE, President, in the Chair.

Diagnosis of Uterine Inversion.

Dr. E. H. TWEEDY described the case of a patient sent to him with a diagnosis of *Inversion of the uterus*. She was a union patient in a far-advanced state of anaemia and shock, and half-witted. Her condition was so serious he did not dare to examine her for at least eight days. Ergot and stimulants were administered and the vagina was plugged. At the expiration of a week he found a round tumour protruding to within an inch of the vulva. It bled easily. Under anaesthesia he failed to make a diagnosis by any of the recognized methods. The cervix could not be felt. Rectal and bimanual examination afforded no information. He, however, established the diagnosis by a method not before suggested. Two fingers were passed into the vagina above and below the tumour, and these were placed on its pedicle. The feeling of the latter was unmistakably that of uterine tissue. He thought it was worth remembering that if there was inversion of the uterus with a polypus the pedicle would give this characteristic feel. He proceeded to remove the myoma, and in doing so he opened a cyst which contained fluid under great tension. There was very severe bleeding from the wound. The uterus was easily inverted by the application of three-bullet forceps. Continuous rectal irrigation was afterwards kept up for twenty-four hours. Dr. SOLOMONS said it seemed to him that the treatment accorded to the patient before operating had saved her life, whereas immediate operation would probably have killed her. The severe constitutional symptoms often associated with uterine polypi, both large and small, were never dealt with sufficiently in textbooks. He wondered if a diagnosis might have been more easily made by splitting the perineum, whereby the operation itself would have been facilitated. Dr. SHELL thought a point of interest was the reference to the palpation of the pedicle of the tumour. He found that the uterus felt like a collapsed tube, whereas a tumour was not hollow and more resistant. Dr. PRUDEN said the difficulty of diagnosis in these cases in which polypus had given rise to inversion was considerable, especially where the polypus was sessile. In such cases it became exceedingly difficult to determine how much of the tumour was polypus and how much was uterus. He congratulated Dr. Tweedy on the jubilant way in which he spoke of reversion of the uterus. He had three cases of the kind where the inversion complicated parturition, and some months elapsed before they came under treatment. In such case the reposition was effected by steady pressure applied to the fundus while the cervix was held by two-bullet forceps. He had shown at a meeting of the Section a simple repositioner which had proved very helpful in the proceeding. Dr. TWEEDY, in replying to the remarks, said he found it very easy to push back the uterus in one case, but in the second there was some difficulty.

Complications of Hysterectomy.

Professor ALFRED SMITH recorded a case in which, after performing a subtotal hysterectomy, he proceeded to make the peritoneal toilette, when he found his finger pricked by some sharp instrument. On investigating the cause he found the point of a needle sticking through the wall of a small intestine. On searching further more needles were found, some lying in the omentum, others projecting from the wall of the intestine but covered by a smooth covering, as if a diverticulum had been formed from the intestinal wall. The appendix, which was markedly hypertrophied and congested, was removed. An x-ray photograph revealed two needles and one pin in the lumen of the appendix. The patient complaining of more abdominal pains, aggravated on pressure, was skiagraphed. Two of the plates located three needles, one on the right side evidently broken, another on the left side at pelvic brim, and a third somewhere about the pubis. A second laparotomy was

performed, and all three needles successfully removed. In all, ten needles and one pin were found. The general literature of foreign body appendicitis due to sharp-pointed metallic bodies was dealt with. It was remarkable that so many needles could be swallowed with impunity, and the intestinal wall perforated, with so little disturbance to the organism; the presence of three sharp-pointed metallic bodies in the appendix was unique. The PRESIDENT said the case demonstrated further the difficulty of diagnosis. It had been suggested that these needles were probably taken in a packet when the patient was a child, so that probably all the needles were taken in at the same time, and it was well known that when a needle entered the body it travelled in the most extraordinary manner to different parts of the system. Dr. PIREFOY referred to the case of a lady who had come under his care, having swallowed, during an epileptic fit, a plate with four teeth on it. They, however, passed through the alimentary canal in a fortnight afterwards. Dr. JELLET referred to a case treated at the Adelaide Hospital some years ago in which thirty-nine needles were removed from a girl's stomach, and within two years she returned with a further crop. Dr. ROWLETTE said that some years ago, in a *post-mortem* examination at Stevens's Hospital, he found an inch and a half pin in the appendix which had given rise to abscess of the liver. He considered that foreign bodies were more common as the cause of appendicitis than reports showed.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.

At a meeting on December 13th, 1912, Mr. G. H. EDINGTON, Vice-President, in the chair, Dr. T. K. MORRO reported the last phase of the illness of a patient shown to the society on May 3rd, as a subject of *Splenomegaly*, polycythæmia, increased arterial tension, arterio-sclerosis, cardiac hypertrophy, albuminuria, and gangrene. He died on June 21st. Dr. J. H. TEACHER described the *post-mortem* findings. A large atheromatous patch in the abdominal aorta had involved the orifice of a common trunk which supplied the superior mesenteric artery and coeliac axis, producing complete occlusion. The circulation had been restored and maintained through an extraordinary development of arteries and veins in the omentum and in adhesions between the upper abdominal viscera and parietes. The principal source of this was the inferior mesenteric artery. The spleen showed a large infarction and advanced general fibrosis. The splenic artery was obliterated. There had been thrombosis of the portal vein, possibly secondary to the infarction of the spleen, and the circulation had been restored by the development of a mass of cavernous tissue between the root of the mesentery and liver. There was no increase of marrow in the long bones, and that of the ribs appeared normal. There was marked atrophy of the kidney, secondary to arterial disease. Dr. J. SHAW DUNN gave an account of the Grawitz tumour of the kidney or *Renal hypernephroma*, based on the investigation of eleven tumours of this nature examined in the pathological department of the Western Infirmary during the past three years. The tumours exhibited varied in diameter from 2 to 7 inches; some appeared well encapsuled, and others tended to invade renal tissue; their colour varied according to the degree of hæmorrhage and necrosis present, but the well-preserved tumour tissue was of a very characteristic bright opaque yellow, due to the presence of fat. Histologically, the tumour cells were shown frequently to contain abundant fat, doubly refractive material, and glycogen. Their striking dissimilarity to the renal cells had led Grawitz in 1885 to suppose that these tumours might arise from aberrant portions of suprarenal tissue, a view which held the field for over twenty-five years. Recently it had been shown, specially by Stoerk, that in cirrhotic kidneys certain areas of renal tissue might undergo metaplasia, with production of cell characters resembling those in Grawitz tumours. This was confirmed by Dr. Dunn, who was inclined to regard the tumour as a true cancer of renal tissue, probably growing from the altered renal epithelium lining minute cysts in senile or cirrhotic kidneys. Metastatic growths might occur in lung, liver, or in one or other of the bones. Dr. J. R. RIDDELL showed a series of negatives and lantern slides illustrative of *Plastic skiagraphy*. Dr. W. P. GIBB, reporting further on

the tumour of biceps muscle shown at the last meeting, submitted a note by Dr. Joshua Ferguson on the histological findings. The tumour had proved to be an angioma, spreading diffusely amongst striated muscle bundles and in the fat.

GLASGOW OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.

At a meeting on December 11th, 1912, the President, Dr. LINDSAY, showed a fresh specimen of an *Abortion sac* which exhibited a marked disproportion between the size of the embryo and the containing sac. Professor JARDINE gave a practical demonstration on the *Management of difficult labour*, showing the various manipulations on the phantom, and exhibiting the several instruments required. He also showed numerous specimens of fetal abnormalities, and in particular a full-sized pregnant uterus with Bandl's ring and rupture of the lower uterine segment. Dr. Jardine dealt first with occipito-posterior presentations, explaining the mechanism in cases which rotate normally. In speaking of non-rotated cases of occipito-posterior presentation the method of inserting the hand and producing rotation to the front, while the anterior shoulder is pushed round by the external hand, was demonstrated. Also shown, in connexion with cases in which the shoulder cannot be felt externally on account of obesity, was the method of producing rotation by pushing the fingers of the hand in the vagina upward and completing the movement from the vagina. Face presentations were next demonstrated. Easy flexion of the head by the hand—the fingers over the occiput and the thumb on the forehead—was advocated. When a tumour of the neck existed the treatment was version. Version should be performed early. When the case had become malrotated, with the chin backward, the only method of delivery, except in the case of small children, was craniotomy, done through the orbit or mouth. The difficulties encountered in impacted breech cases where the membrane had ruptured and the uterus was moulded round the fetus were attributed to the upper uterine segment retracting, the lower segment becoming thinned out, and the retraction ring gripping the child round the chest or abdomen, the heels being above the ring. In these cases the patient should be deeply anaesthetized and one foot brought down; this was generally sufficient to relieve pressure, and delivery could be effected by traction on the foot. In transverse cases early treatment by version must be done. If impaction had occurred, or where an arm was down, version, unless performed by an expert, was dangerous, on account of the probability of rupture of the uterus occurring. In these cases the child was generally already dead, and decapitation should be performed. In performing decapitation, Ramsbotham's hook might be pushed through the lower uterine segment. The speaker showed his modification of Braun's hook; it had a smaller curve and a sharp cutting edge. When an arm was down, it might be necessary to cut through the chest from the upper side of the neck to the lower axilla. Bandl's ring as a cause of obstruction was discussed. Two cases were mentioned where the ring formed a distinct ledge in front of the presenting head. The treatment advocated in these cases was Caesarean section. Sometimes cases were met with where the ring was firmly contracted round the neck, the head of the child being free; early rupture of the membranes had taken place in these cases, and often embryotomy was necessary. The ring might form in the third stage of labour and cause retention of the placenta above it—the so-called hour-glass contraction of the uterus. In contracted pelvis the question was not so much the diameter in actual inches as whether a head could get through a particular pelvis. These cases should be diagnosed early and Caesarean section arranged for when necessary. In some cases the anterior parietal presentation would come through, whereas in a pelvis of the same size a presenting head of similar size would not come through if the presentation were a posterior parietal one. It was important to diagnose these varieties of presentation as the forceps might be quite effectual in the anterior, but delivery by the forceps impossible in the posterior. In anterior cases the forceps in its traction simulated Nature's method, while in the posterior parietal presentation the instru-

ment, by pulling down the anterior half of the head, made matters worse. In posterior presentations version should be performed early, or, if possible, the posterior presentation should be changed into an anterior one by manual manipulation, the posterior parietal bone being pushed up so as to allow the anterior to come down. Forceps might then effect delivery. The methods of performing craniotomy were described and the instruments demonstrated. The value of Professor Jardine's combined instrument for crushing and extraction was pointed out.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

At a meeting on January 3rd, Dr. G. P. SHUTER, President, in the chair, the following were among the exhibits:—
Mr. OSWALD L. ADDISON: *Cirroid aneurysm* in a boy, aged 7 years. A small swelling appeared on the side of the head eighteen months ago, and during the last few months it had increased in size. On the corresponding side of the head, over the right temporal muscle, there was a large tortuous vessel about 2 in. in length, running vertically. Pulsation was marked, and the vessel wall felt much thickened.
Mr. ASLETT BALDWIN: A boy in whom he had reduced successfully a congenital dislocation of the left hip joint by *Lorenz's method*. The hip appeared to be quite sound; movement was free, and the patient was able to play football. Two radiographs illustrated the condition before and after reduction; in the latter picture the head of the femur was opposite, but apparently not in the acetabulum. It was explained, however, that this was due to the fact that the cavity was filled with fibrous tissue at the time the radiograph was taken. After some months this fibrous tissue was absorbed by the pressure exerted by the head of the femur, and the latter entered into its natural position in the socket.
Dr. T. C. STOREY (for Dr. H. J. Davis): A case of *Epithelioma of the middle ear* in a man, aged 58, with a long history of discharge from the ear. Few cases had been reported, and in literature it was stated that such growths originated usually from the tympanic end of the Eustachian tube, and followed trauma. In this case there was no history of an injury.
Mr. N. BISHOP HARMAN: *Congenital deformity of both fore-limbs* and of the *External recti muscles* of each eye in a boy, aged 16, the only child of a father who had similar deformities of the hands. Both were shown by Dr. C. W. Chapman at the Clinical Society of London in 1900, but the ocular defect of the son was not recorded. In discussing this case Dr. SEYMOUR TAYLOR referred to the subject of "maternal impressions" as a cause of congenital deformities, and Mr. BISHOP HARMAN replied that here there were two generations showing a similar but progressive defect in development. Since it was hereditary it was due to a germ-plasm defect, and a maternal impression that could produce this inheritance must have occurred when the germ plasm which grew the elder of these two men was laid down. This meant that the maternal impression affected the grandmother. The first generation "sinned," and the second received bad germ plasm which figured in the third and fourth generations. Mr. BISHOP HARMAN also showed a case of *Monocular albuminuric retinitis* in a woman aged 63. She had some degree of hemiplegia a year ago, and was now complaining of eye trouble. In the right eye the macula was dotted with white patches of exudate with minute haemorrhages, and the disc was blurred. The left eye was free from changes with the exception of marked angio-sclerosis, which was present in both eyes. Having been asked why one eye only was affected in a general disorder, Mr. Bishop Harman suggested the possibility of the affected eye having had some long-standing defect, such as an error of refraction, since he had noticed that when one eye had had poor vision for many years degenerative changes were apt to appear in that eye earliest. In view of the gloomy prognosis associated with albuminuric retinitis, Dr. SEYMOUR TAYLOR asked for an estimate of the probable duration of life in this elderly patient. Was the condition as grave a sign in old people as in early adolescents? Mr. BISHOP HARMAN replied that the prognostic significance of albuminuric retinitis must be answered by a reference to the age of the patient. In young subjects when retinal changes appeared they appeared early and were of serious import. In the elderly such changes were

much later in appearance and did not imply so grave an issue. He had watched some cases for several years.
Dr. ARTHUR SAUNDERS: *Paraplegia after whooping-cough* in a child aged 5. The paralysis developed a year ago, and was due to supervene on a paroxysm of coughing, and was of the flaccid type. The sphincters were unaffected, and the abdominal and cremasteric reflexes were present.

HUNTERIAN SOCIETY.

At a meeting on December 11th, at St. Bartholomew's Hospital, the following were among the exhibits:—
The PRESIDENT (Mr. A. H. Tubby): A specimen of growth removed from the large intestine of a man aged 52. Clinically, there was a swelling in the right lumbar region. There had been no vomiting, constipation, or signs of obstruction. The diagnosis lay between an enlarged cystic kidney and a *Growth of the large intestine*. An exploratory operation showed it to be the latter, and the growth was enucleated and some enlarged glands dissected out. Some twelve months after the operation the patient was entirely well.
Mr. GIRLING BALL: (1) A vault of the skull, the seat of an *Osteoplastic flap operation* two years before death. Also shown was the brain of the patient, a girl aged 20, the subject of a right-sided hemiplegia since birth. There was a lack of development of the whole of the convolutions in front of the Rolandic fissure, the ventricle in this side (right) being markedly distended with clear fluid. The condition seemed to be one of porencephaly. (2) A case of *Carcinoma of the pylorus* to illustrate the condition of a gastro-enterostomy ten days after the operation.
Dr. W. LANGDON BROWN: A case of malignant *Ulcer of the stomach* with communication into the transverse colon.
Dr. WESTERMAN: A case of *Pharyngo-mycosis* simulating follicular tonsillitis.

Rebicus.

IMMUNITY AND VACCINE THERAPY.

THERE has been much need for a handy textbook on immunity suitable to those, not actually engaged in laboratory research, who desire (and who does not?) to learn the main facts regarding the modern development of pathology that is making itself so felt in practical medicine. The *Manual of Immunity*,¹ by Dr. ELIZABETH T. FRASER, admirably meets this demand. The various textbooks on immunity that have been published, chiefly abroad, are so long, involved, and tintured with the ideas and theories of the particular schools from which they have emanated that their only use is as works of reference to other laboratory investigators, and a perusal of such works by the practitioner would lead him to conclude that a working knowledge of the problems and advances can only be gained, if at all, by many years of practical study. Any one who would sift the wheat from the chaff and explain in simple language the real facts of immunity must needs have an intimate experience of the work of the various schools, a good critical faculty, and the gift of lucid exposition. Miss Fraser, who has herself done good original work on immunity, is to be envied the possession of these qualifications; the manual which she has written is a pleasure to read, and the charming little touches of humour here and there add to the interest of the style. The first chapter is devoted to a historical survey, brief but lacking in no essential particulars, of the observations that go to make up our present knowledge. The respective parts played by the body fluids, the cells, and the micro-organisms are separately considered in successive chapters, and one is gradually introduced to the application of the knowledge to diagnosis. Such reactions as the Widal test, the precipitin reaction, opsonic estimations, Wassermann reaction, and even the recent serological methods for the diagnosis of malignant disease, are carefully explained. We gather that the authoress, after considerable experience of the technique, does not place any great reliance on opsonic estimations either in diagnosis or during the treatment of bacterial

¹*A Manual of Immunity: For Students and Practitioners.* By Elizabeth T. Fraser, M.D., late Assistant Bacteriologist, Glasgow Royal Infirmary; Beit Research Fellow, Glasgow; MacLachlan and Sons. 1912. (Cr. 8vo, pp. 209. 5s. net.)

diseases. The rationale of complement deviation tests is clearly set forth, so that the Wassermann reaction can easily be understood. Miss Fraser is rightly scornful of the "simplifications" that have recently been introduced: all of them accentuate and add to the fallacies of the original method. To obtain reliable results, so far from attempting to simplify Wassermann's technique, one must adopt rigorous controls of the variable factors in the reaction, a precaution to which even Wassermann does not pay sufficient attention. She prefers Boas's method, which is described at length, and which is certainly very reliable, though in certain respects it does not seem to be as scientifically perfect as the Browning-Mackenzie method, in which non-variable antigens are employed, and where the variability of the complement is accurately ascertained on each occasion. A chapter is devoted to the practical consideration of serum and vaccine therapy, and the phenomena of anaphylaxis are briefly reviewed. Ehrlich's "side-chain" theory, instead of dominating the book as is generally the case, is rightly relegated to an appendix, so that the reader is in a position to understand it clearly and to form some appreciation of its value. A glossary of technical terms brings the book to a close. We congratulate Miss Fraser on this interesting little manual, and are safe in predicting for it a wide circulation.

In the recently issued fourth edition, Dr. ALLEN has considerably enlarged and completely rewritten his work on *Vaccine Therapy*.² Whilst continuing to uphold his belief in the accuracy of the determinations of the opsonic index, when performed by skilled hands, he admits, we are glad to find, that adverse criticisms have served a useful purpose by leading to a closer scrutiny for possible sources of error, and to improvements of technique for the purpose of avoiding them. He also concedes that there is a difficulty, especially with regard to the tubercle bacillus, in explaining the precise scientific significance of the opsonic determinations of the phagocytic activity of the polymorphonuclear leucocytes. He writes:

Phagocytosis of the tubercle bacillus is normally performed, not by the polymorphonuclear leucocytes which require prior opsonization of the bacilli, but by the lymphoid and endothelial cells, which may well be capable of dispensing with this preliminary.

Incidentally it is to be regretted that the author does not make his views on this matter a little clearer. Does he mean that normally, in the living tissues, polymorphonuclear leucocytes do not ingest tubercle bacilli? And to what type of "lymphoid" cells does he attribute phagocytic properties? But, to return to the main point, he proceeds:

It might well be asked, therefore, what earthly use is there in determining the phagocytosis performed by certain cells which normally do not perform the task after opsonization of the bacilli when normally this may not be requisite?

This is rather clumsily expressed, perhaps, but still one must admit that it is a pertinent question. His answer, and a very fair answer too, is that the weight of the above objection is minimized by the results of experience, taken in conjunction with clinical observations, which show that "whatever may be the deficiencies of the method, it yet does furnish something of a reliable guide to the processes whereby the body tissues defend themselves against invasion by the tubercle bacillus." This is a subject upon which further light might probably be thrown by animal experiment. It should be possible, by recording the opsonic indices of tuberculous animals and then killing them at various stages of the disease and examining their tissues, to determine how far the opsonic index really is a reliable guide. Whatever one may think about Dr. Allen's theories, where there is room for differences of opinion, in two respects his book is unquestionably good. It gives an excellent account of the technique of opsonic work, and it provides a useful record of the progress which has been made in the applications of vaccine treatment to the bacterial diseases of the various parts of the body.

² *Vaccine Therapy: Its Theory and Practice*. By R. W. Allen, M.D., B.S. Fourth edition. London: H. K. Lewis, 1912. (Demy 8vo, pp. 454; charts 12. 9s. net.)

The first edition of Dr. JULIUS CITRON's book on immunity, diagnosis, and therapeutics³ was published in 1910; the second edition consists of a series of nineteen lectures, which are intended to place before the student and practitioner the essential facts of immunity in so far as this subject lends itself to practical therapeutics. Dr. Citron has fulfilled his object with conspicuous success. He has avoided the lengthy excursions into theory which few except those actually engaged in research can be expected to master, but at the same time he never shirks the difficulties of his subject. Writing in a clear, business-like style, he tells the practitioner exactly what he ought to do and provides him with the scientific reasons for every step he takes. Dr. Citron is didactic without being unduly dogmatic, and whenever he expresses definite opinions on matters which are still the subject of controversy it is evident that he has no intention of forcing his own ideas upon the reader, but aims at presenting him with definite information the clear comprehension of which will enable him to think for himself. The two chapters on the use of tuberculin in diagnosis and treatment form an excellent introduction to this subject of rapidly increasing importance; the advice given is good on the whole, but perhaps some authorities would think that the author might have warned the novice a little more strongly against possible risks attending the application of the ophthlmo-reaction. Upon the obscure question as to the scientific explanation of the tuberculin reaction Dr. Citron propounds an interesting theory, the value of which must be left to the future to decide; at all events, it may serve as a useful working hypothesis, and it is important that the clinician should have at the back of his mind some sort of reasonably scientific explanation of the action of tuberculin if he is to treat his patients intelligently. Lecture VII, on diphtheria antitoxin, may be specially recommended to practitioners who are not content with merely injecting something from a bottle but want to understand the why and wherefore of what they are doing. Opsonins come in for their fair share of recognition, and we are glad to see that the enterprise and originality of Sir Almroth Wright is now gaining from German scientists the appreciation he deserves. Dr. Citron is also particularly good in his lectures on the Wassermann reaction, anaphylaxis, and the chemical therapeutics of atoxyl, salvarsan, and allied products.

DIABETES AND SOME OTHER METABOLIC DISORDERS.

THE portly volume on diseases of nutrition,⁴ one of a series of manuals published under the same direction, is the work of F. RATHERY, A. GY, L. BABONNEIX, and J. CASTAIGNE. The first writes on rheumatism, obesity, emaciation, gout, oxalaemia, diabetes mellitus and insipidus, and "arthritis"; Babonneix writes on osteomalacia and rickets, while Castaigne and Gy collaborate in the articles on alcoholism, saturnism, and the other intoxications. The articles are written in a systematic way, and generally give an adequate account of the present position of knowledge of the various subjects with which they deal; the positive statements are for the most part based on adequate authority, but there is a disposition in the writers to rely too exclusively on their own countrymen and to ignore views which have not an autochthonous origin. For example, under pellagra there is no mention of Sambon's work or of the occurrence of cases in Scotland, where maize is not an article of diet. Further, it is doubtful whether outside France there are many believers in "arthritis," to which an article is devoted; it is defined as "a morbid temperament which reacts by a great vulnerability of the connective tissue, with a tendency to hyperplasia, to fibrous transformation, and to fibrous retraction." M. Babonneix's article on rickets may be singled out for special praise. It is surprising to read that the author of the article on diabetes would "accept for insurance every case of fat diabetes

³ *Die Methoden der Immunodiagnostik und Immunotherapie und ihre praktische Verwertung*. Von Dr. Julius Citron. Zweite erweiterte und verbesserte Auflage. Leipzig: Georg Thieme, 1912. (Roy. 8vo, pp. 300, with illustrations, M. 8.)

⁴ *Manuel des maladies de la nutrition*. Sous la direction de MM. G. M. Debove, Ch. Achard, J. Castaigne, Par L. Babonneix, J. Castaigne, A. Gy, et F. Rathery. Paris: Masson et Cie, 1912. (Royal 8vo, pp. 1080; figs. 119. Fr. 20.)

over 35 and cases of simple diabetes (that is, cases in which the sugar disappears from the urine on strict diet) whose coefficient of assimilation is sufficiently high and whose urine does not give Gerhardt's reaction" (the ferric chloride reaction). As cases of grave diabetes often show in the early stages most gratifying reaction to treatment, and as many, if not most, fat diabetics are bad lives, we can only express our disagreement with such teaching. Again, in the same article we are told that "gluten bread" contains only 10 to 15 per cent. of starch. From numerous analyses we can say that this is misleading; the late Mr. Callard told the writer of this notice that it was impossible to bake gluten bread with less than 25 per cent. of starch, and at that time all the French gluten breads sent here contained 35 to 40 per cent. No doubt breads made from a milk basis with the addition of coconut or almond flour may contain only 5 or 6 per cent. of carbohydrate, but these are not properly termed "gluten bread." The article gives a table of a "strict diet," but no detailed instructions for feeding patients after they have gone through this stage. The writer describes the dyspnoea of diabetic coma as causing "terrible anguish"—a statement we are unable to confirm. In the discussion of diabetes insipidus no distinction is drawn between those cases which begin with thirst and those which begin with polyuria; cases in which hydronephrotic degeneration of the kidney has been found associated with grave deficiency of urea are not even mentioned.

This book on the relations of carbohydrate metabolism to internal secretion, by Dr. PAUL HÖCKENDORF,⁵ is a review of the work done on this subject during recent years, especially in its bearing upon the pathogenesis of diabetes. The plan of the book is to describe in successive chapters the advances that have been made in our knowledge of (1) the nerve centres that preside over the production of glycogen and of sugar, especially the work of Ivor Bang, published in Hofmeister's *Beiträge* (1907, No. 10), (2) on the formation of sugar from fat by Magnus Levy and his co-workers, (3) the work of Missiroli and others on the influence of the thyroid upon the formation of sugar by the splitting of proteins, (4) that of B. Aschner on the fat-splitting function of the pituitary body, and (5) the significance of the internal secretion of the parathyroids for sugar synthesis and urea formation. The last chapter is a summary of the bearing of these discoveries on the theory of diabetes. According to the author, the proximate cause of diabetes is the inability of the liver cells to store glycogen, this in turn being due to insufficiency of the glycogen-forming ferment either in consequence of deficiency of hepatic ferment or of the pancreatic ferment which combines with the former to produce glycogen or of both at the same time. He suggests that the failure of hepatic ferment may be caused by the action of abnormal metabolic acids on the liver cells or by functional aberrations of the glands concerned in sugar synthesis, the thyroid, pituitary body, and parathyroids. The pancreatic defect may be due to primary disorders of that organism, especially to fibrosis. At first the excess of sugar in the blood is converted into fat so that no glycosuria occurs, but later a stage is reached when this process of conversion is no longer possible, and hyperglycaemia and glycosuria result. The presence of hyperglycaemia paralyses the glycogen-forming nerve centre, while a reduction of the sugar in the blood restores its function and permits the resumption at least in part of the glycogen-forming function of the liver and pancreas. The failure of the liver to store up glycogen leads to "glycogen hunger," and consequently to a nearly permanent process of synthetic sugar formation, so that a vicious circle is established.

THE SNAKES OF SOUTH AFRICA.

In the second edition of *The Snakes of South Africa*,⁶ Mr. F. W. FITZSIMONS has published much first-hand information about snakes that is not only of great interest

to the scientist but also of practical use to the traveller. As director of the Port Elizabeth Museum the author has for many years kept snakes in confinement, but the book is in no sense written in the style so often associated with a museum official. He gives evidence throughout that, in addition to his museum duties, he has had numerous opportunities of observing the habits of snakes in their native haunts, and has thus been able to control and correct impressions gained from observing these reptiles in confinement. The author gives us a good deal that is new with reference to the mambas—one of the most deadly of all poisonous snakes—and records many hitherto unobserved facts about the ringhals or spitting snakes. Apart from the general interest of the book to naturalists, there is much practical information as to the treatment of snake bite. The author has recorded, very impartially we think, the results of his investigations upon the numerous native "cures" for snake bite, and has conclusively demonstrated their worthlessness. On the other hand, he gives the results of many of his own experiments with antivenene, and concludes that this serum has not only prophylactic properties, but is the only known reliable antidote when once the snake poison has entered the general circulation. If injected in doses of 25 c.cm. (intravenously if possible) its effect is very rapid, and there is no doubt that it should be given, if practicable, even in apparently hopeless cases. Reference is also made to the treatment by ligature and the early application of potassium permanganate to the freely-incised wound. The book is illustrated with many good photographs and one indifferent coloured plate.

"MEAT HYGIENE."

It was not until some six or seven years ago, and then only in consequence of the startling disclosures that were made, that the United States Government paid any serious attention to the control of the food supplies of that country. The methods of inspection and the regulations then introduced were largely based upon those in force in Germany, so that the *Textbook of Meat Hygiene*⁷ written by Dr. EDELMANN, the Royal State Veterinarian of Saxony, has not inappropriately been translated by two expert officials of the United States Bureau of Animal Industry. The explanation (or, to use the exact words of the author, the justification) of the use of the term "meat hygiene" is that it includes anything which concerns the procurement of wholesome meat foods for man, their value to the public health, and the dangers which threaten the consumers of diseased or unsound meat. Having in mind this broad conception of his subject, the author has produced a work which is far more than a treatise on the examination and inspection of meat, on methods of slaughtering, and the construction of abattoirs. All these matters are dealt with, and in a detailed manner, but there are chapters also on the conservation of meat, on meat poisoning, on the *post-mortem* changes in meat, and on abnormal conditions and diseases, infectious or otherwise, of food-producing animals. The translators have included an interesting account of the methods of inspection of meat now enforced in America. The principal official in charge of inspections at all stations where slaughtering is done must before appointment have completed a three years' course at a reputable veterinary college, of which institutions only fourteen are recognized. A Civil Service examination has then to be passed, when the successful candidate is employed for six months on probation. If this is satisfactory he is not even then given full power to pass or condemn meat, but is placed with an experienced inspector that he may learn the law and regulations and the methods of their application. Promotion is said to depend entirely upon efficient and faithful service. In the laboratories connected with the Bureau of Animal Industry are officials selected through Civil Service examination in the principles of bacteriology and chemistry, with special application to meats. There are also meat inspectors of two classes, to examine live stock and the slaughtered animals

⁶ *The Snakes of South Africa, their Venom and the Treatment of Snake Bite*. By F. W. Fitzsimons, F.Z.S. New edition. Cape Town: T. M. Miller; London: Longmans, Green. 1912. (Roy. 8vo, pp. 533, with over 200 illustrations. 12s. 6d. net.)

⁷ *Textbook of Meat Hygiene, with Special Consideration of Antemortem and Post-mortem Inspection of Food-producing Animals*. By Richard Edelman, Ph.D. Translated by John R. Mohler, A.M., V.M.D., and Adolph Eichorn, D.V.S. London: J and A. Churchill. 1912. (Roy. 8vo, pp. 398; 152 illustrations and five coloured plates. 21s. net.)

respectively. Neither class seems to be required to have special training. The law is very stringent as regards the bribery of these officers, the minimum punishment for giving or receiving a bribe being a fine of £1,000 and one year's imprisonment. The work is profusely illustrated, and the coloured plates are admirably executed.

ARGENTINA.

THE readjustment of any fixed idea concerning hitherto unknown persons or places is usually rather an unsettling process; and to those who have always been accustomed to hear the Argentine Republic spoken of as a veritable El Dorado it may cause some surprise to learn that this great wealth is quite a modern development, and the present flourishing condition of the land of comparatively recent date. It is little more than a hundred years ago since the first real attempt was made to utilize on a large scale the practically unlimited resources of this vast country; whilst for two hundred and fifty years previously that which is now the richest and most prosperous of the South American Republics had been regarded merely as the vassal State of Chili and Peru. Mr. W. H. KOEBEL, in his most interesting book, *Argentina, Past and Present*,⁸ relates that the Spanish explorers who in the middle of the sixteenth century took possession of the territory on the banks of the River Plate were chiefly concerned with it as a means of opening up a fresh route into Peru and the adjacent countries; and it was not until 1810, when the colony broke away from Spain, that the foundations were laid of her present prosperity. The extent and magnitude of this prosperity may be gathered from Mr. Koebel's enthusiastic account of this modern land of Canaan. He writes with the great advantage of first-hand knowledge, and his facts have therefore a value apart from their own interest, as his descriptions possess a charm quite independent of their literary merit. There is no lack of the latter, however, for Mr. Koebel writes with ease and fluency, and has the happy knack of bringing a scene before the eyes of his readers in a few graphic sentences. His narrative makes excellent reading, even when regarded solely as an unusually interesting book of travels; but the author has had another and more serious object in view. His pages are full of sound practical advice as to the life and prospects which lie before the young Englishman who meditates starting life afresh in this corner of Spanish South America. The intending emigrant could hardly do better than make a careful study of this attractive volume; it is well printed in large, clear type, and profusely illustrated with excellent photographs.

NOTES ON BOOKS.

ALTHOUGH the Royal Sanitary Institute established an examination for health visitors and school nurses more than four years ago candidates have hitherto had to consult a variety of textbooks when preparing for the examination. Dr. HUTT's *Hygiene for Health Visitors, School Nurses and Social Workers*⁹ appears, therefore, very opportunely, for it has been designed to cover the ground of the syllabus of the institute. The initial chapter on physiology is clearly and concisely written and in language sufficiently plain not to alarm the student at the outset. Each subject is thoroughly treated in its appropriate chapter, and on nearly every page there are practical hints which cannot fail to be of service to health visitors or school nurses when actively engaged in carrying out their duties. The work is thus far more than a textbook for examination purposes and should assist in increasing the efficiency of the certificated official. The chapter on the prevention of communicable disease is one which a zealous health visitor would find herself constantly wishing to refer to in the course of her work, for it would enable her to explain intelligently why the advice she tenders is correct and why it should be carried out. There are over seventy illustrations in the book, nearly all of which have been

judiciously selected. They add materially to the value of the work, which we can confidently recommend to those for whom it has been written.

It is difficult to believe that every year there is so much that is new in surgery that it requires a volume of over six hundred pages to tell about it. But in the *Year Book on General Surgery for 1912*,¹⁰ edited by Dr. JOHN B. MURPHY of Chicago, there seems to be something new on every page. If it is not a new operation or a new method of technique it is a new view or a new opinion. And so knowledge grows. The editor apparently makes no claim that the new thing will find a permanent place for itself, but he is content to let it be found in his pages—opinion based on experience will soon find for it a true place. The introduction is from the editor's vigorous pen. He thinks that surgical technique is now almost universally thoroughly established, that the average major operation is performed in all large clinics with an almost identical detail, that the immediate management of fresh wounds is a policy of non-interference except for removal of injured infected areas. But we note with some surprise that "simple fractures are very commonly plated with the Lane or other bone-plate on the third or fourth day after the accident." We feel sure that the percentage of primary operated fractures is still so low that the word "commonly" is unwarranted. However, on a later page an important qualification is introduced when he says that in the discussion of the relative values of the operative and non-operative methods the personal equations of both operator and patient must be considered in each individual case. The arrangement of the matter is such that it can be easily followed, the index is copious, and the book is one which ought to have a place very close to the surgeon's elbow on his study table.

In a small book entitled *On Gastroscopy*¹¹ Dr. WILLIAM HILL has brought together a great deal of information on the subject indicated. His main object is to describe the special method of examining the oesophagus and stomach devised by himself to secure both a direct and indirect vision of the part under observation. Incidentally he describes and illustrates practically all the methods at present known. A good deal of the matter is a rehearsal of statements made by the author at various times in our own columns. The volume concludes with a valuable bibliography of the subject.

The twenty-fourth volume of *The Transactions of the Southern Surgical and Gynaecological Association*¹² relates to the proceedings of this body at its meeting in Washington some twelve months ago. It is, as usual, freely illustrated by plates and woodcuts in the text. The different papers read and discussed number as many as forty-two, and cover between them the majority of the conditions coming within the range of general and gynaecological surgery. Among them is a paper by Dr. C. L. REED entitled "The Farce of Medical Ethics," the particular point of medical ethics in question being the dishonesty of the medical attendants of patients dividing with consultants the fees received by the latter. From the discussion which followed it would appear that this medical crime is somewhat prevalent in certain parts of the United States.

In the volume entitled *First Steps to Nursing*¹³ Miss MABEL CAVE, Matron of Westminster Hospital, gives a comprehensive account of what the occupation of nursing has to offer, and deals in detail with the qualities, physical and moral, which those who desire to become nurses should possess. She also gives a very good idea of the work they have to perform and of the knowledge which as probationers they will be expected to acquire. It is an informing and well-written volume, and deserving of the compliments paid to it by Sir John Wolfe Barry in the preface supplied by him.

⁸ *Argentina, Past and Present*. Edited by G. G. P. Head, M.D., and Colonel Mix, A.M., M.D. Volume ii. *General Surgery*. Edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in the Northwestern University, Chicago. Chicago: The Year Book Publishers, 1912. (Cr. 8vo, pp. 616; plates 33, figs. 49. Dols. 2.00.)

⁹ *Hygiene for Health Visitors, School Nurses and Social Workers*. By William Hill, B.Sc., M.D. London: John Bale, Son, and Danielsson, 1912. (Demy 8vo, pp. 53; figs. 47. Price 3s. 6d. net.)

¹⁰ *The Transactions of the Southern Surgical and Gynaecological Association*. Vol. xxiv. Edited by W. D. Haggard, M.D. Nashville, Tenn.: Published by the Association, 1912. (Med. 8vo, pp. 693.)

MEDICAL AND SURGICAL APPLIANCES.

Axis Traction Forceps.

DR. E. C. STACK (Barton-on-Trent) writes: The advantages I claim for the design of tractor illustrated in the accompanying drawing are that the forceps have the very simple attachment of the original "Neville's," which enables them to be used equally well with or without the tractor. Also the tractor can be put on or taken off at any stage of the delivery. They differ from and are superior to the original "Neville's" in that the latter were admittedly

not in the real pelvic axis, while my tractor, $1\frac{1}{2}$ in. longer in the longitudinal limb, gives practically the same axis of traction as Milne Murray's and the other more recent

instruments, an axis through which force is much more economically applied and delivery more easily effected than in the original "Neville's." With forceps of this design the general practitioner has a reliable instrument for all those easier cases where instrumental delivery may be desirable, and at the same time a powerful help in really difficult midwifery. The blades can be made to suit the wishes of each user.

BOARD OF EDUCATION.

FOURTH ANNUAL REPORT OF THE MEDICAL OFFICER.

THE fourth annual report¹ of the medical officer to the Board of Education, which made its appearance some two months later in the year than its predecessor, is divided into fourteen sections, each dealing with one or more of the various aspects of school work, and some eight appendices. Nominally it relates only to the year 1911, but it contains information as to many events subsequent to the end of that year.

An introductory chapter, in which the contents of the volume are described as a summary of work done rather than a full appreciation or scathing criticism thereof, indicates certain main tendencies perceptible during the year.

(a) Concurrently with improvement and extension of arrangements for remedial treatment (which will be further encouraged by the Treasury grants) local education authorities are taking a more comprehensive view of their responsibilities.

They realize that the prescription of drugs, the performance of operations, and similar forms of remedial treatment do not necessarily go to the root of the matter or cover the whole field, and that any effective scheme for the upbringing and equipment of the subnormal child must involve the liberal use of such preventive and curative means as physical exercises, provision of meals, manual training, and special and improved methods of education.

(b) Consonant with the general character of the policy set forth by the Board of Education in sundry memorandums, the active interest of a good many local education authorities is extending outside the limits of actual school life. Hence they are endeavouring to make the work of school hygiene (a term apparently used to cover every measure concerned in the medical guidance of the education of children) effective by means calculated to improve the physical and domestic influences to which a child is submitted before it reaches the age of 5 years and thus comes directly under the care of the education authority. Similarly, they are regarding the mental and physical fitness of the child for good employment on leaving their schools as a criterion of the methods adopted thereat, and are becoming more and more reluctant to lose touch with the leavers when they obtain their first employment. Among other results has been the bringing into existence of work described as "mother-craft," which is stated to be having an indirect but beneficial effect on

the health and rearing of children prior to their attainment of school age.

(c) During the year was demonstrated the necessity—if a school medical service is to be effective—of the whole work done in connexion with schools being under the jurisdiction of the local education authority, which should place the school medical officer in such a position that he can really be responsible for the unification of all the various activities concerned. These are medical inspection, medical treatment, sanitation of schools, provision and management of special schools for the defective, the teaching of physical training and personal hygiene, and the feeding of school children. Only if properly correlated can the full value of these contributory activities be secured.

MEDICAL INSPECTION.

Numbers Inspected.

Satisfaction is expressed at the fashion in which local education authorities have grappled with the duties imposed upon them in regard to medical inspection. Their arrangements for the year ending July 31st, 1912, included the inspection of about a million and a quarter entrants and leavers; while at least a quarter of a million ailing or defective children were specially inspected, apart from the requirements of the code. Besides this, in over a hundred areas arrangements were in action for the inspection of groups intermediate between the entrants and leavers. Several authorities have completed the inspection of all the children on their rolls.

Schedule of Medical Inspection.

The schedule of medical inspection originally suggested by the Board, and in regard to the suitability of which there was some dispute, is stated to have worked well. Few defects, it is believed, are overlooked when the schedule is properly used, and little or nothing that might be regarded as investigation of an inquisitorial or unnecessarily elaborate character has taken place. In the case of 344 schools permission has been accorded to hold the inspection elsewhere than as originally prescribed, namely, on the school premises.

Organization.

Satisfaction is also expressed at the amount of co-ordination secured between the Public Health and the School Medical Service. At the end of the school year terminating July 31st, 1912, schemes of medical inspection had been approved in 302 out of a total of 317 areas, and in 243 of these the school medical officer was also medical officer of health. In 135 areas such medical officer was not deemed to require an assistant, but in the other 167 areas there were altogether 597 assistants, 212 being whole-time and 385 part-time officers. In the 15 areas whose arrangements had not been approved at the time of writing the report (October, 1912), there were 45 school medical officers. The School Medical Service for England and Wales thus consisted of 943 medical practitioners wholly or partly employed in this work, 74 of them being women. The arrangements for medical inspection in the county of London, which in previous reports were the subject of severe animadversions, are detailed, but no opinion concerning them is expressed beyond saying that their reorganization, which was in view at the time of the last report, had since been more or less completed.

Nurses and School Attendance Officers.

In more than two-thirds of all the areas nurses or health visitors are employed in connexion with the school medical service. Those in the direct employ of the authority, either as whole or part time officers, numbered 632, while in some other areas nurses were supplied as required by local nursing associations. Some progress was also made during the year in bringing about closer co-ordination between the school attendance department and the medical service. A school-attendance officer, especially if he be a whole-time officer, can be of great service to the medical department by keeping it posted up in regard to absences due to medical causes.

Miscellaneous Matters.

During the year a large number of special inquiries by school medical officers or their assistants were either in

¹ Annual Report for 1911 of the Medical Officer to the Board of Education, 1912. London: His Majesty's Stationery Office. (Med. 8vo, pp. 324. Price 1s. 5d.) (Cd. 6530.)

progress or completed. The diversity of the questions to which they related illustrate the comprehensiveness of school hygiene. Apart from the interest of the results of such inquiries and their possible importance from an educational point of view, local education authorities are advised that they will do well to encourage work of this order. In an increasing number of areas the authorities are undertaking medical inspection not only of elementary but also of secondary schools. In the teaching of physical exercises increased interest and steady improvement is being shown. In Essex this work is under the inspection of the school medical officers, and this should everywhere be the case. The instruction in hygiene given at the training colleges, as evidenced by the results of written examinations thereat, is still not satisfactory. The Board regards with special interest all efforts aiming at stimulation of the enthusiasm of teachers in regard to physical education and increasing the effectiveness of their methods, for wise physical education of children is a matter of extreme importance. In regard to sanitary and lavatory accommodation at schools, steady improvement was visible.

THE PHYSICAL CONDITION OF SCHOOL CHILDREN.

As in previous reports the section on the physical condition of school children consists mainly of more or less lengthy excerpts from the reports of school medical officers; little attempt has been made to correlate them or to draw therefrom conclusions as to the different forms of defect in England and Wales as a whole. This year, however, the account of matters is preceded by an excursus on the general subject of medical inspection.

It would appear that some medical officers confine their work to the detection of defects which directly influence a child's capacity for benefiting from the educational opportunities afforded it, and this does not meet Sir George Newman's view of what should be done. The medical inspection of any child should, he holds, be made of direct benefit to that child, and it is the beginnings of disease that should be sought out. Not only is a higher degree of clinical study and investigation required than has been rendered in some areas, but a more thorough appreciation of disease as a crippling agency in the child. The whole life and condition and circumstances of any child under inspection in relation to disease should come within the purview of the medical inspector.

Solid progress in this matter depends upon two broad conditions—first, upon the medical inspector's *professional work*, his medical knowledge, his accuracy, caution, thoroughness, and particularly upon his avoidance of besetting fallacies, both in his examination and in his deductions and interpretations; and, secondly, upon his capacity as a *practical administrator*. The fulfilment of the first condition calls for imagination, as well as clinical ability, exact observation, and experience; the school doctor must learn to understand much more fully than hitherto the sequelae of even minor morbid conditions. The fulfilment of the second demands a wide knowledge of the circumstances of the case, and of what is expedient, practical, and reasonable in the way of remedy or prevention. In both parts of his calling, its medical side and its administrative side, the school doctor needs to carry with him the true spirit of research and investigation into the unknown, combined with common-sense knowledge of things as they are and of the powers which his authority and the law have placed in his hands.

Malnutrition.

Such figures as are supplied indicate great variation in the prevalence of malnutrition. A considerable proportion of the ill-nourished children rank well in point of intelligence. For such children, it is noted, the ordinary school curriculum is in some respects unsuited. Stress is laid on the definite value, in connexion with estimates of malnutrition, of weighing and reweighing children at different periods.

Uncleanliness.

Much still remains to be done before the discreditable conditions of uncleanliness among many school children can be removed. It is continuous, not spasmodic, action in this connexion that is of value. The less the attention paid to personal cleanliness in the child's house the greater the need for inculcating self-respect in this regard at school. The Board is prepared to consider proposals from local education authorities for the installation of shower baths; in some areas these already exist.

Defective Vision.

The number of authorities which have made special provision for the detection of defects and diseases of the eye has increased, and is increasing, but by this time there should be facilities for the adequate examination and treatment of all cases of defective vision in every area.

Defective Hearing.

In most areas estimation of the degree of defective hearing is not carried out with sufficient exactitude: the whisper test is described as the most suitable. The inadequacy of the provision in most areas for the prompt and persistent treatment of the allied conditions, discharging ears, enlarged tonsils and adenoids, should receive the serious attention of their authorities. Stress is laid on the necessity of after-treatment if an operation for adenoids or enlarged tonsils, however skilfully performed, is to be of much utility.

Ringworm.

Attempts to eradicate ringworm cannot be successful unless notice is taken of its occurrence in children under school age. The saving in school attendances is very great in areas in which x-ray, not drug, treatment is in use (average school attendances lost at Bradford under x-ray treatment 35, as compared with 287 under drug treatment).

Heart Disease.

Discontent is indicated with regard to the amount of attention paid to the subject of heart disease among school children. Its diagnosis is not difficult as compared with that of tuberculosis, and many cases are probably overlooked. Treatment for acute disease cannot be properly undertaken, but much can nevertheless be done to prevent the extension of defect and bring about early compensation. The kind of attention which should be paid to such children is described.

Tuberculosis.

The reports show further diminution in the number of cases of tuberculosis diagnosed, and this is regarded by Sir George Newman as difficult of explanation. The real diminution is probably not equivalent to the diminution observed since 1908, yet the amount of attention devoted to the subject is probably greater than previously. Possibly some part of the decline is due to the exclusion of tuberculous children from school. The experience of school medical officers as a whole appears, it is said, to show that pulmonary tuberculosis in a form which can be diagnosed with certainty is rare among school children. The arrangements for treatment appear to have undergone not much development during the year under review. The existing provision for the treatment of tuberculous school children is altogether insufficient, especially in regard to surgical tuberculosis. In selecting sites for new schools the provision of facilities for open-air instruction should be borne in mind; likewise the desirability of establishing sleeping camps in connexion with open-air schools, or even in playgrounds of ordinary elementary schools. The relationship of the tuberculosis dispensary to the school medical service will need careful adjustment in order to secure effective co-ordination. An ordinary medical inspector is not always practised in the diagnosis of pulmonary tuberculosis, and the power to refer tuberculous children to specialists might be of great assistance. Subject to certain provisos, the Board considers that a school clinic and a tuberculosis dispensary might, if necessary, be housed in the same building. In regard to tuberculosis in general, the following are the main points submitted for the consideration of education authorities:

1. Improved arrangements for securing the detection and diagnosis of the disease among children, possibly in association with the tuberculosis dispensary when such exists.
2. The provision of additional accommodation for residential treatment, particularly of "surgical" cases.
3. An extension of open-air teaching by means of open-air schools, playground classes, etc., and, if possible, by the establishment of "night camps."
4. The need for systematic and prolonged after-care and following up.

ROYAL MEDICAL BENEVOLENT FUND.

At the December meeting of the Committee twenty-six cases were considered, and grants amounting to £217 made to twenty-two of the applicants. Appended is an abstract of the cases relieved:

1. L.S.A., aged 68. Used to have an excellent practice in the south-west of London, but lost it through ill-health and other misfortunes, and is now trying to re-establish himself in a working-class district. Relieved four times, £51. Voted £12.
2. Daughter, aged 54, of late M.R.C.S. Nursed her father for several years before his death, and is now unfitted to maintain herself. No income. Relieved five times, £52. Voted £15.
3. Daughter, aged 63, of late M.R.C.S. Only income £12 a year. Voted £12.
4. Widow, aged 63, of L.S.A. Since husband's death has held a post as companion, etc., but is now in bad health and unfitted for regular employment. Voted £12.
5. Widow, aged 62, of L.S.A. Since husband's death, more than twenty years ago, has supported herself in different ways, but is now no longer able to do so on account of bad health. No children. Voted £12.
6. Daughter, aged 71, of late M.R.C.S. Only income 15s. a week. Voted £5, and to be advised to consider the purchase of an annuity with such of her capital as she can control.
7. Widow, aged 41, of M.B., C.M. Aberdeen. Practically unprovided for at husband's death a few months ago, and being deaf is obliged to depend upon relations who can ill afford to help. Three children, one receiving an education through the kindness of a friend, and the other two candidates for an institution. Voted £10.
8. Widow, aged 68, of L.R.C.P., L.R.C.S. Edin. Several years ago, with the assistance of two daughters, started a school, which has just supported them, but no longer pays owing to the opening of a secondary school. The daughters are endeavouring to obtain posts as governesses, and meanwhile are in considerable difficulties. Voted £12.
9. Widow, aged 45, of M.D. Quite unprovided for at husband's death from phthisis a few months ago, and is quite incapacitated by a spinal complaint. No income; two children, aged 6 and 4, who are temporarily sheltered at a Church Army home. Voted £5, and case to be again considered after further inquiry.
10. Widow, aged 50, of late M.R.C.S. Husband's means exhausted by a long illness which preceded his death; no children. Is endeavouring to establish a boarding house, but finds great difficulty in meeting expenses. Relieved three times, £30. Voted £10.
11. Widow, aged 53, of L.S.A. No income, and tries to support herself by needlework. Two children, one receiving a small salary as a governess, the other earning a few shillings a week by sewing. Relieved seven times, £70. Voted £12.
12. Widow, aged 66, of L.F.P.S. Glasg. Supplements a pension of £20 a year by addressing envelopes. Relieved fifteen times, £146. Voted £5.
13. Widow, aged 67, of M.R.C.S. No income, and health too bad to allow regular occupation. Relieved three times, £36. Voted £12.
14. Widow, aged 57, of L.R.C.S. Edin. No income; endeavours to maintain herself by taking a lodger and doing needlework. Three children, one in ill health, and the others only just self-supporting. Relieved four times, £54. Voted £12.
15. Daughter, aged 65, of late M.D. Edin. Only income £10 a year, and unable to do anything to support herself, because obliged to nurse two older and invalid sisters. Relieved seven times, £84. Voted £12.
16. Widow, aged 64, of L.R.C.P., L.R.C.S. Edin. Has just obtained a pension from a charitable fund, but had to spend so much on canvassing that she is in temporary difficulties. Earns a few shillings a week by taking lodgers. Relieved thirteen times, £97. Voted £5.
17. Widow, aged 39, of M.R.C.S. Since husband's death a few years ago has endeavoured to support herself by dealing in cast-off clothing, but failed for want of capital. Two children, aged 6½ and 3½, the elder very delicate. Relieved once, £10. Voted £10.
18. Daughter, aged 62, of late M.D. Is in feeble health, and having no means is dependent on a sister whose only income is derived from two small pensions. Relieved three times, £36. Voted £12.
19. Daughter, aged 29, of late M.R.C.S. Is a typist, but owing to bad health is only able to earn a few shillings a week, and is at present out of work. Relieved four times, £22. Voted £5 and case to be further considered.
20. Widow, aged 67, of L.R.C.P. Edin. Supplements an income of £20 a year by crochet, but finds great difficulty in selling her work. No children. Relieved thirteen times, £150. Voted £12.
21. Widow, aged 82, of M.R.C.S. Four children, aged 51 to 45, three being deaf and dumb. Has a small income, but asks for a little help on account of their afflictions and her own infirmities. Relieved ten times, £65. Voted £5.
22. Widow, aged 39, of M.B., C.M. Abern. Since husband's death six years ago has supported herself as a companion, but is now in difficulties owing to an illness that has lasted some months. Two children, both at an institution. Relieved once, £5. Voted £10.

Contributions may be sent to the Honorary Treasurer, Dr. Samuel West, 15, Wimpole Street, W.

LITERARY NOTES.

The Bookseller of January 3rd, 1913, states that the total number of publications issued in this country during 1912 was 12,886. Of these 367 are classified under the heading "Medical and Surgical."

Speaking of his admission to the English College of Surgeons Sir Charles Bell says: "The College received me with all possible respect. The question asked me—facetious dogs!—was of what disease I thought Buonaparte would die? And so I was admitted." This was in 1813. Bell does not record his answer. Neither he nor his examiners could have foreseen the lingering agony of St. Helena—

La chaîne, le rocher brûlé du ciel d'Afrique
Et le Titan—et le vautour!

Messrs. Macmillan and Co. will publish on January 14th the second volume of the translation of Professor Luigi Luciani's *Human Physiology*, which they are issuing. The volume deals with internal secretion, digestion, excretion, and the skin.

The January number of *Bedrock* contains the text of Professor Metchnikoff's Priestley Lecture to the National Health Society on the warfare against tuberculosis. Psychological research forms the subject of interesting contributions by Dr. Ivor Tuckett, Sir Ray Lankester, and Sir Bryan Donkin; Dr. A. M. Gossage writes on crucial tests of evolution, and Dr. Eric Pritchard discusses the milk problem. The other contents are up to the high standard to which the previous issues of this "quarterly review of scientific thought" have accustomed its readers.

In *Paris médical* of December 28th Dr. Monsson-Lanauze gives an account of Guillaume Loyseau, a surgeon of Bergerac in Périgord, who was held in high esteem by all the warriors of his day, notably by Henry IV when King of Navarre. He saved the life of one of the King's stoutest lieutenants, Geoffroy de Vivant, to whom was due the victory at Coutras in 1587, where he was dangerously wounded. Loyseau gave a detailed account of the wound in his *Observations médicales et chirurgicales*; it was customary at the time to cite the names of the patients, especially if they were people of importance. The case is sufficiently remarkable to deserve a brief record. De Vivant received two spear wounds, one going through the whole thickness of the right arm, the other above the pubes, going upwards towards the stomach. By this blow de Vivant "was thrown backwards on the crupper of his horse; the rider was going so fast that the wood of the spear broke, and the iron remained deeply fixed in the belly." He had often been badly wounded before, but said he had never felt such pain. He had been struck on his breastplate earlier on the same day with such force that the lance broke and the iron fell on the saddle between his thighs; it dropped out when he was taken off his horse, and hence was thought to be the cause of injury. When Loyseau saw him on the third day he found that the abdominal wound had been overlooked by the surgeons. Finding, however, that the severe pain persisted, that there was much bleeding into the dressings behind, and that there was continual need of the bedpan, he probed the wound and found about half a foot upwards from the opening a hard foreign body. He made an incision four finger-breadths in length and found two splinters of wood. Later, as the pain and bleeding continued, he probed again and found the iron end of the spear; to extract this he had to enlarge the wound and pull the foreign body out with his hand. Just as Loyseau had done this the king sent for news of the patient; by way of answer the surgeon sent him the spearhead, whereat His Majesty marvelled exceedingly, and abused the other surgeons for having overlooked such a wound. The next day the patient took some broth, and an enema was administered; part of both the broth and the enema came out through the wound. Loyseau then applied a balsam to the wound night and morning, forbidding solid diet. "God so blessed this work that on the sixteenth or seventeenth day I applied only a solid vulnerary plaster, and the said Sieur de Vivant mounted his horse and came to sleep at Saint-Sernin at the house of a relative of his being perfectly cured." Henry himself did Loyseau the honour to consult him for an inveterate gonorrhoea. So successful was the treatment that in 1591 Loyseau was

appointed one of the King's surgeons in ordinary "with all the honours, authorities, prerogatives, pre-eminences, franchises, liberties, wages, rights, fruits, profits, revenues, and emoluments belonging to" that office. Among these privileges was exemption from all taxes and immunity from billeting of troops.

One of the great Jewish physicians of the Middle Ages was Moses Ben Maimon, commonly known as Maimonides, who was born at Cordova, then one of the greatest centres of Arab culture, in 1135 or 1139. He was educated there, and after wandering about for several years with his family he became physician to Saladin, whose name is well known to us owing to his relations with Richard Coeur de Lion. Maimonides records that every morning he went to the palace, and if any of the numerous officials and dependents there were ill he had to prescribe for them, getting back to his own house in the afternoon when "almost dying with hunger." There he would find, in his own words—

Jews and Mohammedans, a varied crowd who are seeking my medical advice. There is scarcely time for me to get down from my carriage and wash myself and eat a little, and then until night I am constantly occupied so that from sheer exhaustion I must lie down. Only on the Sabbath day have I the time to occupy myself with my own people and my studies, and so the day is away from me.

Maimonides wrote on philosophy as well as medicine. The most interesting of his writings was a series of letters on dietetics written for the son of Saladin, who seems to have been something of a neurotic, suffering from indigestion, constipation, and depression. The rules laid down by Maimonides have become part of the popular medical tradition. In view of the originality claimed by so many minor prophets of the present day for views that are almost as old as disease, it may not be amiss to give a summary of them. We should eat and drink only when hungry and thirsty, and should be particularly careful of the regular evacuation of the bowels and bladder. The inclination should as far as possible be satisfied at once. A man must not overload his stomach, and should not drink much during the meal, and only of water and wine mixed. Food should be taken always in the sitting position. There should be no riding or walking or movement of the body until digestion has finished. Day and night should be divided into twenty-four hours. We should sleep for eight hours, and so arrange our sleep that the end of it comes with the dawn, so that from the beginning of sleep until sunrise there should be an interval of eight hours. We should leave our beds at the time that the sun rises. During sleep a man should lie on his side—the beginning of the night on his left and at the end on his right. He should not go to sleep for three or four hours after eating and should not sleep during the day. Fruits that are laxative—as grapes, figs, melons, gourds—should be taken only before meal-time and not mixed with other food. We should eat what is easily digestible before what is difficult of digestion—the flesh of birds before beef, and the flesh of calves before that of cows and steers. In summer we should eat cooling food, acids and no spices. In winter, on the contrary, warming foods, rich in spices, mustard and other heating substances should be taken. Large salt fish, old cheese, old pickled meat, young new wine, evil-smelling and bitter foods are often poisonous. Large fish, cheese, milk more than twenty-four hours after milking, the flesh of old oxen, beans, peas, unleavened bread, sauerkraut, onions, radishes should be taken only in small quantities and in the winter time. Beans and lentils are to be recommended neither in winter or summer. As a rule we should not eat tree fruits, especially when they are dry, and even less when they are green. The fruits that are to be recommended dry as well as fresh are figs, grapes, and almonds. Honey and wine are not good for children, though beneficial for older people, especially in winter. Special care should be taken to have regular movements of the bowels. Every medical means should be taken to overcome constipation. Young people should be given salted food, materials that have been soaked in olive oil, salt itself, or certain vegetable soups with olive oil and salt. Older people should take honey mixed with warm water early in the morning, and four hours later should take their breakfast. This should be done from one to four days until the constipation is overcome. Immoderate eating is a poison to men and the cause of

many of the diseases that attack them. Most diseases come from eating either too much or unsuitable food. Every week at least a man should take a warm bath. He should not bathe when hungry nor after eating till the food is digested, and should bathe the whole body in warm but not too hot water, and the head in hot water. Afterwards the body should be washed in lake warm water, and finally cold water should be used. Bleeding should not be frequent; it is only meant for serious illness. After the age of 50 there should be no bleeding. Whoever observes these rules of life faithfully will live long without disease, and in the fullness of his years he will die a natural death. Only the healthy should keep these rules. Whoever is ill or a sufferer from any injury or has lost his health through bad habits, for him there are special rules for each disease only to be found in the medical books. Every change in a life habit is the beginning of an ailment. Maimonides rejected astrology, and was never afraid to say he did not know anything. He died in 1204, and his thought had a great influence on philosophy as well as medicine.

SCIENCE NOTES.

THE nature of the Roentgen rays has long been a matter for speculation. The original theory of Stokes that they consisted of sets of ether ripples was generally accepted, in spite of the fact that no evidence could be produced of refraction, reflection, or diffraction. The failure of the strongest magnetic fields to produce deviation pointed to ether disturbance and seemed to negative certain attempts to prove that the rays were corpuscular in character. More recently it was suggested by Professor Bragg of Liverpool that the rays may consist of neutral pairs of corpuscles. He was led to this conclusion as the result of some very ingenious experiments on the secondary radiations arising from surfaces irradiated by the x rays. This view was strongly combated by Professor Barkla of King's College, who produced further experiments as well as explanations of Bragg's results based on the more generally accepted ether-pulse view. The fact was, no crucial experiment had been devised. A few weeks ago Herr Laue announced a startling result. He found that when a narrow pencil of x rays passes through a crystal of zinc blende curious regular markings appear upon a photographic plate placed behind the crystal. It looked at first as if this had to do with some diffraction effect; but Mr. W. L. Bragg (son of Professor Bragg), as the result of an experimental and theoretical investigation of the phenomenon, showed that the new results may be regarded as reflections from certain cleavage planes existing in the crystal or, very probably, boundaries of molecular groups. This latter view is strengthened by the fact that the distribution of the rays of the beam are what might be expected from the recent theories of Barlow and Pope on crystal structure. In *Nature* of December 12th, 1912 Mr. Bragg described an experiment carried out on the suggestion of Mr. C. T. R. Wilson, F.R.S., in which the cleavage plane effect is clearly demonstrated. A narrow beam of x rays, obtained by a series of diaphragms, was allowed to fall at an angle of incidence of 80 degrees on a strip of mica 1 mm. thick mounted in thin aluminium. A photographic plate enclosed in two light-opaque envelopes was placed behind the mica in such a position that the direct rays would give a darkening, whilst, in addition, if any rays were reflected they also could affect the plate. Such an action was observed. It is almost certainly not merely a surface action, although an increase in the thickness of the mica did not produce an increase of the effect upon the plate. Mr. Bragg demonstrated that there was true specular reflection obeying the usual optical laws. At a glancing angle the reflection was very marked. It would seem, therefore, that the x rays are composed of at least two sorts of rays, one capable of reflection and the other not. And, not for the first time, it would follow that both apparently antagonistic theories are right after all. It now remains to examine the respective ionizing and other properties of these rays, and to test their relative therapeutic values; and already, we believe, the workers in the radiotherapeutic department of the Cancer Hospital have taken up the question. The fact that the reflected rays can be concentrated ought to prove of great service.

British Medical Journal.

SATURDAY, JANUARY 11TH, 1913.

ARRANGEMENTS FOR MEDICAL BENEFIT.

DURING the past week decisions have been reached by members of the profession in many parts of Great Britain which seem to make it certain that it will be possible for the Government to bring medical benefit into force in many areas on the appointed day, January 15th. In some districts definite arrangements have been entered into, and in others a reluctant assent has been given to a proposal in general terms to go on the panels and to work under the Act. The decision seems in practically every case to have been taken under economic pressure, which the more fortunate members of the profession in various districts found it impossible to advise their younger or less fortunate brethren to resist. In his speech to the Advisory Committee—which some of those members of the British Medical Association who resigned in response to its call last summer have rejoined—Mr. Lloyd George indulged in re-priminations to which it does not seem worth while to retort at length. It must, however, be pointed out that he clearly could not have understood the scheme of the Association when he talked about the inexplicable change which had taken place in its attitude towards the approved societies. The profession has for many years objected to friendly society control, and it objects to it and will resist it just as strongly now as ever. The alternative policy of the Association in going to the approved societies is meant to offer to insured persons a better service than that of the Government, and free from the hampering regulations of the Government service. The approved societies would do the administrative work, the doctors on their side would guarantee an efficient medical service under the sole control of the Local Medical Committees. Mr. Lloyd George again threatened the profession with the dire consequences of maintaining its independent attitude. The first threat to "close the panels" for unspecified periods, those who had joined them being authorized to take assistants and partners, is contrary to the policy frequently expressed at earlier dates, some of them quite recent, by Mr. Lloyd George, and does not seem to be authorized by the Act. As to the second—to introduce a system of whole-time medical officers where no panel which could be deemed adequate had been formed—the Commissioners, it seems certain, would not have been able to carry it out in more than a few districts. The fact seems to be that in their anxiety to bring medical benefit into force by the appointed day a campaign has been started in the Advisory Committee and in the press in which what is lacking in solid fact and argument is made up by a combination of bluff and intimidation. The result has been to produce a feeling of apprehension and anxiety which has lent additional force to the arguments of

those members of the profession who on various grounds were disposed to give a trial to the Act. Some of them, believing that the object of the Act was beneficent, were ready to overlook its defects; others had come to the conclusion that these defects had been so materially diminished through the efforts of the British Medical Association that it might be tested for a period, and that this test would, on the principle *solvitur ambulando*, inevitably lead to amendment. It is clear, however, that in the great majority of districts the decision to enter into provisional arrangements for the first three months was due to the pressure of economic necessity.

The Insurance Commissioners, through Mr. Claud Schuster, have approved a scheme agreed in Manchester and modelled on that already adopted in the neighbouring borough of Salford—centres of the most densely populated industrial areas in the country. A similar scheme submitted by the Council of the Administrative County of Lancashire has, it seems, met with the acceptance of representatives of the medical profession in that area. In each case the scheme is stated to embody arrangements for the provision of medical benefit in accordance with the Act and the Regulations. The main point appears to be that the Insurance Committee enters into an honourable agreement that medical attendance shall be given on the ordinary lines of private practice, and undertakes that the total sums available for medical attendance and treatment of insured persons shall be distributed among the doctors giving treatment and attendance to such persons in accordance with a scale of fees to be settled. The sum thus available is to be the limit of the liability of the Insurance Committee—except for drugs and medical appliances—and each doctor accepting service is required to give an undertaking that he will not make any claim or bring any action against an insured person or the Committee for additional payment, but he is not precluded from making an arrangement beforehand with any individual insured person for the payment of higher fees agreed between them. If the total amount is insufficient to meet all the charges of the doctors in accordance with the scale, the amount payable to each doctor will be subject to a *pro rata* reduction. Further, the committee of doctors undertakes that every insured person in the area shall receive adequate medical treatment and attendance, and that every insured person shall have the free right to arrange with any doctor within the accepted service to attend him during the continuance of the scheme.

In London the London Medical Committee has instituted a strenuous campaign, and has raised a fighting fund. Its guiding principle has been to secure for the insured person in the administrative County of London the free choice of doctor. The Committee was well aware that its task was no light one, and it has been meeting from day to day. It has kept the press well informed of the progress of affairs, and, although its communications have met with a different sort of welcome from different papers it has succeeded in thoroughly arousing public attention and in interesting insured persons. Posters and leaflets have been displayed and distributed telling the insured in what way they may be able to retain the services of their own doctor, and forms claiming this right have been filled up by insured persons and forwarded to the London Insurance Committee in very large numbers. The enthusiastic meeting, summoned at three days' notice and attended by over eighteen hundred medical practitioners, at Queen's Hall on Tuesday last, which is

reported in the SUPPLEMENT, was organized by the Committee, and, in addition, meetings of insured persons, which are very largely attended, are held every evening in various parts of London, and resolutions expressing the determination of the insured persons to have full freedom to choose their own doctor, whether he be on the panel or not, are being passed by overwhelming majorities. The London Medical Committee is very much encouraged by the evidence that the insured persons are on the side of the doctor, and one immediate result of what it has done is shown by the small response to the immense efforts made by the London Insurance Committee to obtain an adequate panel. The official figures, which are published elsewhere, show that the total number of doctors willing to serve on the panel in the 29 boroughs into which the administrative County of London is divided is 759, although it is claimed that this should be increased by 100 doctors residing a short way beyond the boundaries of London who are said to have undertaken to attend insured persons within. Official lists for other parts of the country have not been published, and the statements which have appeared in the press must, in respect of many districts, be received with reserve. It is probable, however, that in many others panels which are held to be adequate have been provisionally formed, and in not a few the large majority of doctors practising in the area have joined, though in many instances under protest, and with a strong feeling that they are being coerced and unfairly treated.

It must be borne in mind that all arrangements now made are provisional, for the period from January 15th to April 14th, and are subject to revision at the instance of either party, the Insurance Committees or the medical profession. It should be noted that the Commissioners, in requiring that the arrangements made now by Insurance Committees should be only provisional, did not profess to be acting out of consideration for the medical profession; the reason assigned for taking this course was that the register of insured persons was not complete and could not be made complete by January 15th, and that in consequence the allocation of insured persons to the care of individual practitioners could not be carried out by that date. The Insurance Committees were enjoined to make provisional arrangements which would afford reasonable certainty that every insured person entitled to medical benefit would, on the presentation of a card issued to him by the Committee, obtain treatment in accordance with the promise of the Act and Regulations. In this strawberry-tinted card the insured person is so informed, and he is directed to apply to the post office, or the officer of customs and excise, for the list of doctors willing to give such attendance.

The provisional nature of the arrangements cuts both ways, but it is abundantly evident that during the next three months the utmost vigilance must be observed, and that the profession has never stood in greater need of local organization with central co-ordination, such as the British Medical Association alone affords, than at the present time. It is of course possible, if not probable, that some of the conditions now regarded with the greatest distaste and suspicion by the medical profession may prove in working to be of minor importance, while others not hitherto brought into prominence may give rise to serious difficulties. This was the case in Germany, where some of the more intolerable defects in the law became evident only after it had been brought into force. The German medical men

then had to set to work to organize defence associations, whereas the profession in this country is already provided with such machinery in the British Medical Association. We have good reason to know that this opinion is strongly held by the great bulk of the profession in this country, and that not only will those who are already members rally to it but that others who have not yet joined it will hasten to do so. We are in a position to give a categorical denial to the statements which have been circulated by Government organs in the press to the effect that large numbers are resigning their membership of the British Medical Association. This is not the case. At this season of the year a certain number of members for various private reasons terminate their membership. This year the number of resignations has been in some districts slightly in excess of the average, but only slightly. Some have undoubtedly been actuated by the mistaken opinion that a member by so doing relieves himself of the obligation of the pledge and undertaking into which he freely entered. The pledge was asked for at the expressed wish of the members of the Association, and as was pointed out last week can only be abrogated if they express the wish that it should cease to be of force. During the last year or eighteen months the number of members of the British Medical Association has increased enormously—in many districts by over 50 per cent. This is true of Great Britain; it is true also of Greater Britain, and the home members have received many gratifying assurances of sympathy and support from their fellow members in the overseas dominions.

A RIDDLE OF RELICS.

THE extraordinary interest displayed in everything relating to Napoleon has in recent years led in France to the growth of a dense and tangled forest of literature. In this country the interest is hardly less keen. A good many of the books dealing with his career and character—his victories and his defeats, his administration, his opinions on politics, religion, love, and all manner of subjects, his marriage, his mistresses, the garments wherewith he was clothed, the food he ate and how and when he consumed it, his physical infirmities, his last illness and death—have been translated. Nor have books written in English been wanting, the most notable being Lord Rosebery's *Last Phase*, in which the great Emperor is discussed by one who combines with the largeness of view of the statesman and the insight into character of the man of the world a rare gift of literary expression. The medical aspects of Napoleon's last illness have been discussed with great ability by Dr. Arnold Chaplin in a book reviewed in the JOURNAL of December 28th, 1912. In this issue we publish an address in which Professor Arthur Keith surveys the case from a different and, as far as we are aware, entirely novel point of view. The new facts he adduces in evidence are of the highest interest, and his presentation of the case is marked by remarkable ingenuity.

Professor Keith's address may be resolved into two theses. One is that the fragments of small intestine, which are said to have been given by Barry O'Meara to Sir Astley Cooper, and which, on the death of the famous surgeon, came into the possession of the Royal College of Surgeons of England and are now in its museum, were taken from the body of Napoleon. The other is that the ill health of the Emperor at St. Helena before the development of the gastric

cancer from which he suffered was caused by Malta, or as it is now styled, undulant, fever. There are, then, two wholly distinct questions: Are the relics authentic? And is the theory of undulant fever proved by such evidence as is available? The theory does not stand or fall by the authenticity of the relics, for it is obvious that Napoleon may have had undulant fever, while the pathological evidence of the disease may have been buried with him.

To most the question of the authenticity of the relics is the more interesting. It is well known that there are in the museum of the Royal College of Surgeons of England two small pieces of human bowel taken from the lower part of the ileum which came from the museum of Sir Astley Cooper, and were described in the MS. catalogue of that museum as "Incipient fungus in the glands of an intestine, Napoleon. Barry O'Meara to Sir Astley Cooper." The specimens are described in the edition of the Pathological Catalogue of the College Museum, revised by Sir James Paget in 1883, as the seat of cancerous lesions. Grave doubt was, however, expressed by Paget as to the authenticity of the relics. The reasons for his scepticism are that no mention of such lesions is made in Antommarchi's report of the *post-mortem* examination, where it is stated that the mucous membrane of the intestinal canal appeared to be in a sound state; that O'Meara, who gave them to Cooper, was in England when Napoleon died, having been recalled nearly three years before the end of the drama at St. Helena; and, finally, that Napoleon's body was so closely guarded that it is improbable that anything could have been taken away.

M. Frémeaux, one of the highest authorities on everything relating to Napoleon, admits that it is possible, though highly improbable, that any part of the Emperor's body can have been abstracted; but he insists that it is impossible that any such specimen can have found its way to the museum of the College of Surgeons. The examination, which was made by Antommarchi, was carried out under the eyes of seven English surgeons, and several representatives of Sir Hudson Lowe and of the Emperor's household. When the body was sewn up, one of the surgeons, Rutledge, was ordered to take charge of the remains, and Dr. Chaplin, who has gone to the original sources, the "Lowe Papers" in the British Museum, says that from his account therein contained there can be no doubt that he never lost sight of the corpse till it was soldered down in the coffin. The heart was placed by Rutledge in a silver vase with spirits of wine, and the stomach in a silver pepper-box, without any preservative, the supply of spirits of wine having been exhausted. When the coffin was opened in 1840, the two silver vessels were found in it. Rutledge says that Antommarchi begged to be allowed to take away the stomach that he might show the family the disease which had killed the Emperor, while Madame Bertrand asked that she might have the heart. These requests were refused, a fact which goes to show that the order that nothing should be taken away was no mere formal injunction. It must be remembered that Sir Hudson Lowe, all the time he had had the Emperor in his custody, kept a watch of the most jealous kind on his movements, and visited the slightest breach of his orders on the part of officers under his command with swift and severe punishment. It must be remembered, too, that the case was far outside the domain of ordinary *post-mortem* experience, and the watch must therefore be taken to have been proportionately strict. There-

fore, though it may be admitted to be within the bounds of possibility that something was removed, it requires a somewhat vigorous "wish to believe" for it to be accepted as a fact that this was actually done.

As to the disease shown in the fragments of intestine which form the relics, Cooper and Paget agree in describing it as cancer. This has been disproved by examinations of the specimens by modern methods. Sir Frederic Eve found, on making microscopical sections of the outgrowths, that they were not cancerous. A further examination, made more recently by Mr. Shattock, shows that the lesions represent a solitary and an agminated gland of the lesser size. In form and size, he says, they resemble such glands when enlarged from inflammatory or hyperplastic conditions. There is no indication that either is the seat of a carcinomatous inroad from the epithelium. In both glands hæmorrhage appears to have occurred, and bacteria, probably *B. coli*, can be plainly seen in them.

Professor Keith's faith that the relics might prove authentic rested, he tells us, on his belief in Sir Astley Cooper, who had, as is well known, special opportunities of acquiring anything of particular medical interest. Moreover, he was the trusted medical adviser of Lord Liverpool, the Tory Prime Minister during the captivity of Napoleon, and he was well acquainted with Lord Bathurst, Secretary for War and for the Colonies, who had Napoleon specially under his care. Professor Keith takes it for granted that he must often have been consulted by these two men about the Emperor's case. If he is right in this conjecture some part of the responsibility for the medical muddle at St. Helena must be transferred from the doctors there to Astley Cooper. We know that it was the official view, obstinately held and impressed on the doctors, that Napoleon was not ill at all. When the Emperor was actually dying that egregious person, Lord Bathurst, who had treated the plague of rats at Longwood as a matter for stupid jesting, wrote: "If he be really ill he may derive some consolation by knowing that the repeated accounts which have of late been transmitted of his declining health have not been received with indifference." There is no reason whatever to call in question the judgement or honesty of Sir Astley Cooper, but we think we may be excused for not having the same trust in Barry O'Meara. As O'Meara had left St. Helena nearly three years before Napoleon's death, it is obvious he could not have stolen the specimens himself. Professor Keith thinks that they were given to him by Antommarchi. Of this there is no proof. Both men were in London in August, 1821, and it is likely enough that they may have met; but Professor Keith's conjecture that they would meet "and see if they could not retrieve their position and convince the public that they were right in their diagnosis" is scarcely felicitous in view of the fact that Antommarchi's own examination had already shown that the diagnosis was wrong. All the rest is more or less plausible assumption. Neither O'Meara nor Antommarchi was a person whose unsupported word could be relied upon, a fact which Professor Keith seems to us to slur over. He thinks they were maligned, but we are inclined to believe that he wastes his sympathy. Antommarchi, on whom Professor Keith mainly pins his faith, interpolated a statement to bolster up the hepatitis theory in his report of the *post-mortem* examination, and later published the pathological plates of his master, Mascagni, as his own. Apart from this his book from internal evidence is untrustworthy. Professor Keith says Antommarchi was much misunderstood;

our impression is that he was too well understood. It is his credit, not his scientific knowledge, that is in question, and on that point we think we may safely accept the judgement of Napoleon and Lord Rosebery.

The authenticity of the relics, then, finally depends on the indirect testimony of O'Meara, who gave them to Sir Astley Cooper. Great collectors are usually enthusiasts, and strange things have been palmed off on them by interested persons. Cooper may have therefore accepted the relics without too close an inquiry into their provenance. On the whole we would say, as Falstaff's tailor said of Bardolph, that the defenders of their authenticity should procure us better assurance than O'Meara; we like not the security.

Coming to the second thesis, Professor Keith shows that the supposed growths are enlargements of Peyer's patches, and he says that these lesions, together with the clinical notes made by the doctors, prove that the Emperor suffered from a disease in which the lymphoid tissue of the body is subject to enlargement. Both the clinical and the pathological evidence correspond to those of undulant fever, and there was abundant opportunity for the conveyance of infection. This is a theory, plausible enough in itself, but it does not, if accepted, prove the authenticity of the relics. What Professor Keith has to show is not only that the owner of the diseased intestine suffered from undulant fever, but that the owner was Napoleon. The pathological examinations throw light on the nature of the disease in the part subjected to inspection, but none on what we regard as the principal problem. Professor Keith has proved that Sir Astley Cooper and Sir James Paget were mistaken in thinking that the lesions were cancerous; he has shown it to be highly probable that Napoleon suffered from undulant fever. But while thanking him for a communication of quite exceptional interest, we think he has somewhat strained the evidence as to the relics. At any rate his solution of the riddle leaves us with the impression that the only safe conclusion is what Rabelais might have called *Un grand peut-être*.

THE SENSORY PHRENIC AND ITS ORGANS.

THE habit of regarding the phrenic as no more than the motor nerve supplying the diaphragm is, we believe, deeply ingrained in most medical men. To learn the full extent and variety of its sensory distribution comes, to one who is not a professed anatomist, perhaps with something of a shock; and this aspect of its functions is worthy of the thorough and well-documented analysis to which it has recently been subjected by Dr. Kidd.¹ For the last twenty years or so the sensory phrenic has been unduly neglected by clinicians. Both Hippocrates and Galen were aware that subdiaphragmatic pains were sometimes associated with pains in the region of the clavicle, and Dr. Kidd would have us believe that these Fathers of Medicine were also acquainted with the anatomy of the various sensory branches of the phrenic nerves.

Be that as it may, no further clinical advance was made till 1835, when Bouillaud referred some of the pains of the cardiac neuralgias and the pain of pericarditis to irritation of the phrenics. In 1853 Gueneau de Mussy wrote a most interesting clinical

account of diaphragmatic pleurisy and its relationship with the phrenic nerves, and showed how spontaneous pains in the region of the shoulder and above the clavicle might be afferent phrenic pains due to such diseases as pericarditis, pleurisy, and hepatitis. In 1871 Peter described diaphragmatic or phrenic neuralgia, a clinical entity the existence of which would nowadays be denied by many; his paper is described as "by far the greatest piece of clinical work ever done on the sensory phrenic," and he emphasized the fact that the phrenic is a mixed nerve, and not exclusively motor. The additions made to our clinical knowledge of the phrenic nerves since Peter wrote are few; James Ross (1883) made the addition of hepatic abscess to the morbid conditions that might underlie pain over the shoulder-tip, but made no further original contribution to our knowledge of the sensory phrenic.

In 1891 the proof that many of the nerve fibres in the phrenics were sensory and afferent in function was furnished by Ferguson. In a fatal case of progressive muscular atrophy with paralysis of the diaphragm, he found *post mortem* that about one-third of the fibres of the phrenic nerve were normal, while partial or complete degeneration had taken place in the remaining two-thirds. Experimental section of the phrenic nerve or of its contributory cervical dorsal nerve roots in the cat confirmed his view that only two-thirds of the nerve fibres in the phrenics were motor fibres. Ferguson's discovery of these sensory fibres was confirmed three years later by Sherrington, and in 1898 Sand found that the sensory fibres of the diaphragm are connected with the third to the sixth cervical spinal ganglia. Dr. Kidd believes that these sensory fibres are of two sorts—muscle-sensory and postural. As he points out, there are many gaps in our knowledge of the phrenic nerve: What is its developmental history? Does it contain non-medullated nerve fibres? In which of its branches do the afferent fibres mainly lie? What is the ganglionic origin of its suprarenal branches? All these are important questions crying out for investigation. It is certain that branches of the right phrenic go directly to supply the pleura, pericardium, diaphragm, peritoneum, inferior vena cava, and right auricle of the heart, and, by way of the diaphragmatic plexus, also to the liver, coronary ligament, and right suprarenal body. The left phrenic nerve supplies the pleura, the pericardium sometimes, the diaphragm, and, by way of the coeliac plexus, the left semilunar ganglion and the left suprarenal body.

Large numbers of cases of referred phrenic pains have been misunderstood by clinicians in the past for want of appreciation of the extent to which the sensory phrenic supplies—or, as for want of definite anatomical proof one ought perhaps to say, presumably supplies—the organs on either side of the diaphragm. In any case of pain in the neck, the shoulder, the clavicular region, the inner side of the upper arm, it may be that the pain is a referred pain from one of these viscera by way of the sensory phrenic nerve. Thus, such various disorders as old pleuritic adhesions at the base of the lung, peritonitis, pericarditis, angina pectoris, cancer or abscess of the liver, suprarenal tumour, gall stones, cervical tabes, aortic aneurysm, may all by pains in the neck and shoulder betray themselves to the clinician whose attention has once been directed to the sensory fibres of the phrenic nerve. To diagnose neuritis or neuralgia in such instances, and to confine treatment to the aching neck or shoulder, are clearly inadequate

¹ The Sensory Phrenic and its Organs. By L. J. Kidd. *Review of Neurology and Psychiatry*, vol. ix, p. 587.

procedures, though cases in which this has been done cannot be very infrequent.

There are other interesting points in Dr. Kidd's paper—the possible connexion between arthritis of the shoulder and diaphragmatic disease, for example, or the part played by the sensory phrenic in the development of a diaphragmatic hicoughing tic. For these we must refer the reader to the able and timely original article in which Dr. Kidd has set out no small amount of novelty, together with much sound learning that has been undeservedly forgotten.

INSECTS, DIRT, AND DISEASE.

It is about thirty-five years ago since the idea that insects might act as disseminators of disease was given a sound basis of fact by the observations of Manson, Lewis, and other workers on the life-history of filaria, and its transmission by the mosquito. It is almost exactly eighteen years since Manson published in this JOURNAL the hypothesis that malaria was transmitted by mosquitos, founding himself on general considerations as to the etiology of the disease and the nature of the parasite discovered by Laveran in Algiers. It is rather less than seventeen years since Ross proved the truth of this hypothesis by his brilliant observations in India. At about the same time Manson ventured the forecast that we were then only at the threshold of a great expansion of knowledge of the part played by insects in the dissemination of diseases both of man and animals. It appeared then to many of those most disposed to accept the truth of the prophecy that it would be found to apply chiefly to the diseases of tropical and subtropical countries. How far short of the facts this opinion fell appears from Dr. C. J. Martin's lecture before the Royal College of Physicians of London, the publication of which is concluded in this issue. He confined himself to bacterial infections, but had a formidable indictment to make. The biological interest of the way in which the insect porters of infection do their evil work is less than that which attaches to the more complex story of the part played by insects in the cycle of the protozoal, trypanosomic, and filarial parasites. In the bacterial diseases with which Dr. Martin deals the insect is not an essential, though it may be the most frequent, disseminator. The relation is to so large an extent accidental in, for instance, typhoid fever that the disease may easily remain endemic or become epidemic in the absence of flies; on the other hand, the circumstances may be such as to make the insect a most important, if not the most important, factor, as in the typhoid fever of camps. In the cases of typhus fever, relapsing fever, and bubonic plague, the importance of the part played by the insect—the louse, the tick, and the flea respectively—is greater, and there is good reason to believe that effective prevention of the access of these parasites to man would go a very long way to prevent the prevalence of these three diseases which they are undoubtedly capable of disseminating. As to poliomyelitis, the evidence is incomplete, but there is reason to put the biting stable fly, *Stomoxys calcitrans*, under suspicion, since it has been proved capable of transmitting this terrible disease. There are few insects which so well have earned the contempt bred of familiarity as the house-fly, few which excite so much repugnance in the normal, cleanly man as the louse. The lesson of Dr. Martin's lecture seems to be that repugnance is a more healthy attitude of mind towards domestic insect pests than contempt. If the louse means loathsome, personal uncleanliness, the fly and the flea mean domestic dirt which ought to be not less loathsome.

THE DEFINITION OF STILLBIRTH.

At the November meeting of the Royal Statistical Society¹ Dr. Reginald Dudfield read a paper on stillbirths in relation to infantile mortality. The chief medical interest of the subject centres on the definition of the term "stillbirth." In the JOURNAL of August 31st, 1912, will be found a notice of the valuable report on infantile mortality prepared by a committee of the Royal Statistical Society presided over by Dr. Dudfield. In that report a definition of "stillbirth" was submitted by the chairman for discussion, in which functional activity of the heart was taken to be the basal sign of life, and the period of gestation required to bring the product of conception within the category of births was assumed to be seven lunar months. The definition did not form part of the conclusions adopted by the committee, and in criticizing this definition we ventured to point out that the question whether the heart does or does not beat cannot always be answered by any but skilled observers, and that the age of the fetus can only be determined by a *post-mortem* medical examination. With respect to the former point, Dr. Dudfield admits that "the final test of life—whether in a newborn child or in an adult—must involve a knowledge of medical and physiological sciences which is not possessed by the un instructed and popular world." With regard to a determination of the period of gestation, Dr. Dudfield is of opinion that his definition should be amended. At his request the subject was referred by the Council of the Obstetrical Section of the Royal Society of Medicine to a committee of that body, and the following definition was approved by them: "A stillborn child means a child which measures more than thirteen (13) inches in length from the top of the head to the heel, and which, when completely extruded from the body of the mother (head, body, and limbs, but not necessarily the afterbirth), exhibits no sign of life by crying, or breathing, or by pulsation in the cord at its attachment to the body of the child or by beating of the heart. (N.B.—The final test of life is the pulsation of the heart, but this can only be ascertained by an expert.)" Dr. Dudfield prefers the following modification of this definition: "A 'stillborn child' means a child whose body at birth measures not less than 13 inches (32 centimetres) in length from the crown of the head to the sole of the heel, and who, when completely born (the head, body, and limbs of the child, but not necessarily the afterbirth, being extruded from the body of the mother), exhibits no signs of life—that is to say, whose heart has ceased to function, as demonstrated by the absence of pulsation in the cord at its attachment to the body of the child and absence of any heart sounds or impulses. (Note.—Crying and (or) breathing—being secondary signs of life, manifested only when the heart is acting—can be relied upon as signs of life, but the absence of either or both is not to be held to be proof of the absence of life in the child.)" In the course of a discussion of the suggested definitions Drs. Amand Routh and Walter Griffith expressed a preference for the form proposed by the Obstetrical Section, and emphasized the difficulty, alluded to in our previous remarks, of detecting the pulsations of the fetal heart when beating feebly. Drs. Butler and M. Greenwood, jun., took a similar line, pointing out also that, from the purely scientific point of view, it might be questioned whether there were any one basal test of life, Dr. Butler remarking that "there is no physiological necessity for relying upon evidence of circulation as the sign of life or its absence as the sign of death." In his reply Dr. Dudfield observed that the doubts as to the possibility of giving one basic test of life or death did not seem to him pertinent to the matter under discussion. He said that the test of life which was being sought was one that could be used in the ordinary

¹ Journal of the Royal Statistical Society, December, 1912, p. 1.

routine of medical practice. Persistence of the heart's action had been selected as the test of life in a newborn child, because common experience pointed to the fact that in ordinary routine work resuscitation of an apparently dead infant was not possible after the heart had ceased to beat. It will be seen that Dr. Dudfield's critics objected to his use of the heart-beat in the definition on two grounds—namely, that if the definition were to be regarded as a scientific enunciation it was not strictly accurate, and if it were merely to be taken as a working rule it involved a higher degree of skill than was usually available. Dr. Dudfield's reply suggests that he desires the definition to be regarded from the point of view of practice, and we think that from that point of view many will be found to agree with those who preferred the form advocated by the Obstetrical Section. The whole subject is one of great interest, and the Royal Statistical Society in general, and Dr. Dudfield in particular, deserve the hearty thanks of the medical profession both for the original report on infantile mortality and the illuminating discussion which Dr. Dudfield has initiated.

DYNAMICAL DIAGNOSIS OF THE PULSE.

CHRISTEN¹ of Berne has recently raised the question why many clinicians consider palpation of the pulse of more value than tracings by the sphygmograph or sphygmomanometer. This opinion was shared by the late Sir William Broadbent. He proceeds to answer the question by pointing out that there are two important qualities of the pulse—namely, "plenitude" and "intensity" of pulse-beat, about which sphygmomanometry give us no information. These qualities can be appreciated by palpation; if they are to be measured an exact definition must be established. What is called "plenitude" of the pulse is an appreciation of the blood volume which is filling the collapsed artery by the action of the pulse-beat. The "intensity" is the mechanical energy required for filling the artery against an obstacle. In other words, the greater the systolic increase, the greater the obstacle overcome by the pulse-beat, the greater will be its "intensity." The latter may be found accurately by multiplying the two former quantities. No problem in physiology is so essentially dynamical as the circulation. Pressures as measured by the sphygmomanometer are static quantities only. The filling of a collapsed artery against a given pressure is a dynamical process, and the mechanical energy required is therefore a dynamical quantity. Christen suggests that palpation may equally be transformed into a scientific method. Two of the factors in this connexion—namely, the plenitude of the pulse and its intensity—have already been defined. The third factor is the obstacle set in the way of the pulse-wave in place of the palpating finger. For this purpose the ordinary inflated pneumatic armlet is used. By means of an apparatus he has devised called the "Energoneter," Christen claims to be able to compute these factors. A manometer of minimal inertia and friction is necessary, and for this purpose he finds a delicate metallic manometer is best. A mercurial gauge would be unsuitable, and would falsify the results. He interprets the method of ascertaining the plenitude and intensity of the pulse in a description of the practical use of the instrument. Usually the intensities of healthy people vary between 200 and 350 gr. cm., according to their body weight, whereas in cachectic conditions the intensity remains below 100 gr. cm. The author chooses the calf of the leg for demonstration, as the amplitude of oscillation is somewhat greater than in the arm. The results of energometry are not only independent of the thickness of the soft parts and the elasticity of the armlet, they are equally

independent of the gas volume within the armlet. From investigations on the elasticity of the arterial wall, Christen concludes that the particularly high values of intensity in arterio-sclerosis are partly due to elastic energy, and not to the intrinsic energy of the pulse-beat. Energonetry opens up new fields of clinical investigation based upon exact mathematical conceptions.

MEDICAL TERMS IN THE "NEW ENGLISH DICTIONARY."

THE current part of the *Oxford English Dictionary*¹ is the first of the tenth volume of the whole work; in other words, Sir James Murray and Drs. Craigie and Bradley, who are associated with him in the editing of this *magnum opus* of lexicography, have reached the last volume of their great task. Much remains to be done, for the eighth and ninth volumes have to be finished, and this is only the first part of the tenth, and yet with all the three editors at work the end is really in sight and may perhaps be reached in three or four years. The first medical term in this instalment is *tibia*, with its adverb *tibiad* and its adjective *tibial*; Sir James Murray has succeeded in getting an illustrative quotation on the last-named from the sixteenth century, from a book of *Physicke* (of 1599), which tells "if it be a tibialle Fracture, he must continuallye lye on his Backe." The word *tie* has a very interesting history; in French *tic* (*tiq*, *tiqet*) was first the name of an equine affection, a disease "which on a sudden stopping a horse's breath, makes him to stop, and stand still," and was perhaps related to the Italian *tiechio*, a whim or caprice; now it is a disease characterized by spasmodic twitching of certain muscles, especially of the face, but most often it is used as a synonym for *tic-douloureux* in which the twitching of the facial muscles is accompanied by severe neuralgia of the fifth nerve and its branches. *Tick*, which is a name for several kinds of mites or acarids, has an obscure etymology, and has come prominently into notice lately in connexion with some tropical maladies; it is quite a different word from *tick*, meaning a cover containing feather or flocks, as well as from *tick*, signifying a pat, tap, or beat, as "a tick of the pulse." In describing the sound of the heart-beat the words *tick-tack* are often used, but they are usually put in the French form, *tic-tac*. Another interesting term is *tincture*. At first it meant the (supposed) essential principle of any substance in solution; thus, "tincture of the Moon was a dissolution of some of the more rarify'd parts of Silver" (hence Moon) "made in Spirit of Wine, and whetted by Alkali-Salts." Now, in modern pharmacy, it signifies "a solution, usually in a menstruum of alcohol, of some principle used in medicine, chiefly vegetable, as tincture of opium (laudanum), but sometimes animal, as tincture of cantharides, or mineral, as tincture of ferric chloride." *Tincture* has also a number of obsolete meanings, such as the action of staining, a blemish, a physical quality other than colour, etc. The *Dictionary* does not miss any rare terms, although, as a matter of fact, there are not very many in this section; amongst these the surgical instruments known as *tire-fond* and *tire-tête* may be noted. *Toilet* has many meanings, but "the cleansing of a part after operation" is not omitted. Finally, the balsam of *tolu*, with all its derived words (*toluate*, *toluene*, *toluides*, *toluidine*, etc.), is not forgotten; indeed, the whole chemistry of the substance is compressed within thirty-seven lines, and illustrative quotations occupy forty-seven more. Doubtless there are slips and printers' errors in the *Dictionary*, but it is hard indeed to detect them.

¹ *A New English Dictionary on Historical Principles*. Edited by Sir James A. H. Murray, T. Tombs. Volume x. Oxford: At the Clarendon Press; Henry Crowde. Double section, January 1st, 1913. Price 5s. (\$1.25).

THE DIAGNOSIS OF VENEREAL DISEASE.

A LITTLE more than a year ago the Public Health Department of the City of New York initiated an investigation into the extent of the prevalence of venereal disease of all kinds within its area. The first step taken was to direct all superintendents of public institutions to report promptly to the Board cases of venereal disease of any kind coming under their notice, and a similar request was made to a certain number of private medical men. After some months' experience the Board resolved to proceed a step further, and has now requested every medical man practising within the confines of New York City to report every case of venereal disease seen by him during the year 1913. In reporting any case the name and address of the patient are to be omitted, but the age and sex are to be stated, together with the character, stage, and duration of the infection, and, if possible, the date of its acquirement and its source. Each report is to be filed by the Board under a descriptive number which is to be given to the reporting medical man. Forms on which to make the reports are to be supplied, together with stamped envelopes for their transmission. The information furnished is to be regarded by the Board as absolutely confidential, and the records are not to be deemed public records, and will therefore be inaccessible to members of the public. A further step is the establishment of two clinics to which patients can be sent by medical men, if they so desire, for the purpose of having a precise diagnosis of the disorder made, one of such clinics being open in the morning, the other in the evening. The Wassermann test and bacteriological examination of discharges will also be performed free of charge, and outfits for taking specimens will also be supplied free. This enterprise constitutes, we believe, an entirely new departure in any country, and can hardly fail to produce some very interesting figures. Possibly, however, those figures will be incomplete, for a certain proportion of medical men are likely to fail to supply the reports requested. In addition, the records of a certain number of cases are likely to be duplicated, since patients with venereal disease are very prone to change their medical advisers, and apparently the Board's arrangements include no method by which any given case can be distinguished or identified with one previously brought to the notice of the Board. The precise object of the Board in making the investigation is also not very clear, since the collection of the statistics in view can hardly affect the question of treatment or the facilities for infection. Possibly, therefore, the Board is merely laying the foundations for some further measure, or desires to attract attention to the serious loss of health due to the causes in question by laying before the public what are certain to be very high figures. Still the public can hardly fail to be already aware of how immense is the damage done by venereal disease, especially syphilis, or of the fact that in no other connexion are the sins of the father so relentlessly visited on the children, and of the further fact that syphilis plays a large part in filling the asylums for the insane. Despite this knowledge, any attempt to introduce measures likely to reduce the possibilities of infection would be met, if past experience in this connexion is any gauge, by the most strenuous resistance on the part of a certain number of the British public. But to the second feature of the New York undertaking different considerations apply. The arrangements for the precise diagnosis of venereal diseases are certainly calculated to promote its more accurate and enduring treatment, and some step of the kind is certain to be found necessary in connexion with the National Insurance Act. Venereal diseases are among those which medical men on the panels will have to treat, and undoubtedly they will not infrequently require diagnostic assistance. Laboratory diagnosis in this connexion will, indeed, be one of those many side sources of heavy expenditure for which Mr.

Lloyd George is not known so far to have made provision, though he has made an undefined reference to the need for the employment of modern means of exact diagnosis. An additional point worth noting is that the records of their work that medical men on the panels will have to keep will, so far as the insured classes are concerned, automatically supply returns of a kind equivalent to those now being sought by the New York authorities, though possibly the interests of individuals will not be so fully safeguarded.

SOMERSAULTS AT SIXTY.

At a recent meeting of the Swedish Medical Society, the transactions of which are published in the November number of *Hygiea*, an address, followed by a demonstration, was given by Dr. H. Hogner, who expatiated on the advantages of walking on the hands. This gymnastic feat he began to practise at the age of fifty as a cure for gastroptosis. He has now completed his sixtieth year, and almost daily practises this and similar exercises, such as pedestrianism and various movements of the stomach, legs, and arms. He also attached great importance to somersaults, and found that walking on his hands had become almost as natural a mode of progression as walking on his feet. He pointed out that daily somersaults had contributed to the perpetual youth of a famous American beauty, and that such exercises could be performed by anyone with energy and application, provided he was not too stiff or clumsy. He also attached great importance to temperance in eating, and the surrender of that comfort and good living which he contemptuously termed ill-living. He concluded by saying that walking on the hands, with the exercise it entailed, was the best combination of gymnastic movements, and that it comprised the good effects of all. It therefore deserved to rank as the best gymnastic exercise for the promotion of long life and continuous youth. After the address Dr. Hogner illustrated how a man of sixty can walk on his hands and perform somersaults. We do not wish to belittle Dr. Hogner's treatment, the adoption of which by certain elderly epicures might not be amiss. But a similar doctrine has already been advanced and practised by the hero of Lewis Carroll's lay:

"You are old," said the youth, "as I mentioned before,
And have grown most uncommonly fat;
Yet you turn a back somersault in at the door—
Pray, what is the reason of that?"

We are a little tempted to wonder why Dr. Hogner does not include standing on his head among his other gymnastic accomplishments. Like Father William he might find this exercise free from danger to the cerebral hemispheres.

THE INTELLECTUAL STANDARD OF DOCTORS.

A CORRESPONDENT in a weekly paper which has lately devoted a considerable amount of its space to abuse of doctors, writes that, apart from professional knowledge, the intellectual standard of medical men is much higher abroad than in this country. "Abroad" is a wide term, but it would appear that it is intended to mean France and Germany. English doctors, we are told, make no pretence to be classical scholars, "but how few there are who are really at home in either French or German!" To which we may retort, How few of the English clergy, lawyers, and so forth, who are placed on a pinnacle by the writer, are really at home in either French or German! There is not the slightest reason, as far as we are aware, to believe that doctors are linguistically inferior to parsons or lawyers. It might also be asked, How many Frenchmen are really at home

in English? The Germans, to be sure, are better linguists, but it must be remembered that Germany does not give English doctors anything like the same chance of becoming familiar with her language that we give to the invading Teuton. The writer's assertion that English doctors are inferior in general culture to their French and German brethren is, as far as we have had an opportunity of forming a judgement, entirely unwarranted by facts. It is true that many of the keenest minds of the nation are attracted to fields of activity which offer a better financial return. But fortunately many men of intellect are attracted to the profession by the interest of the work, and it would be strange indeed if medical men whose education is more elaborate and costly than that of any other class of the community should have a lower intellectual standard than that of other professional men. Men of culture, as a rule, delight in the society of doctors. Quite recently we had occasion to quote the experience of the famous French writer, Jules Lemaitre, on this subject. It is recorded by Boswell that Johnson "in general had a peculiar pleasure in the society of physicians." Sir James Paget, as is mentioned in his *Memoirs and Letters*, sat one evening at that very select club, Grillion's, between Gladstone and Matthew Arnold. The talk turned on professions, and Gladstone said that medicine, steadily developing and improving, was the profession of the future. Arnold said he had been much impressed in America by the superiority of the doctors over the clergy and the lawyers. As regards classical culture in particular, that is becoming more and more the appanage of a highly specialized class. Members of Parliament no longer quote Latin, and the time is long past when, as Sydney Smith said, a false quantity in early life was a serious stumbling-block in the career of a young politician. Yet we have some first-rate classics in our ranks, and many men of wide and varied culture that need fear no comparison with any one of any country or profession.

NEW YEAR HONOURS.

In the note upon the honours conferred at the New Year the names of two officers of the Indian Medical Service were accidentally omitted. The distinction of C.I.E. has been conferred upon Lieutenant-Colonel W. J. Buchanan, M.D., who has been Inspector-General of Prisons in Bengal for eleven years, and has initiated several reforms in the Jail Department. He has been for several years editor of the *Indian Medical Gazette*. The other officer honoured in the same way is Major W. G. Liston, M.D., Director of the Bacteriological Laboratory at Parel, and senior member of the Plague Research Commission.

The Secretary of State for the Colonies has appointed Lieutenant-Colonel Sir William B. Leishman, M.B., C.M.Glas., R.A.M.C., F.R.S., Professor of Pathology at the Royal Army Medical College, London, to be a member of the Advisory Medical and Sanitary Committee for Tropical Africa.

UNDER the will of the late Mrs. Ellen Greer, the Royal National Hospital for Consumption at Newcastle, co. Wicklow, and the Molyneux Asylum for the Blind, near Dublin, each receive a bequest of £500.

MR. WILLIAM LANG, F.R.C.S., consulting surgeon to the Royal London Ophthalmic Hospital (Moorfields Eye Hospital), has given a special donation of £450 to the hospital for the endowment for three years of a clinical research scholarship.

THE Bavarian Administrative Council has decided that there is no legal objection to the practice of cremation in that country. As a result of this decision, the City Council of Munich has lost no time in utilizing the crematorium of the Cremation Society, which was already in existence.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

School Medical Inspection. In reply to Mr. Charles Bathurst the President of the Board of Education stated, on January 1st, that the total expenditure on medical inspection and treatment of children in elementary schools in England and Wales, as shown by the returns received from local education authorities for the financial year 1910-11, amounted to £186,999. This was the latest year for which complete returns had been received. The whole of the cost was borne by the local authorities. In reply to a question by Mr. William Thorne on January 6th, the President of the Board of Education said that all the local education authorities had appointed school medical officers. Sixty-seven local education authorities had received sanction under the Education (Administrative Provisions) Act, 1907, for the establishment and maintenance of school clinics. Some authorities had established more than one clinic, and others had been established by voluntary effort, but he could not give the exact number.

Sanitary Authorities.—Mr. Stanier asked the President of the Local Government Board, on January 1st, the number of sanitary authorities, other than a rural district, who had populations of 50,000 and upwards, 100,000 and upwards, 250,000 and upwards, and 500,000 and upwards; respectively? The President of the Local Government Board replied that the numbers in England and Wales were as follows:

| | | |
|---|-----|-----|
| With a population of 50,000 and upwards | ... | 122 |
| " " 100,000 | " | 65 |
| " " 250,000 | " | 16 |
| " " 500,000 | " | 3 |

Twenty-seven metropolitan boroughs were included in these figures.

Disposal of Trade Effluent.—In reply to Mr. Tyson Wilson, the President of the Local Government Board stated, on January 3rd, that he had a bill in preparation dealing with the reception and disposal of trade effluent as recommended by the Royal Commission on Sewage Disposal.

Ophthalmia at Hanwell.—Mr. Burns, in replying to a question by Lord Ninian Crichton-Stuart on January 6th, said that the number of children isolated or treated during the outbreak of ophthalmia at the Park School, Hanwell, was 159; the number of children resident in the Park School on December 31st last was 337; and their average age about 5½ years. The outbreak was attributed to the admission of children the condition of whose eyes, though there was no active disease, was unhealthy, and such children were not in future to be admitted. The buildings were used as an ophthalmic school up to March, 1903, and were not made use of for other purposes until the experts consulted advised that this could safely be done.

Mental Deficiency Bill and Scotland.—Mr. Duncan Millar asked the Secretary for Scotland, on January 7th, whether his attention had been drawn to the resolutions adopted at a large meeting of representatives of parish councils from all parts of Scotland, recently held in Glasgow, in favour of a separate bill for Scotland dealing with the care and control of the feeble-minded. Mr. McKinnon Wood, in reply, said that he could not at present give any undertaking on the subject, but he expected shortly to receive the views of the parish councils in greater detail, and would then be in a better position to come to a final decision. There was a good deal to be said for a separate bill.

Canada.

[FROM OUR SPECIAL CORRESPONDENT.]

DOMINION MEDICAL COUNCIL.

THE organization of the Medical Council of Canada, at a meeting of representatives of the various provinces in Ottawa on November 7th, 1912, was the first-fruits of the Canada Medical Act, or what is commonly spoken of as the "Roddick Bill."

History.

The prime mover in securing the passage of this Act was Dr. T. G. Roddick, of Montreal, a man well known and honored both by the profession and the public. The condition of things which weighed upon Dr. Roddick, and for the removal of which he began his labours nearly fifteen years ago, although somewhat modified since then by other circumstances which have arisen in certain parts of the Dominion, still remains and practically prevails throughout Canada. A medical man, no matter how well qualified by diploma or by additional long experience, cannot cross, perhaps, a country road or stream in the exercise of his calling, if such streak on the map should happen to be the boundary line of his province, without violating the laws of the other province and becoming at least technically liable to penalties. At the same time he is unable to remove this barrier without going through the ordeal of an examination not only in the final practical professional subjects, but in most cases in the earlier scientific subjects—chemistry, anatomy, physiology as well, and of course in addition paying a licence fee. Such a state of matters is annoying and embarrassing to the practitioner, even though to some extent he understands why the thing is so; to the public, who cannot appreciate the reasons set forth, it seems ridiculous.

Two methods at first presented themselves by means of which it appeared that the difficulty might be removed. The first was what is known as direct interprovincial reciprocity, by which each province would agree to accept registered practitioners in good standing coming from any other province. The second might be called indirect reciprocity, as by it each province would first secure recognition and reciprocity with Britain, and as the natural outcome of this, interprovincial reciprocity could easily result. Attempts to attain the objects in view by the first method had failed for reasons which need not be gone into. The method which involved that each province should first secure reciprocity with Britain has been adopted by Nova Scotia, Quebec, and Prince Edward Island, and so far as these provinces are concerned has been eminently successful. But all the provinces for one reason or another did not see fit to proceed along this line.

The aim of the "Roddick Bill" which became the Canada Medical Act, 1902, was to endeavour to accomplish the object in view by creating a general medical council for the Dominion, and by establishing a Dominion qualification and a Dominion register, with the intent that any person who should obtain such qualification after examination before a board of examiners appointed by the Council or should otherwise become registered in the Dominion register should *ipso facto* be entitled without further examination to registration for practice in any and every province of Canada.

The great difficulty which from the first confronted Dr. Roddick was the fact that under the British North America Act the Dominion Parliament could not pass an absolute Act dealing with the matter. It was necessary that any such Federal legislation in order to become operative should be endorsed by the addition to the Medical Act of each province of what is known as an "Enabling Clause." The Medical Board of Nova Scotia, while fully alive to the practical difficulties which would still have to be met even after the Act should become operative, was among the first, if not the first, of the provincial councils to secure the necessary enabling legislation in 1903, but it was not until after much discussion in the various councils and medical associations, and after a further amending Act had been passed, that in 1912 the last province in the Dominion passed an enabling clause making it possible for the Dominion Council to be organized and begin operations under the Act.

Constitution of the Council.

The setting of the date and place for holding the organization meeting at Ottawa devolved, under the Act, upon the Minister of Agriculture, but instead the Government appointed the Hon. W. J. Roche, M.D., Secretary of State, to assist the various provincial councils in the organization of the General Council. Under instructions from Dr. Roche the bodies entitled to representation were requested to select their representatives, and later these representatives were notified to attend at Ottawa in the Parliament building on the morning of November 7th, 1912, for the purpose of organization. Under the Act the Council must be composed of:

(a) Three members who shall be appointed by the Governor in Council, each of whom shall reside in a different province; but until such time as the provinces of Saskatchewan, Alberta, and British Columbia shall have been entitled to university representation, two of the three members so appointed shall be chosen from two of these provinces.

(b) Two members representing each province, who shall be elected under regulations to be made in that behalf by the Provincial Medical Council.

(c) One member from each university or incorporated medical college or school in Canada having an arrangement with a university for the conferring of degrees on its graduates, engaged in the active teaching of medicine, who shall be elected by the university or by such college or school under such regulations as may govern in that behalf.

(d) Three members who shall be elected by the homoeopathic practitioners in Canada, each of whom shall reside in a different province.

In accordance with these requirements, the following representatives were selected from the various provinces:

Alberta.—Dr. R. G. Brett, Banff; Dr. John Park, Edmonton.
British Columbia.—Dr. R. E. Kechnie, Vancouver; Dr. R. E. Walker, New Westminster.

Manitoba.—Dr. J. S. Gray, Winnipeg; Dr. R. S. Thornton, Deloraine. University of Manitoba: Dr. J. R. Jones, Winnipeg.

New Brunswick.—Dr. A. B. Atherton, Fredericton; Dr. W. W. White, St. John.

Nova Scotia.—Dr. A. W. H. Lindsay, Halifax; Dr. John Stewart, Halifax. Dalhousie University: Dr. D. Fraser Harris, Halifax.

Ontario.—Dr. W. Spankie, Wolfe Island; Dr. R. J. Gibson, Sault Ste. Marie. Queen's University: Dr. J. C. Connell, Kingston. Toronto University: Dr. J. M. McCallum, Toronto. Western University: Dr. H. A. McCallum, London.

Prince Edward Island.—Dr. S. R. Jenkins, Charlottetown; Dr. Alex. McNeil, Summerside.

Quebec.—Dr. E. P. Normand, Trois Rivières; Dr. Arthur Simard, Quebec. Laval University: Dr. E. P. Lachapelle, Montreal. Laval University: Dr. P. C. Dagnan, Quebec. McGill University: Dr. F. J. Shepherd, Montreal.

Saskatchewan.—Dr. W. A. Thomson, Regina; Dr. A. McG. Young, Saskatoon.

The Governor in Council appointed Dr. T. G. Roddick, Montreal; Dr. W. Bapty, Victoria, B.C.; and Dr. G. A. Kennedy, Macleod, Alberta.

The homoeopathic representatives were: Dr. E. A. Hardy, Toronto; Dr. G. E. Sugden, Winnipeg; Dr. J. D. Morgan, Montreal.

First Meeting of the Council.

All the representatives with one exception were present. The first session was opened by an address from the Hon. Dr. Roche, now Minister of the Interior, who, after pointing out the importance of the undertaking and congratulating Dr. Roddick and the members of Council on the success so far attained, called upon the meeting to elect a President and to proceed with the general business of organization. Dr. Roddick was thereupon elected the first President of Council, and Dr. Thornton, vice-President. Several committees were appointed and set to work. It was soon fully realized by all that the real difficulty was yet to be met—that is, to decide how, when, and where the examinations should be held and what the nature of the examinations to be exacted for the diploma of the Council should be. The various committees worked hard day and night. The reports submitted by them were carefully considered and criticized, but the Council had to adjourn before a final decision to adopt any report was reached.

It would, however, be a serious mistake to conclude that nothing had been accomplished. By free open discussion in the Council room and personal talks in private many misunderstandings were cleared away, and if any came with any narrow sectional aims and claims it was made apparent that the final best interests of any province or teaching body would be advanced through consideration

for others and by decisions and regulations which would tend to the general good. Marked harmony prevailed in all discussions and increased as time passed. As new light was thrown upon different matters members were willing and prepared to modify the views they had at first expressed and even to amend the vote they had at first recorded. As a result of the modification of views which came about through these discussions it became evident that, instead of finally adopting any of the reports submitted it would be better to adjourn the Council, and to refer all reports to a small special committee for revision and amendments, and that all other matters bearing upon the working of the Act which might or might not have been discussed should be referred to the same committee for careful consideration, with instructions to report at an adjourned meeting in Ottawa, in June, 1913, about the time of the meeting of the Canadian Medical Association in London, Ontario. The registrars of Nova Scotia and Manitoba, Dr. A. W. H. Lindsay, 241, Pleasant Street, Halifax, and Dr. J. S. Gray, 358, Hargrave Street, Winnipeg, were requested to act as such committee and they have already undertaken the duties thus imposed upon them.

Scotland.

(FROM OUR SPECIAL CORRESPONDENTS.)

ROYAL INFIRMARY OF EDINBURGH.

Effect of the Insurance Act.

The annual report of the managers of the Edinburgh Royal Infirmary presented to the annual meeting on January 6th stated that there were 796 patients in the infirmary on October 1st, 1911, and that 11,895 were admitted between that date and October 1st, 1912, so that the total number treated during the year was 12,691. Of these, 7,563 were discharged cured, and 838 died. Deaths within forty-eight hours after admission numbered 181. The percentage of deaths to cases treated was 6.6, against 6.9 last year. Deducting those dying within forty-eight hours of admission, the percentage was reduced to 5.2. The number of out-patients was 39,566.

In response to a representation from the members of the surgical staff, the managers had agreed, in the interests of the patients and the surgeons alike, to appoint to each ordinary surgeon, to each gynaecologist, and to the surgical out-patient department a qualified assistant to supervise the administration of anaesthetics, and rules have been made for the guidance of these officers. As each supervisor is to receive an honorarium of £20 per annum, this will represent a future annual charge of £200.

In their last report the managers stated that they had grave misgivings as to the effect the National Insurance Act would have upon contributions. These features had unfortunately proved well founded, for the voluntary contributions to the infirmary funds showed a total diminution of £1,340 as compared with the figures for the preceding year. Apart from the subscriptions of individuals who had intimated their withdrawal of future support, there was a marked falling off in the collections made in public works and establishments since midsummer. If this state of affairs continued, the full effect of the Act will not be known until the expiry of another twelve months or more.

In July, after a meeting with representatives of the honorary medical and surgical staff and serious deliberation, the managers adopted the following resolutions:

1. That in present circumstances, insured persons being entitled to medical benefits under the Insurance Act, should not be treated in the out-patient departments of the hospital except in accident cases, urgent cases, and suitable consultation cases.
2. That the honorary staff shall be entitled to exercise the option (recognized in private practice) to decline to meet any practitioner in consultation should such a course be considered advisable, but always provided that no patient shall be denied immediate advice or treatment if that be requisite on medical grounds.
3. That the question of investigating the circumstances of applicants for the benefits of the hospital by means of almoners or otherwise is one which will require time and care in consideration owing to its undoubted complexity. The managers will, however, give the subject their most careful attention in due course.

As there seemed to be widespread misunderstanding in the minds of the public as to the meaning and effect of the board's decision with regard especially to the first resolution, an official communication was published, pointing out that the first resolution was only to apply to out-patient cases, and to them even with this important reservation—that all serious, urgent, and proper consultation cases would continue to be attended without question as heretofore. In other words, there would be no change in the policy of the infirmary in the reception or treatment of persons coming to the institution, with the sole exception of those attending as out-patients whose injuries or ailments were of such a nature as could readily receive proper attention from the ordinary practitioner. It was further pointed out that this modification would involve no hardship upon the working classes, who, under the Insurance Act, would be provided with ordinary medical attendance. Nor would it in any way limit the usefulness of the institution, whose greatest work was, of course, done in treating the in-patients in the wards; for as regards these the position would be that, as cases calling for hospital care, they were, *ipso facto*, urgent cases, and would be admitted and treated as freely as in the past. All dependants of insured persons who were suitable cases would continue to receive treatment as formerly.

Inquiries were recently made by the Local Government Board as to whether the managers were proposing to enter into an arrangement with the Insurance Committees for the treatment of tuberculous cases, as if so the institution would require to be inspected and passed in the first place. After consideration it was agreed to intimate that in the meantime, at least, the managers had no intention of coming to any such agreement.

There are at present about 560 employees—nurses, servants, and others—who come under the provisions of the Act, and the contributions by the institution on their account will amount to £365 or thereby per annum.

GLASGOW FOG AND THE DEATH-RATE.

The medical officer for Glasgow, Dr. Chalmers, in a report to the Health Committee, states that the death-rate for the week ending December 7th, 1912, was 25.6, compared with 19 for each of the weeks preceding, and with 17 for the corresponding weeks of last year. The contrast, he says, afforded illustration of the results of low temperature when combined with fog. In the week ended December 7th the deaths rose from 289 to 385, those of children under 5 from 118 to 157, and those of persons over 60 years from 66 to 102. Respiratory diseases, which in the week ended November 30th had numbered 78, rose to 115, which was equal to 34 per cent. of the total deaths, and a rate of 6.6 per 1,000 of the population. Having in recollection the experience of the week ending February 10th, 1912, when Glasgow had prolonged low temperature, but no fog, the recent experience served to mark how rapidly fog and low temperature, when combined even for a short period, were disastrous alike to persons at both extremes of life.

HOSPITAL RECONSTRUCTIONS.

At a meeting of the directors of the Arbroath Infirmary, held a few days ago, the question of the reconstruction of the infirmary was discussed. From a circular issued to the directors it appeared that estimates obtained by the Building Committee for the work showed that the approximate cost would be £14,500. One of the directors, Mr. Balfour, of Inchoch, offered £1,000 towards the construction of a new building and a large subscription towards the cost of furnishings. Dr. Mackintosh, Western Infirmary, Glasgow, assisted in drawing up the plans.

The Hamilton Town Council has agreed to proceed with the erection of a new hospital at an estimated expenditure of £20,000.

THE CONSCIENTIOUS OBJECTOR.

At a meeting of the Public Health Committee of the Inverness Town Council held last week the Convener said that, in consequence of the relief given to conscientious objectors to vaccination, the result had been that non-vaccination had been increasing. If an outbreak of small-pox occurred, the results, he was afraid, would be extremely serious. He found that the committee had absolutely no power, because the parents had the right to become conscientious objectors. It was a serious menace

to the health of the community to have so many children unvaccinated.

HOME FOR SCOTTISH NURSES.

Shortly after the death of King Edward VII the suggestion was made that the nurses of the country should pay a fitting tribute to a monarch who recognized in many ways the great and beneficent work they accomplished. The proposal soon took definite shape, and a sum of £9,000 was raised by the nurses and their friends to establish homes for nurses as a fitting memorial. A home was established at Clapham with accommodation for twenty-one nurses. The London Committee suggested the establishment of a similar home—or more than one if necessary—north of the Tweed, and for this purpose a sum of £3,000 was promised. A Scottish committee, which has taken the scheme in hand, proposes that there should be one home in the east of Scotland and another in the west, but states that £3,000 will not be sufficient to meet the expenses of the establishment, though the institutions will eventually be self-supporting. The sites of the homes have not yet been definitely settled upon, but it is thought that the home in the East of Scotland should be somewhere near Edinburgh.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

THE DUBLIN CLINICAL HOSPITALS AND THE TEACHING OF TUBERCULOSIS OFFICERS.

EARLY last summer the Local Government Board made public the qualifications that they considered necessary for tuberculosis officers under the sanatorium benefit of the new Insurance Act. These were, in general terms, either (1) residence in a sanatorium, (2) a course of instruction in the diagnosis and treatment, etc., of tuberculosis, (3) other means by which the Local Government Board was satisfied that the candidate was specially qualified to diagnose and treat tuberculous patients. At the time exception was taken by the medical profession in Ireland to this third method, and it was pointed out that unless the men appointed as whole-time tuberculosis officers were specially qualified, they would not command the respect and co-operation of practitioners throughout the country. The Local Government Board stated that the third method of qualification would only be made use of in exceptional cases. The Committee of the Allan Ryan Home and Collier Dispensary in Dublin then advertised a fortnight's course of instruction for candidates for these posts, and issued certificates to those who attended it; altogether over thirty medical men entered their names for this course. The Local Government Board, however, said that it would not recognize this certificate as proof of the necessary qualification.

The Committee of the Allan Ryan Home then approached the clinical hospitals of Dublin, asking them to combine in giving a six months' course of instruction in tuberculosis. But the clinical hospitals were unwilling to associate themselves with these institutions which had no standing as teaching bodies, and thought it better that their instruction should be given as a separate course. Representatives therefore interviewed the Local Government Board, and at its request drew up a scheme for a course of post-graduate instruction in tuberculosis, which would include both surgical and medical clinics, pathology, and teaching in special subjects such as ophthalmology, laryngology, and gynaecology. As the Local Government Board had in the meantime recognized a six months' course to be given by the Allan Ryan Home as a sufficient qualification, the clinical hospitals asked that their course should be made an essential part of the course, as otherwise it would be useless for them to go to the trouble of establishing it for the few men who would be likely to take it out.

The Local Government Board has now replied, thanking the clinical hospitals for the time and trouble which they have taken in formulating the draft scheme, and concurring in their views as to the advantages to be gained by future tuberculosis officers from attending a course of instruction given by so large and experienced a body of teachers having under their care such a vast

amount of clinical material comprising the various forms of pulmonary and surgical tuberculosis. The Board goes on to express its regret that the committee should have attached the imperative condition that the course must be regarded "as essential," as it would be impossible for the Board to accept this condition at present, chiefly because, as there is no similar course anywhere in the United Kingdom, it would compel all tuberculosis officers in Ireland to take it and would therefore be unfair to many of those who were already undergoing training not only in Ireland but also in England and Scotland. The Board, however, expressed the hope that the committee would carry the scheme into effect, as it felt satisfied that in course of time it would come to be recognized as an almost indispensable qualification for persons taking appointments in connexion with the administration of the Tuberculosis Act in Ireland. The Board states that it is prepared to assist the committee as far as possible and to bring the course under the notice of tuberculosis officers.

It is calculated that the number of whole-time tuberculosis officers under the Act in Ireland will only be about forty, certainly less than fifty, and already over thirty men have entered their names for the course given by the Allan Ryan Home. These, with a few who are believed to be taking out a course in England or Scotland, leave a very small number, not more than about a dozen at the most, who would be likely to attend the course given by the clinical hospitals, and, once the appointments throughout the country are made, there would only be an occasional applicant for the course as a vacancy occurred. In these circumstances it can be seen at once that it would be useless for the clinical hospitals to go to the trouble of establishing and conducting such an elaborate scheme of instruction for the small number of men who would be available to attend it unless the Local Government Board change its mind and makes the course an essential one.

Special Correspondence.

PARIS.

Treatment of Cancer by Radium.—The Tolerance of the Peritoneum towards Foreign Bodies.—Hæmolysis.

At the last meeting of the Surgical Society several reports on the treatment of malignant disease by radium were read and discussed. M. Regnier reported the case of a patient who was admitted to hospital in January last with a sarcoma of the femur the size of a fetal head, attended by considerable oedema of the leg. An aperture was made into the tumour by means of a trocar, and the tube of radium was left in the tumour for forty-eight hours. After the first application the tumour diminished considerably in size, the pain disappeared, and the oedema diminished. At intervals of some weeks three further applications of radium were made, and the tumour decreased until it was a small hard sclerosed mass of the size of a walnut. M. Chiffelian then removed this small tumour, which was adherent to the femoral vein. On microscopic examination it was found to consist of fibrous tissue and deformed tumour cells. A second case reported by M. Regnier was one of inoperable cancer of the uterus. Four applications of radium were made with great amelioration in the patient's general condition as well as in the diseased uterus. The patient's weight increased from 53 to 63 kilos, the sanguineous discharge stopped and the tumour diminished in size. There was, however, a large mass of secondary growth in the abdomen, and though the patient was greatly improved temporarily, recovery could not be looked for. M. Sieur reported a case of epithelioma of the larynx treated with good result. M. Schwartz related a case of sarcoma of the forearm greatly benefited by radium treatment; and M. Hartmann stated that he had seen very good results from radium in the treatment of lymphosarcoma. Radium must be introduced into the tumour mass to obtain beneficial results and not merely laid on the tumour.

M. Walther recorded an interesting case of perforated appendix with escape of a coprolith into the peritoneal cavity. The history of the case was interesting, as it shows how the peritoneum may in some cases be entirely protective. The patient was on board an Atlantic

liner when he was suddenly attacked with severe pain in the right side. He lay down for several hours, the pain passed off, and he soon felt quite well again. Six weeks afterwards M. Walther opened the abdomen and removed the appendix, which showed a cicatrix near the tip. Lying free in the left side of the peritoneal cavity was a coprolith which had evidently burst through the appendix six weeks earlier.

At a recent meeting of the Society of Biology Professor Achard and Dr. Foix reported the results of recent researches into the phenomena of haemolysis. They found that the blood corpuscles of the dog were much more fragile than those of man or rabbits. Extracts of different organs of the dog haemolysed the red corpuscles much more readily than either in man or rabbits; and with extracts of human and rabbits' organs, also, haemolysis of the dog's corpuscles occurred much more rapidly than either of the other species. The substance in the extracts is not a true haemolysin, but appears to belong to the group of lipoids; it is soluble in alcohol. The blood corpuscles of the dog are haemolysed by the lipid sodium oleate. The haemolysis caused by heating serum to 56 C. they attribute to the destruction of a protecting substance in the serum, and not to the production of a haemolysin, since the addition of fresh unheated serum prevents haemolysis.

VIENNA.

Annual Report of the Board of Health for the Year 1911.—New Lectureship at the University of Vienna. —Foreign Body in the Trachea.

THE annual report of the Vienna Board of Health for the year 1911, which has recently been published by the municipal authorities, contains much that should be of particular interest to its medical readers. For example, the report states that in 1911 there were 3,018 doctors practising in the city of Vienna, the population of which at that time amounted to 2,120,000; that is to say, there was one doctor to every 555 inhabitants. Forty-seven of these practitioners were women. It should be added, however, that these figures are not strictly accurate, since the report includes the hospital doctors, who, of course, have no outside practice. This high ratio of medical men amongst the general population is, perhaps, one explanation of the small incomes earned by so many members of the profession in Vienna. The following figures may be of interest as showing the statistics of different diseases during the year 1911. No case of small-pox and only 4 of cholera were reported during the course of that year, whilst the number of typhoid cases sank from the 465 of the previous year to 323. There were 4,606 cases of scarlet fever in place of the 4,038 of 1910; whilst the diphtheria returns showed a decrease from 3,076—of which 279 died to 2,679 with 219 deaths. The mortality in diphtheria cases was therefore only 8 per cent, instead of 36 per cent., as in the days before the treatment by serum. In the present instance 2,624 of the 2,679 cases reported were treated with serum; and it should be remembered that the majority of deaths occurred in those cases where the disease was recognized or the serum injected only after the fourth or fifth day of illness. A great decrease was also to be observed in the number of cases of measles, there being only 8,073 cases reported during 1911 in place of 12,657 during the previous year, whilst the number of deaths from this disease sank from 687 to 334. An even greater decrease was remarked in the cases of epidemic cerebro-spinal meningitis, of which 19 cases occurred in 1911, 32 in 1910, and 298 in 1907. Five cases of anthrax and 4 of poliomyelitis (13 cases of the latter disease had occurred during 1910) were reported in 1911; and it is interesting to note that every one of these cases was imported, and in each instance the patient was a hair-worker. As regards the death-rate in Vienna during the year 1911, it was, though actually higher, yet relatively lower than in the preceding year—namely, 16.45 instead of 16.75 per 1,000. An increase was noticed in the number of deaths from new growths, organic diseases of the heart, and gastro-intestinal diseases in infants; whilst there was a marked decrease in the mortality arising from diseases of the respiratory organs. Out of the total number of deaths (which amounted to 33,215)

were due to tuberculosis, and 15.7 per cent. to tuberculous disease of the lungs. These figures are almost exactly the same as those of the two previous years, thus showing that the campaign against tuberculosis has as yet had no appreciable results.

A new lectureship at the University of Vienna has just been founded in memory of the late Professor Nothnagel. The first lecture was delivered a few days ago, when a most instructive paper on the importance of the liver for the metabolism of sugar was read by Professor Hofmeister of Strassburg. This is the first time that the memory of one of our famous physicians or surgeons has been perpetuated in this fashion, the custom of commemorating the dead by the endowment of a lectureship being hitherto quite unknown in Austria.

An interesting case of a foreign body in the trachea was described some time ago by Professor Koschier at the meeting of the Medical Society. Fifteen months previously a man had been brought to him who had already undergone tracheotomy, and who was then suffering from attacks of suffocation. No history of the case could be obtained, and when Koschier removed the tracheotomy tube for examination he found that he was unable to replace it, and had to perform tracheotomy immediately in order to save the patient's life. A mass of granulations was removed from below the site of the tube without much effect upon the condition of the patient; but finally, after dividing the whole anterior aspect of the trachea, a piece of bone was discovered and removed with some difficulty, and the dyspnoea at once disappeared. Up to the time of Professor Koschier's demonstration the nature of the bone had not been ascertained. It had evidently either been inadvertently swallowed by the patient or had passed, owing to suppuration of the thyroid gland, into the trachea, as has happened once before. The history of the case, if it were known, might help to clear up the mystery.

Correspondence.

THE FUTURE ORGANIZATION OF THE ASSOCIATION.

SIR.—In a letter to the BRITISH MEDICAL JOURNAL (published at the beginning of February, 1911) in defence of contract practice, I pointed out that the low scale of pay for such work was due to our want of unity, and also to the fact that our subscription to the British Medical Association was too ridiculously small to enable it to become a proper fighting or even defensive organization.

Then came the Insurance Bill, and after its passage into law I wrote another letter to the BRITISH MEDICAL JOURNAL (December, 1911) emphasizing my former contention and pointing out how few modifications of the bill had been brought about by the action of our Association with its existing machinery.

The subsequent concessions of the Chancellor were not due to the fighting power of the British Medical Association, but simply to the fact that under the original provisions of the Act it was impossible for any ordinary practitioner to undertake the work at the prices offered. Hence the 27,000 pledges, which would certainly have been kept had not Mr. Lloyd George correctly gauged the situation, and, with consummate skill, thrown the golden apple at exactly the right moment.

Relieved of the fear of any great loss of income, men with families to maintain and other financial obligations to meet felt that they could no longer face ruin in an unequal fight between the Government of the country with its unlimited resources and our Association, officered almost entirely by amateurs, and with a fighting income of 4s. a member per annum, and a guarantee fund which must utterly fail to compensate men in any fair-sized town where a State medical service was set up.

Of course our best thanks are due to our amateur leaders, to the members of our Council for their hard work and devotion, to our State Insurance Committee for its untiring labour, and also to those Divisional and Branch secretaries who have done their work conscientiously and well. We are also indebted to our Representatives for their plucky and exhausting attempt to crowd into two strenuous days an amount of work which

might easily occupy a fortnight. The lot of the unfortunate Representative is not a happy one. He receives his instructions from a meeting at which perhaps a quarter of the members of the Division are present. Between this date and the Representative Meeting most important events may occur, totally altering the position of affairs, yet he is bound to vote according to his instructions, and often against his own judgement.

With such an organization how can we expect success when it comes to close fighting? Surely it is time for us to recognize the fact that the British Medical Association must either relapse into the condition of a purely scientific body, or it must, whatever the cost and trouble, be turned into a trades union with well-paid officials and ample funds.

Many artisans pay 1s. 6d. a week and more to their unions, and surely we, with so much more at stake, can afford the modest sum of 2s. a week or £5 5s. a year. Let those who are too stingy to increase their subscription or too proud to be associated with anything so low as a trades union stay outside until they find out their mistake.

The Representative Meeting should be abolished and the Council in future should consist of a President, the Medical and Financial Secretaries, the Editor of the JOURNAL, and the Branch Secretaries, all specially appointed whole-time men with large salaries and considerable powers of negotiation, but subject on all really important matters to a postal referendum of the whole of the British Medical Association members.

This Council should meet regularly once a month, and oftener when necessary, and sit day by day until all business is settled without undue hurry. In the interval it should be the duty of every Branch Secretary to attend all Branch Meetings and as many Divisional meetings as possible, and to keep in touch with all Divisional Secretaries. He should also be provided with a motor car, and should be expected to visit and make the acquaintance of every medical man in his Branch, keeping up the interest of members and bringing non-members into the fold. He should be provided also with a clerk to do the purely clerical work and to collect overdue subscriptions.

The Branch Secretaries would thus keep the Council in touch with the wishes of men in all parts of the country, and every practitioner would feel that he was a recognized unit.

Divisional Secretaries should also be paid a reasonable sum for their services, and we should then be entitled to grumble at them or replace them if they failed to carry out their duties.

There should be a large reserve fund for fighting purposes and for assisting any members suffering loss from loyalty to the Association; also a benevolent fund for helping those in distress through unavoidable circumstances, and last, but not least, a department cutting off any possible supply of blacklegs by assisting men to find appointments, assistantships, and practices.

I sincerely hope that when our Representatives meet on January 17th they will spend their time in laying the foundations of a new and a stronger Association, rather than pelting one another with the ruins of the old one. Judging by the number of men who have already put their names upon the panels, the policy of the medical profession and that of the British Medical Association as formulated at the last Representative Meeting are no longer identical; and if the British Medical Association is to retain its position of authority a new policy must be inaugurated. The last four lines of "The Lesson," with one or two small alterations, for which I apologize to Mr. Rudyard Kipling, are singularly appropriate to our present situation:

It was our fault and our very great fault; and now we may turn it to use.
 We had 27,000 reasons for failure, but not one single excuse.
 So the more we work and the less we talk, the better results we shall get;
 We have had no end of a lesson; it may make us a union yet!

—I am, etc.,

North Shields, Jan. 4th.

F. C. MEARS.

SIR,—The serious defeat of the last few days should make the leaders and members of the British Medical Association and the rank and file of the medical profession

think furiously. Inherent defects of organization and weakness and absence of cohesion among the individuals are the causes of the *débâcle*. We have allowed ourselves to be turned out of an impregnable position by a few skeleton battalions and the feints and false attacks of an adroit antagonist, aided, as he has been, by defections from among our leaders, who vainly try to whitewash themselves by pointing to irregularities in our Enlistment Act (Pledge).

Reeriminations as to the past are useless, and I do not intend to indulge in any. As to the future, much may be done. A lost battle does not necessarily mean the loss of the campaign. We have been badly hustled and from inexperience have run away from the feeblest of Rogeys. But we can regain our breath and formation, our war chest (which should receive prompt attention) is intact, and no serious damage is done beyond some loss of prestige. The lesson should be valuable. The remedy is obvious:

1. The Council must be granted liberty of action and given full control over affairs. Peace or war should be decided by vote of the Representatives but all executive details should be left in the hands of a committee. The Council must be purged of all who cannot act loyally with a majority. Resignations on the field of battle are disgraceful.

2. The Divisions must stop crying out that they are betrayed if the Council finds it necessary to withdraw from a position found to be untenable, or to change front to meet an attack on either flank. To have to consult the Divisions on minor points is impractical and absurd. The Divisions should relieve the Council from all anxiety as to the condition of the finances and agree to act loyally by one another and sink minor differences. They must recognize the fact that it is impossible for each one of twenty thousand men to have his own way, and they must obey orders and observe the rules of strict discipline. No other course is open if a victory is desired.

For good or evil the National Insurance Act is with us, and panels are in existence for three months at least. If the medical profession is satisfied with the conditions laid down and the state of affairs the matter is ended. If dissatisfied, it must set to work on sensible lines and with the determination to fight to a finish.—I am, etc.,

Southport, Jan. 6th.

FRANCIS J. BALDON.

SIR,—Now that the profession has been defeated—and no reasonable man can deny that it has been defeated—in its efforts to obtain terms consistent with its dignity and character, it will be well to look into the causes of our discomfiture, and see what can be learnt from them. Apart from Dr. Addison's efforts on behalf of the Government, our defeat is due entirely to the policy, or lack of policy, of the Council of the Association itself. Not only have we had individuals such as Sir Victor Horsley and Dr. Lauriston Shaw betraying our best interests, but we have had no support from the Council as a body. How is this? Were the efforts of those in favour of working the Act sufficient to nullify the efforts of those supporting the rank and file? Presumably the Council felt itself unable to recommend such methods as addressing meetings of insured persons and canvassing the country in general. It may be said that these steps are being taken now, but they are, of course, months too late. Even if we get the masses on our side now it will not alter the fact that hundreds of us by sheer economic pressure have been compelled to break our pledges and go on the panels. As a result of the Council's weakness, to whatever cause it may be due, each man in the profession has had to fight not as one of a disciplined force, but as one of a mob of individuals. He has felt himself to be alone in the fight, without support and *without reserves*. Why the Association was not better prepared for the fight it is very difficult to say, considering that the Chancellor's intentions were known quite two years ago.

The final stroke was the resolution passed at a Representative Meeting to treat insured persons through approved societies while remaining off the panels. This was, of course, a most appalling blunder. It broke a cardinal point, and so gave scores of waverers the excuse that their pledges were no longer binding, and quite ignored the obvious fact that the Government could not allow it to be done.

No, Sir, whatever efforts are made now we have lost our

fight, and have now to consider the future. To every thinking man it must be obvious that this struggle is but the prelude to a far greater one—that in which efforts will be made to force us to become the puppets of a State Medical Service. This will most certainly take place in five years, probably in three. Are we to enter that fight as we entered this, unprepared, no war chest, with disordered ranks and disloyal captains, or shall we be found ready, shoulder to shoulder, with leaders who will lead and not simply consent to be pushed?

This is a question beside which the present one sinks into absolute insignificance. First of all, let there be no more silly talk of "blacklegs"; let an act of oblivion cover the past. Next, let us be loyal to the Association, on the panel or off the panel, remembering that it is our duty to strengthen it by cohesion and subordination of personal interests, not to weaken it by internal dissensions. And, above all, let us see to it that we have a Council composed, not simply of men of high professional standing, but men of business ability, men who have been proved to possess the gift of organization and to really represent our best interests. The *débâcle* of to-day must lead to the victory of to-morrow, and "Unity" must be the watchword.—I am, etc.

London, S.W., Jan. 5th. J. H. MEERS, M.R.C.S., L.R.C.P.

THE LIFE-HISTORY OF SPIROCHAETES.

SIR, In the issue for December 14th E. H. Ross, in an article on An Intracellular Parasite Developing into Spirochaetes, writes in reference to the spirochaete of syphilis: "Intracellular stages of the various other spirochaetes have been described by many authorities . . . but the relations between the various bodies described above and the *Spirochaeta pallida* were not hitherto demonstrated."

In an article on the *Spirochaeta pallida* published in the *Glasgow Medical Journal* for March, 1906, I wrote in referring to Siegel's bodies: "In my opinion, the *Spirochaeta pallida* and the *Cytorrhycles luis* are different stages in the life-history of the same parasite." Again, in the *BRITISH MEDICAL JOURNAL* for May, 1906, in an article on the *Spirochaeta pallida* and its variations, a number of figures and photomicrographs are shown to demonstrate the intracellular parasite. The whole article is a plea for the view that the *Spirochaeta pallida* is only one stage in the life-cycle of the infective agent in syphilis.

In 1907 a demonstration of the variations of the *S. pallida* was given at the Medico-Chirurgical Society, and the paper appears in vol. xc of the *Transactions*. On that occasion I stated that it was my intention to show part, at least, of the life-cycle of the parasite. The intracellular parasite was again illustrated. Similar small bodies to those found in syphilis were shown under the oil-immersion lens as being associated with the *Spirochaeta pertenuis*. These few facts may prove that the intracellular bodies were in 1906 already recognized as being associated with the *Spirochaeta pallida* in syphilis.—I am, etc.

Glasgow, Jan. 2.

ALEX. MACLENNAN.

BOVINE AND HUMAN TUBERCULOSIS.

SIR.—The leading article on the Italian investigation on this subject in the *BRITISH MEDICAL JOURNAL* of November 23rd, 1912, p. 1485, is full of interest. Professor Gossio traverses all the findings of our Royal Commission. He endeavours to upset what we have come to regard as settled theories. His principal conclusion is that where there is much tuberculosis in animals there is little tuberculosis in man, and that where there is much tuberculosis in man there is little or no tuberculosis in animals. It would tend to a clearer understanding if in discussing this subject we could distinguish between bovine and human tuberculosis. It has long been agreed that these two conditions are due to different types of bacilli. This was very clearly set out in the excellent paper in the *JOURNAL* of November 23rd, 1912, by Dr. John Fraser. Our present system of nomenclature is clumsy and leads to confusion.

Professor Santoliquido affirms "that in the North of

Italy, where is grave diffusion of bovine tuberculosis and where milk is largely used, peritoneal tuberculosis is not proportionately increased, while in the Midlands, where little milk is drunk, and where often bovine tuberculosis is unknown, peritoneal tuberculosis is high." Italy must be peculiar in this respect, for we are told that in regions like Australia and the Sandwich Islands the infection of the inhabitants has followed the introduction of tuberculous cattle. The poorer classes in China do not suffer from tuberculosis, whereas among the dominant Tartar class (milk and meat consumers) the disease is prevalent. In South America, where the use of milk is almost unknown, or used only after being boiled, the natives are not affected. Tuberculosis is unknown in Morocco, where there are no European dairy cows. In Guernsey the proportion of cattle affected with tuberculosis is about $\frac{1}{2}$ per cent., and Dr. Bishop, the medical officer of health, says that "the forms of human tuberculosis are consequently exceedingly rare." In England and Wales, in 1909, 10,000 children under the age of 5 died from tuberculosis (other than pulmonary tuberculosis), and it is estimated that 70 per cent. of our dairy cattle are affected with tuberculosis! During the last forty-five years the returns show a reduction in the death-rate from all forms of tuberculosis of 27.9 per cent. in Great Britain, the reduction in deaths from phthisis reached 66 per cent., while the corresponding reduction from tabes mesenterica only reached 3 per cent.

Adami says that "impure and infected milk is the essential factor in the production of abdominal tuberculosis in children, if mesenteric tuberculosis were in the main due to infection with human tubercle bacilli, then with the lessening of tuberculosis in adults there ought to be a corresponding diminution in the number of cases of tabes mesenterica in children, and this has not occurred." Having regard to these facts and opinions, we can scarcely be expected to agree with Professor Santoliquido's conclusion "that the fatal march of this contagious disease will not be stopped, even for a moment, simply by rendering meat and milk free from infection."

I would especially draw Professor Santoliquido's attention to the experiments of the British Royal Commission with the anthropoid apes. When these animals were fed with milk from a tuberculous cow they developed general progressive tuberculosis.

We may await with equanimity the publication of the full reports of the Edinburgh investigation. The foretaste Mr. Stiles has given us is comforting—"that a large proportion of surgical tuberculosis, at any rate in children, was of bovine origin."—I am, etc.

Beverly, Dec. 2nd, 1912.

T. READMAN.

THE MADNESS OF KINGS.

SIR,—I speak under correction, but I submit that there is not a tittle of evidence that Nebuchadnezzar suffered from lycanthropy, or kyanthropy, as Aetius calls it. Practically the sole authority we have on this disease is Oribasius, for though it is described in detail by Aetius, Paulus Aegineta, and others, they took their descriptions word for word from Oribasius, either directly or through Marcellus Sidetes, who transcribes him literally. The description given by Oribasius is detailed and definite, and leaves little room for mistakes in diagnosis. "Those affected by this malady go out of their houses in the night time, and in everything imitate wolves, wandering about the sepulchres of the dead till daybreak. You may know them by these symptoms: their countenances are pale, their eyes heavy, hollow, dry, without the least moisture of a tear; their tongues exceedingly parched and dry; no spittle in the month; extreme thirst; their legs, from the falls and bruises among stenes and thorns, are full of incurable sores." Aetius and Paulus Aegineta say they open the tombs of the dead, but neither of them seems to have seen a case, and both Oribasius and Aetnarius say "they run about among the tombs." The demoniac of the Gospels, who seems to have been a lycanthropist, "had his dwelling among the tombs" (Mark v, 3), "abode in the tombs" (Luke viii, 27). No such habit and no such symptoms are recorded of Nebuchadnezzar. He did not voluntarily go out of his house in the night time: he was "driven from men." He

did not imitate wolves in anything, unless it is a practice of wolves to eat grass as oxen, which I believe is not the case. So far from suffering from extreme drought, his body was wet with the dews of heaven. To suppose that he suffered from lycanthropy is clearly a mistaken diagnosis.

On the other hand, I agree with you, Sir, that there is no evidence whatever that Saul, King of Israel, was insane; and I go further than you, and maintain that it is very unfair to suggest that his jealousy amounted to insanity. His crown was not nailed to his head. On the contrary, it fitted very inescapably, and David was a popular, and therefore a dangerous rival. Eastern potentates and primitive potentates, such as Saul, have usually a very short way with rivals to their thrones, and it is much to Saul's credit that he exercised such exemplary forbearance towards David. There has been much speculation as to the nature of Saul's malady when the evil spirit was upon him, but it seems to me as clear as day that it was nothing but this—he was bored to death. Saul was eminently a man of action—a fighter. The common resource of every military man in times of peace is the chase; and from this occupation Saul was precluded, no less by the customs of the Jews than by the Rabbinical law. It is very remarkable, though I think it has never been remarked, that in the whole of the Old Testament there is no simile or metaphor drawn from the chase, nor any allusion to hunting, except in the description of Nimrod, who was not a Jew, and in the despicable stratagem of Jacob, who lived before the Jews were a people. Saul, therefore, was precluded from the chase; he was not a legislator, nor, if he had been, would he have been able to initiate legislation; for the Rabbinical law already regulated the lives of the populace down to the minutest detail, and brooked no interference. His elevated position cut him off from ordinary occupations, and from much social intercourse. There was nothing to divert the poor man in his solitary grandeur; and, being a Jew, and therefore having a natural taste for music, he found his sole refuge from boredom in listening to the music of David's harp. It says much for Saul's magnanimity that he would send for his rival, and permit him to display his accomplishment in the presence of his sovereign and the court. It is small wonder that the presence of that formidable rival, and the display of his superior skill, should sometimes exasperate beyond bearing an irritable monarch; and if this irritability was from time to time increased, as we may conjecture it was, by the jarring of a false note, or by the faulty execution of a run or a shake, is it any wonder, is it any discredit to Saul, that he corrected the offender with a javelin? The very fact that he took care to miss—Saul was a good marksman, and David was within easy distance—is further evidence of Saul's good nature. Who of us, even in these humanitarian times, would exercise such forbearance in similar circumstances? For my own part, I feel thankful that, when present at certain public concerts, I have not had a javelin handy. My skill with the weapon does not compare with Saul's, but I shudder to think of the lifelong remorse I might now be suffering, in the neighbouring parish of Portland, if I had had Saul's opportunities.

I do not know whether your list of kings who were insane is intended to be exhaustive. Perhaps it was an ardent patriotism that moved you to omit from the list the Sovereign in whose name this realm was administered a hundred years ago. If we are to include among the insane the degenerates—a term whose meaning has not been fixed, but which is generally employed to stigmatize those whose tastes and habits we do not approve—I am afraid we could furnish from the illustrious roll of our own monarchs several other examples—William II, Richard II, Edward II, Charles II, and James II, for instance. It will be noticed by the curious that all these are the second bearers of their respective names, and if we add, as some historians would agree, the name of the second George, we find it a rule, broken by the Henrys only, that the second bearer of any Christian name is always a degenerate. It would be interesting to inquire whether the rule obtains in private families also. I could furnish several examples from my own acquaintance. Perhaps I may be permitted to forestall inquiries by adding that no previous member of my family has been entitled to sign himself

Parkstone, Jan. 4th.

CHAS. MERCIER.

ANTIVACCINATION AT THE CHILDREN'S WELFARE EXHIBITION.

Sir,—May we ask you to publish the following letter which we have sent to the *Daily News* in consequence of the antivaccination stall at the Children's Welfare Exhibition?—I am, etc.,

London, W., Jan. 3rd.

MACLEOD YEARSLEY.

131, Harley Street, W.

January 13th, 1913.

To the Editor of the *Daily News*.

Sir,

On invitation we gave our names as patrons of the Children's Welfare Exhibition now open at Olympia, and which has been organized by the *Daily News*.

We have learned that the exhibition is being utilized to oppose the carrying out of vaccination.

As we cannot too emphatically express our disapproval of such an object, and as our names have been associated with the exhibition, we think it only right to say that we should never have permitted them to appear in connexion with it had we any idea that such use would be made of the exhibition as the one referred to.

We remain,

Yours very truly,

H. MACNAUGHTON-JONES,

C. W. SALEEBY,

MACLEOD YEARSLEY.

P.S.—Since the above was written, the following letter has been received by Dr. Macnaughton-Jones. Doubtless the directors were within their rights to make arrangements for the use of any stall at the Children's Welfare Exhibition, but they cannot defend their action in inducing medical men to become, even indirectly, patrons of a stall the object of which they entirely repudiate, and which is distinctly contrary, in their belief, to children's welfare":

The *Daily News*, Ltd.,

Bouverie Street,

London, E.C.,

January 6th, 1913.

Dear Sir,

In reply to your letter of the 5th inst., the Antivaccination League has taken and paid for space at the Children's Welfare Exhibition on precisely the same terms as ordinary traders; no solicitation or preference has been extended to them. In these circumstances I think you will see that the directors of the exhibition could not have refused to accept them as tenants of a stall without entering into controversial matters—a course which would generally be regarded as improper.

Yours faithfully,

EDWIN COOKE,

Director.

Universities and Colleges.

UNIVERSITY OF LONDON.

MEETING OF THE SENATE.

A MEETING of the Senate was held on December 18th, 1912, the Vice-Chancellor, Dr. W. P. Herringham, in the chair.

Recognition of Teachers.

The following have been recognized as teachers in the subjects indicated:—

King's College for Women: Dr. Janet E. Lane-Clayton (Physiology).

St. Bartholomew's Hospital Medical School: Mr. Alexander Macphail (Anatomy); Mr. Raymond B. Etherington Smith (Surgery).

London Hospital Medical College: Dr. Robert Hutclison (Pharmacology); Dr. Hubert M. Turnbull (Pathology).

London School of Medicine for Women: Dr. Frederic Wood Jones (Anatomy).

King's College Hospital Medical School: Mr. Charles E. Wallis (Dental Surgery).

St. Mary's Hospital Medical School: Dr. Thomas G. Stevens (Midwifery).

London School of Dental Surgery: Mr. Arthur Hamilton Tebbutt (Bacteriology).

National Hospital for the Paralyzed and Epileptic, Queen Square, W.C.: Dr. Conrad M. Hinds Howell, and Dr. Samuel A. Kimmer Wilson (Neurology), Mr. Leslie J. Paton (Ophthalmology).

Mr. Vivian Bernard Orr has been granted probationary recognition as a teacher of anaesthetics at the Westminster Hospital Medical School for a period of two years as from December, 1912.

Conferral of Titles.

The title of Professor of Pathology in the University has been conferred on Dr. Frederick William Andrewes, of St. Bartholomew's Hospital Medical School, and that of Reader in Physiology in the University upon Dr. M. S. Pembrey,

of Guy's Hospital Medical School. The titles were conferred on the recommendation of relevant boards of advisers acting under the regulations on university titles.

Report of Professor of Protozoology.

An abstract of the report of the Professor of Protozoology for the year ending June 30th, 1912, was received. It contained a list of works published by the department. The full report has been forwarded to the Colonial Office, and will be included in an official publication.

Award of the Paul Philip Reitlinger Prize.

Mr. Frederick J. F. Barrington, M.Sc., of University College Hospital Medical School, has been awarded the Paul Philip Reitlinger prize for 1912 for an essay on the innervation of the bulbo-urethral glands and their histological changes during activity. The prize, which is of the value of £39, was founded with funds given to the university by Mr. Albert Reitlinger in memory of his son, a student of St. George's Hospital Medical School, who died in December, 1911. In 1913 the prize will be awarded for the best essay on the influence of the conception of evolution on moral or social philosophy.

D.Sc. Degree in Bio-Chemistry.

The degree of D.Sc. in bio-chemistry has been conferred on Dr. Hugh Maclean, an internal student, of the Lister Institute of Preventive Medicine. His thesis was entitled "A contribution to the study of lipoids," and consisted of two parts—the phosphatides of the kidney, and the purification of phosphatides. In addition Dr. Hugh Maclean submitted several other contributions to the advancement of science published independently or conjointly.

Senon Lectures in Laryngology.

The first course of lectures under the Senon Lecture Trust will be delivered on January 22nd and 24th, at University College, by Dr. Peter McBride, late lecturer on diseases of the ear, nose, and throat at the University of Edinburgh. The chair at the first lecture, which will be on Sir Felix Senon's personal history and career and the circumstances which influenced his career, will be taken by Sir Rickman Godlee, Bart. The second lecture will deal with Sir Felix Senon's work and its influence on laryngology, with special reference to general palsy, laryngeal paralysis, and malignant disease. The foundation was established in May, 1911, by Sir Felix Senon, K.C.V.O., M.D., who transferred to the university, for the foundation of a lectureship and medal in laryngology, the sum of £1,040 presented to him by the British laryngologists on his retirement from practice. Admission to the lectures will be free by ticket, to be obtained from the Secretary of the University College, Gower Street, E.C.

Advanced Lectures in Physiology.

The following advanced lectures in physiology are announced during the second term:

Eight lectures on the relations of electrolytes to living tissues, by G. R. Mines, M.A., at the University on Tuesdays, at 5 p.m., beginning January 21st.

Eight Page-May memorial lectures on the functions of cerebral cortex, by F. W. Mott, M.D., F.R.S., at University College on Fridays, at 5 p.m., beginning on January 24th.

Four lectures on colour vision, by F. W. Edridge-Green, M.D., at University College on Wednesdays, at 5 p.m., beginning on February 19th.

Four lectures on recent work in chemical physiology and pathology, by Otto Rosenheim, Ph.D., at King's College on Mondays, at 4.30 p.m., beginning on February 10th.

Eight lectures on animal heat, by M. S. Pembrey, M.D., at Guy's Hospital on Thursdays, at 4 p.m., beginning on January 16th.

The course of lectures by Professor G. N. Stewart announced for the second term has been postponed until the third term.

Lectures by the Professor of Protozoology.

A course of twenty-one lectures on the protozoa will be given at the Lister Institute, Chelsea, by Professor C. A. Minchin, M.A., F.R.S., on Mondays, Wednesdays, and Fridays, at 5 p.m., commencing January 20th. The course is intended to provide instruction (a) to students past the intermediate stage—that is, to those preparing for the B.Sc. examination pass or honours, or taking protozoa as a special subject for the B.Sc. examination, or to those preparing a thesis upon the group for the D.Sc. degree; (b) for medical men and others interested in the practical aspects of protozoology. The course is open free to all members of the university, to all medical men, or registered medical students, and other persons on application to the Academic Registrar.

KING'S COLLEGE.

The Early Diagnosis and Control of the Specific Treatment of Tuberculosis by Dr. Carl Spengler's Methods.

A course of six lectures and demonstrations with practical work will be given at the University Laboratories, 62, Chandos Street, Strand, W.C., by Mr. W. H. Fearn (voluntary bacteriological assistant to Dr. Carl Spengler), on Dr. Spengler's methods for the diagnosis and control of the specific treatment with immune substances (i.e. of tuberculosis). The class will meet on Monday and Thursday afternoons, commencing Monday, January 20th, at 5.30. The fee for the course is £4 4s. Further particulars can be obtained on application at the above address to Professor Hewlett, who will be glad to receive inquiries at once, as the class will not be held unless at least six students enter.

MEDICAL SERVICE IN THE HIGHLANDS.

THE report of the Highlands and Islands Medical Service Commission, which met under the chairmanship of Sir J. A. Dewar, Bart., M.P., has just been issued.

The committee was appointed to consider how far the provision of medical attendance in these districts is inadequate, and to advise as to the best method of securing a satisfactory medical service therein, regard being had to the duties and responsibilities of the several public authorities operating in such districts.

The committee examined a large number of witnesses, and travelled over the Highlands and Islands to see for themselves the conditions under which the medical men in these districts performed their duties.

There are several outstanding features which demanded their special attention, for instance, the poverty of the crofters, the insanitary condition of the dwellings, the survival of superstition, the need for hospitals and nurses.

The following summarized conclusions are put forward by the committee:

(a) That on account of the sparseness of population in some districts and its irregular distribution in others, the configuration of the country and the climatic conditions, medical attendance is uncertain for the people, exceptionally onerous or even hazardous for the doctor, and generally inadequate.

(b) That the straitened circumstances of the people preclude adequate remuneration of medical attendance by fees alone.

(c) That the insanitary condition of life prevailing in some parts render medical treatment difficult and largely ineffective.

(d) That in default or disregard of skilled medical advice and nursing, resource is not infrequently had to primitive and ignorant methods of treating illness and disease. These methods are a source of danger, especially in maternity.

(e) That there is danger of physical deterioration from defective dieting, and more markedly in the infantile and juvenile population.

(f) That rural depopulation is not a feature of the whole area of one remit, and even when notable the necessity for medical provision is not materially reduced.

(g) That the local rates, from which the doctor's income is derived, are in many cases overburdened.

(h) That, owing to the industrial conditions, the Insurance Act is only very partially operative.

(i) That, in short, the combination of social economic and geographical difficulties in the Highlands and Islands—not to be found elsewhere in Scotland—demands exceptional treatment.

The report next proceeds to examine the conditions affecting the adequacy of medical service, among which are mentioned defective means of locomotion and communication.

The Committee is of opinion that the general inefficiency of the existing medical service is produced by:

- (a) By inadequate remuneration.
- (b) By inability to provide for old age and infirmity.
- (c) By difficulties of locomotion and communication.
- (d) By insecurity of tenure under the parochial system of appointments.
- (e) By the difficulty of obtaining suitable house accommodation.
- (f) By lack of facilities for holidays and post-graduate instruction.

Recommendations.

The recommendations of the Commission are as follows:

(a) It is clear that, having regard to the economic conditions prevailing in the Highlands and Islands, the extent to which the foregoing services are at present subsidised from imperial funds is quite inadequate, and that as local resources are in many parishes already wellnigh if not wholly exhausted, any general amelioration of the existing medical service cannot be achieved without a further and more substantial subsidy.

(b) It is shown that in the Highlands and Islands, general medical practice rests very largely on the subsidy from the Poor Law authority, and to a much less extent on subsidies from other public authorities. But it must be pointed out that the remuneration from these various authorities bears no proper relation to the work done or to the degree of responsibility involved. Consequently the individual practitioners are discouraged, and medical service as a whole suffers.

(c) But the Committee are of opinion that by proper administration of an additional imperial grant all these public services could be so developed and correlated administratively as to provide a more satisfactory financial basis for general medical practice.

(d) For the administration of any subsidy granted by the Treasury for the carrying out of the policy indicated in this report the Committee suggests that a central authority and a local authority be constituted.

(e) The Committee, after carefully considering the administrative conditions, are of opinion that a special central authority and a special local authority would be required.

(f) The Committee suggest that the central authority should contain a representative of each of the four principal central departments concerned with the administration and control of medical services, namely, the Local Government Board for Scotland, the National Health Insurance Commission, the Scottish Education Department, and the General Board of Lunacy; a representative nominated by the General Council of Medical Education and Registration of the United Kingdom; a chairman nominated by the Secretary for Scotland approved by the Treasury.

(g) In making this recommendation the Committee have had regard to all the medical interests involved, the duties and responsibilities of the public authorities operating in the Highlands and Islands, and the desirability of bringing about, as far as is practicable, a consolidation of the various services. The central authority thus constituted would act under regulations made by the Treasury.

(h) To enable the central authority to administer the suggested grant with due regard to the conditions of each locality, a local authority would also be required. It is not desirable to multiply authorities without necessity, and in the Highlands and Islands, on account of the difficulties and expense of attending meetings, this principle deserves special consideration. As it is of primary importance to retain the administrative interest of the parishes, and as all the parish councils are already represented on the District Committee, which is the local authority for public health, the Committee recommend that the local authority for the administration of this special grant should be the District Committee along with representatives from the Insurance Committee of the county or District Insurance Committee, a representative from any county or district nursing association, or, in default of such association, a representative nominated by the District Committee, a representative from the local Branch of the British Medical Association; and an officer from one of the central departments concerned—this officer to act as assessor. The medical officer of health for the county or chief medical officer of health for the district might attend meetings of the Committee for the purpose of giving advice and assistance.

It would be the duty of this Local Medical Service Committee to prepare a scheme of improved medical and nursing service for submission to the central authority with a view to an Imperial grant.

Medico-Legal.

ALLEGED PERSONATION.

A MAN, whose age was given as 47, was charged in the name of Richard Henry Barber at Bow Street on January 7th with having, on November 16th, 1906, wilfully procured himself to be placed on the *Medical Register* by making and producing false and fraudulent representations in writing, and with having between February 12th and March 9th, 1912, at Trexton, near Rotherham, forged and uttered nine certificates of death. The circumstances of the death of Dr. Richard Henry Barber in Oregon, U.S.A., were related in the report of the proceedings before the General Medical Council at its last session (SUPPLEMENT, December 28th, 1912, p. 734). The accused, while being conveyed from Liverpool to London, escaped, but was rearrested. He maintained an obstinate silence during the hearing; but Dr. Maurice Craig, who examined him in Baustead Asylum, gave his opinion that he was perfectly sane. Mr. Bodkin, for the prosecution, stated, according to the report in the *Times*, that the prisoner had no medical qualification and his name was not Barber. The magistrate granted a remand for a week.

THE Lent term of lectures at the Brompton Hospital for Consumption will commence on Wednesday next, when Dr. Inman will give a lecture on recent investigations into the pathology of tuberculosis at 4.30 p.m.

The Services.

"HONORARY PHYSICIANS AND HONORARY SURGEONS TO THE KING" IN THE ARMY.

SURGEON-GENERAL GEORGE J. H. EVATT, C.B., writes: Since 1858 we have had certain *honorary* appointments given to distinguished medical officers of the army with the above titles. I think this high honour would gain in actuality and definiteness if the title was changed to "Field" Surgeons and "Field" Physicians to the King. The officers chosen are past-masters in their own speciality of war experience, and my suggested title would emphasize the fact. Where an officer was Surgeon-General I would call him "Field Surgeon-General to the King."

Obituary.

THE LATE PROFESSOR REDFERN. — A correspondent writes: To your very interesting biography of Professor Redfern, whom Aberdeen is proud to have possessed, though for too short a time, it might be well to add that although no doubt he got inspiration as regards eloquence and teaching faculty from Bennett, the real influence was from Goodsir. At that period that great genius was in the zenith of his powers, and as he had the Ludwig-like faculty of suggesting fertile plans of research to his pupils, Redfern got from him the hint to study the development of cartilage.

Medical News.

DR. ROBERT JONES, Resident Physician and Superintendent of the Claybury Asylum and Lecturer on Mental Disease to St. Bartholomew's Hospital, has been elected an honorary member of the Clinical Society of Mental Medicine of France.

DR. LEONARD HILL, F.R.S., and Dr. Henry S. Kenwood have been appointed respectively civilian physiologist and civilian sanitary expert to the Army Medical Advisory Board in succession to Dr. M. S. Pembrey and Dr. L. C. Parkes, whose terms of service expired on December 31st, 1912.

A SERIES of ten lectures on the diagnosis and treatment of cancer is about to commence at the Cancer Hospital, Fulham Road. They will be given at 5 p.m. on each Wednesday, from January 22nd to March 26th, both days inclusive, and will be free to all medical practitioners and senior students.

A COURSE dealing with diseases of the chest, and designed to cover six months, will commence at the Royal Hospital for Diseases of the Chest, City Road, London, E.C., next Tuesday. The work will include lecture demonstrations, tuberculin administration, clinical study, and practical bacteriology. Information as to the fees and hours of attendance can be obtained from the dean of the hospital, Dr. Barty King.

AT the seventh annual dinner of the past and present students of the Royal London Ophthalmic Hospital the chair will be taken by Mr. W. A. Brailey, consulting ophthalmic surgeon to Guy's Hospital, who in his early days did such valuable work as curator and registrar to Moorfields. The dinner will take place at the Imperial Restaurant, Regent Street, W., on Thursday, January 23rd, at 8 p.m. Further particulars can be obtained from Mr. Herbert Parsons, 54, Queen Anne Street, W.

THE usual monthly meeting of the Executive Committee of the Medical Sickness, Annuity, and Life Assurance Society was held at 429, Strand, London, W.C., on December 20th, 1912. Dr. F. J. Allan was in the chair, and it was reported that for the last few months the claims had been steadily diminishing, but not, it was feared, in sufficient numbers to neutralize the excess in the first half-year. During the last two months there had been an excellent increase in the new proposals. The premium rates of the society are such that at age 30 for £7 2s. 6d. per annum a man may secure £4 4s. a week for twenty-six weeks in case of illness, and after that £109 4s. per annum until the age of 65 in cases of permanent incapacity. The society is run entirely on mutual lines, and the profits all go to the members. Since 1884, the year of its foundation, over £17,000 has been returned them under this heading alone. Prospectus and all further information can be obtained from Mr. Bertram Sutton, Secretary, Medical Sickness and Accident Society, 33, Chancery Lane, W.C.

Letters, Notes, and Answers.

Authors desiring reprints of their articles published in the *BRITISH MEDICAL JOURNAL* are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

Queries, answers, and communications relating to subjects to which special departments of the *BRITISH MEDICAL JOURNAL* are devoted will be found under their respective headings.

QUERIES.

A. asks for suggestions in the treatment of a lady, aged 22, who suffers from offensive breath. The teeth are good, and she is not a mouth breather; she does not suffer from constipation, but the stools are offensive, and the tongue is always a dull white. The conditions have been treated with small and repeated doses of calomel, with salol, besides the usual stomachics, and she has had a long course of soured milk, but nothing has made any difference.

BRAIN EXTRACT.

MR. PHIROZE A. DALAL (Bombay) writes to express the hope that Dr. Maule Smith (*BRITISH MEDICAL JOURNAL*, 1912, ii, p. 1451), will give further details as regards the dosage and method of administration of brain extract.

IODINE AS A SKIN ANTISEPTIC.

MR. VAUGHAN PENDRED, F.R.C.S. Eng. (Ilford) writes: A month ago I did a ventrifixation operation for a stout woman. The abdomen had been four times painted with 2 per cent. tinct. Iodi. The conditions were as aseptically perfect as possible in a modern hospital. On removing the stitches on the ninth day pus (2 drachms) welled up from a deep sinus. A well-known London surgeon, whom I saw operating without iodine on the patient's skin, told me that he had seen two bad suppurations follow dependence on iodine. It would be very helpful if your readers would kindly tell us whether they have met with a like fate.

ANSWERS.

DR. MARGARET SHARPE (London, W.) writes in answer to "T. H. G." (December 21st, 1912, p. 1740): Fistula can be cured easily and rapidly by electricity with the minimum of pain and discomfort to the patient.

C. M.—(1) The foul smell from the auditory meatus may be due to suppuration in the ethmoidal or frontal sinus. This should be ascertained, if possible, by transillumination. If pus is found in any of the accessory nasal cavities surgical treatment is required. Failing this, a careful examination of the tympanic cavity would reveal the cause of the smell, and would account for the itching if a source of irritation were found. This naturally must depend on the exact condition of the ear and the neighbouring organs. (2) Few physiologists hold that the formation of uric acid is favoured by sodium chloride. Haig, in his book on uric acid, mentions that chlorides and many other anions diminish the excretion of uric acid, and consequently favour the accumulation of the same in the blood and tissues. This action of chlorides is recognized, and can be clinically demonstrated in cases of uric acid diathesis, in which an increase in the quantity of the acid is found in the blood after the ingestion of an excess of chlorides.

THE TREATMENT OF HAEMOPHILIA.

C. W. C.—The paper by P. Emile-Weil was published in the *Presse médicale*, 1909, pp. 673-76.

LETTERS, NOTES, ETC.

INSENSIBLE PERSPIRATION.

DR. JOHN HADDON (Hawick, Scotland) writes: I have a postcard from an anonymous correspondent in London saying that it would be interesting to know the weight lost in the day by insensible perspiration. I cannot answer anonymous correspondents except through the *JOURNAL*, and I hope you will allow me to answer him. I could make such an observation for the whole day, but there are so many factors to take into consideration that it can never be satisfactory. The loss, however, is very considerable, and most, of course, upon a hot day under severe exercise. I have known $\frac{1}{2}$ lb. lost by the skin and lungs in a walk of six miles, which gives some idea of the value of exercise. Another correspondent asks when the verses on Dr. Jephson's one prescription appeared in the *JOURNAL*, and I am sorry I cannot tell him, but they are worthy of being reprinted in a prominent part of the *JOURNAL*, along with the paragraph from the *EPILOGUE* on "Idiopathic Anasarca."

DRAW-SHEETS.

A SUBSTITUTE for draw-sheets which when shown by Dr. Vickerman Hewland at a recent meeting of the Hastings Division was regarded with considerable approval consisted of a flat muslin bag with a slit on one side and containing a piece of mackintosh and a layer of cotton-wool. The idea

was that when the pad was soiled the mackintosh should be removed by the slit and the whole of the rest of the appliance burnt. It was stated that the cost of the material was 2d., this estimate covering cheap butter muslin and cheap cotton-wool. The size of the pad shown was 18 in. square, but obviously one could be made to suit the needs of any particular case. The pad was devised by a lady in Hastings, who originally intended to patent it.

SANITARY TOWELS.

MESSRS. ARNOLD AND SONS have recently put upon the market some sanitary towels which are claimed to present the advantage of not getting stiff and of not being liable to drop off. Instead of being enclosed in muslin, with tapes attached thereto, the padding of antiseptic wool is covered by a network of thread, drawn out at either end to form a loop continuous with the rest of the fabric. In addition, there is on the lower surface of the padding a sheet of impermeable material. The device, which is said to have been worked out by a medical man, is entitled the "Mosana," and on the grounds stated may be regarded as justifying the claims made in respect of it. It is made in several sizes, the prices ranging from 1s. a doz. to 3s. a doz. in the case of those intended for use after confinement.

A HOSTEL FOR SANATORIUM PATIENTS.

DR. C. MUTHU (Hillsgrove, Wells, Somerset) writes: So much has been said about the after-care treatment of sanatorium patients that one is surprised that so little has been done for those who leave the sanatorium more or less fit for work, and who wish to continue the open-air life after returning to their work. It is admitted that for these patients something should be done which would combine the sanatorium treatment with home life. When I was in London I came across a hostel (Sussex House, Bishopswood Road, Highgate, London, N.) with these objects. The proprietress has had six years' sanatorium work, and has been a Sister in one or two sanatoriums, and is very enthusiastic. The house is situated on the northern heights, with plenty of open-air space around, the rooms are large and airy, and it is within easy distance of the city. The place has been established for about a year. Having seen it and stopped there for a time, I can speak from personal experience. It is just the place for those who have been in an open-air sanatorium and who want to live where the open-air treatment combined with home life can be carried out with pleasure and comfort.

AN ADHESIVE BOOK-MARKER.

DR. CALANTARIENS, of Scarborough, has invented an ingenious marker, which may prove very useful for certain purposes, especially, perhaps, for marking pages when doing work which involves a good deal of reference backward and forward. It is made of soft leather, such as is used for kid gloves, and is of the shape of a featherless arrow, $\frac{1}{2}$ in. long. The back of the head is covered with some adhesive material, and, when gently pressed on to the page, it adheres with sufficient force to keep its place, but can be easily removed. It does not seem to injure the paper in any way, but works better with smooth than rough paper, as it becomes clogged after a time with fluff from the latter; it can, however, be cleaned with water, dried, and used again. The inventor suggests that a set of the markers, which are made in different colours, would be useful for turning over music leaves. The markers, which are called "Students' Markettes," can be obtained from Harrods and the Army and Navy Stores, price 1s. a dozen.

TO WORKHOUSE MEDICAL OFFICERS.

DR. R. W. H. MEREDITH (Wellington, Somerset) writes: A short, dark, stout man who says he is an ex-soldier, and gave the name of John Kelly, has been "working" workhouses and hospitals in the West of England in a very interesting manner. He has the power of inflating his parotid glands and causing a subcutaneous emphysema extending from the temples to the middle of the chest. He takes about a quarter of an hour to inflate himself and about two or three days to absorb. The emphysema about the upper part of the chest, however, remains a long time. If he is not attended to, however, as seems best to him, he has become violent. He has likewise suffered from retention of urine when it pleased him. He is quite interesting for a few days, but should not be left when there are no male attendants, as he has been insolent and at times dangerous to nurses. I should be glad to hear from any one who has had him under treatment.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|--------|
| Eight lines and under | ... | ... | 0 4 0 |
| Each additional line | ... | ... | 0 0 6 |
| A whole column | ... | ... | 2 13 4 |
| A page | ... | ... | 8 0 0 |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restant* letters addressed either in initials or numbers.

PERICOLITIS.

BY

T. CARWARDINE, M.S., M.B.LOND., F.R.C.S.,
HONORARY SURGEON TO THE BRISTOL ROYAL INFIRMARY.

PERICOLITIS has its simplest manifestation in the local peritonitis which accompanies the firm impaction of a faecal mass in the colon. The bowel is congested and granular, and peritoneal exudate surrounds the area.

In lesions of the mucous membrane of the colon causing infection through the lymphatics the adjoining mesentery becomes thickened and shortened from chronic inflammation, a feature met with opposite the diseased area in chronic appendicitis, which causes kinking of the appendix at its middle or proximal part.

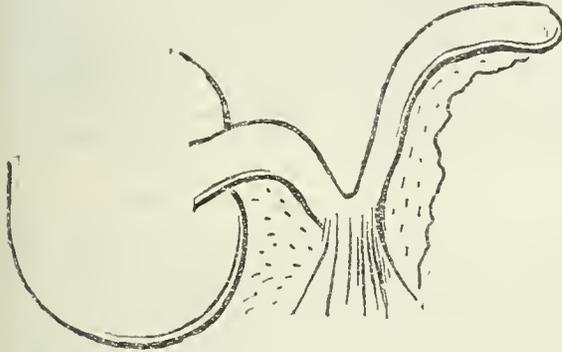

Fig. 1.—Effect of chronic inflammation of the mesentery of the appendix—mesoappendicitis.

It cannot be doubted that infection is a factor of the local exudate around the faecal mass in the one case and of the contracting scar in the mesoappendix in the other case. They are but simple instances of pericolicitis, which, in some of its more complicated forms, I propose to consider in relation to the kidney, appendix, and gall bladder.

The correct interpretation of vague pains and tenderness in the right lumbar and iliac regions may be very difficult, especially in the female; and my own experience of the important part played by pericolic adhesions is in accord with that of some recent observers. In nephroptosis we have an opposite extreme to the simple illustrations already given, yet pericolic inflammation and adhesions may result from wandering kidney and demand treatment.

PERICOLITIS FROM WANDERING KIDNEY.

Wandering kidney sometimes causes colitis. This is primarily mechanical, from local irritation, from displacement and distension of the ascending colon, and from the strain on the colic vessels acting more readily upon the veins than on the arteries, and so inducing passive congestion. In addition, the colitis causes infective inflammation of the pericolic tissues. Thus a vicious circle is induced, mechanical on the one hand, infective on the other; the caecum and ascending colon being in lymphatic connexion with the right kidney, so that bacteria and toxins can pass from the colon to the kidney.¹ Whether as a result of mechanically-induced nephritis, or by infection from the colon, the fact remains that wandering kidneys requiring operation always show distinct adhesions on the true capsule with whitish areas of fibrosis at their attachments. It is the surrounding capsule which is really loose, even permitting the kidney to pass with it across the middle line of the abdomen.^{2,3} Such patients are usually thin, but as the fatty capsule of the kidney is often well marked, the view that emaciation is caused by toxins from the bowel acting upon the fat would seem to be untenable.

In more advanced cases the intraperitoneal pericolicitis may be so distinct as to prove a dominating factor in the causation of symptoms, as in the following cases:

CASE I.—Attacks Resembling Appendicitis.

Mrs. C. had suffered from "bilious attacks" for years, beginning with severe headaches and accompanied by distension,

nausea, anorexia, and occasional vomiting. They lasted for two days, and she applied hot-water bottles to the abdomen to obtain ease, which was associated with a sensation of something moving before she was relieved. A month before I saw her with Dr. Lees she had a severe attack of pain and tenderness in the right iliac fossa, with fullness and indefinite swelling, and she had a recurrence with slight fever subsequently. In the earlier attacks the pain was epigastric; in the later ones in the region of the appendix and like colic.

The right kidney was freely mobile, with tenderness, gurgling, and indefinite resistance in the caecal region. In March, 1911, a long ilio-lumbar incision was made and the muscles separated. The middle of the ascending colon was adherent to the parietal peritoneum, and beset with numerous bands which required division with scissors, with intervening cystic spaces containing clear fluid. The caecum was dependent in the pelvis, dilated and hypertrophied. The appendix was small and apparently normal, and the other organs were healthy. The kidney was fixed by the writer's method,⁴ and the patient has been cured of her attacks (Fig. 2).

Fig. 2.—Pericolicitis from wandering kidney with cystic spaces containing clear fluid.

CASE II.

A woman, under the care of Dr. Powell, first noticed severe pain in the right side fourteen months before, with a history of previous indigestion. The pain passed to the right shoulder-blade and was followed by tenderness in the right side. Urination had been frequent for a year, and sometimes the patient detected a swelling.

The right kidney was fixed after excising some fatty capsule. Strong pericolic adhesions required division, also some between the ascending and transverse colon; the caecum was low down in the pelvis. With the patient on her side the whole of the fatty capsule with its fascia dropped away from the parietes, together with the kidney, leaving an exceptionally large retro-peritoneal space reaching to the middle line mesially and down to the false pelvis below (Fig. 3).

CASE III.—Wandering Kidney fixed with only Temporary Relief. Subsequent Exploration and Treatment of Pericolicitis.

I was asked to see a lady with Dr. Roberts in July last with wandering kidney dating from confinement many years previously. She complained of a dragging feeling in the loin aggravated by two recent falls, with abdominal tenderness; and on one occasion, when in London, she experienced a sensation of "something turning over inside." Belts had not given relief.

In September her kidney was fixed, but soon after her return home the abdominal pain, tenderness, and attacks of faintness described as "qualms" returned. Consequently I explored the right loin in November through a long sphincter incision. The kidney was absolutely fixed, but there was very obvious pericolicitis, the ascending and transverse colon being bound together; a special tongue of mesentery of the ascending colon was adherent to the peritoneum of the loin, and beneath this the ascending colon towards its upper part was deeply angulated and constricted by strong pericolic bands with intervening empty spaces. It required time and patience to restore the colon to natural conditions, and the adherent portion of the mesentery of the ascending colon had to be cut away except a piece above which was stitched to the under surface of the liver to support the hepatic flexure.

Very soon after the operation she began to lose the "qualms," abdominal pain, and tenderness, the bowels acted more freely than before, and she is at the present time restored to health.

A case of nephritis with granular casts which appeared due to chronic appendicitis is recorded by Pilcher, pericolic

adhesions and recent perinephritis being present; also the case of a constipated patient who had passed blood and been advised to have her kidney removed, but whose renal symptoms cleared up after the removal of a chronically inflamed appendix, and the release of the caecum and ascending colon from pericolic bands.

MEMBRANOUS PERICOLITIS, WITH SYMPTOMS OF APPENDICITIS.

The association of membranous pericolicity with symptoms of chronic appendicitis has been graphically described by Lewis S. Pilcher.¹¹ The bands may be thin and veil-like, membranous, or as firm sheets of fibrous tissue binding down the caecum and appendix. They tend to restrict peristalsis and to angulate the colon and appendix (Figs. 9, 10, 11, 12, 13). They must have been observed repeatedly, although Jackson (1908) has given us a clear description.⁵ In most of the cases of pericolicity described by Pilcher the appendix had been removed previously, either during an acute attack or for supposed chronic appendicitis. The persistence of symptoms in the right iliac region and loin led to further operation, and after dealing with the pericolic adhesions the patients were either cured or greatly relieved.

Parker Syms⁶ described a case diagnosed as appendicitis which presented little sign of it at operation, yet the ascending colon was enveloped in a typical Jackson's membrane, spreading from the parietes over the colon, which moved freely beneath it.

Laue has described similar adhesions between the outer wall of the colon and the parietes in connexion with chronic constipation, and regards them as hypertrophy of the membranous anchors of the bowel, compensating for the strain of prolonged stasis but also interfering with peristalsis.⁷ As regards intestinal stasis, he submits the argument that inflammation of the appendix is not necessarily the primary condition; that bands of adhesions may form about the ascending colon and hepatic flexure as a result of constipation and the erect posture.⁸ Charles Mayo suggests that in some cases these bands and films may be due to late rotation of the bowel and descent of the caecum from its hepatic position after the formation of the parietal portion of the peritoneal cavity in the fetus.⁹ The reduplication of the ascending colon, which one occasionally meets with surgically, supports this view in certain instances. Generally speaking, the opinion of Gerster¹⁰ and Pilcher,¹¹ that they are the result of off-repeated or long-continued mild infections of the peritoneal covering of the caecum and appendix, is no doubt correct. Moreover, it should be noted that although the initial appendical attack may subside completely, the accompanying pericolicity may persist in the form of fibrous bands.

Symptoms and Diagnosis.

The symptoms of pericolic membranes have a great similarity, and resemble closely those of chronic appendicitis. Discomfort and pain are complained of in the right iliac region, with tenderness on deep pressure. These vary with diet and exercise, and colicky cramps occur which may be felt and even seen. Caecal constipation is caused by the defective peristalsis and mechanical impediment, and pain is caused by muscular spasm. This faecal stasis, where absorption is normally active, causes symptoms of auto-intoxication. The pain is often referred to the stomach, and secondary digestive disturbances are common.

The diagnostic value of *x* rays may be great in determining the position and size of the caecum and any angulation of the colon. Twelve hours after a bismuth meal, given after a thorough clearance of the bowels, supplemented if necessary by an enema of bismuth emulsion shortly before the examination, the colon and caecum may be examined, the disposition of the appendix may be seen, and by repetition at intervals one can determine approximately the relative stasis in the caecum. But operation will alone determine the conditions with precision.

Operation.

The incision will necessarily be such as to expose the parts more freely than has been customary. It may be a vertical incision towards the outer part of the right rectus, as advised by Pilcher, or the long ilio-lumbar gridiron incision, with separation of the musculature,

which I have employed. The bands are then divided with scalpel or scissors until the bowel is set free, and the bare parts are covered over with peritoneum. Generally the bands are divided near the bowel, and are then utilized to cover the bare parietal areas by anchoring them behind the bowel with a few stitches, any free visceral ends of the adhesions being sutured to the bowel in front, close to their attachment. The incision should be long enough to expose the terminal ileum, caecum, and the whole of the ascending colon; and the history of a previous removal of the appendix should not preclude such an exploration.

In an examination of the after-histories of 100 cases operated on for chronic appendicitis, E. MacD. Stanton¹² found that 36 were not cured, either from erroneous diagnosis, such as the non-recognition of gall bladder or renal conditions, or from some factor not appreciated at first. Of these he states that mobile caecum accounted for the greatest number, 16 per cent., and in them the relief by appendicectomy was only temporary. The symptomatic importance of mobile caecum, and the value of operations for its relief, are variously estimated; and inasmuch as uncomplicated mobility of the caecum is not the cause of pericolic adhesions, except on the constipation theory, the consideration of mobile caecum as a primary condition may be omitted from a consideration of membranous pericolicity.

PERICOLITIS DUE TO APPENDICITIS.

CASE I.

A little girl, aged 11, under the care of Dr. Thompson, had an attack of pain of gradual onset three years before, with sickness and slight pyrexia. Five weeks previously she had a sudden attack of pain, was not sick, and remained in bed a few days but without feeling quite well afterwards. There was no history of indigestion or biliousness. The appendix was found to the outer side of the colon, pointing upwards, and there were adhesions between it and the outer side of the colon, also pericolic adhesions joining the ascending and transverse colon (Fig. 4).

CASE II.

In this case there had been pain settling in the appendix region, with tenderness, rigidity, and initial sickness. The appendix was firmly bound down behind the caecum, and firm bands united the head of the caecum to the ileum a few inches away from the ileo-caecal junction, so that a free loop of ileum was suspended thereby (Fig. 5).

CASE III.—Appendicectomy without Relief: Pericolicity Discovered at Subsequent Operation.

A girl of 15 was seen in July last with Dr. Harvey with symptoms of appendicitis. Pain of three months' duration, was very severe at times though sometimes absent; referred to the right loin, thigh, and iliac region, where there was tenderness; the pulse was quick with slight pyrexia. The appendix was removed without drainage. On returning home the pain recurred in the right loin and towards the back. It was very severe at times, and worse when up and about. I saw her again in October. Nothing could be felt in the abdomen, and I suspected pericolicity. X-ray photographs after bismuth meals revealed very distinct stasis in the caecum, bismuth remaining therein unaltered from twelve to seventeen hours, and still present after forty hours. A long ilio-lumbar sphincter incision was therefore made through the former scar. The caecum was dilated, and, together with the ascending and transverse colon, was bound down by pericolic films, including omental bands which were attached to the outer part of the colon, the head of the caecum, and the scar (appearances, Fig. 6; skiagrams, Figs. 7 and 8).

CASE IV.—Pericolicity from an Abnormally Placed Appendix, causing Attacks of Biliary Colic with Jaundice.

A lad of 20 was seen with Dr. Lucas in 1908 with a history of sudden pain at the navel two years previously, followed by attacks resembling gall-stone colic, with jaundice, marked flatulence and vomiting, and so severe that he used to double himself up over the back of a chair. The gall bladder and cystic duct were buried in firm adhesions, separable with difficulty. No stone could be found, the gall bladder was drained, and he passed several mucous stools for the first five days after operation. Seven months after he had an attack of general peritonitis, when its cause and that of the previous pericolicity was found in a gangrenous appendix that passed almost vertically upwards behind the caecum and ascending colon, the tip being apposed to the lower border of the duodenum close to the common bile duct (Fig. 14).

CASE V.—Pericolicity from Abnormally Placed Appendix (? Developmental) and Symptoms of Gastric Ulcer.

A woman was referred to me by my colleague, Dr. Nixon, with a view to gastro-enterostomy if the indications were obvious. The history was that of pain after food ever since she was a girl, with much flatulence and occasional vomiting and haematemesis. There was localized tenderness in the epigastrium to the left of the middle line. Exploration revealed

a tortuous ascending colon, with adhesions between the bends and firm ones uniting the ascending and transverse colon together. The appendix, which was very long, passed up under a filamentous covering in the ascending mesocolon to the hepatic flexure, where it turned to the left, its extremity lying for some distance in the gastro-colic omentum, and the gall bladder was adherent at this site. Gastro-enterostomy was not indicated, the stomach was normal, and the long appendix was removed after dividing the filamentous pericolic covering (Fig. 15).

CASE VI.—*Tuberculous Pericolicitis.*

A little boy was seen recently who gave a history of a few

previous attacks of appendicitis. The appendix was accordingly removed, and on examination of the region a hard mass of tuberculous glands could be felt behind and to the outer side of the caecum and in the lower part of the mesocolon, whence they were excised. Professor Walker Hall reported the appendix to be the seat of early tuberculosis (Fig. 16).

Actinomycosis.

In the later stages of actinomycosis of the appendix, which is not at all uncommon, the pericolic tissues become infiltrated and sinuses form in the loin, prior to

the involvement of the hepatic region and subsequent death of the patient (Fig. 17).

Pins in the appendix have been noted by many surgeons, and may cause pericolicitis. In a collection of 63 published cases R. H. Fowler refers to a case of W. W. Keen, in which the tip of the appendix was solidly incorporated in the bladder. At the age of 7 the patient had dysuria, and a pin, which he believed he had swallowed, was removed from the urethra.¹³

Periolic adhesions may cause intestinal obstruction, as in a case recently operated upon at midnight, in which a coil of small intestine had passed under a band of such origin.

CHOLECYSTITIS WITH PERICOLITIS.

Inflammation of the gall bladder, leading to localized peritonitis in its neighbourhood, is a common cause of pericolicitis in the hepatic region, and is invariable in severe or long-standing cases. The following will serve as an example of pericolicitis following cholecystitis of pregnancy:

The last child was 7 years old, and the pain, of five months' duration, was first noticed in the epigastrium and passed round to the back. It was of a severe shooting character, worse at night and on walking, doubling her up, and relieved by the vomiting which always occurred. She had had indigestion for two years. There was tenderness in the epigastrium, not over the gall bladder, which could not be felt. At the operation the gall bladder was thickened and mottled, but no stone was present in it or in the ducts. Marked pericolicitis was present, the ascending colon being adherent to the anterior abdominal wall and the liver adherent to the gastro-hepatic omentum. In particular there was a strong band of omentum adherent to the lumbar peritoneum (Fig. 18).

It will be seen, therefore, that pericolicitis is a frequent accompaniment of inflammatory affections of the appendix and gall bladder. Its persistence as bands and adhesions may give rise to symptoms after the successful treatment of the original focus, particularly in appendicitis. In wandering kidney it is now demonstrated that pericolicitis may coexist with encysted intraperitoneal collections of fluid. In the surgery of the right loin more attention will doubtless be paid to this associated condition by more complete examination of the region at the time of operation; and, by extended observation, the pathology of vague pains and after-pains will be more fully understood.

THE bequests made by Miss Alphonsine Sarah Jarry, of Settle, Yorkshire, included one of £600 to Halifax Infirmary.

WOLBACH AND TODD, in the Third Report of the Expedition of the Liverpool School of Tropical Medicine to the Gambia in 1911, state that they have established the presence throughout the Gambia of that form of ulceration occurring in the tropics which is associated with the presence of spirochaetes and fusiform bacilli. In 17 cases the pathological history of the ulcers was studied; although they varied greatly in their gross appearances, their histological features had so much in common that they could be regarded as having a common etiology. The conditions observed excluded as etiological factors, syphilis, varices, acid-fast bacteria, blastomyces, Leishmania, actinomyces, and the streptothrices. The presence of spirochaetes in nine of their cases lends support to the view that they are the cause of the process. These spirochaetes corresponded accurately to the parasites described by v. Prowazek, Keysselitz and Mayer, Balfour, and other authors, and named by v. Prowazek *Spirochaeta schaudinni*. Subcutaneous inoculations made by the authors into white rats gave negative results.

A Lecture

ON

SOME POINTS ABOUT DRAINAGE OF THE ABDOMEN UNDER VARIOUS CONDITIONS OF INFLAMMATION.*

By ARTHUR E. BARKER, F.R.C.S.,

SURGEON TO UNIVERSITY COLLEGE HOSPITAL, AND CONSULTING SURGEON TO THE QUEEN ALEXANDRA MILITARY HOSPITAL, MILLBANK.

The subject chosen is one pre-eminently difficult to handle. Anyone dealing with it even in the most detached way is very liable to be misunderstood. I hope I shall be able to avoid this in the present instance.

I want to speculate from evidence before us as to whether the current views on drainage of the abdomen in inflammatory conditions may not in some cases be modified with advantage to-day, as they have required to be in the past.

I need hardly remind a senior audience that not so long ago stirring debates took place in our societies as to the employment of drainage of the abdomen in such simple non-inflammatory conditions as early and uncomplicated ovariectomies. Yet now such a measure is rarely if ever adopted; the wound is at once sewn up. The reason is obvious. Any effusion which follows such an operation nowadays is either absolutely aseptic or the few organisms which may have gained access to it from without are easily disposed of by the germicidal properties of the fresh exudation with its phagocytes, and are absorbed by the extensive lymph sac which the peritoneal sac may be described to be. The effect of discarding drainage in such simple aseptic cases was, of course, to reduce the number of weak scars and consequent ventral herniae, and to diminish the liability to subsequent dangerous adhesions about the track of the drain. A painful after-treatment was also avoided, as was also a great loss of fresh healthy serum which otherwise would be returned by the lymphatics to the system with benefit.

Appendicitis.

Let me now ask you to recall the earlier medical experiences of appendicitis before the operative treatment of the affection became established. From these it soon became clear that many acute cases could recover without opening the abdomen, and without any escape of pus or other effusion either externally or into the intestines. It was a fair deduction from such experiences that the peritoneal cavity could dispose of a large amount of septic inflammatory matter. Otherwise none of these cases could have recovered.

Later on it was recognized that in many cases the amount of septic matter was too great to be left entirely to the resources of nature, and abscesses were encouraged to burst under fomentations, or operations were undertaken to evacuate them. But even here much was left behind which was not carried off by drainage, and could only be destroyed on the spot. From our experience of these operations we now know that ventral herniae and kinks of the intestine were not uncommon sequelae. But the operations on these very ventral herniae themselves following upon extensive suppuration within the abdomen have taught us, perhaps, more than anything else of the marvellous powers the peritoneum possesses of arresting and repairing the damage done. We have undertaken a radical cure, perhaps, a year or so after we had actually seen all the coils of bowel in the right flank matted together by foul lymph, and have found in many cases no traces of adhesions and all the peritoneal surfaces polished and as healthy looking as if they had never been involved in so dangerous a septic inflammation. Another point must have struck many surgeons after making long incisions to evacuate appendiceal abscesses. The ends of the incisions have been stitched up, leaving a drain in the centre, and we have seen the ends heal practically by first intention, in spite of being bathed in pus under a fomentation for days in many cases.

* Delivered at the Medical Graduates' College.

From all this it has seemed to many surgeons both at home and abroad, that perhaps we have been too wholesale in routine drainage when dealing with inflamed appendices, and that more discrimination is desirable. In other words that, after the removal of the inflamed organ and the septic products around it as far as possible by careful mopping, we might perhaps with advantage in some cases stitch up the abdominal opening after cleaning its edges, and obtain primary union with all its advantages. Here, of course, some traces of the septic matter would be left behind within the abdomen; but this, as we have seen from our experience noted above, can be disposed of by the defensive powers of the peritoneum.

Those who have taken this view can now point to numerous cases of acute epityphlitis in which inflamed and even gangrenous appendices surrounded by septic effusion have been dealt with and which have yet healed *per primam* after careful suture. In some of these cases the septic fluid from within has obviously flowed over the edges of the wound during the operative manipulations, and the inflamed lymph-covered organ has perhaps been in contact with them, and yet the result has been as perfect as if this had not been the case. Of course there remain a large number of cases in which thorough and prolonged drainage appears absolutely called for by common consent. This is our great difficulty, only to be overcome by experience. But it appears equally obvious that there are many in which drainage can be dispensed with to the great advantage of the patient, immediate and remote.

So far, then, as can be seen from clinical and experimental observation, a very considerable amount of septic matter is tolerated by the peritoneal surfaces, and can be prevented by them from doing irremediable injury when not in too great amount or overpoweringly virulent. That the virulence of the particular infection affects the issue is, of course, generally known. But that this general knowledge does not sufficiently affect our practice is what I am trying to bring out. We must all realize that every case of acute appendicitis is not the same affection, though the same organ is attacked in all. Let us take examples.

One patient is seized, and within a few hours has all the symptoms of profound toxæmia, which may be present to a degree almost precluding hope of recovery, with or without operation. In his case, if an operation is done, but little is found but a perforated vermiform appendix and a small quantity of a thin, greasy exudation from all the deeply injected peritoneal surfaces in view, but without a trace of plastic lymph. The intestines are distended, and more or less parosed. All we can do here, if we operate at all, is to remove the appendix, and with it a source of further infection. But the toxic infection has got a firm hold, and the natural forces alone can arrest it, aided, perhaps, by measures to be alluded to presently.

Another patient has an apparently similar attack; the same time has elapsed, but the general condition in this case is fairly good; there are, in other words, no marked symptoms of toxæmia, or very few. But if we open the abdomen we find what might at first sight be taken for a worse local condition. There is an inflamed appendix, as in the first instance, and the changes around it look more severe. But they are localized. There is much plastic lymph about, and the intestines in view are little, if at all, injected, parosed, or dilated. These are the cases which used to, and still do, get well with and sometimes without operation.

Now, these two conditions belong to entirely different categories. They are almost different diseases. In the first death will frequently follow, in spite of any operation which can be done for the local catastrophe. The general infection is too profound. The initial dose of poison has multiplied and saturated the whole system, either because the micrococcal strain was more than usually virulent, or because of a low standard of resistance in the individual.

In the second condition the virulence of the cocci is lower, is controlled by the greater vitality of the patient, and their effects are expended locally. It is unnecessary to refer to the particular cocci concerned in both processes. They may possibly be the same morphologically, but of a different strain as regards virulence.

Such differences in the cases we have to treat are seen daily. Is it rational that they should all be dealt with in

the same stereotyped way when we come to operate on them? I think not, and an ever-increasing number of operators are of the same opinion, to judge from the literature of appendicitis, both home and foreign. It must not be forgotten, too, that there are many degrees of severity between the two extremes just mentioned. And herein lies our difficulty—a difficulty which has led to a too uniform method of procedure. But we are growing every day in knowledge of the vital processes in action, and ought to be, and are, better able to discriminate as to the aims of operative procedure to be applied to each variety. We have come so far as to realize that the milder attacks may be left until they have passed off, and then operated on for the removal of the appendix without drainage. We are coming to know what cases of suppuration must be drained. We are getting to believe that some cases with actual pus formation need not be drained, and acting on this belief, have obtained results which contrast very favourably with those treated by prolonged and often troublesome drainage.

The question is, Can we, by careful clinical study, determine during an operation whether an acute appendicitis ought to be drained or not? I think such a thing is possible. Let us take a case or two by way of illustration. It is quite clear that in all so-called "interval cases," or *appendicite à froid*, no drainage is required. We close the wound after removal of the organ, and expect and obtain primary union. But on a recently inflamed organ we often find much discoloured and foul lymph, with adhesions to surrounding parts, and not infrequently more or less turbid fluid. Can we venture in such a case to close our wound after removal of the organ and careful mopping with gauze, and dispense altogether with drainage? Experience shows that we certainly can in a large proportion of cases, and my own lists show that this practice is increasingly common and successful. And yet, when we come to think of it, these conditions are septic, and it can hardly be claimed that the removal of the inflamed organ can be accomplished without more or less contamination of our incision edges. Why, then, do these adhere and unite faultlessly, as they certainly do in many cases? This can be explained in several ways: Either the inflammatory exudation on and around the vermiform appendix was practically sterile, or, if not, the amount of organisms already inhibited by the action of effused serum was not enough to overpower the active tissue cells of the freshly made wound and the plastic lymph which repairs it. In some cases we have found that the effused fluid in such cases poured out in response to the infection from the inflamed vermiform appendix is actually sterile. No organisms have been grown from it on the ordinary culture media. The appendix itself was undoubtedly infective, but the serous fluid effused around it was probably prophylactic, as we know it to be elsewhere, and inhibited the development of the organisms. It was not to be wondered at that here the wounds healed primarily. But what about other cases where there has been a small abscess round a putrid appendix? Here, too, we have had in some cases the best results from immediate closure of the wound. We must suppose, then, that though some of the pus did undoubtedly reach the edges of the wound, the same inhibiting forces had affected the cocci in it, and that they were overpowered by the patient's own living cells in the wound, just as part of a wound which is being drained, and is consequently covered by pus, may heal up *per primam*.

In some few instances we have underestimated the chances of infection, and some suppuration, usually very slight, has taken place in our closed wound. But it is notable that the peritoneal conditions have in no case been unfavourably influenced by this. When the wound has shown blemishes it has apparently been due to the accumulation between the skin and the deeper stitches of some blood clot which has proved a suitable soil for the growth of organisms. Usually the escape of a little turbid serum through the stitch holes or of broken-down blood clot from a corner of the wound has been followed by sound union, as though nothing had happened. In some very few cases the insertion of a subcutaneous drain has been necessary, and a stitch or two have worked out. But in the end union has taken place with apparently no more loss of time than had the wound been drained from

the first. Such blemishes will be inevitable occasionally until we have accumulated experience enough to know how far we may go with non-drainage, and what cases must have a drain from the first. So long as the intra-peritoneal conditions are not unfavourably influenced by non-drainage, the superficial processes are of secondary importance. Of course, if we follow the routine of draining all inflammatory intra-abdominal processes without exception, we escape the need of discrimination. But in this case there will be many more weak scars and ventral herniae to be dealt with subsequently, and probably more dangers from adhesions and infection from without.

If we endeavour to lay down formulae for our general guidance in such cases, they would be somewhat as follows: Given a case in which on opening the abdomen an inflamed vermiform appendix is found, around which there is a moderate amount of obviously plastic lymph shutting off the process, whether it be suppurative or not, and if outside the abdomen contain a certain amount of clear effusion and the intestines in view are normal in appearance, if at the same time the patient's condition is good, his colour fresh and his pulse moderate in frequency and in quality, and if the offending organ can be removed with comparative ease, I am inclined to close the wound carefully without drainage. The clear fluid around the immediate area of trouble is probably prophylactic, and will often be found to be sterile.

But if, on the other hand, on opening the abdomen, a rotting or inflamed appendix be found with little or no plastic lymph anywhere, and the intestines in view are red, injected, and dilated from paresis and covered by a greasy exudation or immersed in a thin ichorous, discoloured effusion; and if this picture is associated with feeble, rapid pulse, great asthenia, loss of colour, perhaps frequent vomiting—in short, with clear signs of toxæmia—it is better to drain freely. The œcæci in this case are particularly virulent and have led to a completely aplastic peritonitis, with toxæmia and consequent loss of general vitality. All that we can do here is to remove the exciting cause in the form of the peccant appendix (if this can be done without prolonged operation) and keep the wound open in the hope that some of the toxins, at all events, may escape from the peritoneal cavity by drainage. We are dealing here with a profound general poisoning, and the prognosis is extremely grave. Such cases must be spared from all prolonged exposure to the depressing effects of manipulations and the anaesthetic. In most all search for the appendix should be left for a subsequent operation unless it present itself at once. From evidence before us it appears more than probable that the effect of chloroform plays a large part in the general depression.

While writing the above I have seen 7 cases which illustrate the varieties alluded to on which I have operated with the last few days:

1. A mild quiescent case; appendix removed; no drainage.
2. A mild active case; appendix removed; no drainage.
3. A severe general case with much effused aplastic fluid in the right flank reaching to the diaphragm and producing cough, but with only moderate toxæmia and a relatively fair pulse; appendix removed; free drainage.
4. Severe inflammation with sloughing appendix and abscess, but general condition fairly good—organ removed; free drainage.
5. Severe attack with localized abscess and appendix imbedded in wall of cæcum. Temperature high. Organ dissected out; drainage.
6. Intense inflammation; appendix imbedded in caecal wall and acute enlargement of mesenteric glands in the angle between the ileum and colon: caput coli and last two inches of ileum solid with œdema; appendix removed, no drainage. The patient had incipient pneumonia with much herpes on cheek and lips. Temperature very high before operation.
7. Intense inflammation of distal third of appendix with pus just about to burst through its serous coverings in many white patches; vascular adhesions all round; organ removed; wound closed without drain.

All 7 cases recovered. Of the 6 with fresh acute inflammation 3 were drained, and are practically quite well; 3 were stitched up without any drain, 2 of these healed without a flaw, one showed a perfectly healed skin incision with a little turbid serum from two stitch holes. A few days later: The wound is now dry, and has all the signs of primary union, being firm and soft. One of the cases (No. 4) in which drainage was employed would, I now think, have done equally well or better without drainage. Not so long ago all, except the first, would have

been treated with drainage, and would probably ultimately have developed ventral herniae.

PERFORATION OF STOMACH AND DUODENUM.

This same question—whether we ought to drain or not—confronts us after operations for several other acute inflammatory conditions within the abdomen. Nowhere is it more momentous than after perforation of the stomach or duodenum. Here after we have closed the perforation it is difficult in some cases to say whether drainage should follow or not. I have treated many in both ways, and have gained the impression that those whose wounds have been closed at once have suffered less from the catastrophe itself and the operation than those whose wounds have been drained. I do not think I have ever regretted not having drained. I have often concluded that drainage had been of no use if not actually injurious. One thing is, I think, pretty clear, namely, that if a drain be used the escape of fluid is only from the abdomen in the immediate neighbourhood of our wound. No effectual means of draining the abdomen have yet been devised. We ask ourselves, then, is it worth while to drain an area not larger than could be covered by the closed hand, and probably for not longer than 24 hours? For by this time the field of operation will be shut off from the rest of the abdomen by plastic exudation. Indeed, I have often speculated whether, in some cases at least, our drain has not prevented the completion of this plastic process, and interfered with the apposition and union of the damaged viscera with the parietal peritoneum and other parts around. And if an aplastic peritonitis is the sequel to a perforation the fluid effused will gravitate into the flanks, and here it could not be withdrawn by any drain in the epigastric incision. Fresh wounds in the flanks might be made, but they are, as a rule, unsatisfactory in these cases. Indeed, a patient with aplastic diffuse peritonitis after perforation is in a desperate condition from which no amount of drainage will save him, and each fresh opening in the abdomen weakens him. His own powers of resistance alone can save him. I have seen collections in the flanks and pelvis appear and disappear in these cases without incisions.

From all these considerations I have been led for several years considerably to modify some older views about drainage in such cases. In many of them after careful mopping of the infected surfaces, however extensive, the wound in the abdominal wall has been completely closed in many cases. And I cannot recall one in which there has been reason to regret the practice. There is good ground for believing, as already stated, that fresh serum in the peritoneum and other serous cavities is germicidal, and further, dilutes the toxins produced by the bacteria. It is effused rapidly, and quickly absorbed, carrying the toxins with it, to be eliminated by the kidneys. The leucocytosis which is at the same time induced, acts further in destroying the septic germs, and between these two processes the infection is controlled if only the patient's general vitality is maintained. We believe we can assist in the cycle of events in several ways. For instance, copious subcutaneous or intravenous infusions of normal saline solution, or of 5 per cent. of glucose in distilled water, not only help to raise the vascular tension lowered by sweating, vomiting and toxæmia, but also further the dilution and elimination of the toxins by the kidneys; moreover, leucocytosis is said to be increased by these means.

The same processes for the destruction of bacteria are seen in operation in other analogous cavities of the body, notably the joints and spinal canal when infected through the blood stream. A joint thus recently infected may be found to swarm with bacteria. Subsequent aspirations may show—except in the most virulent infections, usually from without—an ever diminishing number of organisms, until at last they cannot be found either in smear preparations or by cultivation. The same is seen in cases of spinal meningitis. I have had several which have recovered perfectly. Two are recorded (and many more collected from other publications) in the *Transactions of the Royal Society of Medicine*, 1907, where suppurative meningitis of the dura, producing almost hopeless general conditions, recovered under no other treatment than repeated withdrawal of the highly infected fluid by repeated tapping of the lumbar sac.

There is much evidence, then, for the belief that the serous cavities of the body, being so important, are provided with specially powerful defensive works to protect them from bacterial invasion. It should be our aim to assist them surgically when they are in danger of being overpowered by the accumulation of bacteria and their toxins—sometimes by evacuation with drainage, sometimes by evacuation without drainage. We should always study to interfere as little as possible with the natural protective agencies. Overhandling, over-disturbance, overstimulation with chemical germicides, have long been recognized as harmful, and I feel sure that over-free use of drainage also often plays an injurious rôle. The mere fact that a wound in the epigastrium is kept open by the insertion of foreign material must more or less disturb the vascular balance within the abdomen; and the presence here of an open wound is more painful during the first few critical days than a closed one, on which the movements of respiration have less effect. The daily readjustment, too, of drains and dressings must cause a great addition of pain with all its depressing influences at the patient's weakest time, besides increasing the risk of added sepsis. I do not think there can be any question that a patient's general condition is more satisfactory with a closed wound healing more or less by first intention under a dressing untouched for days than with an open wound.

Of course an attempt to obtain primary union may not be quite successful in some cases. Invisible septic particles may have lodged in the wound and may infect the deeper or superficial stitches, and some of these may suppurate. But this, if it occur at all, will take place after some days, during which the peritoneal cavity has, at all events, been at rest. At the worst in such cases some of the deep stitches have worked out without delaying the general recovery longer, perhaps, than had the wound been drained. This is a small price to pay for getting the abdomen closed at once and giving the patient rest for the first few days while the catastrophe within is repaired. As a matter of fact, the number of cases of perforated gastric and duodenal ulcers treated by immediate closure of the abdominal wound, treated in my beds by myself and others, has largely increased, and primary union has been the result in an ever larger proportion of late. Some will continue to be drained after such lesions, but I think fewer and fewer.

Here, again, the character of the fluid met with when the abdomen is opened will help to decide the point in question. If much putrid food has escaped from the perforation and the resulting peritonitis has yielded an acid fluid as tested at once by litmus paper, the case is a bad one. If, besides, there is deep injection of the intestines with distension, and little or no plastic lymph is seen, we may count on a virulent form of infection, which would inoculate our wound at once and prevent its healing. Here I should drain freely, but with small hope for the patient.

But in some cases of fasting stomach there is little extravasation through the perforation. Here we find a bland whey-like alkaline or neutral fluid with no deep injection or distension of the intestines, while they show an inclination to adhere by plastic lymph. In these cases, after careful cleansing of all the pockets of the peritoneum accessible to swabs on holders, I am now inclined to close the abdomen completely without drainage. Many such cases have healed without further trouble by primary union. For instance, in a case of duodenal perforation the diagnosis was very obscure, and an opening was made over the vermiform appendix, which was under suspicion. The whole peritoneal cavity was full of the bland fluid alluded to, and there was some free gas. Recognizing the true condition now, I opened in the epigastrium, found the perforation near the pylorus, and closed it. After thorough swabbing of the whole peritoneal cavity I stitched up both wounds without drainage, and permanent primary union without a flaw was the result, the patient being soon well.

PYOSALPINX.

Let us take now another acute abdominal condition. If on opening the abdomen a pyosalpinx with localized peritonitis is found, there need be less hesitation. Here the immediate closure of the wound may be done in the large majority of cases. In the first place, it is known to

bacteriologists that the pus from pyosalpinx is sterile in about 50 per cent. of ordinary cases. In this group there is no special reason for drainage if oozing from adhesions can be quite controlled. But in the other half of the cases the violence of the bacteria mitigated by long residence in the body is low, as indicated by the plastic exudation and the absence of inflamed and pained intestines, and a carefully sutured wound will heal *per primam* in the majority of cases in spite of the pus. I have seen this over and over again, and also after ruptured tubal pregnancy.

INTESTINAL GANGRENE.

Again, in another class of lesions the same question has to be considered. I allude to gangrene of the gut from internal strangulation. Here, except where there has been perforation and faecal extravasation, drainage should be avoided after removal of the damaged portion. The plastic processes appear to me to be more perfect without a drain, which may prevent the apposition of healthy structures around our line of suture. I could produce many instances to illustrate this point; one or two will suffice. A few years ago I had to remove four feet of small intestine black and gangrenous from constriction of an omental band. On opening the abdomen, over a pint of dark putrid flocculent fluid escaped. After the excision of the gangrenous coils and junction of the ends, the wound was completely sutured without drainage, and primary union followed. Her doctor tells me the lady has remained perfectly well ever since, with no signs of adhesions. Another similar case occurred to me in hospital a few years earlier. Here I removed 5½ ft. of small gut for gangrene with a couple of pints of dark putrid fluid. Perfect primary union followed without drainage. The patient was a feeble woman of 76, and was quite well when I last saw her two years after operation. In both cases the putrid fluid, one would have thought, ought to have interfered with primary union, but it did not.

In cases of removal of the caecum where we open up areolar planes it may be a different matter. Drainage may perhaps be required unless we are perfectly certain of our asepsis in removing the gut. To deal with more or less sepsis in the peritoneal cavity is quite another thing to arresting its progress in areolar tissue. But even here drainage may be discarded in many cases, as I know.

I have asked your consideration of these points and given you some of my experiences in the hope of drawing your attention to a subject upon which our conclusions are not yet fully crystallized and in an attempt to arouse a more careful clinical study which must always go hand in hand with bacteriological work. I am addressing experienced practitioners, not young student beginners who might be likely to draw wrong conclusions from the speculations offered them. These are of no recent growth. It must be more than twelve years ago since I ventured to publish a paper on this subject. And experience, in many cases combined with what we have learnt from bacteriology, has served to confirm and amplify the deductions then put forward.

THE Royal Dental Hospital, Leicester Square, has received from the executors of the late Captain T. B. Heathorn a donation of £400.

THE Association of Infant Consultations and Schools for Mothers, which is now doing its work as a department of the National League for Physical Education and Improvement (4, Tavistock Square, London, W.C.), has in view a competition in the subject of mothercraft, the competitors being women attending the various schools for mothers in London. It is proposed that each of the schools shall select by competition not more than six representatives, and that these shall subsequently take part in a competition held by the association itself for prizes in nine classes of work. Among the latter are dressing and undressing a baby, laundry work, cooking, cutting out and making garments, knitting, and cleansing babies' bottles. A prize will also be given for the baby evidencing the best condition and greatest care, provided that it is shown by a mother in possession of a favourable report as to her home for a period of not less than three months signed by a health visitor or other responsible person. The competition is to take place during the health week, April 6th to April 12th.

APPENDICOSTOMY IN PLACE OF COLOSTOMY FOR RELIEF OF OBSTRUCTION CAUSED BY IRREMOVABLE CANCER OF THE RECTUM AND COLON.

D. W. G. SPENCER, M.S., F.R.C.S. (ENG.),
SURGEON TO THE WESTMINSTER HOSPITAL.

IT IS POSSIBLE to show, in cases of cancer of the rectum and colon too far advanced for excision, that colostomy, in particular left inguinal colostomy, is often an operation in excess of the requirements; and that in such cases appendicostomy can afford sufficient relief, whilst avoiding the great discomfort and disability provoked by colostomy. There is no sufficient evidence that colostomy checks the progress of the cancer itself, and it does not prevent pain from setting in when the pelvic nerves become involved. Left inguinal colostomy is especially indicated for inoperable cancer of the lower part of the rectum; when the disease is situated higher up appendicostomy may be substituted.

Even when the colostomy has been performed in a completely successful way, yet the irregular escape of gas and faeces, excited by any unusual incident, is the cause of grave discomfort. The patient, if a man, finds himself unable to dispense with the services of a nurse, and when the advance is slow the continuous attendance of a nurse becomes very trying. If a wife or daughter acts instead of a nurse, the changing of the dressing, especially at night, induces weariness and disgust, and when time proves that the colostomy has been done for a non-malignant condition, then the limitation which the colostomy imposes upon an active life becomes a heavy burden; a man cannot go an hour from a lavatory because he cannot be sure when he may need to clean himself. One patient upon whom left inguinal colostomy was performed, for what was diagnosed as inoperable cancer, died seven years later, apparently not of the cancer at all. Another similar case has lived longer still, cut off from active life, as just mentioned. Both have bitterly complained to their friends of the excessive nature of the operation.

My practice of appendicostomy owes its origin to the late Mr. Keetley, although I do not find that he or any subsequent writer on appendicostomy has advocated it as I do here. Moreover, in the reports of recent discussions on cancer of the rectum and colon by those especially interested in these subjects, no one advocated any other alternative than colostomy for inoperable cancer; at the same time there appears in such discussions no due recognition of the great discomfort incidental to colostomy, even when perfectly successfully carried out.

Before using it as recommended in this paper I had successfully employed appendicostomy in several cases for the relief of tympanites complicating acute appendicitis. In two cases in which the tympanites persisted after the appendicitis, unrelieved by other measures, the reopening of the wound and the establishment of an appendicostomy afforded relief, and the patient recovered without a fistula persisting.

I have made the appendicostomy opening just at the funnel-like junction with the caecum as seen when the appendix is drawn out. Into this is inserted a winged rubber catheter, or a glass cannula with a flange which is fixed by turning in the margins as described in the gastrostomy method known by the names of Kader and Sam. Such a fistula will close spontaneously if the tube be soon left out, say after ten days. If a tube is kept in, a valvular fistula becomes established. If after, say, three months the catheter is then omitted to be regularly passed, the fistula will tend to scab or skin over, but is readily reopened.

By attaching rubber tubing and a funnel to the outer end of the catheter fluid may be run in or gas and faecal fluid siphoned off, without moving the patient or his dressings. When the distension has been once relieved an ounce or two of olive oil shaken up in a pint of soap and water, and run in early in the morning, will induce a motion per rectum in an hour or so, sufficient for the next twenty-four hours.

If olive oil is not sufficient, a cloche or more of castor

oil or magnesium sulphate may be added, but excess excites repeated motions and has to be avoided. Seybala are got rid of by increasing the amount of soap and water run in. When the motions are thus regulated there is but rarely any escape of gas or faecal fluid by the fistula, and the patient can get about with a pad and bandage over the fistula, without fear of having to change it or of any faecal odour being perceptible. Should he find later on, as in the few, that the bowels can be regulated by aperients and the catheter is no longer passed, the fistula will scab over and then no dressing at all is required.

The cases upon which I have performed appendicostomy divide themselves into three classes:

1. Cases of acute intestinal obstruction who survived only a few days.
2. Cases which lived for months whilst the disease pursued its course to the end.
3. Cases who returned to active life.

During this period I have performed left inguinal colostomy in two cases for inoperable cancer involving the lower third of the rectum, and in two other cases certainly suffering from inoperable cancer I advised that there were no sufficient indications for any operation at that time.

1. Cases of Acute Intestinal Obstruction in which Appendicostomy was done, and Gas and Fluid Siphoned off until the Distension was Relieved.

(a) Female, aged 53, with inoperable cancer of the sigmoid flexure. Appendicostomy was done on March 4th, 1910, and she died the next day.

(b) Male, aged 65, with cancer of the splenic flexure and transverse colon. Appendicostomy was done on December 16th, 1909, and he died on December 23rd.

(c) Female, aged 78, with cancer of the ascending colon and multiple growths all over the abdomen. Ileo-sigmoidostomy and appendicostomy were done on December 11th, 1908, and she died on December 13th.

(d) Male, aged 32, with cancer of the upper part of the rectum. Appendicostomy was done on December 29th, 1910, and he died on January 8th, 1911.

There was in these cases no recurrence of the distension; the nurses frequently ran in fluid through the tube, and siphoned off faecal fluid without disturbing the patients; also faeces passed per rectum.

2. Cases which Survived for Some Months.

(a) Female, aged 56, with cancer of the upper part of the rectum. Appendicostomy was performed on November 9th, 1910, and she died on June 12th, 1911. Meanwhile the patient got about, and did not suffer until about three weeks before death. She was under the observation of Dr. Francis of Usbridge.

(b) Female, aged 64, with cancer of the sigmoid flexure and a secondary mass in the anterior edge of the liver which came to involve the transverse colon. Appendicostomy was performed on March 25th, 1911, and she died on August 11th, 1911. She remained comfortable, and was able to get out in a bath chair. She suffered very little. She was under the observation of Dr. Collier of Westminster and Dr. Lush of Hampstead.

(c) Female, aged 62, with cancer of the upper part of the rectum. Appendicostomy was done on November 7th, 1911, and she died on March 5th, 1912. She got about well at first and was under the observation of Dr. Bennion of Orpington. During the last few weeks she suffered a great deal of pain.

(d) Female, aged 57, with inoperable cancer of the upper part of the rectum. She had become exhausted by irregular attacks of fever, the cause of which was obscure until the intestinal obstruction intervened. Appendicostomy was done on August 15th, 1912, after which she remained in a comfortable state without either obstruction or pain but with irregular elevations of temperature until her death on November 10th. She was under the care of Dr. F. H. Spooner.

The colleagues under whose observation these patients were after the establishment of the appendicostomy agreed with me in instituting comparisons favourable to appendicostomy, as affording a sufficient relief from obstruction. In none of these was there any marked haemorrhage or discharge from the growth. The fluid ran in through the appendicostomy fistula every morning produced a sufficient motion and prevented any recurrence of intestinal distension and obstruction.

3. Three Cases who Returned to Active Life after the Appendicostomy.

(a) Female, aged 65, with inoperable cancer of the upper part of the rectum. Appendicostomy was done on April 16th, 1912, and I saw her on November 15th. She had got a little thinner but was quite active, the abdomen flat, the stulous opening in

which she was keeping the catheter surrounded by healthy skin. She had been running in only a small amount of olive oil and soap and water daily, but the growth was advancing and the amount required to be increased. She was under the observation of Dr. Glegg of Datchet.

(b) Male, aged 58, with inoperable cancer of the rectum at the level of the promontory, of which there had been symptoms for more than a year. Appendicostomy was done on November 2nd, 1910. A year later he came to the hospital to see me; he had been working meanwhile as a packing-case maker. He had passed a catheter through the fistula for three months, then, finding he could regulate his bowels by aperients through the mouth, he had omitted to pass it, and the fistula had become covered by a thin skin. He had latterly felt himself getting weaker, and proposed to work half time; the growth had made some advance. He attended again on November 25th, 1912—that is, two years after the operation; he had continued at work, and only complained of what he called “chronic diarrhoea.”

(c) Male, aged 65, bachelor. A large fixed mass occupied the left inguinal region, in the centre of which was an abscess coming forwards to the surface, and upon this intestinal obstruction had supervened. Appendicostomy was performed on October 9th, 1909, and at the same time the abscess incised; it seemed to be situated in the middle of a mass of cancer round the sigmoid flexure. On November 28th he was able to leave the nursing home with the abscess healed. On February 10th he had recovered sufficiently to resume his previous active life, the bowels acting well when fluid was run into the fistula, and from which there was no regurgitation. He could manage this himself, and had only a manservant to attend on him. The mass in the left inguinal region had shrunk to a hard fixed mass. He continued under the observation of Dr. C. P. Sampson. In September, 1911, a friend who travelled with him on the Continent described him as in magnificent health.

Perhaps time may prove that in this case the disease was really inflammatory.

GANGRENE OF THE VERMIFORM APPENDIX AND OF A COIL OF SMALL INTESTINE; OPERATION: RECOVERY.

By JOHN D. MALCOLM, F.R.C.S. EDIN.,

SENIOR SURGEON TO THE SAMARITAN FREE HOSPITAL.

The conditions in the case related below seem sufficiently unusual to be put on record:

A single woman, aged 31, gave the following history: In May, 1911, she had an attack of pain in the right side of the abdomen, which ceased after a few days. Six months later, on November 2nd, at 2 a.m., she was again seized by a similar but more severe and continuous pain. Dr. D. M. Mackenzie of Southall saw her, and diagnosed acute appendicitis. The bowels acted, but the pain increased rather than diminished. The woman, who was in domestic service, was taken in a cab by her own home on November 2nd, and was admitted to the Samaritan Free Hospital at 7 p.m. on November 4th, sixty-five hours after her illness began.

She was then flushed, and looked very ill. The temperature was 100° F. The abdomen, which moved only slightly in respiration, was tender and distended, there being marked resistance to pressure over the caecal region. The rectum was loaded, and an enema caused the bowels to act, after which the distension of the abdomen subsided, and all pain ceased.

When I saw the patient, about two hours later, she still looked very ill, but the flushed condition had given place to extreme pallor, the pulse was feeble (140), and the abdomen was flaccid, there being neither pain nor tenderness nor resistance to palpation anywhere. By combined pelvic and vaginal examination an ill-defined soft mass of tissue was felt in the upper part of the pelvis on the right side. The woman was not collapsed, and she felt very much better when the pain ceased. The relief was so great that I hesitated about operating, but the history and the conditions observed seemed to indicate that an examination by incision was necessary.

At 10 p.m., sixty-eight hours after the first onset of pain, a short incision was made parallel to Poupart's ligament on the right side, and immediately several ounces of bluish-black fluid of the consistency of serum escaped from the wound. This fluid had no resemblance to pus. It was apparently free in the peritoneal cavity, and my first impression was that a ruptured extrauterine foetation existed, and that the indefinite mass in the pelvis was blood clot. Further examination showed that a piece of intestine was gangrenous, and a second incision was made in the middle line to allow free access to the parts. A loop of small intestine in a necrotic condition was partially and lightly adherent round the lower end of the caecum. This coil after

being easily separated was wrapped in swabs, and placed out of the way in the middle of the abdomen. It was then seen that the vermiform appendix was gangrenous and perforated. It was adherent to the inner side of the caecum, and had been surrounded by the dark coloured fluid most of which had already escaped or been swabbed away. The appendix was removed by crushing and ligaturing its base and inverting the stump by a purse-string suture.

Then the unhealthy portion of small intestine was again exposed. It had a faintly putrid odour, and its surface over a length of about 12 in. was dead, being in some places quite black, in others having various shades of grey. The junction between the diseased and healthy parts was well defined. The bowel was double-clamped and divided above and below the necrosed portion and the mesentery of the isolated piece was cut away. There was just enough small intestine left attached to the caecum to allow a lateral anastomosis to be made after inverting and securing the retained divided ends of the bowel.

The peritoneal cavity was drained through both incisions, and there was a very free discharge of yellow serum for a few days, but except a looseness of the bowels, which continued for rather more than a week, there was no complication of any kind during convalescence, the highest temperature being below 101° F.

The patient came to the hospital on March 22nd, 1912, four and a half months after the operation, to report that she was quite well and that the bowels gave no trouble. She wished to know if she might emigrate to Canada, and I thought she might safely do so.

The necrosis of a coil of small intestine which occurred in this case is a condition which I have not seen before in association with gangrene of the appendix. Some years ago¹ I suggested that gangrene of the appendix frequently occurred without any symptoms until after a portion of its wall had died. I published a case² in which profuse haemorrhages from an opened appendix abscess cavity were associated with areas of gangrene.

These were seen when the apposed and apparently healed surfaces of the wound were separated with a view to finding the bleeding point. They consisted of dark-coloured superficial areas, about a quarter of an inch in diameter, scattered over the freshly exposed cut surfaces, exactly like cultivations of an organism upon a solid nutrient material. No bleeding point was found, but there was no further haemorrhage, and the visible necrotic areas gradually separated after the wound was laid open and drainage of its deep part was made very free. It seemed certain, therefore, that the necrotic areas were caused by the action of an anaerobic microbe which destroyed the wall of some vessel or vessels in the deep part of the abscess cavity. As there was no sign that the abscess would not heal well in that case until the first haemorrhage took place, it may be inferred that the cause of the necrosis did not induce any irritation or inflammatory reaction.

The gangrene of the intestine in the case now related seems also to have been due to some microbe in the fluid around the gangrenous appendix. It is hardly possible that the intestine could have been in the condition described for the three days, or very nearly three days, of the patient's illness. I am inclined rather to think that the pain was due to tension within the appendix; that relief was due to rupture of the appendix; and that the necrotic change in the bowel was very recent, being caused by an exceedingly rapid action of some micro-organism in the fluid that escaped into the peritoneal cavity after the patient's admission to hospital. Serous fluid of a yellow colour, and more or less clear, is often seen collected in a pool around a gangrenous appendix, although not held there by adhesions. In the case now recorded the fluid was of a very dark colour, and apparently it had a necrogenic effect upon the bowel.

It is, of course, conceivable that the condition of the bowel was the cause of pain, and that the cessation of pain was due to the emptying of the intestine by the action of the enema and to the consequent relief of tension within it; but it is very difficult to believe that an enema would act if the bowel had been even for a very few hours in the condition above described; and the pain was of very nearly three days' duration.

Pain is undoubtedly sometimes due to the escape of the contents of a vermiform appendix into the peritoneal cavity; but there is quite commonly a stage, as in this case, in which after the appendix has ruptured, and apparently immediately after its rupture, there is for a time complete freedom from pain.

It is a question whether an enema should have been administered when the patient was admitted to the hospital. In this particular instance the effect was good, for the operation was easier with the intestines collapsed than

it would have been if they had remained dilated. But if acute appendicitis requiring operation is diagnosed, it is usually better to operate first and to clear the bowel afterwards. The enema seemed to determine the onset of the condition in which alarming symptoms subside, and therefore its effect was to help the patient not to a cure but to a further stage of the disease, to that dangerous state in which the practitioner is tempted to believe that his patient is better, and that operative interference is not necessary. If this view had been adopted in the case now recorded, it is certain that a few hours' delay would have made the conditions very much more serious, if not altogether hopeless. An operation then, or a *post-mortem* examination, would have shown an intense general peritonitis affecting the parts around the appendix region most severely.

Whatever the exact interpretation of the symptoms may be, the case illustrates (1) the imperative need for operative treatment in certain cases of appendix mischief, and (2) the importance of sudden cessation of severe pain as a sign that the conditions have become not less but more urgent. I do not believe that appendix cases can be understood until it is recognized that there are two distinct forms of mischief—one, inflammation commencing in the mucous membrane; the other, gangrene brought about by the action of a necrogenic microbe which causes no inflammation until the dead part is separating, or has separated. Each of these conditions may complicate the other, but typical cases are easily defined. There can at least be no question that, in many cases of gangrene, operative treatment is alone of use, whilst there are other cases in which even severe inflammation causes little real danger.

But the difficulty of recognizing which condition exists is sometimes so great that the surgeon thinks the safest course is to assume the worst, and operate at once, believing that if the patient would recover without operation, an operation will not prevent his recovery, and knowing that if the appendix is ruptured without adhesions having formed, delay in removing it is exceedingly dangerous, whilst a sufficiently early removal is almost always successful.

TWO CASES OF GANGRENOUS APPENDICITIS WITH UNUSUAL HISTORIES.

BY

GERALD S. HUGHES, M.B., B.S. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON, YORK COUNTY HOSPITAL.

THE two cases of appendicitis the histories of which are given below were met with within twenty hours of each other, and, showing as they do several points of interest, are, I think, therefore worth recording.

CASE I.

J. P., male, aged 9 years, was first taken ill on September 1st, 1912, when he complained of pain in the stomach. He had previously been healthy, although from infancy he had from time to time complained of pain on passing water. When seen first he had no objective symptoms; the pulse was 88, and the temperature normal, the belly soft without any tenderness; a bismuth mixture was prescribed. Between September 1st and September 6th he was seen each day. The pulse remained steady and below 90, and the temperature both night and morning was normal. When seen he was generally playing with his toys and free from pain, though there was always the story that he occasionally would cry out with paroxysmal attacks of sharp pain. His bowels were opened each day. On September 6th I was sent for as the child had been attacked with severe pain while passing a motion. On examining him an hour after the pain had commenced I found his belly wall absolutely rigid. The pulse was 80, and the temperature 98.8°. The tongue was moist, but he wore a somewhat worried look. I diagnosed acute abdomen, and had him removed to hospital. On admission the temperature was 101.4 and the pulse 120. I operated immediately and found the belly full of pus. On feeling for the appendix I found it hanging over the edge of the pelvis. It was adherent to the bowel and bladder, but was separated with ease. It was a long one; the first 2 in. appeared healthy, but distal to this it was enlarged to the thickness of one's thumb. It was gangrenous and had a perforation. On opening it I found a

concretion the size and shape of a "monkey nut." The appendix was removed, the pus swabbed out and the belly drained in four places, in each loin and in each flank. The boy made an uneventful recovery.

CASE II.

J. C., male, aged 32, came to consult me on his way home from work on September 5th, complaining of severe pain in his abdomen; the pain was localized and was eased by pressure. I found no tenderness of the abdomen. I was able to feel the outline of the pelvic brim throughout its whole extent, and no tenderness was elicited on deep pressure; the pulse was 80 and the temperature 98.2°. He was sent home to bed with a simple remedy. I was called to see him on September 7th, and found that he had been vomiting all the preceding night. The pulse was 88 and the temperature 98.6°. There was no tenderness on deep pressure in the iliac region nor in any part of the abdomen. The tongue was moist, but his face had a slightly anxious taint.

I think because of the remembrance of the case of the preceding night more than because of any definite signs or symptoms, although the man's expression was suggestive, I determined to explore his abdomen. On opening the belly a little clear fluid escaped. I felt for the appendix and found it lying in exactly the same position as in the case of the boy, hanging down into the pelvis against the bladder. I removed the appendix, and here again found the first $\frac{1}{2}$ in. healthy, the distal 3 in. gangrenous and enlarged to the size of a small banana. I put in a large drain, swabbed up the fluid in the abdomen, and sewed the rest of the wound up. This patient also made an uneventful recovery.

On incising the appendix I found the dilatation full of pus and containing six tin tacks and eight little shot. To explain the presence of this medley I subsequently discovered that the patient up to eight years ago followed the trade of a joiner, when he was accustomed to hold the nails in his mouth. The nails, he explained, were thrown from a box which contained small bits of lead and other remnants into his mouth, and he remembered that he often got odd bits of lead, etc., in his mouth with the nails.

From these two cases several interesting and instructive lessons, I think, may be gained.

Neither patient had a raised temperature or quickened pulse, although in both cases we must, I think, presume that pus was present in the appendix before the acute symptoms arose. I think the explanation of this lies in the fact that the appendix in each case was chronically thickened by the presence of the foreign bodies and therefore there was no escape of poison into the circulation and no infection of peritonium.

In the case of the child the perforation occurred obviously while he was straining at stool, which is an interesting point.

The paroxysmal pain which each patient suffered before the acute symptoms was a true appendicular colic, the organ trying to expel the foreign bodies it contained.

Almost all surgeons are now agreed as to the advisability of operating immediately appendicitis is diagnosed, but here were two cases with an appendix enormously dilated which were not diagnosed before acute symptoms supervened, although both cases were examined systematically and thoroughly with one clinical method omitted—that is, examination per rectum. The excuse for this is obvious: there was nothing to lead one to suppose mischief in the appendix, although it was carefully examined, but I feel confident that, had a rectal examination been made, the local tenderness would have thrown light on the condition one had to deal with, and spared the patients the acute termination which so greatly endangered their life. These cases emphasize the importance of this examination being made as a matter of routine in all abdominal cases.

Another point which both these cases illustrated is the importance of the abdominal facies. When first seen, except for the rigid abdomen in the case of the boy, neither patient had any objective symptoms except this worried anxious look.

THE late Dr. Frederic Bagshawe, of St. Leonards, left estate valued at £80,817, of which £78,534 was net personality.

HEARSEY, in his sleeping sickness *Diary* (Part XVIII) for the Nyasaland Protectorate, states that since the issue of the last number 17 additional cases of the disease have been diagnosed by Dr. Shircore. These, added to the 76 previously recorded, make a total of 93 cases. The value of a new drug, "Dye B. S. (Brieger and Krause)," was tested in some of the cases, but Dr. Shircore finally came to the opinion that it was not only useless as a therapeutic agent, but might even be harmful.

THE METABOLIC UTILITY OF RECTAL FEEDING.*

BY

N. MUTCH, M.A., M.B., B.C.,

BEANEY RESEARCH STUDENT IN MATERIA MEDICA, GUY'S HOSPITAL, AND

J. H. RYFFEL, M.A., B.C., B.Sc.,

DEMONSTRATOR OF PHYSIOLOGY, GUY'S HOSPITAL,

In order to alleviate starvation, when a patient cannot be fed by the stomach, it is the custom to introduce various food materials into the rectum. This procedure depends on the assumption that such materials can be absorbed by the colon and are metabolized in a normal manner when absorbed. When given in this way saline solution is undoubtedly useful as a source of water. Dextrose solution is fairly well absorbed, but starch and fat are probably of no value. The utility of protein is doubtful. Langdon Brown found no increase in urinary nitrogen as a result of giving partly predigested protein by the rectum, and concluded that earlier observations, showing that as much as 50 per cent. of the protein given might be absorbed, were largely fallacious owing to the notorious difficulty of washing out the colon completely.

1. *The Disappearance of the Nitrogen of Peptonized Milk and of Dextrose from the Colon.*

To a girl 6 years of age, who could not be fed by the mouth, 10 per cent. dextrose was given per rectum for two days. Peptonized milk was then given for two days, and then 10 per cent. dextrose again for two days. The whole of each enema was retained; but, as is customary, the colon was washed out at the end of each day with saline solution. The nitrogen recovered in this way up to fifty-eight hours after the last administration of milk amounted to only 0.34 gram out of a total of 2.80 grams given in the milk, so that 88 per cent. of the nitrogen was apparently absorbed. Of the dextrose 99 per cent. was absorbed. The urine showed a good reaction for indican on the days when milk was given, and none when dextrose was given, so that evidently some bacterial decomposition of the protein preceded absorption.

It may very well be the case that bacterial decomposition is necessary before protein can be absorbed in this way. As various toxic substances may thus be produced, it becomes doubtful whether rectal feeding with protein is desirable, even when considerable absorption takes place.

2. *The Influence on Metabolism of Dextrose Administered by the Rectum.*

The abnormalities in the urine during starvation, which are due to lack of carbohydrate, are: (a) The presence of creatin†; (b) the presence of acetone, diacetic acid and oxybutyric acid with the resulting acidosis and increase in the proportion of nitrogen as ammonia.

Cathart has shown that, when a diet consisting only of carbohydrate is taken, these abnormalities are largely prevented, and the total daily nitrogen of the urine is less than in starvation, and that, when carbohydrate alone is taken after starvation, the creatin and acetone bodies disappear rapidly, but the fall in urinary nitrogen and in the proportion of nitrogen present as ammonia is much less rapid.

We have investigated the changes produced in the urine by the administration of dextrose per rectum in four cases—a girl, a boy, and two men. The girl has already been referred to. No definite changes were observed on giving dextrose by the rectum, but the periods were probably too short. As is usual with children in starvation, the acetone bodies were present in considerable quantity, as much as 0.57 gram total acetone and 1.94 grams oxybutyric acid being obtained on one day by Shaffer's method of estimation. On the first day of the second period of dextrose the urine contained 0.05 per cent. lactic acid, or 0.36 gram per diem, which fact

indicates that there was considerable formation of lactic acid from dextrose by bacteria in the gut.

In the other 3 cases 10 per cent. dextrose was given by the rectum for various periods, of which the greatest was six days. In one case the effect of increasing the dextrose was observed; in another dextrose was given by the rectum after a period of starvation and followed by milk given by the stomach; in the last case the effects of saline per rectum, dextrose per rectum, dextrose by the mouth, and milk and eggs by the mouth were compared. Dextrose absorbed from the rectum was found to cause a reduction in the daily amount of creatin and of total nitrogen in the urine roughly equivalent to that of similar amounts of dextrose, or other carbohydrate, when given by the mouth, but to be far less efficient than that given by the mouth in reducing acidosis and the formation of the acetone bodies. In these cases the lactic acid in the urine was scarcely above normal, and only traces of lactic acid were found in the material returned from the rectum, so that the failure of the dextrose enemata to influence the acetone bodies can scarcely be accounted for by bacterial change occurring in the alimentary canal, and we have no other explanation to offer.

One of the adult cases had had rectal salines, but no food, for a week, owing to oesophageal obstruction, which was probably malignant. He was then given 10 per cent. dextrose per rectum, so that he received and retained 114 grams dextrose on the first day and 170 grams on the second, third, and fourth days. On the third day the operation of gastrostomy was performed with chloroform anaesthesia. On the fifth day feeding by the stomach was begun, so that he received on this day protein nitrogen 0.95 gram, fat 6.1 grams, carbohydrate 37 grams. The allowance of food was increased day by day, so that on the eighth and seventeenth days he was receiving 100 grams and 210 grams of carbohydrate respectively.

No diacetic acid was detected at any time. When dextrose was given by the rectum the daily creatin fell continuously. The anaesthetic on the third day caused a distinct acidosis, but no increase in the creatin. The nitrogenous excretion was probably influenced by the anaesthetic. It showed no diminution up to the fourth day. On the fifth day the carbohydrate given by the stomach was much less than that given previously by the rectum. A marked rise in the creatin occurred, and a rise in the nitrogen greatly in excess of the nitrogen in the food.

Table showing Results Obtained.

| Day. | Grams per Diem. | | | | Acetone. | Acidity cc. N/10 per Diem. | Ammonio Ratio per Cent. |
|------|-----------------|------------|----------|------------------|----------|----------------------------|-------------------------|
| | Total Nitrogen. | Creatinin. | Creatin. | Oxybutyric Acid. | | | |
| 2 | 9.95 | 0.92 | 0.37 | 0.070 | + | 232 | 5.3 |
| 3 | 8.97 | 0.80 | 0.31 | — | + | 419 | 8.5 |

In these experiments 10 per cent. dextrose was employed in order to obtain as large an absorption of dextrose as possible, but for general use a 6 per cent. solution in tap water, which is isotonic with blood, would be found more convenient as it is less irritating; 15 oz. or more of this solution given four times a day is frequently well retained by an adult, if the rectum is thoroughly washed out once a day with saline solution. It is more useful than saline solution in that:

(a) The 100 grams or more of dextrose which is thus daily supplied to the body causes a diminution of nitrogenous waste.

(b) The substance employed to render the solution

* Expenses of this investigation have been defrayed from a grant made to J. H. Ryffel by the Science Committee of the British Medical Association.

† Some creatin is normally present in the urine of children, but not in that of adults.

isotonic is oxidized in the body, so that isotonic dextrose solution is more efficient as a source of water than an equal volume of isotonic salt solution.

In conclusion we desire to thank Dr. Hale White, Mr. Symonds, and Mr. Steward, of Guy's Hospital, for permission to publish the results of investigations made on patients under their care.

RENAL CALCULUS IN CHILDHOOD.

WITH A REPORT OF TWO SUCCESSFUL CASES OF NEPHRO-LITHOTOMY IN YOUNG CHILDREN.

BY

ROBERT OLLERENSHAW, B.Sc., F.R.C.S. (Eng.),

HONORARY SURGEON TO SALFORD ROYAL HOSPITAL; HONORARY SURGEON TO MANCHESTER NORTHERN HOSPITAL FOR WOMEN AND CHILDREN.

As to the infrequent occurrence of stone in the kidney in young children all writers are agreed. Sir Henry Morris,¹ in an analysis of 283 cases of renal calculus, met with only one case in a patient under 10 years of age. Drew records the removal of a uric acid stone from the kidney of a child aged 6 years. The rarity of calculi causing symptoms at this period of life seems somewhat extraordinary, when one remembers that at autopsies on the bodies of infants it is extremely common to find small brown granules of uric acid deposited in the pelvis and calyces of the kidneys. Holt² considers that very small calculi are common in infancy, but in a series of 1,000 autopsies made by him on the bodies of children under 12 years only one stone of any noteworthy size was found.

It is probable that the almost exclusively fluid diet of the first two years of life is responsible for the solution, or washing out, of these uric acid granules, though the earlier histories of certain cases which come to operation in later years make it extremely likely that the calculi were present in childhood. Morris records that on several occasions he has met with a history of symptoms dating back from twenty to thirty years, showing that the calculi existed in quite early life. Amongst his cases also are those of children of 13 and 11 years who had presented symptoms of calculus for seven and three years respectively.

Heaton³ gives an account of the successful removal of a uric acid stone weighing 35 grains from a female child of 11 years; the patient suffered severely from shock after the operation, but ultimately recovered. Amongst cases in which calculi were found at autopsies are three reported by Newton Pitt.⁴ These were all uric acid stones, and weighed 2 grains, 4 grains, and 2 grains respectively, being found in children under 2 years of age who died of diphtheria and bronchopneumonia. In the second of these cases the mother noticed polyuria but no haematuria; in the last case haematuria was observed, but in the first case there were no renal symptoms at all. A similar case is noted by Partridge⁵; at autopsy a stone of 4 grains weight was found in the pelvis of the left kidney. The child had shown no symptoms suggesting the presence of a calculus, and no examination of the urine was made. Death occurred from pneumonia.

The reputed uncommon occurrence of stone in the kidney in children is probably the chief reason why it is overlooked when actually present. Again, renal pain is practically always referred, by a child, to the abdomen, and so is ascribed to gastro-intestinal disturbance, the most common of the complaints of childhood. The pain may also be referred to the hip or spine, and produce simulation of disease in these regions to such an extent that the kidneys are never suspected, and escape examination. Pain due to renal calculus depends on the position and mobility of the stone or stones; the kidney substance is insensitive, the pelvis and calyces highly sensitive. The pain is frequently referred to the groin; in boys it is accompanied by retraction of the testicle, which is much more commonly seen at this stage of life than in later years.

It is obvious, from what has already been said, that in children, as in adults, calculi may be present without causing any symptoms. The most constant and reliable symptom, however, is haematuria. Lumbar pain is not common in children. The presence of fine uric acid sand should be looked for in suspected cases; the urethral irritation caused by this substance is sometimes a cause of nocturnal incontinence, and the urine of patients suffering from this trouble should always be carefully examined for uric acid crystals. Transient haematuria may be caused by the effect of these small grains on the tender kidney tubules, and is not of much importance; if it persists it must be regarded as serious and especially so if there be pain along with the haemorrhage.

In infants from 6 to 18 months old the commonest cause of haematuria is scurvy, and it must be borne in mind that blood may be present in the urine for some days before tenderness of the limbs becomes noticeable. In Drew's case, mentioned above, intermittent lumbar pain was the only symptom; there was no haematuria, but a skiagram revealed the presence of a calculus.

In May, 1912, Dr. J. J. Cox asked me to see the following case:

A little girl, aged 3 years, who had been suffering from intermittent haematuria for some weeks. In May, 1911, there had been a similar attack, and I am informed that on one or two occasions the child complained of some slight lumbar pain. From that time until January, 1912, there was no further evidence of any disease, the child appearing to be in perfect health. For three months before the time when I saw her the general health had been failing, though the child looked well nourished. Dr. Cox noticed the presence of slight haematuria and a little tenderness in the back; on some days blood was absent, but a trace of albumen was always there. On no occasion were casts or pus cells present.

Cystoscopic examination showed the escape of clear urine at regular intervals from both ureteric orifices. Nothing abnormal was seen beyond some slight congestion round the orifice of the left ureter. A skiagram showed the presence of a calculus in the left kidney, the rest of the urinary tract being quite clear.

Operation.

On May 20th, 1912, the usual lumbar incision was made, the kidney exposed and brought out on the loin. Careful palpation afforded no indication as to the whereabouts of the stone, but the radiogram showed that the stone lay about 1 in. above the lower pole. The cortex was incised along its convex border over the position of the shadow and a rough spiculated stone about 3 in. in diameter was removed. The cortex was sewn up by interrupted catgut stitches, the muscles brought together and the wound closed, a small rubber drainage-tube with gauze filling ("cigarette" drain) being placed down to the kidney.

After-History.

The drain was removed in forty-eight hours. The wound was quite sound at the end of ten days and the child pursued a quite uninterrupted convalescence. On the fifth day after the operation there was but a mere trace of blood in the urine and by the end of the week it had disappeared entirely.

Calculi removed (actual size).

Case I.—Composition, uric acid; weight 4 grains.

Case II.—Composition, calcium oxalate and phosphate; weight 16½ grains.

The second case came under observation on June 26th, 1912.

A boy, aged 8 years, a patient of Dr. Mumford, had suffered from occasional attacks of abdominal pain in the left side for twelve months; during the last three months the attacks had been more severe. The pain was of an aching character and was frequently accompanied by vomiting. On examination nothing abnormal was found except some little tenderness below the twelfth rib in the left lumbar region and also by deep pressure on the kidney from the front. The urine contained 0.05 per cent. of albumen but no blood. Microscopic examination was negative and the cystoscope showed no abnormality. A skiagram was taken and showed a calculus in the lower pole of the left kidney, which was slightly enlarged.

Operation.

On June 28th, 1912, a rounded, very hard spiculated stone weighing 16½ grains was removed from the lower part of the left

renal pelvis. The wound was treated as in the previous case; the child was up and about in three weeks, and left the hospital on July 22nd. He has had no trouble since that time.

Such cases impress upon us the importance of being on the look-out for renal calculi, which are probably much more common during childhood than is generally supposed. In cases of abdominal, spinal, hip-joint, or lumbar pain where the signs and symptoms are not clear, the urine should be carefully tested and a microscopic examination made. The kidney area should be closely examined and a skiagram taken of the whole urinary tract. If possible a cystoscopic examination should also be made.

If no sepsis has occurred, the prognosis is excellent. Post-operative shock is the only real danger. Heaton's second case suffered severely from shock, and Aldibert lost one case out of a series of three in children. When sepsis is present a fistula may persist—this happened in Morris's case and required nephrectomy to remedy it. Palliative treatment by alkalis and other solvents may be effective when mere sandy particles are present, but when a calculus exists of size sufficient to be shown on an x-ray plate, it is quite certain that nothing short of operation will remove it. It must also be borne in mind that the sooner the operation is undertaken the better the condition of the kidneys, and therefore the better the chances of success.

THE QUALITATIVE AND QUANTITATIVE EFFECT OBSERVED ON POLYMORPH NEUTROPHILE LEUCOCYTES IN THE TREATMENT OF TUBERCULOSIS BY TUBERCULIN.

By E. HAMILTON BLACK, M.B., CH.B. EDIN.,

ACTING RESIDENT ASSISTANT MEDICAL OFFICER, COUNTY AND CITY ASYLUM, HEREFORD.

It is with diffidence that I desire to draw attention to the following phenomena noticed by myself in a series of cases, some of which I have not previously seen recorded. From a clinical standpoint they may have great significance. Some of these observations have not been checked, so far as I know, by other contemporary workers, and therefore require confirmation. An important change occurs in the qualitative and quantitative values of polymorph neutrophile leucocytes after tuberculin treatment in those cases of tuberculosis in which these values on investigation have been found to be poor and below the normal. No doubt this fact has been overshadowed or perhaps overlooked by workers investigating the more complex questions in relation to dosage, antibodies, tox-immunity, etc.

One phenomenon observed, due to the formation of antibodies, is the increased power of the neutrophile polymorph leucocytes to draw into their substance the invading micro-organism—a fact made use of in estimating the opsonic index.

I have repeatedly observed by a series of counts that this increased power is almost equally shared by what I term "all qualities" of neutrophile polymorph leucocytes—that is to say, by those having one or more than one nucleus. This should be kept clearly in mind, in view of the following facts which I have from time to time carefully collected, and which I think are deserving of consideration on account of their clinical significance.

First, the phagocytic value of polymorph neutrophile leucocytes in drawing into their substance tubercle bacilli is increased in proportion as the number of nuclei contained in them is also increased. This is contrary to the view held by some that those neutrophile leucocytes with more than one nucleus are examples of degenerated forms.

Counts were taken from a series of slides prepared from emulsions of leucocytes treated by control serums, and those freshly obtained from tuberculous patients. Whether the tuberculo-opsonic index was high or low, it was found that the average values were maintained throughout with

little variation as follows: Taking equal numbers of the variously nucleated neutrophiles, the number of tubercle bacilli ingested by polymorph neutrophile leucocytes with one nucleus was found to be about 10 per cent., by those with two nuclei about 18 per cent., by those with three nuclei about 22 per cent., by those with four nuclei about 25 per cent., and by those with five nuclei about 25 per cent. These figures represent the combined results of all the counts made from the whole series of slides. Charts 1, 2, and 3 are some examples of the counts made from the series of slides above mentioned. Hence, instead of those

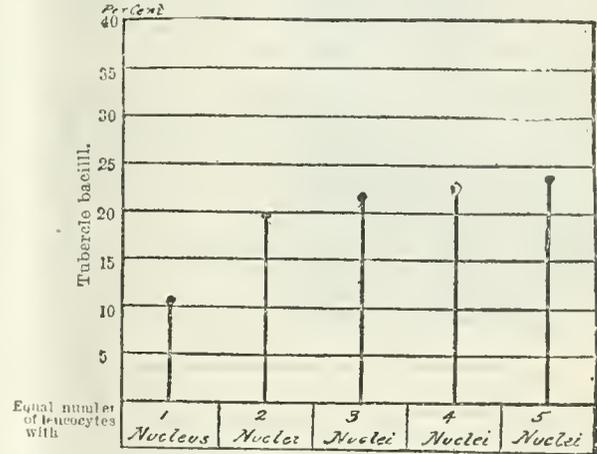

Chart 1.—Phagocytic values. The number per cent. of tubercle bacilli ingested by equal numbers of the variously nucleated polymorph neutrophiles treated with fresh serum from the blood of a phthisical patient.

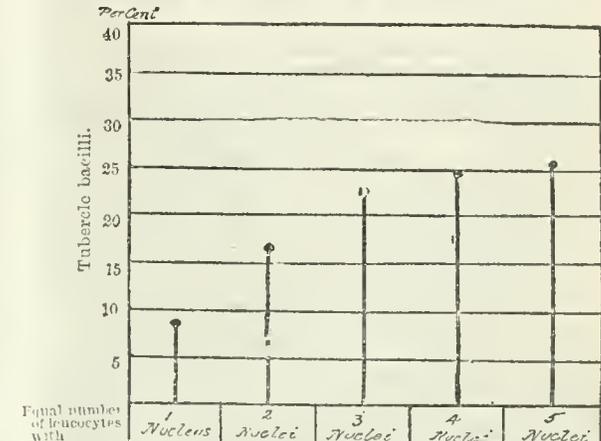

Chart 2.—Phagocytic values. The number per cent. of tubercle bacilli ingested by equal numbers of the variously nucleated polymorph neutrophiles treated with the fresh serum from the blood of a healthy non-tuberculous subject.

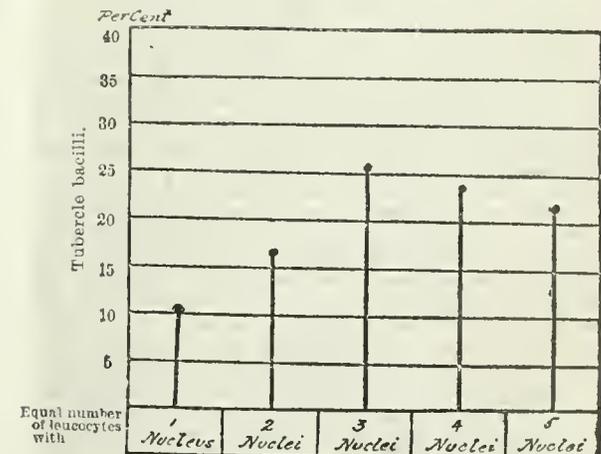

Chart 3.—Phagocytic values. The number per cent. of tubercle bacilli ingested by equal numbers of the variously nucleated polymorph neutrophiles treated with fresh serum from the blood of a phthisical patient.

with more than one nucleus being assumed to be degenerated forms, their phagocytic value proved to be actually increased; from my observations I concluded that they were also examples of more mature forms, and better fitted to carry on the defensive work in the body economy. As curious coincidences they were even occasionally found with nine distinct nuclei, arranged round the periphery of the cell, and containing a large number of bacilli; they were not unlike giant cells.

It was observed that the effect of repeated doses of tuberculin (given to a number of tuberculous patients whose polymorph neutrophile leucocytes were found to be of low value) was considerably to increase that value, by reason of increasing the number of nuclei in each cell.

In the normal blood there are, roughly, 5 per cent. of mononuclear polymorph neutrophile leucocytes, 30 to 35 per cent. with two nuclei, 40 per cent. with three nuclei, 20 per cent. with four nuclei and over. The following is an example of a series of cases in which the nuclei were estimated before and after treatment with repeated doses of tuberculin.

Before treatment polymorph neutrophiles with one nucleus were estimated to be 33 per cent., after treatment

ment increases both the quality and quantity of the leucocytes. Further, since it has been shown that the more mature polymorph neutrophiles are of greater phagocytic activity, and also that the relative proportion of these is increased by tuberculin treatment, as is likewise the total number of leucocytes per cubic millimetre, the total result must be to increase the resistance of the whole body organism against the invading enemy.

These observations were made in the course of a study of the behaviour of the tuberculo-opsonic index of a number of insane tuberculous patients, who were being treated by injections of tuberculin, and were designed to assist in forming an opinion as to whether the treatment was of real benefit in such cases, since in dealing with the insane we are sometimes confronted with anomalous conditions which have to be taken into consideration in the diagnosis, prognosis, and treatment by tuberculin. The trophic centres and nervous organization generally may be so altered and possessed of such low dynamic quality that not only can the body nutrition be largely modified by the foregoing conditions, but that there may be actual wasting from this cause, apart from that caused by the presence of tuberculous foci.

The degree of malnutrition in the insane may be

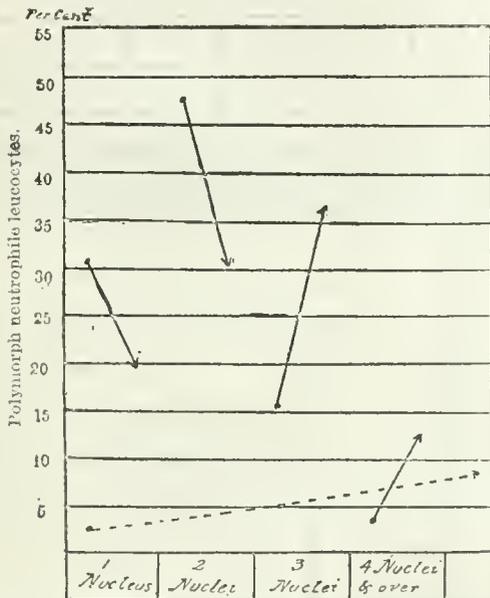

Chart 4.—The percentage of the various nucleated polymorph neutrophile leucocytes in the blood of a tuberculous patient, E. G., before and after repeated doses of tuberculin injected for treatment. 1,000 leucocytes per c.mm. shown by the broken line, indicating the increase after repeated injections of tuberculin.

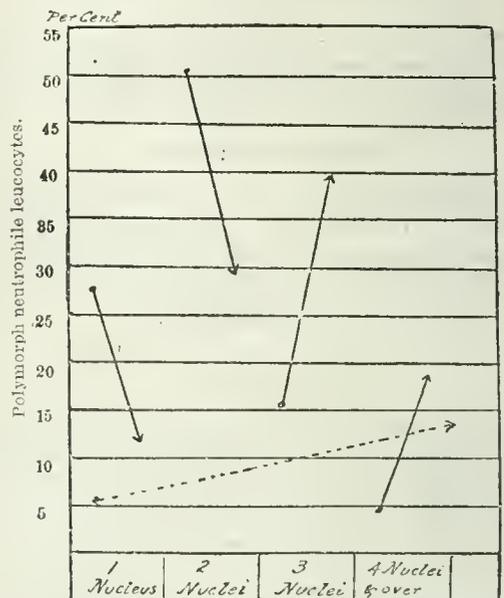

Chart 5.—The percentage of the various nucleated polymorph neutrophile leucocytes in the blood of a tuberculous patient, Mrs. S., before and after repeated doses of tuberculin injected for treatment. 1,000 leucocytes per c.mm. shown by the broken line, indicating the increase after repeated doses of tuberculin.

9 per cent.; those with two nuclei 40 per cent., after treatment 32 per cent.; those with three nuclei 16 per cent., after treatment 42 per cent.; and those with four nuclei and over 11 per cent., after treatment 16 per cent.

Charts 4 and 5 are two other examples of the same series of cases illustrating the increase in the number of nuclei after treatment with repeated doses of tuberculin. This nuclear increase was noted in all cases in which counts were taken and reactions obtained by doses of tuberculin, which were never given in such small doses as are injected in order to avoid reactions.

The number of leucocytes in normal blood is from 8,000 to 10,000 per cubic millimetre. In most chronic tuberculous cases, as I expected, it was found to be much below normal. After repeated injections of tuberculin, therapeutically administered, the number of leucocytes per cubic millimetre was increased in all cases in which counts were made. For example, before treatment in one case the leucocyte count was estimated to be 3,000 per cubic millimetre, and after several injections of tuberculin this was raised to 9,000 per cubic millimetre; in another case the count before treatment was estimated to be 6,800 per cubic millimetre. After several injections of tuberculin, the same rose to 14,500 per cubic millimetre, and so on (*vide* Charts 3 and 4).

From the foregoing observations it may be deduced that in certain cases of tuberculous disease tuberculin treat-

further complicated by persistent refusal of food, apart from any recognized definite cause. The above classes of patients, unlike those in whom the nervous organization is still unimpaired, are slow at first to gain weight under tuberculin treatment, or may show no improvement for some considerable time, or at first may even continue to lose weight, in spite of the fact that the symptoms and focal lesions show distinct and marked signs of improvement, and that the temperature, previously remittent, has steadily remained normal after treatment with tuberculin, or the tuberculo-opsonic index has been raised, and the qualitative and quantitative values of the polymorph neutrophile leucocytes have markedly increased. So, if at first the body weight and nutrition in such a class of the insane are negative or slow to improve, the eventual results justify a recommendation for the continuance of the tuberculin treatment.

UNDER the will of the late Mr. George Harwood, M.P. for Bolton, the Bolton Infirmary and Dispensary receives a bequest of £1,000.

THE General Council of King Edward's Hospital Fund for London held its usual January meeting on January 13th. The resolutions providing for the work of the current year, adopted at the meeting in December, were formally approved, and the list of appointments made to the General Council and to various committees by the governors of the Fund was read out.

**OBSERVATIONS ON
SUSPENSION LARYNGOSCOPY, WITH THE
NOTES OF A FEW CASES.**

By EDWARD D. DAVIS, F.R.C.S. Eng.,

ASSISTANT SURGEON, NOSE, THROAT, AND EAR DEPARTMENT,
CHARGING CROSS HOSPITAL; CLINICAL ASSISTANT (IN CHARGE),
LARYNGOLOGICAL DEPARTMENT, MOUNT VERNON
HOSPITAL FOR CONSUMPTION AND DISEASES
OF THE CHEST.

PROFESSOR KILLIAN, of Berlin, has recently devised and adapted a new method for the examination of the pharynx and larynx. The head of the patient is suspended in an extended position in such a way as to bring the mouth, pharynx, and larynx into one line so as to obtain a direct view of these structures.

The patient lies flat on his back on a firm table, with the head and neck extended over the edge and supported

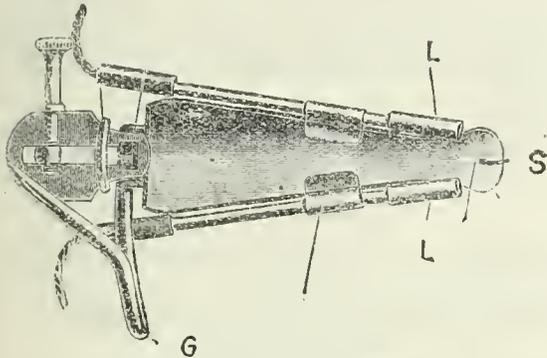

Fig. 1.—L, Lamp; G, gag; S, spatula.

by an assistant. A spatula or tongue depressor is fixed to a long handle with a hook for attachment to the horizontal bar of the stand. The spatula is placed over the tongue and epiglottis of the patient as far down as the arytenoid region. It is then attached by the hook to a horizontal bar fixed to an upright stand. When the spatula and hook are adjusted and the desired view is obtained, the assistant releases the head, which is then suspended as shown in the illustration. The arm of the hook should be inclined obliquely downwards and not hang vertically above the mouth of the patient. The mouth is gagged open by the special device with a screw adjustment attached to the handle of the spatula.

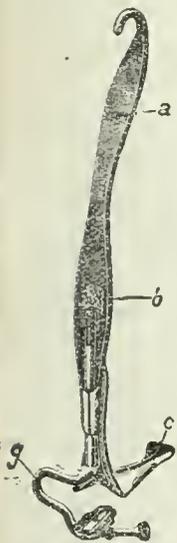

Fig. 2.—A, Handle; B, screw adjustment for gag; C, spatula; G, gag. (Pfau, Berlin.)

Professor Killian has devised fourteen different spatulae, but of these there are only four, of varying sizes, which are commonly used.

The illumination I have most frequently used is the reflected light from an ordinary forehead mirror, although in some cases a small electric torch has been found useful. Professor Killian himself uses a Kirstein head mirror and lamp, but an efficient illumination is obtained from two small lamps attached to the edges of the spatula, as shown in Fig. 1. During operations the light from the two small lamps is said to be obscured by the blood, but for demonstration purposes the illumination is extremely

good. Another method of illumination is by means of a lamp fixed to the gag in the angle of the mouth.

The anaesthetic employed by Professor Killian in the majority of cases (about 50) in which this method was employed was scopolamine and morphine given two hours before operation and a second dose after one hour. The dose administered was morphine gr. $\frac{1}{2}$, scopolamine gr. $\frac{1}{100}$. Occasionally slight chloroform anaesthesia was added. In patients under 16 chloroform anaesthesia is advisable, with an addition of 8 to 10 drops of a 1 per

cent. solution of cocaine to restrain the cough. In the cases about to be recorded chloroform anaesthesia was used with a preliminary swabbing of the tongue, pharynx, and larynx with a solution of 20 per cent. cocaine and adrenalin.

The pharynx is perfectly seen, and a view of the posterior plate of the cricoid cartilage with the arytenoids can be obtained. The faucial tonsils are particularly well shown, and the position appears to be an excellent one to adopt for enucleation of the tonsils. The only apparent disadvantage is the unusual aspect; all the manipulations would be upside down. The base of the tongue, the vallecula, the epiglottis, and the arytenoid region are well shown. The posterior two-thirds of the vocal cords are seen under favourable circumstances, but the anterior commissure of the larynx cannot be seen even when the larynx is pressed backwards from the outside.

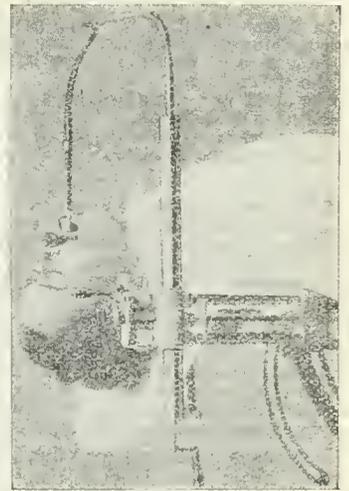

Fig. 3.

After a number of trials of the position on different patients the method was first employed to remove a safety pin from the pharynx of an infant aged eleven months.

CASE I.

A male infant of 11 months swallowed an open safety pin $\frac{1}{4}$ in. in length, and was immediately brought to Charing Cross Hospital. Although the child did not appear to be distressed or dyspnoeic, and the pin could not be seen when the tongue was firmly depressed, yet the house-surgeon could feel the upper end in the pharynx.

The child was chloroformed and placed in position for suspension laryngoscopy, and then the pin was easily seen lying vertically on the posterior pharyngeal wall, with its bent point uppermost and embedded in the lateral wall of the pharynx. It was opposite the opening of the larynx, with the lower end about the level of the upper edge of the cricoid cartilage. The shaft of the pin near the pointed end was seized with Patterson's forceps and pushed downwards to free the point. The forceps were then slipped down the shaft of the pin to its lower extremity, and the whole pin rotated on its point, so that its position was exactly reversed with the lower end uppermost, and was then withdrawn in that way without damage to the pharynx.

The chief advantage of the position of the patient lies in the comprehensive view of the pharynx obtained as compared with the small area visible by the oesophagoscope; also more room is afforded for the manipulation of instruments and better illumination of the field of operation is obtained.

CASE II.

A woman, aged 34, complained of smarting pain when she swallowed hot or cold fluids and of difficulty in swallowing solid food. There was distinct tenderness when pressure was applied to the cricoid cartilage, forcing it backwards on to the pharyngeal wall. Examination with the laryngoscope showed slight redness and oedema of the left arytenoid. These symptoms and signs indicated an epithelioma; accordingly, the patient was anaesthetized with chloroform and placed in the position for suspension laryngoscopy. The upper edge of a warty epitheliomatous ulcer was seen on the posterior pharyngeal wall, behind the cricoid cartilage and surrounding the lumen of the pharynx.

A piece for microscopy could have been removed with ease, but the oesophagoscope was used to complete the examination of the limits of the growth; a piece for examination was then punched out with Bruning's forceps and proved to be an epithelioma.

CASE III.

A male patient suffering from advanced laryngeal tuberculosis, with ulceration of the vallecula and of both ventricular bands. The ulcerated epiglottis had been previously removed with epiglottis punch forceps used in the usual manner.

The patient was examined in the position for suspension laryngoscopy after the application of 20 per cent. cocaine solution to the tongue and pharynx. A very satisfactory view of the larynx was obtained and it was seen to be easily possible to eurette the larynx in this position.

It was proposed to do this at a later date, but unfortunately

owing to a mistake the patient was discharged before this was done. Had the operation been carried out, it was proposed to anaesthetize the patient with scopolamine and morphine.

CASE IV.

An infant, aged 4 months, presented the symptoms of laryngismus stridulus with some stridor. It was considered to be a case of infantile epiglottitis with inspiratory collapse of the arytenoids.

The child was examined by suspension laryngoscopy with chloroform anaesthesia, but owing to vomiting and a considerable secretion of mucus the view was unsatisfactory. An attempt with the bronchoscope was equally unsatisfactory.

CASE V.

A boy, aged 3 years, was said to have laryngeal or tracheal obstruction, and the attacks of dyspnoea were so severe that an examination by the bronchoscope was considered necessary.

The child was chloroformed and the pharynx and epiglottis were swabbed with 10 per cent. cocaine and adrenalin solution. He was placed in the suspension laryngoscopy position, and a good view of the pharynx and arytenoid region was obtained, but the vocal cords were invisible. Accordingly the apparatus was discarded for the bronchoscope, which showed the glottis and trachea perfectly, but nothing abnormal was found.

The child was then returned to the usual prone position adopted for removal of adenoids and an adenoid growth which was previously known to exist was removed.

For cases requiring examination and manipulation of the pharynx and larynx suspension laryngoscopy will probably supersede the oesophagoscope and bronchoscope.

The comprehensive and clear view obtained, the more efficient illumination, the increased space for the manipulation of the instruments with both hands free, appeals to one who is accustomed to use the bronchoscope.

It is important to select the cases, and as a rule those patients who can be examined by the bronchoscope and its open spatula are suitable for suspension laryngoscopy. It is unnecessary to add that the new method is useless for examinations of the oesophagus and bronchi, but the bronchoscope and oesophagoscope can be used when the patient is already in the position for suspension laryngoscopy.

The patient with a large open mouth and no front teeth is excellently adapted for suspension laryngoscopy, and the suitable case will be easily recognized if a trial or a preliminary examination with an ordinary Kirstein tongue depressor is made without the use of local or general anaesthetics. Patients suffering from tuberculous laryngitis, who have been educated by frequent manipulations of the larynx make exceptionally good subjects, in addition they are not adversely affected by morphine and scopolamine. Unfavourable after-results are rare. There is no pain and the unusual position and strain on the hyoid muscles does not cause discomfort, and the tongue can be protected from the sharp lower incisor teeth by covering these with a piece of lint; as a matter of fact the tongue is not so sore as when a tongue clip has been used during a long anaesthesia.

The position is that usually adopted for cleft palate operations, but the method of fixation and gagging is a distinct improvement.

The blood can be siphoned out of the pharynx and naso-pharynx by a soft rubber tube passed through one nostril.

RECOVERY AFTER TAKING 8½ GRAINS OF CORROSIVE SUBLIMATE.

By A. LEONARD FULLER, F.R.C.S.I.,

HONORARY ASSISTANT SURGEON, ROYAL UNITED HOSPITAL, BATH.

The following notes are, I think, interesting in consequence of the age of the patient and the quantity of sublimate.

J. H., aged 85, had been in the habit of passing a catheter for himself four or five times during the twenty-four hours. He was a very careful and methodical old gentleman, and the solid of sublimate containing 8½ grains with which he made a solution for the catheter was always placed in one particular spot on his mantelpiece, whilst a cachet of urotropine, which he always took in the evening, was placed in another.

All went well for twelve years, but on the evening of February 9th, 1912, the unexpected happened and he swallowed the solid in mistake for the cachet. The mistake was at once recognized, and he drank a tumblerful of barley water, as was

his custom after the urotropine, and sent for me. I arrived within half an hour and administered white of egg and water. He retched and brought up blue-stained mucus. I then passed the stomach tube and washed out the stomach with large quantities of albumen-water and milk and water. There was frequent and urgent desire for the bowels to act, but very little more than mucus was passed. The patient became extremely collapsed, he was cold and pallid, and there was a clammy sweat. The pulse was almost imperceptible and quite uncountable. I administered strychnine hypodermically and gave him milk and brandy by the mouth. Hot blankets and bottles were applied.

When I visited him the next morning he had revived somewhat, but was still in a very critical condition. The nurse told me that during the night the soiled linen was stained blue. During the next few days the bowels continued to be very irritable, but his general condition improved. Cremor magnesia and brandy were administered in milk at frequent intervals, and he took a good deal of albumen water. After a slow convalescence he quite recovered from the effects of the poison.

The dose taken—8½ grains—appears to me to be sufficiently large to be worthy of record. Though patients have recovered after larger quantities, nevertheless others have died after considerably smaller. A fatal case after 2½ grains is recorded, death ensuing in three weeks from diarrhoea.¹

Memoranda :

MEDICAL, SURGICAL, OBSTETRICAL.

A CASE OF CARCINOMA OF THE OESOPHAGUS WITH COMPLETE PARALYSIS OF THE LARYNX.

COMPLETE bilateral paralysis of the larynx is so rare a condition as to merit publication of the following case.

The patient, a male, aged 52, and by occupation a coal-heaver, was first seen about the middle of July, 1912, when he came to the Stanley Hospital complaining of loss of voice, difficulty in swallowing, and obstruction to the breathing. These symptoms had developed in the order given at intervals respectively of five months, two months, and one month previously.

On examination the patient was seen to be much wasted. The voice was very weak, being little more than a toneless whisper. Respiration was impeded to the extent that, although there was no stridor, inspiration required distinct effort. No glands were felt in the neck. On attempting laryngoscopy the breathing became very difficult, and there was ineffectual coughing with purulent expectoration. After cocaineization, however, a view of the larynx was obtained. Both cords were in the cadaveric position. In endeavouring to phonate they remained motionless, and in the deep, gasping inspiration which the patient took a moment later, instead of flying widely out, they merely flapped slightly downwards and inwards quite passively in response to the partial vacuum produced in the trachea.

The patient was admitted and examined with the x rays. An oesophageal stricture was detected just above the thoracic inlet, and, as some of the bismuth meal appeared in the bronchi, a fistulous communication between the trachea and oesophagus was diagnosed.

The patient became rapidly worse, and after a week in hospital the respiration had become distressingly embarrassed. Since the glottis was known to be fully wide enough for the respiratory needs, this difficulty in breathing was attributed to fungation of the growth into the trachea, and, in the hope of getting a tube through the obstruction, tracheotomy was performed. The operation, however, gave no relief, and the patient died a few hours subsequently.

The *post-mortem* examination revealed a growth of the oesophagus nearly 3 in. in length, and almost entirely limited to the anterior wall. The upper limit of the tumour reached to within 1 in. of the lower border of the cricoid. Anteriorly the growth had ulcerated into the trachea, largely obstructing it. After careful dissection, both recurrent nerves were found hopelessly involved, and in fact for about 1 in. of their course it was quite impossible to dissect them through the growth. The left

nerve was caught in an extension of the tumour itself just above the arch of the aorta, while the right nerve was implicated in a mass of glands behind and above the subclavian artery.

The case is, I believe, an example of a very rare condition. The chief points of interest may be summarized thus:

(a) Limitation of the growth to the anterior wall of the oesophagus.

(b) Early involvement of the recurrent nerves, leading to a change in the voice, before the onset of symptoms of oesophageal obstruction.

(c) Complete destruction of the function of both recurrent nerves.

(d) Fistulous communication with the trachea, which, however, did not occasion any pulmonary inflammation.

COURTENAY YORKE, M.D., B.S.,

F.R.C.S. Eng.

Liverpool.

HYDATID OF THE SUBMAXILLARY GLAND.

The patient, a little Kaffir girl, presented a somewhat pendulous tumour immediately below the left ramus of the mandible. It was probably about six years since the tumour was first noticed, and it had caused no symptoms. It occupied the left submaxillary triangle, and the skin over it was thin, but not adherent. It was movable, fluctuating, tense, and of regular surface. It projected a little into the floor of the mouth, but was not attached to bone. It suggested a half-buried, plastic globe of fluid about 2½ in. in diameter.

Adhesions made dissection difficult, but eventually the cyst was found to be closely related to the submaxillary salivary gland, lying below, and external to, this structure, which enveloped its upper part. In removing the cyst entire, some gland substance was damaged and snipped away.

The cyst contained 79 c.cm. clear fluid, many scolices, hooklets, and some small daughter cysts. The specific gravity of the fluid was 1005, without albumen. The wound was drained. Within twenty-four hours sufficient saliva had escaped from the wound to seak through the dressings, but on the third day this ceased, and the wound rapidly healed.

IODINE AND TYPHOID FEVER.

IN the BRITISH MEDICAL JOURNAL (1907, vol. ii, p. 143) I gave my favourable experience of the treatment of this illness by tincture of iodine. In the same volume (p. 262) Dr. David Walsh wrote in confirmation, stating that his own successful results had been, and suggested a collective investigation comprising a large number of cases treated in this very simple way.

The *Journal de médecine et de chirurgie pratiques* for December 10th, p. 967 (Art. 23868) publishes a very remarkable article which I venture to bring before the notice of the readers of the BRITISH MEDICAL JOURNAL. In it the literature of the last few years on the subject is reviewed, and the evidence is so favourable that it seems to me the time has arrived to put this method through the only practical test there is, and which Dr. Walsh suggested—that is, that the metropolitan fever hospitals, with all the means at their disposal, should undertake the treatment of a sufficiently large number of cases, well checked and observed, to pronounce definitely on its merits.

It appears to be confirmed that in enteric fever there is a marked diminution in the number of leucocytes; that iodine has a marked influence in increasing their number and thus helping in the defence of the organism invaded; that it also brings about a mononuclear reaction¹ which favours immunity.

During the last few years the administration in enteric of small and frequently repeated doses of pyramidon (½ to 1 grain every half-hour) has been largely tried in France, and also in Germany as a substitute for baths in keeping down the temperature. It may be that

pyramidon might be a help to the iodine treatment, but all these points can only be satisfactorily settled by large statistics. The mortality attending enteric fever leaves still much to be desired, not to say anything of the amount of extra labour attending the nursing of these cases by frequent baths and spongings, if simpler and more successful means of dealing with them can be found.

Reports

ON

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

BOLTON INFIRMARY, LANCASHIRE.

A MULTILOCLAR OVARIAN CYST OF GREAT SIZE.

(Reported by RONALD BUTE MACFIE, M.B., F.R.C.S. Edin.)

THE following case, treated at the Bolton Infirmary when I was resident surgical officer thereat, presents points of interest.

The patient was a married woman, aged 42, who had only had one child, and that twenty years ago. She had never been very regular at the menstrual periods, and there had been no sign of the menses since the beginning of her existing complaint. This was twelve months previously, when she experienced vague abdominal pain and suffered from constipation.

The Conditions Found.

On examination a huge tumour was found to be occupying the abdomen, extending from the ensiform cartilage above to the symphysis pubis below, and measuring 32 in. between these two points in the median line. The umbilicus was situated 8 in. above the symphysis pubis, and at this point the tumour appeared to be somewhat elongated. The point of greatest girth was 6 in. above the umbilicus, and here the measurement was 57 in. The entire tumour was dull on percussion. There was no pain or tenderness and no marked interference with respiration or the heart's action. She was able to go about without much discomfort; in fact, when she came to seek advice she walked up to our out-patient department and showed no signs of discomfort or exhaustion. Vaginal examination revealed nothing of note; the cervix was normal in situation and character.

Operation.

The patient willingly consented to operation, and the following points of interest were revealed:

The abdominal wall was oedematous, the fat was 2 in. in depth, the musculature was very poor. There were some thin adhesions to the anterior abdominal wall from the tumour.

The tumour was tapped and its fluid contents drained off as far as possible; the tumour being then easily delivered through the wound—it was seen to be a multilocular ovarian cyst, growing from the right side and deriving its proliferant blood supply from three sources, which were: (1) The pedicle. (2) By means of a very well developed ligament of Clado (which contained an artery of medium calibre and several veins); a point of note in this region was the vermiform appendix, which was hypertrophied to almost the dimensions of the small intestine. (3) The omental adhesions.

The pedicle and omental attachments were ligated; the ligament of Clado with the appendix was then removed, and the tumour, being thus separated from all its attachments, was removed.

Size of the Tumour.

The fluid contents of the tumour measured 58 pints (7½ gallons). Each pint weighed 1½ lb.; so that the total weight of the fluid contents was 72½ lb. The tumour weighed 13½ lb.; therefore the total weight of tumour and contents was 86½ lb., or 6 st. 2 lb. 4 oz.

Remarks.

Whether the above measurements constitute a record for size and weight I cannot say, but I think the case is interesting both for the size of the tumour and its sources of blood supply.

I am much indebted to Mr. Douglas Gray for permission to publish these notes, and to Dr. Cecil Barnham for photographing the abdomen prior to operation. I should add that the patient has made an uninterrupted recovery.

EDINBURGH OBSTETRICAL SOCIETY.

Wednesday, January 8th, 1913.

Dr. HAIG FERGUSON, President, in the Chair.

Primary Ovarian Pregnancy.

MR. GEORGE CHIENE, in a paper on ovarian pregnancy, illustrated by lantern slides, described the case of a married woman, aged 34, who was admitted to hospital supposed to be suffering from acute appendicitis. There was no amenorrhoea. Ruptured ectopic pregnancy was suspected, and, the abdomen having been opened and a large quantity of blood evacuated, a cherry-like mass was found protruding from the uterine end of the right ovary. The ovary was removed. It was cut in serial sections, and the mass was found to be blood clot, in which chorionic villi were imbedded. There was no fetus discovered. No corpus luteum nor decidua cells were present. The approximate age of the pregnancy was two to three weeks. Dr. BERRY HART said it was an undoubted case of ovarian pregnancy.

Biometrics and Pregnancy.

Dr. BERRY HART, in a paper on the insemination-parturition interval in mammals as studied by biometric curves and length of human pregnancy, said the probability curve of the figures for 912 ewes prepared by Tessier was narrow and symmetrical, like that of coin-tossing, when 50 was thrown for a certain number of times. In the figures for cattle—1,206 in all—from the Tessier and Earl Spencer series, the curve was similar, but somewhat skew. Von Winckel's 245 cases in the human, where the infants weighed over 4,000 grams, gave a probability curve less narrow and with several peaks. The majority of cases lay between the 284th and 286th days, reckoned from the first day of the last period. The minimum was 240, and the maximum 334 days. The author believed that the calculation in the human should be reckoned from the first day of the period, and the date of labour would be somewhere in the fortnight with the 280th day as its centre. The delay of the date of labour was not necessarily due to an actual prolongation of pregnancy; it might simply mean that the fertilized ovum corresponded to the next period. There was no exact number of days for the duration of human pregnancy, and the human probability curve was as yet unknown. Dr. BARBOUR thought that Dr. Hart's curves would be of small value as applied for prophesying the date of labour. They were of great theoretical interest. Dr. HAULTAIN disagreed with the belief that an actual prolongation of pregnancy might not occur, and mentioned a case where the child was two and a half months overdue, and weighed 14 lb.

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

At a meeting on January 10th, Sir WILLIAM OSLER, President, in the chair, the following were among the exhibits:—Dr. J. D. ROLLESTON: *Diphtheritic hemiplegia* in a boy, aged 5. It had occurred suddenly on the twenty-first day of the disease. Peripheral neuritis had also been present. Dr. F. PARKES WEBER: *Non-syphilitic arteritis obliterans* ("thrombo-angiitis" of Leo Buerger), with intermittent claudication of the left leg. The characteristic symptoms of the disease were: (1) Redness or cyanosis of the foot, when it was allowed to rest in a dependent position; (2) pallor of the foot on movement of the ankle-joint; (3) intermittent claudication with cramp or pain in the calf or instep on walking for a few minutes; (4) absence of pulsation in the arteries of the foot, notably in the dorsalis pedis artery. Also a case of *Chronic acholuric jaundice*, with anaemia, slight splenomegaly, and nervous disorder, in a woman aged 43. There was no undue fragility of the red corpuscles. Wassermann's test was negative. Dr. W. ESSEX WYNTER: *Acholuric jaundice* after splenectomy in a girl aged 22. The jaundice had disappeared and blood appearance improved. Dr. FRANK SYLVAN: Cases of *Pulmonary tuberculosis* before and after gymnastic treatment. In one case the vital capacity had increased from 3,100 c.cm. to 5,500 c.cm. from November

26th, 1912, to January 6th, 1913. Dr. H. D. ROLLESTON: *Actinomyces* of the liver in a syphilitic subject. Mr. JOHN D. MALCOLM: Two cases of *Nephrectomy* for hydro-nephrosis, the first thirteen years and the second sixteen years after nephrolithotomy. In the latter, half the kidney only was affected, and this was removed, leaving the remainder. Mr. PHILIP TURNER: *Abscess of the liver (left lobe)*, ten years after an abscess in the right lobe. Dr. A. F. HERTZ and Dr. W. JOHNSON: *Polio-encephalomyelitis*, associated with optic neuritis, nephritis, and myocarditis and a case of *Bilateral hemiatrophy of the face*.

UNITED SERVICES MEDICAL SOCIETY.

At a meeting on January 8th, Fleet Surgeon BASSETT-SMITH, President, in the chair, Lieutenant-Colonel G. DOUGLAS HUNTER, R.A.M.C., in a paper on the *Tactical employment of field medical units*, said instruction in this subject should consist not merely in the learning of principles, but in the application of these principles to the solution of concrete problems. This could be attained in peace, by the working out of the disposition of medical units on the map according to definite schemes of attack and defence, by staff rides, and by subsequent conferences to discuss the points raised. As regards the preliminary measures in real warfare, great stress was laid on the importance of intimate co-operation between the A.D.M.S. and the divisional commander and his staff. The success or non-success of the medical arrangements would depend upon whether the A.D.M.S. thoroughly grasped the situation and comprehended the object which the commander had in view. As to the points to be dealt with in operation orders for medical services, these might be tabulated as follows: The body of troops each medical unit would serve; the times and order of march; the area allotted to each unit, with limits of frontage if possible; sites of dressing stations (these might be laid down beforehand in operations of defence, but rarely in those of attack); the place to and roads by which field ambulances would evacuate their wounded; site of divisional collecting station; places to which reports and messages to the A.D.M.S. should be sent. During the actual fighting the A.D.M.S. would have to leave the actual collection and removal of the wounded to the initiative of the officers commanding field ambulances and the regimental medical services. He himself must be mainly concerned in co-ordinating the work of the different units under his command with the requirements of the fighting troops and in endeavouring to maintain the link between field medical units and the clearing hospitals. Whatever the method of evacuation adopted it was imperative that the field ambulances should be cleared, so as to be ready for a further immediate advance after a successful attack. The A.D.M.S. or his staff officer should always remain at divisional head quarters so as to receive messages from the medical units and take action on the information as it came to hand. At present the means of communication between him and the officers commanding field ambulances were somewhat limited, and it was hoped that there would be improvement in this respect. The medical units in reserve should be in convenient situations, and the A.D.M.S. should always keep in hand as large a reserve as possible to provide for emergencies as they arise. It should be remembered by medical officers that needless exposure of themselves or the bearers to the enemy's fire was unnecessary and reprehensible.

MIDLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.

At a meeting at Bristol, on December 6th, 1912, Dr. WALTER SWAYNE, Vice-President, in the chair, the following were among the exhibits:—Dr. PURSLOW: (1) A specimen of *Tubal pregnancy* exhibiting both threatened abortion and rupture. The patient, a multipara aged 37, five days before her admission to the Queen's Hospital, Birmingham, on March 19th, 1912, was seized with abdominal pain, and uterine haemorrhage occurred one week before the expected period. On the day of admission a much more severe attack occurred, and at the time of operation the patient presented all the signs of severe internal haemorrhage.

The specimen showed a mass of blood clot protruding from the ostium of the Fallopian tube, and also a rent in the wall of the ampullary portion of the tube through which a fetus of eight weeks' development had escaped in its amnion. (2) A uterus the seat of a fibroid undergoing *Necrobiotic degeneration*, removed during the puerperium. The tumour had caused obstruction to the passage of the fetal head, and the question of Caesarean hysterectomy was discussed. Owing to the exigencies of the case, unfavourable surroundings, and absence of fetal heart sounds, it was decided to deliver by the vaginal route. This was accomplished with some difficulty, after version had been performed. The patient made an afebrile recovery, and the uterus containing the fibromyoma was successfully removed during the fourth week of the puerperium. Dr. WALTER SWAYNE: A specimen of *Spontaneous rupture of the uterus* at the thirty-eighth week of pregnancy. The fetus and its membranes had partially escaped into the peritoneal cavity through a stellate laceration at the fundus large enough to admit almost three fingers. The patient, a multipara, aged 37, had been cured two years previously on account of a septic incomplete abortion, but the exhibitor did not think that the uterus had been perforated upon this occasion, as the curettings showed only endometrium, and no muscular tissue. The patient was admitted to the Bristol Royal Infirmary with a diagnosis of concealed accidental haemorrhage. The uterus was removed by Porro's method, but the patient was moribund, and expired at the close of the operation. Mr. BECKWITH WHITEHOUSE: A specimen from a case of splenectomy in a 6-para, aged 30, who complained of severe abdominal pain of sudden onset, with urgency and difficulty of micturition, and presenting a large, solid tumour firmly impacted in the right iliac fossa. The spleen weighed 2 lb. 10 oz. The uterus was markedly retroverted. The patient had made an uninterrupted recovery after the operation, and had continued well. Dr. NEWNHAM described a case of *Foreign body in the peritoneal cavity*. It was a bone crochet needle, which had been introduced into the vagina by the patient in order to procure abortion. Examination under an anaesthetic and exploration of the uterus failed to produce the foreign body, and it was thought that the story was fallacious. The needle was eventually located by the x-rays, and laparotomy successfully performed for its removal. There was much peritonitis present.

HUNTERIAN SOCIETY.

At a meeting at St. Bartholomew's Hospital on January 8th, Mr. A. H. TUBBY, President, in the chair, Professor ARTHUR KEITH delivered the second Hunterian Lecture on the history and nature of certain specimens alleged to have been obtained from the *post-mortem* examination of Napoleon the Great. It was reported in full in our issue for January 11th, at page 53. Dr. ARNOLD CHAPLIN, in proposing a vote of thanks, congratulated Professor Keith on the able way in which the whole subject had been treated. At the same time it did not appear to him that the evidence offered as to the authenticity of the specimens sufficed to outweigh the documentary evidence in existence, and which pointed in the opposite direction. The Hunterian Society was, nevertheless, indebted to Professor Keith for the lecture, which was one of the most important and notable contributions to the closing periods of "St. Helena history" that had yet been made.

LONDON DERMATOLOGICAL SOCIETY.

At a meeting on December 17th, 1912, Dr. MORGAN DOCKRELL, President, in the chair, a discussion took place on the *Anomalies of pigmentation*. To get a clear comprehension of these, the PRESIDENT suggested that as the best classification all pigmentary diseases should be divided into hypertrophic and atrophic, and that each of these be subdivided into congenital and acquired. Under hypertrophic the congenital included the different variety of moles, the acquired being subdivided into lentigo and chloasma. Chloasma would then be, first, idiopathic with its divisions of traumatic and toxic, and secondly,

symptomatic with its divisions of uterine and cachectic. As for atrophic forms, leucoderma represented the congenital and partial, albinism the congenital and universal, the acquired variety being known as vitiligo. Dr. BENCH, discussing etiology, referred to the popular theory as to the origin of birthmarks through maternal influences on the embryo. He had not been convinced as to the truth of this idea, and mentioned the case of the negroes who had black and albino children alternately. Dr. GRIFFITH dwelt on the histology of the pigmentation; and Dr. SIBLEY, discussing treatment, divided the cases into two classes: (1) Those with a loss of pigment, and (2) those with excess of pigment. In the first group, such as leucoderma, he had been able to bring back the pigment by prolonged hyperaemic treatment of the area. For removal of excessive pigment he referred to the application of solid carbonic dioxide, electrolysis by means of multiple needles and ionization, especially with perchloride of mercury, all of which processes he found curative for different forms and degrees of localized pigmentary deposit.

ASSOCIATION OF REGISTERED MEDICAL WOMEN.

At a meeting held on January 7th the PRESIDENT (Dr. Constance Long) read a paper on *Scopolamine-morphine in labour*. She had used these drugs in private practice in 15 selected cases. Labour had not been prolonged beyond the average time, nor had the infant been in any way endangered, in spite of a certain amount of cyanosis at birth. The dangers to the child had been overstated by British writers. Scopolamine was a perfectly safe drug for the mother, provided its dosage were understood; for the safety of the child the initial dose of $\frac{1}{10}$ grain of morphine should not be repeated. The effect of the drug in modifying labour pains, combined with the amnesia commonly produced, might abolish the dread of parturition, and thus induce a rise in the birth-rate. The constant attendance of the physician was not essential, provided an intelligent nurse was in charge; the patient should be kept on her side until the effects of the drug had passed off, and the same precaution should be observed with regard to the infant. Mrs. MEAKIN HAARLEICHER gave an account of the use of scopolamine at Krönig's Hospital, Freiburg. There practically all parturient women were given the option of being put under the influence of the drug, provided no contraindication were present—for example, primary inertia, general debility, placenta praevia. In eclampsia it had been found beneficial. The injections were commenced when the pains became regular and disagreeable to the patient. In about 76 per cent. of cases the action of the drug had been typically successful. Although the patients had been roused by each pain and had been able to answer questions, yet it was found afterwards that they had no memory whatever of the period of labour. No prolongation of labour was noticed. The drug was not found to affect the secretion of milk nor the involution of the uterus; the kidneys were not affected, nor was there any tendency to femoral thrombosis. Some 13 per cent. of the children were born asphyxiated, though this condition could in many instances be traced to causes other than the drug. Infant mortality had been shown by Gauss to be lower in cases treated by scopolamine than in others. Dr. MAY DICKINSON BERRY described the administration of anaesthetics at the Mayo Clinic, Rochester, Minnesota: only *open ether* was used, and it was administered by trained nurses. For operations on the stomach $\frac{1}{2}$ gr. morphine was injected half an hour before their commencement. Light anaesthesia was aimed at, and the amount of ether used was small, 4 oz. in thirty to fifty minutes being the average. No account was taken of the eye reflexes.

PART 2, volume I, of the *Tropical Diseases Bulletin*, deals with papers on plague, undulant fever, filariasis, helminthiasis, and splenomegaly. Adequate abstracts are given of the different papers, so that a man working in the tropics, far away from any library, may keep fully up to date in any or all of the subjects dealt with. In other numbers malaria, trypanosomiasis, beri-beri, and the other subjects that make up tropical medicine, will be treated.

Reviews.

THE GROUNDWORK OF SCIENCE.

MR. WESTAWAY'S book on *Scientific Method*,¹ although primarily adapted to the needs of science teachers, deserves the attention of all who are interested in the principles which underlie and regulate modern investigation. The subject, of course, recalls Professor Karl Pearson's *Grammar of Science*, but the treatment is entirely different, being in the main historical. The author keeps his own views in the background, allowing the numerous authorities quoted, as far as possible, to speak for themselves. His reading has been extensive; and by judicious choice of representative passages a very clear and comprehensive idea of the evolution and present position of scientific method is conveyed to the reader, while in his comments upon doubtful points and antagonistic opinions he proves himself a sound and capable critic.

The book is divided into four sections, of which the first deals with the philosophy and the second with the logic of scientific method. The third gives illustrative passages from the works of scientific discoverers, and the fourth discusses the principles and practice of science teaching. The author holds that the ultimate aim of science is "to reduce the complexities of nature to their fundamental elements, and to express in an exact and quantitative form the relations among those elements." And since the necessary division of labour involved by this task leads to a constant increase of specialism, there is an obvious danger that, in the absence of some contrary influence, the whole will be lost sight of by reason of attention to the parts. This contrary influence is supplied by philosophy, to which the author assigns the rôle of critically examining the hypotheses and results of the scientific specialist, and, so far as may be, co-ordinating them into a self-consistent system of knowledge.

Some twenty pages of the first section are devoted to Lord Bacon; and in these the author gives a good account of the strong and weak points of the Baconian doctrine. It was not merely the insistence upon the necessity of proceeding from the facts of experience that was novel in this doctrine—many of the ancient thinkers had recognized that. But whereas Aristotle, for example, from a cursory consideration of such facts, had rushed immediately to the most general conclusions, Bacon clearly saw and strongly enforced the indispensability of a more cautious and gradual ascent from the particular to the universal. As might have been expected, his attempt to formulate clear directions for the achievement of this end are imperfect and obscure; but there can be no doubt of the soundness of his view as to the importance of the elimination of the non-essential. On the other hand, Bacon seems to have seriously contemplated the possibility of exhaustively cataloguing the facts of nature, and, thereafter, in a few years, by the almost mechanical application of his method, attaining to something little short of omniscience. He also failed to appreciate the scientific utility of deduction and imaginative insight.

In the section dealing with logic there is a full and clear description of the rules formulated by Mill for the guidance of scientific investigators, commonly known as the canons of induction. These comprise five methods of procedure—namely, that of agreement, of difference, the joint method, the method of residues, and the method of concomitant variations. On analysis, however, the first two are found to form the basis of all Mill's rules. In the main the author considers them useful rather as models and tests of logical proof than as practical guides to discovery.

In the chapter dealing with analogy there are some judicious remarks on the fallacies that result from a loose and indiscriminating employment of that somewhat dangerous method. Because two things resemble one another in certain respects, it is not safe to assume, as is commonly done, that they may be regarded as to all intents identical.

Some interesting reading will be found in the third section, mainly consisting of excerpts from the writings of such men as Guy Lussac, Boyle, Newton, and Faraday. In the last section, devoted to science training, the author advocates the heuristic method, of which Professor Armstrong is a well known pioneer. This involves the placing of students in the attitude of discoverers, making them find out things, as far as possible, for themselves.

SYPHILIS.

A VOLUME of contributions to the pathology and treatment of syphilis, by a number of writers, embodying the work on experimental syphilis carried out in Java during the years 1905 to 1908 and continued at Breslau, by Professor NEISSER and his assistants, has been issued.² In the introduction Professor Neisser gives a graphic account of the Java expedition and details concerning the methods of work. The first part of the book deals with experimental inoculation of apes and the results derived therefrom. The chief of these are briefly as follows: Positive inoculations were obtained with human syphilitic material from primary, secondary, and tertiary lesions of the skin, primary and secondary glands, the blood from the organs and also from the nasal mucus from cases of congenital syphilis; with material from syphilitic apes, from the liver, spleen, bone-marrow, ovary, testicle and glands, and also with material from rabbits inoculated with syphilis. As regards the semen, although Finger succeeded in obtaining positive inoculations, Neisser's were all negative, but he obtained positive results by inoculation with ape's testicle. The bearing of this on the question of paternal transmission is mentioned. The length of the incubation period and the results of inoculation were found to depend largely on the quantity of spirochaetes inoculated. It was found that the spirochaetes became generalized before the appearance of the primary sore, an observation which accounts for the usual failure of excision of the chancre. Subcutaneous inoculation was usually negative, but occasionally positive; intravenous inoculation, on the other hand, was generally positive, but intraperitoneal inoculation was always negative. The vitality of the spirochaete was destroyed by drying the material by exposure to a temperature of 10° C. for three hours and by keeping on ice for twenty hours. Material from chancres and condylomata, when kept moist, remained virulent for six to ten hours, and living spirochaetes were found in a still-born fetus fifty hours after birth. The evidence went to show that there is no true immunity in syphilis; when a case is cured reinfection may take place. There is a condition of "anergy"—that is, a state refractory to fresh inoculation as long as the virus is present in the body, but this condition is relative and not absolute, for superinfection is possible, at any rate in the tertiary stage. Attempts to produce both active and passive immunization failed, and also attempts to produce a vaccine; no attenuation of the virus took place after passage through animals. Neisser considers that the severity of syphilis among Europeans in the tropics is due more to their mode of life than to any special malignancy. The disease was comparatively mild among the natives, although tertiary lesions of the bones were common; syphilis of the nervous system was rare, and tabes and general paralysis unknown, possibly owing to the absence of alcoholism. In the next part of the book, which deals with treatment, Neisser points out that the earlier treatment is begun in trypanosome diseases the more rapid is the cure. The action of mercury and arsenic is discussed, and the results of treatment by the numerous organic preparations of arsenic are given. Six apes are said to have been cured by a single injection of arsenobenzol (salvarsan). Quinine was found to have neither a preventive nor a curative action on syphilis, but potassium iodide, contrary to the accepted belief, showed evidence of direct action on the spirochaete. Neisser recommends, therefore, that iodides should be given in the early stages. Although in favour of arsenobenzol, he concludes that this must be combined with mercury and iodides. The next part of the book deals with serum-diagnosis, and is written by Bruck. The

¹ *Scientific Method, its Philosophy and its Practice*. By F. W. Westaway. London: Blackie and Son, 1912. (Post 8vo, pp. 449, figs. 24, 65.)

² *Beiträge zur Pathologie und Therapie der Syphilis*. Unter Mitwirkung von Drs. G. Bärman, C. Bruck, Dohi, Kobazashi, Kuznitsky, Pürekauer, Halberstädter, Prowazek, Schereschewsky, und Siebert. Herausgegeben von Dr. Albert Neisser. Berlin: Julius Springer, 1911. (Imp. 8vo, pp. 624.)

percentages of positive Wassermann reactions given are 94.1 for secondary, 73.9 for tertiary, and 50 to 60 for latent syphilis. As a rule the reaction does not appear till the sixth week after infection Brack remarks that the evidence afforded by serum diagnosis is against the frequency of paternal transmission, though it does not exclude the possibility. He looks upon the reaction as a guide to treatment, and holds that treatment should be continued till the reaction is found, by repeated examination, to be permanently negative. The book concludes with several shorter articles written by other fellow-workers. This record of Professor Neisser's valuable and painstaking researches will form one of the classics of modern syphilology.

Drs. McINTOSH and FIELDS in the preface to their work on *Syphilis from the Modern Standpoint*³ announce that they are not carried away in the flood of enthusiasm which overran the medical world when Ehrlich's discovery was promulgated. They have striven to make a critical survey of the enormous mass of literature on syphilis, to confine themselves to actual facts and to draw logical conclusions from these premises. The true history of syphilis, they say, dates from 1903, the year of the discovery of the spirochæte; up till that date treatment was empirical, since then it has been scientific. The authors are rather sceptical as to the claims originally urged, perhaps in the first flush of excitement, that permanent rapid cures were certain to follow the administration of salvarsan. More might have been made of what has been rightly enough styled a "revolution in the treatment of syphilis." The book, however, is not directly concerned with the cure of syphilis, but rather with the study and destruction of the *Spirochaeta pallida*, though the two subjects appear to be complementary. The researches recorded in the work were conducted in the laboratories of the Pasteur Institute in Paris, and have been continued in the laboratory at the London Hospital. The work is a thorough, painstaking, and practical review of the subject; it is devoid of unnecessary embellishment and detail and every page tells. To those desirous of a clear statement of the new theories and lucid presentation of the new facts this book can be most confidently commended. The volume is well arranged and from the bibliographical point of view complete. Some photographs of the recent German workers in syphilology are given.

Professor ZINSSER's book⁴ on syphilitic affections of the mouth and affections resembling them, is an interesting contribution to syphilography. The introduction deals with the discrimination between the *Spirochaeta pallida* and other spirochaetes found in the mouth—the *S. buccalis* and the *S. dentium*. The former is easily distinguished by being thicker and larger, with fewer and flatter and more irregular spirals. The *S. dentium* is more difficult to distinguish, and it resembles the *S. pallida* more than any other form of spirochaete. It is, however, shorter, with more closely approximated spirals, and has less tendency to lateral bending movements. The diagnostic value of the Wassermann reaction is next discussed, and the author wisely remarks that this reaction is of use only when taken in conjunction with the whole of the clinical picture. In fact, he regards a positive Wassermann reaction as of similar value to a positive history of syphilis. The next part of the book comprises a concise and clearly written account of primary, secondary, tertiary, and congenital syphilitic affections of the buccal cavity. With regard to congenital syphilitic teeth, besides "Hutchinson's teeth," the author considers that hypoplasia of the crown of the first molar, and sometimes of the lower incisors, is pathognomonic of congenital syphilis. Other abnormalities of dentition he regards as of doubtful syphilitic origin. The third part of the book deals with the various buccal affections, which may be mistaken for syphilis, and their differential

diagnosis. Attention is drawn to the danger of syphilitic infection of the mouth through the medium of dental and other instruments. Professor Zinsser's book, which is profusely illustrated with forty colour process plates, should be especially useful to dentists, to whom a knowledge of the various syphilitic affections of the buccal cavity is indispensable.

THE TREATMENT OF CANCER.

In a volume entitled *The Enzyme Treatment of Cancer and its Scientific Basis*⁵ Mr. J. BEARD, D.Sc., has set forth at much length his views on the subject indicated. The book consists largely of annotated references to the author's own writings, added to similarly annotated accounts of what has been said by others regarding his views. It appears to be designed for the information both of the general public and of the medical profession. It is written in a discursive style, and contains a superfluity of references to the facts or theories of the higher physiology, and may therefore not receive from either class quite as much attention as its author would presumably wish, or as it possibly deserves. Summarizing the author's expressions of his views, but utilizing as far as possible his own phraseology respecting them, it may be said that Mr. Beard's treatment of cancer seems to be based upon the application of a trilogy of doctrines—namely, evolution with predestination, the morphological continuity of germ cells, and an antithetic alternation of generations. This trilogy is in effect an indivisible unit, which owes its existence to the author of this volume, though in respect of one of its components he was anticipated, he says, by Weismann. On this basis Mr. Beard set to work to deal with the problem of cancer, advancing his forces along the only two lines by which he deemed it open to attack—namely, embryology and stereochemistry—and together they have achieved the complete overthrow and decisive rout of cancer. The latter phrase, as also most of the others in the foregoing sentences, is that used by the author himself, but it is not to be concluded therefrom that Mr. Beard in any wise suggests that it represents a common view. On the contrary, he makes it clear that though his treatment has at one time and another been tried by quite a large number of workers, the opinions they have subsequently expressed have in most instances been entirely unfavourable to it. The most notable exception is an army officer who some two years ago reported a case of sarcoma treated on the system in question with great success. Though the results of this case were certainly confirmatory of Mr. Beard's views, one or two swallows do not make a summer, and the general impression left by the book can best, perhaps, be described as agnostic. Real knowledge of the chemical biology of abnormal growths is still in the making, and, despite the fact that many workers, of an industry and ability not less than Mr. Beard's own, hold that his views are entirely erroneous, it is possible that one day or other they may be proved to have contained the germ, at any rate, of the final solution of the cancer problem. Meantime, all that can be said is that the clinical results as a whole are far from an encouraging kind; indeed, one would regard them as totally condemnatory but for one circumstance. There is no more certain way of strangling a possibly valuable idea than premature attempts to apply it in practice, and it seems possible that Mr. Beard's conception may have suffered from this cause. The book, at any rate, makes it obvious that when Mr. Beard first invited a general trial of his method he himself was not very clear as to how it should be applied or even as to the part which trypsin and amyllopsin respectively should play therein. Even after this latest exposition of his views a careful student might be puzzled as to the precise lines on which he should endeavour to carry them out. For the rest, Mr. Beard's disappointment that the greatness of his achievement has not been generally recognized is quite comprehensible, but in the circumstances it is on his own head rather than on those of the medical profession that the vials of his wrath should be poured.

³ *Syphilis from the Modern Standpoint*. By James McIntosh, M.D. Abard., Grocers' Research Scholar, and Paul Fields, M.B., B.S. (Camb.), Assistant Bacteriologist at the London Hospital, London; Edward Arnold, New York; Longmans, Green and Co., 1911. (Demy 8vo, pp. 245; plates 8, figs. 5, 10s. 6d. net.)

⁵ *The Enzyme Treatment of Cancer and its Scientific Basis*. By John Beard, D.Sc. London: Clarendon and Windus, 1911. (Demy 8vo, pp. 308; figs. 11. Price 7s. 6d. net.)

DENTAL SURGERY.

*Die Missbildungen des Gebisses*⁶ is one chapter of a comprehensive treatise on the morphology of deformities of man and beast, edited by Dr. ERNEST SCHWALBE of the Rostock University. The writer, Professor PECKERT, has made an extended study of the literature (chiefly of the German literature) of the subject, and having himself a good experience, has succeeded in producing a valuable monograph. He opines that the cause of a great part of all tooth deformities is mechanical, and first makes itself felt when the question of room becomes acute. He finds the origin of some in an earlier period of development than is by many believed; thus gemination is referred to the time of root development, and the formation of a follicular (dentigerous) cyst to some unknown force interfering with the early tooth germ. The short notice of "degenerate jaws" shows the wide divergence of opinion which exists as to the origin of misshapen palates. The author ascribes considerable importance to rickets, but thinks heredity plays an undoubted part. He inclines to the belief in the connexion between idiocy and ill-formed jaws; but we believe it has been demonstrated that the jaws of idiots are generally large and well-formed. The author has tried to exclude all deformities due to post-natal illness, and has not taken cleft palate as part of his domain. The deformities of animals receive but small attention.

In the preface to *The Extraction of Teeth*⁷ Mr. J. H. GIBBS (Edinburgh) tells us that his only justification for adding still another to the list of books upon the extraction of teeth is that he has something new to say. If this were truly his only justification publication of the book is hardly vindicated. Most of the author's points are, at least in the London dental schools, current teaching; certain of them are, indeed, as vigorously combated by some as upheld by others. The author believes he breaks new ground in advising the use of single-bladed "root" forceps for all teeth, many-rooted and single-rooted alike, and thinks to have discovered a new method of use. This is explained on p. 73: "In the case of the (upper) molars and praeinolars firm steady upward pressure is made and whilst maintaining the upward pressure the tooth is moved steadily outwards in one movement . . ." The beginner's fault lies in relaxing the upward pressure as soon as the outward movement is begun, with the result that the lingual blade slips. To those who use the "old-fashioned" molar forceps this upward force is an unnecessary violence, and it is difficult to understand Mr. Gibbs's objection to the employment of the molar forceps on the plea that it is impossible to estimate the strength of a decayed molar crown. This use, however, of none but root forceps; disuse of the elevator; avoidance of "pull"; disbelief in the local use of opium, are no new things in the south. An illustration on p. 68 shows a method of grasping upper root forceps which seems to be both new and useful. From p. 123 we appear to learn that Mr. Gibbs considers dislocation of the mandible a common accident of tooth extraction. He rightly condemns the use of chloroform, but fails in his criticism of local anaesthesia by injection through ignoring regional anaesthesia. The style of the book is rather too rhetorical. On the whole and in spite of the criticisms just made, the book is worth the reading, yet it cannot be said to mark any great advance in the art of tooth extraction.

Dr. HOFFENDAHL's handbook of dentistry⁸ for medical practitioners is, so far as it goes, interesting and practical. He strongly denies the existence of the so-called disorders of dentition, and supports his position well. He gives useful and minute advice concerning the causes of toothache and the temporary treatment of teeth, and as to extraction and the means of producing local anaesthesia. He is convinced of the necessity of a full set of teeth, believing that the loss of but few entails destruction of

the remainder. He urges immediate replacement of a lost tooth. The argument is well set out, but does not stand in the light of experience or of a full knowledge of dental sepsis, and it is in this direction that the book fails. To the author leucoplakia is a mystery, but he has never examined it in the light of dental sepsis. Malignant tumours are mentioned, but the author has not observed their intimate relation to dental sepsis. Finally, out of 160 pages but one is given to tooth affections as the cause of diseases of other organs, and in this there is no note of diseases of blood, intestines, etc., except that "chronic indigestion is often caused by masticatory failure."

Mr. STEWART LERVY McCURDY of Pittsburgh has written *Oral Surgery*⁹ as "the first of a series of textbooks which has been planned by the Commission on Textbooks of the Institute of Dental Pedagogics." The book is divided into two parts—"Principles of Surgery" and "Oral Surgery," but it cannot be said that the author displays profound knowledge of either subject. As examples, under "inflammation" (pp. 7 and 8), we read of contraction, dilatation, and degeneration of vessel walls of the arteries, and the only mention of capillaries occurs in connexion with diapedesis of red corpuscles; under "diagnostic signs" (p. 83) we learn that "strabismus is usually of no particular importance." On p. 376 we read of fibrous ankylosis of the temporo-maxillary articulation; on p. 423 of the "hypoglossus muscle." The author holds that the floor of the orbit may be pushed up by pus in the antrum and the eyeball displaced (p. 344). He appears to be ignorant of the epithelial nature of a dental cyst, describing it (p. 297) under "cysts from the roots of developed teeth"; "it is," he says, "doubtless caused by irritation and infiltration at the apex, as an apex cyst, following the removal of a nerve and filling the root canal." On p. 200, in the course of a chapter on bone regeneration, we are told that "the new bone, known as cloaca, is deposited in concentric layers." There are some good photographic illustrations (though the attempt to photograph intraloral conditions fails), among them that of an impacted first lower permanent molar; and there is an interesting description of a method of wiring fractured mandibles by means of which the author has obtained brilliant results.

That *Mouth Hygiene* was written by Dr. MARSHALL¹⁰ as much with the view of educating the public as of providing the dental profession with a not too technical book on mouth hygiene and mouth sepsis may, perhaps, stand as an excuse for the statement (p. 94) that "many children habitually breathe through the mouth, simply because they have not been taught to breathe through the nose, and not because there are any obstructions in the nasal passages"; and even of the description of antral abscess (p. 136) from which we learn that pent-up pus in the antrum may cause protrusion of the eyeball. A better excuse is found in the author's sincere desire to spread a knowledge both of the evils of mouth sepsis and of the means of prevention, evidenced by such vigorous language as "The only obstacles in the way of a complete revolution in this matter (the prevalence of mouth sepsis) are indifference, prejudice, and ignorance"; and in his outspoken advice to operating surgeons. He thinks stiff bristles will pass "between the dental interspaces"—but, surely, at most they will but begin to enter. In our experience the large brush he advocates for adults is entirely a mistake; a small one allows of far greater freedom of movement. Dr. Marshall served in the United States Army, and we note that during the Spanish-American war from 10 to 12 per cent. of the force was constantly incapacitated for duty by reason of dental disease. The book should do much to effect among the thinking public the revolution Dr. Marshall so ardently desires, and doctors and dentists will find in it much useful information.

⁶ *Die Missbildungen des Gebisses*. Von Prof. Peckert in Tübingen. *Die Morphologie der Missbildungen des Menschen und der Tiere*. Herausgegeben von Dr. E. Schwalbe. IV Lfg. 2. Abtheilung. 5. Kapitel. Jena: Gustav Fischer, 1911. (Sup. roy. 8vo, pp. 69; figs. 58.)

⁷ *Extraction of Teeth*. By J. H. Gibbs, F.R.C.S., L.R.C.P., L.D.S. Edin., Dental Surgeon, Edinburgh Royal Infirmary, etc. Edinburgh: E. and S. Livingstone, 1912. (Demy 8vo, pp. 165; 53 illustrations. 7s. 6d. net.)

⁸ *Taschenbuch der Zahnheilkunde für praktische Aerzte*. By Dr. Kurt Hoffendahl, teacher of dentistry in the Kgl. Friedrich Wilhelm's University of Berlin. Berlin and Vienna: Urban and Schwarzenberg, 1912. (Cr. 8vo, pp. 160; illus. 47. M.4.)

⁹ *Oral Surgery: a Textbook on General Surgery and Medicine as applied to Dentistry*. By Stewart Lervy McCurdy, Professor of Anatomy and Oral Surgery, School of Dentistry, University of Pittsburgh, etc. New York and London: D. Appleton and Co. 1912. (Demy 8vo, pp. 492; 228 illustrations. 12s. 6d. net.)

¹⁰ *Mouth Hygiene and Mouth Sepsis*. By John Sayre Marshall, M.D., Sc.D., Syracuse University, Capt. (Retired) U.S. Army, formerly Examining and Supervising Dental Surgeon, U.S. Army. Philadelphia and London: J. B. Lippincott Co. 1912. (Demy 8vo, pp. 274; figs. 12. 6s. net.)

Under the title *Preservation of the Teeth*¹¹ Captain EUSTACE LEES has devised in durable book form a dental history sheet which is prefaced by a note on dental hygiene. By the use of abbreviations the history of each tooth can be succinctly recorded, and the author rightly thinks this may be of considerable service, when change of locality necessitates change of dentist.

NOTES ON BOOKS.

The edition of *Nisbet's Medical Directory* for 1913¹² has been issued. The first edition was published in 1908, and the regular annual appearance of the volume shows that there is a demand for a condensed publication of this kind. It consists of two parts; the first is a directory in a single alphabetical arrangement of medical practitioners with the address and the principal appointment held, and a note of the principal book or paper published. The second part is a local directory, in which the names are classified under places of residence. The book is well printed on thin paper, and is very convenient to handle.

The thirty-second volume of *The Transactions of the Ophthalmological Society of the United Kingdom*¹³ covers its proceedings during the session 1911-12, and contains as many as seventy-six communications, a considerable proportion being illustrated by charts, diagrams, x-ray pictures, and coloured plates. Included is the report presented by the council of the society at its annual meeting, showing a satisfactory financial position and a membership of over 500. Owing to the holding of the International Medical Congress in London next summer, it was decided to postpone the delivery of the next Bowman Lecture until 1914.

*Books that Count*¹⁴ is, we gather from the preface, intended primarily to help the ordinary reader and the young student to ascertain quickly the aim and scope of the books dealing with various departments of learning "which treat their subjects on broad lines and in point of knowledge, research and reflection approximate to standard value." It may be described as an expansion of the idea of the "hundred best books" applied to biography, fine arts, geography and travel, history, literature, medicine, music, philology, philosophy, religion, science, sociology, and sports and pastimes. It includes brief accounts of about 5,500 books. The labour of compilation must have been very great, and, as far as we have been able to test the lists, the particulars given are accurate. But the selection of books often reminds one of Louis Venillot's lines:

Qui me dira comment se fait l'Académie,
Pourquoi Pantoufle en est et Sabot n'en est pas?

In several of the subdivisions of the section devoted to medicine the "books that count" are conspicuous by their absence, while a place is found for some which certainly cannot be said to "approximate to standard value." To doctors, therefore, the list is of little value, while for the public the books included are too technical. In other sections, notably those of history and literature, much of the information given as to the purpose and general character of the books mentioned is likely to be useful to readers who are not experts. To them, indeed, the work may be recommended as a conveniently condensed *Conversationslexicon* on books in the English language.

Dr. H. J. MACKAY, who is Assistant Director of Medical Services for the Wessex Division of the Territorial Forces, has brought out a second edition of *Improvised Methods of Aid in the Field*¹⁵. It is intended for the use of members of voluntary aid detachments and others, and despite its extreme portability contains an immense amount of information on the subject of devising ways of safely transporting patients, extemporizing hospitals, and other like matters. It is in Germany perhaps that this subject

has been chiefly studied, and the book contains a useful summary of recent German and other Continental literature dealing with it.

There is a certain type of novel that deals with events so far removed from the sober commonplaces of everyday existence that it comes under the heading of romance rather than of fiction. To this class belong many of Mr. and Mrs. EGERTON CASTLE'S clever stories, particularly their latest, *The Grip of Life*,¹⁶ which deals with the gradual awakening of a bookish young don to the stern realities of life. The cause of this awakening is his unexpected accession to a baronetcy, together with the sudden advent of two women into the world he has made for himself in his library; and between them they bring about the metamorphosis of the lonely student into the country squire, the worthy head of an ancient house. This development from the chrysalis into the butterfly is not accomplished without the shattering of many cherished illusions; but Sir Ughtred Maxwell has been born under a lucky star, and is weaned in time from the guilty passion that threatens to poison his existence by the sane and wholesome affection of the generous hoyden whom he finally marries. His emotional sufferings are many and varied enough to satisfy the most inveterate novel reader. The book has much of the rather artificial charm which has characterized its predecessors, and if it does not actually enhance at least should not detract from the reputation of its popular authors.

MEDICAL AND SURGICAL APPLIANCES.

A New Tourniquet for Use in Intravenous Injections.

MR. R. H. JOCELYN SWAN, M.S. Lond., F.R.C.S., London, has designed the pneumatic tourniquet here illustrated for use in giving an intravenous injection. He had found on more than one occasion that after having passed a cannula needle into a vein, the movement during the release of the ordinary rubber tourniquet resulted in the

needle piercing the wall of the vein or even leaving the vein: the pneumatic tourniquet was devised on this account. It is described as follows by Mr. Swan: It consists of a tube of firm rubber connected by a smaller tube to an inflating ball. In this smaller tube is placed a three way valve tap so that the pneumatic tube can be inflated, kept filled or deflated, by a very small movement of the handle of the tap. The pneumatic tube is loosely attached to a firm band of webbing fitted with a buckle to fix on the upper arm. In use the webbing band covering the tube is fixed loosely in position and the latter inflated by pressing the ball: the valve is turned into the mid position, and in a few seconds the veins are made prominent.

After the selected vein is punctured, the valve is again turned to the third position when the tube becomes deflated and the venous circulation of the limb recommenced and the injection given. The deflated tube remains in position until the injection is finished, in this way obviating any movement of the limb whilst the needle is *in situ*, the whole cycle being worked by the operator with ease. I have used this tourniquet now many times and find it answers all the requirements I wished. This appliance has been made for me by Mr. J. H. Montague, 69, New Bond Street, W.

¹⁶ *The Grip of Life*. By Agnes and Egerton Castle. London: Smith Elder, and Co. 1912. (Demy 8vo, pp. 406. Price 6s.)

THE late Miss Mary Houldsworth, of Rozelle, Ayr, bequeathed £500 each to the London Hospital and the Hospital for Sick Children, Glasgow, and directed that a like sum should be paid to any hospital founded in Glasgow and conducted by homoeopaths.

THE Ilford Company has issued a new catalogue giving full particulars of its well-known photographic plates for x-ray work, and of some additions thereto. By way of showing the capabilities of these plates, some excellent reproductions are supplied. Copies of the catalogue can be obtained on application. The address of the company is Ilford, Essex.

¹¹ *Preservation of the Teeth, with Charts to Record their Past and Future Treatment*. By Eustace Lees. Wolverhampton: Alfred Hinde. London: Simpkin, Marshall, Hamilton, Kent, and Co. 1912. (Post 8vo, 1s. net.)

¹² *Nisbet's Medical Directory, 1903*. London: James Nisbet and Co. 8vo, pp. 925. 8s. 6d.)

¹³ *The Thirty-second Volume of the Transactions of the Ophthalmological Society of the United Kingdom*. London: J. and A. Churchill. 1912. (Demy 8vo, pp. 473; plates 25. Price 12s 6d. net.)

¹⁴ *Books that Count: A Dictionary of Standard Books*. Edited by W. Forbes Gray. London: Adam and Charles Black. 1912. (Cr. 8vo, pp. 707. Price 5s. net.)

¹⁵ *Improvised Methods of Aid in the Field*. By H. J. Mackay, M.D., Col. A.M.S.T.F. Second edition. London: Eyre and Spottiswoode, Ltd. 1912. (Post 16mo, pp. 160; illus. 81; diagrams 2. (Price 1s. 6d. net.)

BOARD OF EDUCATION.

FOURTH ANNUAL REPORT OF THE MEDICAL OFFICER.

*(Concluded from page 59.)**"Following Up."*

In his opening remarks on the subject of "following up" Sir George Newman states that the experience of each year has served to bring into stronger relief the place, importance, and purpose of "following up" the ailing or defective child until it receives the treatment of which it stands in need. The evidence available, he suggests, indicates that medical inspection has served to awaken and develop, rather than to weaken, the feeling of parental responsibility. In many parts of the country parents are taking keen interest in inspections and their results. Teachers are also co-operating admirably. The assistance of a school nurse in following up is probably indispensable, but her work should not overlap that done in the sanitary department of the area. Close co-operation between the medical officer and the attendance officer is also of importance. In many areas a large amount of work in the nature of "following up" is being done by voluntary agencies. The medical officer himself has a double duty; he should definitely supervise all the agencies employed by the authority in "following up," having the work done by these agencies recorded on some systematic and simple method. Once he has detected a defect or disease in a child he should keep that child under his observation until he is satisfied that its condition has been remedied, or he finds reason to believe that nothing can be gained by further following up the case. Some figures supplied with references to 35 "typical" areas would seem to suggest that in many of them a considerable proportion of recommendations have been followed by actual treatment; but the figures given are not added up nor are any percentages given, so in this as in many other connexions the reader is left without any precise guidance as to what is the position of affairs.

Medical Treatment.

The sections on medical treatment commence with a chapter setting forth the powers possessed by local authorities in the matter, and what steps they have generally taken. The aims of treatment are discussed; the defects and disorders that have to be dealt with are often merely incipient, or otherwise not serious in themselves; but even if they hardly require to be remedied on their own account, their underlying causes must be seriously considered, the aim being to build up the resistance of the child and to obtain a healthy school population. A very small gain in this direction may spell a disproportionately large gain in the physical health capacity and energy of the people as a whole. Remedies adopted under the medical treatment of school children can seldom be those which can be quickly applied and immediate in effect. They must be of a preventive nature and include a training in hygiene and in habit—in the hygiene of the skin, the eye and ear, and of the teeth—and in the habit of life which affects the organic systems of the body—the muscular, digestive, and excretory systems, the heart and lungs. Measures such as the provision of a pair of spectacles or the extirpation of adenoids are but the beginning of treatment.

Nurses.—During the year under consideration eighty-five authorities received permission to employ school nurses in treatment as well as inspection. "There is hardly any more economical expenditure in relation to school medical work than that laid out on an efficient nursing staff."

Spectacles.—In a considerable number of areas permission has been accorded for the provision of spectacles, subject to the condition that they have been prescribed by medical men of suitable experience, and that, when possible, parents shall be made to contribute towards the cost of them. Children provided with spectacles should be re-examined at intervals, and all points connected directly and indirectly with defective vision kept under consideration. The findings of the committee of the British Association in regard to the influence of school work on eyesight are quoted at length. One of them was to the effect that a serious cause of visual defect was that the books provided were not printed so as to be easy to read.

Ringworm.—A considerable number of authorities have been permitted to provide themselves with special x-ray

clinics, and the number that made arrangements for x-ray treatment of ringworm of one kind and another increased during the year. No dependence can be placed, it is stated, upon a cheap installation, but, given an apparatus mechanically perfect and an intelligent operator, there should be no difficulty in curing practically every case of ringworm within, it is said, five weeks.

Contributions to Hospitals.—It is suggested that the wisdom of the Board in sanctioning arrangements with hospitals for contributions, either as a sole or as one of several means of providing medical treatment for school children, has been amply confirmed. Altogether thirty-one authorities received the sanction of the Board for such arrangements during the year ending July 31st, 1912; besides these, a very large number of other authorities were using hospitals for the treatment of their children. Hence, despite the fact that in some areas the medical staffs or governors of the local hospitals have declined to undertake the treatment of school children, thereby compelling the authority to make its own arrangement, tens of thousands of children in the country have received such treatment, and the voluntary hospitals have thus made a very large contribution towards the immediate relief of ailing school children.

The Board's dealings with the London County Council in regard to its medical treatment schemes are described. It is admitted that a composite scheme is inevitable in London, and in a general way the Board would appear to be satisfied that the present arrangements secure skilled treatment and an adequate degree of control over the various institutions on the part of the Council. An impression is left that the Board is disposed to be more exacting in its requirements in regard to treatment centres than in respect to hospitals.

School Clinics.

The considerable extension during the year of the work of the inspection clinic is regarded by the Board with much satisfaction. At these inspection clinics children noted to be defective at ordinary inspections are further examined, and they form the centres from which all work in the nature of "following up" is controlled. In large towns and in country areas it is useful to have several of them. The establishment of thirty treatment clinics had been authorized down to July 31st, 1911, the end of the school year, and from a list supplied of all those sanctioned up to the end of the following year there would appear to be fifty-six of these institutions now at work under the aegis of the Board. It is held that it is especially the treatment of minor ailments which should be kept in view at these institutions. At some of those which are described in detail and with approval, charges, we note, are made. How they are officered is seldom stated. Generally the treating medical officer would appear to be the school medical officer, aided by clinical assistants, or a health visitor or nurse, or the deputy school medical officer similarly assisted.

Dental Disease.

Stress is laid on the prevalence of dental disease, it being suggested that high as are some of the figures (these indicating on the average of a large number of areas that only 5.6 per cent. of children of school age have sound teeth), the real prevalence is even higher, because the school medical officer at his routine inspection is only likely to note teeth whose decay is easily observable. The prevalence appears to be slightly less in country than in urban schools. Certain reports also reveal some ground for holding that children artificially fed during infancy develop dental caries more readily than others. In a good many areas toothbrush drill and toothbrush clubs have been established. Dental treatment is carried on apparently at about half the school clinics. It is indicated that while many of the causes of dental decay are beyond the control of education authorities, it is feasible to deal with caries in its earliest stages in newly-erupted teeth of the permanent set, with results which are fully commensurate with the expenditure involved. It is on such teeth that attention should be concentrated. Two rooms are required at a clinic for dental use, though they need not necessarily be used solely for that purpose. Their equipment costs between £20 and £40. One dentist working five days a week, or several part-time dentists working for an equivalent

period, should be able to deal effectively with a school population of some 3,000 to 4,000 children. Those who perform the work should be responsible not only for the treatment, but also for selection of the children to be treated. They should be regarded as part of the staff of the school medical officer, and do their work under his general supervision, as only thus can the unity of the school medical service be preserved and due consideration secured for the collateral issues raised by dental disease.

Special Schools.

There are 331 schools classed as special—namely, 36 for the blind, 48 for the deaf, 169 for the mentally defective, 62 for the physically defective, 2 for the phthisical, 6 for the epileptic, and 8 for those requiring open-air treatment. The total accommodation is for 25,266 children, and fifty-two of the schools are maintained by voluntary contributions. Further accommodation is likely to be required. Before the year 1908 only well-marked cases falling into well-defined groups were sent to such schools, but now new and formerly unrecognized cases requiring special educational arrangements are being brought to light by medical inspection. The duty of a school medical officer is to discover subnormal children, make a precise diagnosis of their condition, determine the medical treatment appropriate thereto, and arrange for or afford any medical treatment required.

Deafness.

It is stated that the cost of educating deaf children is not likely to decline or even to remain stationary. Only about 50 per cent. of those who are totally deaf and who have been taught speech on the oral method seemingly use speech after leaving school; but of those who are partially deaf and who have been taught in the same fashion practically all take advantage of their education on this point.

Epilepsy.

It is stated that such after-care returns as are available render it fairly certain that for cases of epilepsy which are at all severe there is usually only one end, whatever be their mental condition—namely, colony life.

Mental Subnormality.

Children in this category are divided into four classes: Dull or backward, feeble-minded, imbeciles, and idiots. Reasons are given for assuming that, leaving out the dull and the ineducable, there must be at present some 24,000 children whose mental condition demands that some special form of education should be provided for them, and for about half this number some kind of provision seems already to exist. In regard to diagnosis, stress is laid on the value of the system of Binet as a means of classifying the mental ability of any given child; and it is suggested that in many areas observation schools—that is, schools to which children could be sent before deciding finally on securing their admission to a special school—would be very useful. The sections on this subject end with an extensive series of desiderata.

Open-air and Allied Schools.

The movement in favour of open-air education is, it is stated, beginning to spread through the schools of the country, some advantage, however small, being taken of whatever facilities exist for open-air training. Stress is laid on the advantages of this fact both to the children themselves, and as bringing nearer the day when the public at large will regard open air as an essential factor in the life of a healthy person. Numerous examples are given of ways in which open-air conditions are being secured. A further type of school, some examples of which already exist, is the "School of Recovery"—a residential school designed for the education and prolonged physical treatment of children whose health is under par from any cause. Sanatorium schools are foreshadowed in a chapter describing how they should be built, officered, and managed.

Mother-craft.

Stress is laid on the value of schools for mothers, and it is indicated that the Board is prepared to make grants to these institutions. It is suggested that it would be of great advantage if the work related not only to infants, but to children, and regret is expressed that at present it

is impossible to exercise any compulsion over actual or prospective mothers. It is also pointed out that it would be of advantage if all children could be kept under skilled observation from their birth up to the time when they already come under the care of the local education authority. Teaching of infant care in elementary schools is useful, but it would be much more useful if continuation classes in this subject were arranged.

Juvenile Employment.

A long chapter is devoted to the subject of juvenile employment, among the suggestions made being that the time has arrived when the information obtained with regard to the children who are about to leave school should be handed on to juvenile employment committees and other like bodies, that steps should be taken to co-ordinate the work of school medical officers and factory surgeons, and that all children who are employed, though still of school age, should attend the school medical officer's inspection clinic as "specials."

Provision of Meals.

The final chapter in the report deals with the question of the provision of meals. It is stated that in some places where meals are provided insufficient care is taken in the way they are served. The children should not only be fed, but be taught how to behave at meals, and to acquire a taste for simple cookery. The provision of meals should not be regarded as a form of Poor Law relief, their true purpose being to ensure that a child's capacity to profit by the opportunities of education afforded to it is not lessened by its being insufficiently or otherwise improperly fed. No meal arrangements can really be satisfactory unless the school medical officer:

1. Has the right to nominate for school feeding any children found at the routine medical inspection or on special examination to be suffering from malnutrition due to insufficiency or unsuitability of food.
2. Is always consulted as to the dietary provided.
3. Has the right and duty of inspecting the actual arrangements made in regard to the preparation, distribution, and service of the meals.
4. Is consulted in all cases of doubt as to the necessity for retaining a child on the feeding list owing to its physical condition.

Before concluding this summary it should be noted that scattered throughout the report are notes as to the information obtained either by Sir George Newman or members of his staff during official visits last year to the Continent, United States, and Canada.

INTERNATIONAL CONFERENCE ON POST-GRADUATE MEDICAL INSTRUCTION.

DURING the International Medical Congress, August, 1913, a conference on post-graduate medical instruction, in connexion with the meeting of the International Committee, will be held in London. Under the auspices of the Privy Council, a British committee, composed of the British delegates to the International Committee and of representatives of post-graduate medical schools has been formed, with Sir William Osler as chairman, to make the necessary arrangements for the conference.

The following programme has been drawn up by the International Committee, of which Professor von Waldeyer is president and Professor Kutner, Berlin, is secretary:

I. Reports:

- Topic 1.—The curriculum of medical education in the United Kingdom.
- Topic 2.—The present condition of post-graduate medical instruction in the United Kingdom.

II. Discussions:

- Topic 3.—The reforms in the present methods of instruction necessary to ensure technical proficiency in the general branches of medical practice.
- Topic 4.—The importance of the sociological aspects of medicine (public health, school hygiene, tropical disease, health insurance, physical training, etc.), in post-graduate medical instruction.

Reports on Topics 1 and 2 will be prepared by Sir Henry Morris and Dr. C. O. Hawthorne respectively. The discussions on Topics 3 and 4 will be introduced by speakers

appointed by the International Committee; Sir Clifford Albutt will take part in the discussion on Topic 3. The British Committee will be pleased to consider offers of short papers relating to the discussion on Topic 4. In connexion with Topic 2, the British Committee will be glad to receive syllabuses of post-graduate medical courses from any institution which through oversight has not already been communicated with. An abstract of all the syllabuses will be published as a part of the Transactions of the Conference.

The honorary secretary of the British Committee is Major C. E. Pollock, R.A.M.C., War Office, Whitehall, S.W.

MEDICAL SERVICE IN THE HIGHLANDS AND ISLANDS OF SCOTLAND.

(Continued from p. 99.)

In our last issue a short account was given of the first volume of the report of the Commission which, under the chairmanship of Sir J. A. DEWAR, M.P. for Inverness, has been inquiring into the conditions of medical service in the Highlands and Islands of Scotland, issued a few days earlier. The report which was issued on January 13th is of great importance, and there is good reason to hope that its recommendations will lead to a bettering of the conditions.

SCOPE AND METHOD OF INVESTIGATION.

The Committee decided to take evidence from the counties of Argyll, Caithness, Inverness, Ross and Cromarty, Sutherland, Orkney and Shetland, and from the Highlands of Perthshire, areas in which isolation, topographical and climatic difficulties, and straitened financial circumstances are found most generally in combination, and therefore areas generally within which the question of adequate medical provision is most pressing. The instruction to the Committee was to consider how far the provision of medical attendance in districts situated in the Highlands and Islands of Scotland is inadequate, and to advise as to the best method of securing a satisfactory medical service therein, regard being had to the duties and responsibilities of the several public authorities in such districts.

With the view of facilitating the inquiry and rendering the collection of information more systematic, two sets of Query Schedules were prepared and issued to all medical men, with few exceptions, practising in the counties above referred to, and to other persons known to be conversant with the problem to be investigated. In all 260 schedules were issued—102 to doctors and 158 to other persons. Of these 87 were returned, duly answered, by doctors and 144 by others. It was decided that the Committee should visit the area of the remit in order not only to take oral evidence on the spot, but also to investigate as far as possible, and by actual observation, the various difficulties connected with medical provision in the localities where they were understood to be particularly urgent. This most praiseworthy decision cost those Commissioners who were not good sailors many hours of discomfort, but they have the satisfaction of knowing that they sacrificed to Neptune in their country's cause. The total number of witnesses examined was 258, selected from all classes of the community and with due regard to the various interests involved.

SPECIAL PROBLEMS.

The report emphasizes the fact that the Highlands and Islands present special features which demand special consideration. The great part of the area investigated is sparsely populated, and in many cases there is no doctor within twenty or thirty miles. In winter especially travelling is difficult, owing to the peculiar geographical configuration, with the result that not alone isolated homesteads, but fairly populous districts, may be for lengthened periods without any means to relieve suffering or stay otherwise preventable disease. This is borne out by the evidence of a Rona fisherman, who said:

It is just the Portree doctor we have, and he must come in a boat, and in the winter time he cannot come. We may possibly have to wait a fortnight for him, and the patient will be suffering pain all the time. It is quite possible the patient may die without seeing a doctor at all.

Dr. Cochrane, Shetland, said:

I have known a case being without medical attendance there (Uapa Stour) for eighteen days simply because they could not cross the Sound.

Dr. Roger McNeil, Medical Officer for the County of Argyll, said:

The population is so scattered that only a comparatively small number are within reasonable touch of a doctor in any one locality. . . . The difficulty of communication sometimes makes it impossible to get medical attendance in time to save life. I know myself of two such cases which occurred in the Island of Colonsay, before a resident doctor was provided, where two married women died before a doctor could be got from Islay, leaving two young families of seven and five, ranging in age from birth upwards, uncared for.

POVERTY OF THE CROFTERS.

Under such conditions the cost of medical aid must obviously be high, and in the great majority of cases even prohibitive. The bulk of the people are, over large sections of the area, in very straitened circumstances, especially at certain seasons of the year, and are consequently unable to pay for medical attendance even when the fee, having regard to time and distance, is quite inadequate to compensate the doctor. Ready cash is a rarity with the ordinary crofter, and the amount is at most so small that when he has provided for the necessaries of life and paid his rent and rates, he has, as a rule, little or nothing left to pay the doctor. The medical evidence was unanimous on this point, one witness declaring that a doctor might count practically on 30 per cent. of his work being gratuitous work, while some placed the number of unpaid visits as high as 76 per cent.

In these circumstances medical treatment becomes eleemosynary, and there is conclusive evidence that, even on that basis, it is not available for a large number of cases of illness, especially among poor non-pauper people. According to the testimony of witnesses, such cases constitute a large percentage of the population, and the high percentage of uncertified deaths is further conclusive evidence in the same direction.

Insanitary Dwellings.

The report refers to the housing problem as lying close to the root of the whole matter. To take one instance: In recent years the Island of Lewis has been reported on unfavourably as having dwellings in a grossly insanitary condition; a paragraph from the last report of the medical officer of health on Lewis is quoted, as follows:

Houses of practically only one room, with damp walls, damp clay floors, sunless interiors, a vitiated and smoky atmosphere, and the cattle under the same roof with the human inmates, the surroundings usually badly drained, and the site often damp. When a case of plithisis occurs in one of these houses isolation is impossible. In too many cases the patient spits on the floor, and on the floors of churches and meeting places, scattering tubercle bacilli all round. When one considers also the probability of the cattle being affected with tuberculosis, under the conditions prevailing what could we expect than a wide prevalence of the disease?

Primitive Customs and Habits.

Some curious examples of the lingering belief in inherited skill and traditional "cures" are given. A witness from the remote island of Rona (Skye), which a doctor rarely visits, was particularly interesting in a description of some of the various "cures" which, in default or disregard of medical advice, are frequently resorted to. He told, for example, of a "cure" recently applied in the case of an epileptic; it consisted of burying a black cock alive beneath the spot where the patient had had the first attack of epilepsy. He also described the successful treatment of a woman suffering from "King's evil" by a seventh son, to whom she had gone all the way to the Island of Scalpay, Harris. On this branch of the inquiry Dr. Tohnie, South Harris, said:

When they have bone disease, they use the old remedies. . . . There was a man suffering from keratitis, and he was not getting well. It is a difficult disease to cure in an old person. He was not getting on, and I had to go one very wild day to see him, and when I arrived he was away from home—it was a fearful day—and he had to drive nine miles and walk about another to an old lady at Lieisto. The old lady made up some rhyme and mixed grasses with water and sand, and sung. He came back and said he was better. The seventh son is supposed to be able to cure such disease. I know of one case of a person who had a carbuncle on the back of his neck, and it did not

heal, and he got a seventh son to come to his house, and every night for a long time he put cold water on it and a sixpence round his neck.

Inferior Diet.

The character of the food consumed, especially by the children, seemed to the Committee a relative fact of serious import. It was brought out that in South Uist no meal is ground, the surplus sheep and cattle are sold for urgent cash, every egg is bartered for shop commodities, and the milk supply is insufficient, especially in winter. The excessive indulgence in over-brewed tea, especially by children, is deplored by several witnesses. Dr. Murray wrote:

The great feature in the decadence of the school child's menu is the abuse of tea. The good old porridge pot has fallen from its high estate, and the tea-pot has been exalted in its place. Probably 50 per cent. go to school on a breakfast of tea and loaf bread, the former usually being brewed. . . . A large proportion of the children live so far from school that they cannot get home for a mid-day meal. These may walk from one to two and a half miles to and from school in all sorts of weather, and they work at their lessons all day on an inadequate breakfast. . . . All this works untold mischief, and it is impossible for the average child—say, in the afternoon—to be in a fitly receptive condition for education.

Tuberculosis often attacks those who are insufficiently nourished, as the examination of Dr. Reardon, South Uist, shows:

Have you much tuberculosis?—Yes.

Both kinds?—Yes, pulmonary and non-pulmonary.

Is it increasing?—I am sorry to say it is.

What do you blame?—To begin with, there is no foundation for the children. The mothers don't nurse their children, and at the age of three months they are supposed to be able to take porridge and sops. The reason for that is that the milk of their cows is given to their calves, and there is no milk for the children. It is a case of the survival of the fittest.

They are rearing calves instead of rearing children?—Yes.

Why do the women not nurse their children?—They are not able; they have not the strength.

Parish Councils Overburdened.

So far the parish councils are the only public bodies that have taken any steps towards the provision of general medical attendance on the inhabitants, but the report declares that any further strain on their resources, under existing conditions, seems in most places out of the question. Speaking of the effect of the Insurance Act, the report continues:

The industrial situation in the crofting districts renders the National Health Insurance Act much less operative in the Highlands and Islands than in other parts of Scotland. Except for casual employment and short periods of service at such occupations as ghillieing and occasional fishing, the crofting population is out-with the compulsory provisions of the Act. The amount of voluntary insurance is at present negligible, and there is reason to believe that in some cases the contributions made during the temporary employment referred to may not be supplemented by the number of contributions necessary to entitle such insured persons to the minimum benefit under the Act.

The general opinion of the witnesses examined in this matter was that any system of insurance by voluntary contribution would, in the economic conditions obtaining among the crofter population, have but little chance of success.

Conclusions.

To summarize the foregoing conditions, which make medical provision in the Highlands and Islands a special problem, the Committee put forward certain conclusions; these will be found on p. 98 of the JOURNAL of January 11th.

Conditions Affecting the Adequacy of Medical Service.

The report next proceeds to examine the conditions affecting the adequacy of medical service, among which are mentioned defective means of locomotion and communication. The advantages of motor cars or boats are reviewed, as is the necessity for an extended telephonic service. The lowness of the average doctor's income is illustrated, cases being cited where the gross income is only £100 per annum, yielding a net weekly wage of between £1 and 30s. A prominent witness, after stating that in many parishes the doctor does not earn more than £50 to £70 a year, went on to say:

In one island that I know the doctor only gets £5 a year from the parish council, and I am sure he cannot make more than £40 a year. He lives alone, and when I called he had his coat off and his sleeves up, and was cooking his dinner.

In view of the inadequacy of his remuneration, it is not surprising to learn that the average doctor is seldom able to take a holiday. The cost thereof, including the fee for a locum tenens, is beyond his means.

This is regrettable in many respects. An annual holiday of, say, four weeks would go far to mitigate the disadvantages of isolation, and to relieve the strain of medical practice.

In connexion with the foregoing the Committee put forward the opinion that the general efficiency of the medical service is impaired by certain conditions which were noted on p. 98 of the JOURNAL of January 11th.

Percentage of Uncertified Deaths.

One of the most conclusive proofs of the inadequacy of medical attendance is the number of uncertified deaths. For the whole of Scotland during the past five years the average of uncertified deaths was about 2 per cent. In the insular rural districts of the county of Ross during 1908-10 the percentage was 47.5 of the total, ranging from 69 per cent. in Uig to 17 per cent. in Stornoway. On the mainland the percentage in some places was as high as 80.9. Many witnesses were disposed to attribute the failure to call a doctor and the consequent non-certification to a fatalistic attitude towards death in the case of the aged, while others put it down to poverty, and also to inaccessibility. Whatever the cause, the report states that "the evidence is cumulative that there is a vast amount of illness among poor non-pauper people not medically attended." Some witnesses put such cases as high as 50, and even 75 per cent. Again, the frequent reference in the evidence to the habitual delay in calling in the doctor, even when there is no fear of a fee, is attributed not alone to apathy or ignorance or poverty, but to an attitude of patience in suffering which has been evolved from the lack of medical advice and assistance in the past.

Popularity of Patent Medicines.

An interesting and not unimportant type of evidence, it is pointed out, indicating inadequacy of medical attendance, is the brisk trade in patent medicines which has developed in recent years, and more particularly in the case of quack medicine of American manufacture.

We are told that the quantity of such medicine sold is much more than that supplied on a doctor's prescription. This practice of self-doctoring is increasing, and will so continue so long as the need to which it owes its origin is not more adequately met by the provision of skilled medical attendance.

NEED FOR TRAINED NURSES.

The Committee states that no matter affecting the welfare of the people of the Highlands and Islands is more urgent than the provision of an adequate supply of trained nurses. Any provision which exists at present is based on the voluntary efforts of individual benefactors and philanthropic agencies, and a tribute is paid to the public spirit and generosity displayed by many proprietors, shooting tenants, and others, in providing nursing attendance for these poor people.

The report suggests a classification of the nursing service as maternity nurses, cottage nurses, and fully trained nurses. As a proof of the insufficiency of the existing supply of nurses, the following passages may be quoted:

Dr. Ross (Barvas) described the attendance of crofters' wives on one another as a "social danger." In North Harris, Dr. Macleod informed us that not only a neighbour, but occasionally even the husband, was the only attendant in confinements, and that in the absence of any trained nursing only a small proportion of these cases received any skilled attendance. He mentioned that he had known of the deaths of as many as three mothers in twelve days. Another doctor told us of a case where a woman, at the crisis of her confinement, read out to her husband from a medical treatise directions to enable him to afford her the necessary assistance.

Evidence was forthcoming from witnesses representing several other parts of the area as to serious, sometimes fatal, results from the lack of skilled nursing. Father McNeill of Eriskay, after stating that the infant mortality there was abnormally high, informed the Committee that no doctor had attended a maternity case on the island for the last seven years, and that on one occasion, when no other help was available, he "had to bring out the medical dictionary and to take it to the schoolmaster to get him to attend." He further stated that last year, out of eleven deaths on the island, no less than five had been of infants under twelve months, and that he attributed this to the lack of a competent person to advise the mother.

The Committee is therefore satisfied:

1. That the total number of nurses is quite inadequate.
2. That in a great part of the area of the inquiry the efficiency of nurses suffers from lack of organization.
3. That, while tending generally to alleviate suffering and remove danger in sickness and disease, efficient nursing is at present urgently required in connexion with:

- (a) The birth and infancy of children.
- (b) The "following up" and treatment of diseases and defects in children as disclosed by school medical inspection.
- (c) Promoting among the people a knowledge of personal and household hygiene, dietary, etc.
- (d) The earlier detection of illness.

Recommendations.

It accordingly recommends:

1. That all existing voluntary nursing agencies, where practicable, be organized under a county or district scheme, but that, in order to retain local interest and support, the system of local nursing committees be continued and encouraged. Such nurses could, by arrangement, be utilized by public bodies under such a scheme, and the public bodies in question could have representation on the Management Committee.
2. That the total number of nurses be largely increased, and that the claim of island communities receive special consideration.
3. That nursing be regarded as an integral part of the medical service, and that in the discharge of her duties the nurse, through the organization, be directly responsible to the medical attendant.
4. That a suitable lodging or residence be provided for the nurse.
5. That the telegraph-telephone system now in use in many parts of the Highlands and Islands be made available for telephonic communication in connexion with the nursing service.

NEED FOR HOSPITALS.

Discussing the need for hospitals, the report says:

Both lay and medical witnesses strongly urge the necessity of providing cottage hospitals, within easy reach or erected near a doctor's residence, and in charge of a competent nurse. At present cases like the following are reported: "I have had to operate in a hut on a case of strangulated hernia, where a clerk gave chloroform, and light was obtained from a tallow candle, held by a neighbouring crofter, who fainted during the proceedings!"

The Committee is quite satisfied from the evidence on these points that the existing general hospital provision is quite inadequate, even if available in every case to the fullest extent of its capacity: that there is urgent need of further provision, and that such provision should be mainly in the form of cottage hospitals, and for the following special purposes:

- (a) To bring near to the doctor a distant case of illness requiring frequent visits.
- (b) To provide for the removal of patients from conditions which render medical treatment futile.
- (c) To reduce the cost and danger of travel entailed in removal from outlying parts to most of the existing hospitals.
- (d) To provide a home for the district nurse and a dispensary for the doctor.

Recommendation.

It is accordingly recommended:

That cottage hospitals be erected at various convenient centres, and of such a size as to accommodate from two to four patients, with a nurse and necessary assistance, and to provide a local dispensary for the doctor; and that the provision of tuberculosis hospitals, more particularly in the larger islands, should receive special consideration.

PROVISION OF MEDICINES.

The question of the provision of medicines and medical appliances is discussed at some length. The Committee notes that, while there is some evidence by druggists to indicate that the dispensing of drugs by doctors is regarded more or less as an encroachment on the druggists' proper sphere, yet so-called "counter prescribing" and advice by druggists are not uncommon. The report suggests that the provision of cottage hospitals at con-

venient centres would largely meet the difficulties as to prompt delivery of medicine, while the doctor might have a chest containing a small stock of the more important drugs conveyed on his motor car.

EFFECT OF THE INSURANCE ACT.

Before suggesting improvements the Committee examine the existing organization of medical services, which are: (a) Public health service, (b) school medical inspection, (c) health insurance medical service, (d) medical service under the Poor Law, (e) general medical practice, and (f) specialized medical service. The correlation of these services with a view to their administrative consolidation, and the provision of more satisfactory financial basis for private practice is fully expounded by Dr. Leslie Mackenzie, a member of the Committee, in an appendix to the report.

In regard to the insurance medical service the report says:

Though this branch of medical service has not yet come into operation, it has to be reckoned with in any scheme of amelioration under our remit. The number of insured persons is not at present ascertainable. In their case it is the duty of the County Insurance Committee to make arrangements for the administration of medical benefit in terms of the Act. In so doing account must be taken of the question of distance and of those geographical and climatic difficulties that have been referred to as prominent factors in the adequacy of the existing medical provision in the Highlands and Islands.

Inquiry was made from time to time as to whether the average crofter would be ready to pay contributions in respect of at least twenty-six weeks—that is, an annual average of 3½d. a week. The invariable answer was that in those districts contribution without compulsion is unreliable, and that even if legislative power to compel were forthcoming the system would still lack the main guarantee of success—namely, an employer responsible for the employed contribution. We are, therefore, convinced that the industrial conditions of the Highlands and Islands are such as to make the provision of the Insurance Act less operative than in other parts of Scotland, and we foresee considerable trouble in providing medical benefits for fully-insured persons far removed from a medical centre, more particularly when it is borne in mind that so large a portion of them are so situated. Special subvention even in their case would indeed appear to be necessary, and the provision of medical attendance for their dependants is also a matter requiring urgent consideration.

GENERAL MEDICAL PRACTICE.

In regard to the scope of general practice in the Highlands and Islands, the report attaches importance to the following statement by Dr. Mackenzie, of North Uist:

The remuneration should be adequate to attract capable men, who would elect to stay. At present, owing to the general poverty of the class that chiefly demands their services, this is not so, with the result that the positions are very frequently occupied by two classes: (a) Young men recently out of college, who make the appointment merely a stepping stone to something better, who remain only a year or two, not long enough to become sufficiently acquainted with the idiosyncrasies of the people, or the diseases that families inherit or are liable to. (b) Older men, who, after perhaps a chequered career, fall back on such places as a last resort and harbour of refuge; while to the capable man who, from inclination or perhaps the force of circumstances, elects to spend his life in these regions, the most hopeful outlook before him is to die in harness, in case he dies of starvation when old age and decrepitude render him unable to continue work.

Frequent Change of Doctor.

In consequence of these unfavourable conditions there is in some districts a constant change of doctors. Certain parishes have, indeed, attained unenviable notoriety in this respect. To give a few instances: In one parish there have been ten doctors and as many locumtenents in twenty-two years, and in two other parishes there have been in ten years seven and five doctors respectively and several locumtenents. Such frequent changes cannot but affect adversely the efficiency of the medical service in these localities.

Forms of Remuneration.

(a) Fees and Subsidies. The question of remuneration from general medical practice has already been referred to in some detail in the discussion as to the doctor's income, and in the paragraph dealing with the economic circumstances of the people. It is unnecessary here to retell the facts. Suffice it to repeat the general conclusion, which is borne out by all parts of the evidence, that private practice, more particularly among the cottier and crofter population, is

far from being remunerative. In some of the poorer districts it is of little consequence as a supplement to the doctor's income. The general effect is very much as put by Dr. Bremner medical officer of health for Sutherland:

The sum paid to the doctor by the parish is hardly sufficient to live on and pay his ordinary expenses, and in many cases he has few or no private patients from which to supplement his income. Consequently, the question of expense is always uppermost in his mind, and at whatever cost to himself he must reach his patient in the cheapest way possible and as seldom as he conscientiously can.

There are, indeed, a few exceptional cases where by reason of continued successful fishing, or liberality of proprietors and shooting tenants, or of a special industry peculiar to a locality (as for instance, quarrying, afforestation, electric works, etc.), the regularity of the people's income is such as to enable them to defray medical services on the very moderate scale of fees calculated on the basis of mileage, of time, and of the degree of professional attention required. It has, however, to be recognized that those who have to pay for distance and time are placed at a great disadvantage as compared with their fellows to whom such heavy additional outlay does not apply. To redress this marked and unavoidable disability should be one of the chief aims of the betterment of medical service in the Highlands and Islands.

Subsidies from Imperial Grants.—The extent to which ordinary medical practice is subsidized by the pauper lunacy grant, the grant in respect of medical officers of health and of school medical treatment, is, as already indicated, of little moment. As regards the grant in aid of medical relief, which, though never adequate, has been the mainstay of local resources in the provision of medical attendance for the inhabitants, it is shown to have fallen to less than half the rate in the pound which ten years ago encouraged parish councils to offer salaries sufficiently high to attract medical men to these remote parts. The steady reduction in this grant has two obvious effects, especially in the poorer districts: it has entailed corresponding increase of the parish rates and has tended to discourage increase of the medical officer's salary.

General Recommendations.

The Committee conclude their report by making certain recommendations, which are detailed in last week's JOURNAL, pp. 98-99, the most important recommendation being the establishment of a central authority for the control and administration of medical services.

After considering the evidence and statements submitted by the medical witnesses, the Committee expresses the opinion in a general way that for public and private medical service (in single practice areas) a minimum income of £300 per annum, with travelling allowance, should be secured to every medical practitioner recognized by the central authority.

In the case of doctors living in a common centre (multiple practice area) where it would be in the public interest to arrange that outlying patients be attended at small fees, the doctors should receive an annual subsidy to enable this to be done.

As suggested by Sir Donald MacAlister, on the analogy of India, a tariff of fees suited to local circumstances should be prepared by the doctor for inclusion in any scheme submitted by the local authority for approval of the central authority.

The relations of the Medical Service Committee to all the other authorities and interests would be adjusted by regulations issued by the central authority, who would be authorized to make grants conditional on the establishment and maintenance of a satisfactory medical service—the conditions to include any special qualifications necessary for medical officers, nurses, and others; questions of tenure of office, submission of tariff charges for private practice and the like. The central authority would act in concert and consultation with the central departments represented on it.

These are the recommendations of the Committee as to what might be the best way to administer the proposed grant; but the Committee recognize the possible objections to the creation of a new central authority, and that the Government may consider it more expedient to administer a grant through the existing central and local authorities acting in concert.

SCHEME FOR CONSOLIDATION OF MEDICAL SERVICES.

Appended to the report is a suggested scheme for the administrative consolidation of medical services, by Dr. Leslie Mackenzie, medical member of the Local Government Board (Scotland), a notice of which we hope to be able to give at an early date.

SCIENCE NOTES.

SOME experiments carried out recently in the Runcorn Research Laboratories of the Liverpool School of Tropical Medicine on the resistance of the bed-bug to various powders, liquids, and gases designed for its destruction are reported in the last number of the *Annals of Tropical Medicine and Parasitology* by Dr. B. Blacklock. In houses it infests the bug dwells in some place where it is protected from attack. It prefers a refuge close to its human source of food supply, and therefore prefers to live in the crevices of a wooden bedstead, or behind the wall paper close at hand, but as it is a rapid walker its refuge may be in a remote corner of the room. It feeds rapidly, running from place to place, stopping for a few seconds to puncture the skin with its stylets, suck up some blood, and pass on. In a few minutes it is swollen and shiny; it appears that it does not as a rule defaecate at once on or near its host, so that there may be no marks on the bed-clothes, even though bugs be plentiful in the room. Eggs may be laid within twelve hours after feeding; they hatch out in seventeen days at ordinary summer temperature, and the young can begin to feed within an hour or two. The vitality of the eggs was found to be destroyed by immersion in cold water for twenty-four hours, and the young are destroyed by moisture, their legs and antennae becoming glued together. The insect powders in common use appear to act mechanically. The powder must be fine, dry, and light, and must come thoroughly into contact with the bug; the fine particles then adhere to the body, antennae, and legs, the insect turns on its back and so struggles until it dies, after a period varying from a few minutes to several days. The eggs do not seem to be injured by the powders, but if the young hatch out in contact with powder, they often become entangled and may die. Bugs do not drown easily, though immersion for twenty-four hours is too much for them; they are killed by boiling water poured on to them, but can withstand water at ordinary scrubbing temperatures. Of the ether liquids tried, carbolic acid (5 per cent. and 10 per cent.), mercury perchloride (1 in 1,000), and paraffin oil, the last was the most efficient, but they can walk over a board smeared with paraffin and survive. There is no evidence, therefore, that insecticide powders or liquids can be depended on to clear bugs out of a house under domestic conditions. Gaseous substances present the best prospect of success, and of such substances sulphur dioxide is both effective and cheap. It kills both the insect and its egg and acts more rapidly at a slight pressure. Unfortunately bugs are not easily killed by deprivation of human blood. A bug kept in a glass tube by Geer without any food at all lived for a year "quite comfortably." Blacklock kept some in a glass tube for three months, and at the end of that time they were still alive and active. In another experiment he put thirty newly-hatched bugs in a tube; some of them died from time to time and their bodies disappeared, but at the end of three months nearly half (fourteen) were alive and active. He states, as a matter of common report, that in the case of old barges infected with bugs very prolonged complete immersion of the woodwork does not destroy the insects, probably because they are so securely hidden that the water never actually comes in contact with them. Considering the tenacity of life they display, it would appear that the means used for their extermination in a house—even sulphur dioxide gas—should be repeated after an interval of a few weeks. The expense of the inquiry was defrayed by Sir E. Durning-Lawrence, as was also that of another made by Dr. Blacklock and reported in the same issue of the *Annals*, into the resistance of the tick, *Ornithodoros moubata*, to various sheep dips. The general conclusion was that, used in the strength recommended and for the time suggested, the dips examined had very slight effect on this particular tick, which is extensively distributed throughout tropical Africa and attacks both man and beast.

SATURDAY, JANUARY 18TH, 1913.

THE CULTIVATION OF THE MALARIA PARASITE.

THE current number of the *Annals of Tropical Medicine and Parasitology*¹ contains a paper by Thomson and McLellan confirming the observations of Bass of the Tropical Medicine School of the Tulane University, New Orleans, to which reference has already been made, as to the cultivation *in vitro* of the malarial parasite. This seems to mark the beginning of another, and it would almost seem the final, stage in the elucidation of the life-history of the parasite and its relation to the disease. Sir Ronald Ross, in a note to the paper in the *Annals*, says that he is quite convinced that the specimens sent to him by Bass, and those made by Thomson and McLellan at Liverpool, give indisputable evidence of the successful cultivation of *Plasmodium falciparum* (the malignant tertian parasite) up to the sporulating forms. "These forms," he says, "are much too numerous in the specimens to admit of the supposition that the parasites have not developed since the blood was taken from the patient. The advance thus made is one of great importance, as all efforts to cultivate the parasites of malaria have hitherto failed since their discovery by Laveran in 1880." Bass states that he has been successful also in cultivating *Plasmodium vivax* (the benign tertian parasite) and *Plasmodium malariae* (the quartan parasite). That the conditions to be fulfilled in any successful repetition of the experiments demand minute attention to detail is shown not only by the failure of all previous attempts made by many investigators, but also by the fact that experiments made early last year by J. A. Sinton at Liverpool to repeat Bass's observation gave negative results, apparently because Bass in his earlier publications had omitted to state that the addition of a solution of dextrose to the cultivation was an important factor.

Thomson and McLellan have succeeded in two cases. The procedure was as follows: The arm of the patient was first scrubbed thoroughly with an alcoholic solution of mercury bichloride; the antiseptic was washed off and the epidermal scales fixed by a 70 per cent. solution of alcohol, which was allowed to evaporate before the puncture was made. It is not advisable to wash the arm with any watery solution, as two points have always to be safe-guarded—namely, that no micro-organisms (usually the *Staphylococcus albus*) be either carried into the vein or deposited in the culture tube, and, secondly, that no antiseptic shall be carried into the culture tube. The median basilic vein was punctured at the bend of the elbow and 8 c.cm. of blood allowed to flow into the syringe, slowly forcing up the piston by its own pressure. It was then transferred as quickly as possible, in order to prevent clotting, into a sterile culture tube containing 0.1 c.cm. of sterile solution (50 per cent.) of Merck's dextrose. Through the

woollen plug with which the tube was closed passed a thin glass rod, which was used to stir up the blood in order to defibrinate it and mix it with the dextrose. Throughout these procedures it was necessary to be careful to avoid air bubbles. The mixed defibrinated blood was then introduced into two culture tubes, the column of blood in each being 1 in. or 2 in. thick. The tubes were incubated at 38° C., when the red blood cells gradually settled, and three layers were formed. A top layer of $\frac{1}{2}$ in. to 1 in. of clear serum, a thin intermediate layer of loose red corpuscles and white cells—the culture layer—and a bottom layer, consisting mainly of red cells, in which the parasites died in periods varying from two to twenty hours. A few of the surface cells were drawn off with a capillary pipette after twelve, twenty-five, twenty-seven, and thirty-two hours. Small drops were placed on clean glass slides, smears were made, fixed in methyl alcohol for twenty minutes, and stained in the usual way with Giemsa or modified Romanowsky solution. It was found that the smears should be somewhat thick, owing to the amount of serum mixed with the cells.

In preparations so made a most remarkable appearance was noted after twenty-five hours' incubation at 38° C., definite segmenting forms being seen in large numbers showing the nucleus broken up into fragments. The paper is illustrated by a microphotograph showing a portion of a slide on which hundreds of these schizonts were seen clumped together. The pigment mass was quite distinct and where segmentation was nearly complete the merozoites were arranged concentrically round it, thus forming the so-called rosette. No evidence of these merozoites having entered new corpuscles and so beginning another generation of parasites was obtained. In a second case examined the results were not so conspicuous, possibly, as Thomson and McLellan suggest, because the patient had been in the habit of taking quinine with great regularity.

They are unable to explain why the parasite should grow in the culture tubes only in the thin layer between the serum above and the main mass of the red blood cells below. The serum was probably filled with antibodies produced by repeated sporulation of parasites, yet it was apparently powerless to stop parasitic growth so long as that growth remained intracorpuseular. After incubation for twenty-seven hours few segmenting forms were found, the probability being that the corpuscles had burst, causing the merozoites to be dispersed, thus subjecting them to the destructive action of the serum and leucocytes. This subject remains for future investigation, as also the question whether the parasites grow better or worse in normal human serum.

AN ENGLISH PHYSICIAN OF THE FOURTEENTH CENTURY.

CHAUCER's picture of the Doctor of Phisyk is a *locus classicus* of our literature. Among the many authors whom he had read is "Gatesden," John of Gaddesden, author of the treatise known as *Rosa Anglica*. This treatise is familiar by name to all interested in the history of medicine, though it may not be very rash to conjecture that it has been more spoken of than read. John of Gaddesden was a man of great note in his day. He had a large practice and numbered royal personages among his patients. Little is certainly known about him, though he is frequently quoted and referred to by later writers. Every stray fragment of information has been

gathered up by Dr. H. P. Cholmeley, and out of the materials thus collected he has made a most interesting book.¹ In it John of Gaddesden is made the central figure in a picture of fourteenth century physic in this country. Around him are grouped details of the medical lore and practice of that day, gathered from contemporary sources and skilfully focussed so as to throw every available particle of light on the subject of the work.

John of Gaddesden was probably born about 1280, and died in 1361. His active life therefore covers the first half of the fourteenth century. He was educated at Oxford, and is mentioned by Anthony à Wood as being a "Doctor in Medicinis" at Merton College in 1320. To become a doctor he must previously have graduated in Arts; this implies an intellectual discipline of considerable severity, however barren many of the problems on which the student's mind was exercised may seem to us. Then the candidate for a medical degree had to spend four years of special study, at the end of which he had to pass an examination. There is no evidence of clinical training being required, and a fourteenth century English physician was let loose on the world unprovided with any other knowledge than such as could be got from books. There was, in fact, properly speaking no school of medicine at all in this country till the early part of the eighteenth century, when those of Dublin, and a little later Edinburgh, came into existence. Hence men had to go to foreign schools, chiefly Italian, to learn the practical part of the art. Although partly conjectural, we may take it that the chronology of Gaddesden's life as given by Dr. Cholmeley is fairly correct. According to this he entered Oxford for grammar at the age of 14 in 1294, and incepted as M.A. He began to study medicine in 1303, and graduated B.M. in 1307, and D.M. in 1309. He wrote the *Rosa Anglica*, or as he called it *Rosa Medicinæ*, in 1314. The preface, written in the pedantic and somewhat grotesquely ornate style characteristic of the period, states that the author's aim was to write a book for the humble to read. The title of the book, he says, has reference to the five appendages which belong to the rose, as it were five fingers holding it, concerning which it is written "Three are bearded, and two are not." That is to say, three of the parts surrounding the rose are hairy, and two are smooth, and the same is the case with the five parts of his book. "The first three are bearded with a long beard, for they treat of many things and about general diseases, and for a discussion of what constitutes a general or common disease, look in the introduction to the second book. The two following books treat of particular diseases together with some matters omitted in the preceding books and they are as without a beard (shorter)." He winds up with the modest remark: "And as the rose overtops all flowers, so this book overtops all treatises on the practice of medicine, and it is written for both poor and rich surgeons and physicians, so that there shall be no need for them to be always running to consult other books, for here they will find plenty about all curable disease, both from the special and the general point of view." The work is largely a compilation from the Greek, Arabian and Jewish physicians, together with the works of his immediate predecessors, such as Gilbertus Anglicus and Bernard of Gordon, but there are not a few records of his own experience. Guy de Chauliac, however, refers to the

book as "a foolish rose of England" in which, instead of the odour of sweetness he expected to perceive, he found only the fables of Hispanus, Gilbert, and Theodoric. Freund's judgement is more favourable. He says that Gaddesden "seems to have made a collection of all the receipts he had ever met with or heard of; and I believe this book can afford us the best history of what medicines were in use, not only among the physicians of that time, but among the common people of England, both in the empirical and the special point of view." Gaddesden never fails to make the most of his successes, which gives Dr. Cholmeley the opportunity of saying that he would have agreed with Matthews Duncan, who used to say to his class, "If you don't believe in yourself nobody else will." The *Rosa Anglica* is best known by the famous passage referring to the use of what may be called a red atmosphere in the treatment of small-pox. By wrapping the patient—"son of the most noble King of England"—completely in red cloth, and having everything about the bed of the same colour, he cured him without pitting. Gilbert Anglicus before him had mentioned that the old women of his day believed that red substances had "an occult property of curing small-pox," and centuries later we find a bill for red cloth supplied when Charles V, as a young man, was ill with small-pox. We need only remind our readers that the treatment of small-pox by red light was advocated by the late Dr. Niels Finsen in this journal only a few years ago.²

Travel in the fourteenth century was an extremely serious business. Besides the perils from shipwreck and robbers, there were the innumerable dangers of infection at insanitary inns. The author of the *Rosa Anglica* advised that those about to go on a journey should, by way of preparation, be bled or purged, so that the body might be cleanly. If the air was foul the wayfarer was recommended to sniff camphor or roses or violets, and if there was a stink, to hold his nose. Sensible directions are given as to eating and drinking, clothing, the care of the feet and the perineum, and keeping the feet warm and dry.

A comparatively small portion of the book is devoted to surgery. Among the operations described are lithotomy, herniotomy, and the reduction of dislocations. John of Gaddesden does not disdain to give directions as to cosmetics for the cure of freckles, pustules, and sunburn. He gives prescriptions for complexion washes, and for sweetening the breath and the body generally. He urges the need of frequent baths and the importance of cleanly underclothing with an insistence that may surprise those who think of the Middle Ages as a time when the gospel of dirt was universally practised. He explains that he writes these things for delicate women and for noble men. There is a section on the care of the health based on the regimen of Salerno. Our modern believers in fruit as the preventives of all disease will doubtless be shocked by his views. After speaking of ill-regulated lives, too much eating, and so on, John of Gaddesden says: "Again with fruits; some eat more of them than of other food, wherein they do not well, for all fruits make watery useless blood and prone to putrefaction." He allows pears, figs, and apples after dinner to those inclined to looseness of the belly; prunes, cherries, raisins, and figs should be taken before dinner. On the whole, however, he says it is best to do without fruit altogether, and he quotes Galen as stating that his father lived for one hundred years because he never ate fruit.

¹ *John of Gaddesden and the Rosa Medicinæ*. By H. P. Cholmeley, M.A., D.M. Oxford: At the Clarendon Press. 1912. (Med. 8vo, pp. 187, 8s. 6d. net.)

² Remarks on the Red Light Treatment of Small-pox, BRITISH MEDICAL JOURNAL, June 6th, 1903, p. 1257.

After the dissertation on health in general comes a discourse on colic, a complaint which seems to have been common in the Middle Ages. Probably we think it appears common because it was more spoken of, just as one might imagine that, from the frequency of allusion to the complaint in popular French speech and literature, it was more common than it is among ourselves, the fact being that the difference is probably due to the curious reticence about such matters caused by the *prud'hommerie Anglaise*. But that our mediaeval ancestors suffered very much like Father Tom in *partibus interioribus* from their appalling diet, there is no doubt. They ate enormous quantities of meat, much of it salted. They also consumed salt fish very largely, and their dishes were seasoned with ambergris and a number of substances that must have made them acutely trying to the most vigorous digestion. An amusing account of mediaeval diet was given in *L'Hygiène* not long ago by a French writer who tried some of the "horifiques recettes" of his ancestors on himself. They were also great eaters of sweets and fruits. This possibly may have inspired John with the bad opinion of fruit that he expresses. The *Rosa*, according to Dr. Cholmeley, may be taken as giving a fair picture of an English physician of the fourteenth century. He was a man of good general education, familiar with the writings of his predecessors. Of anatomy and physiology he knew nothing, but within limits he seems to have been a fairly accurate clinical observer.

On certain points we think Dr. Cholmeley is not altogether fair to John of Gaddesden. He says: "The book bears out the somewhat unfavourable estimate of the character of the leech which is expressed by Chaucer, by Langland through the mouth of Piers Plowman, and by John of Salisbury, for Gaddesden appears to have been fond of his fees, and by no means to have neglected the by-ways of medicine such as diet, cookery, and the care of the complexion or beautifying of the body." He would have been foolish if he had; and as for fees, are we to believe that lawyers were not eager for money, and that ecclesiastics did not look for benefices? Did Chaucer himself forego the emoluments of the various offices he held under the Crown? Samuel Taylor Coleridge said that a certain indifference about money was a characteristic of a gentleman. Whereon Carlyle made the sensible comment that to warrant such indifference a man must have no need of money. John of Gaddesden was rather inclined to magnify his office, but that is a state of mind not altogether unknown at the present day. He seems to have held that medicine was a mystery, the secrets of which should not be revealed to the profane. Yet his book is clearly to some degree intended for the enlightenment of the laity on matters of health; if they were at the same time enlightened as to the author's skill as a practitioner, that, from his point of view, was all to the good.

Dr. Cholmeley has evidently made the study of John of Gaddesden a labour of love, for he has collected everything that bears on the subject from mediaeval literature. His book is, in fact, a storehouse of learning on the subject. He has taken infinite pains to trace and examine the writers whom John might have read, and to give an idea of the contents of their works. His *apparatus criticus* includes, among other things, the text of the regulations of the Emperor Frederick II of Sicily as to unqualified and regular practice in the kingdom of Sicily in the thirteenth century; the text of the decree of Pope Boniface the Eighth concerning the mutilation of bodies, which has so often been mis-

interpreted as meaning the prohibition of dissection; and a version of the *Isagoge*, or introduction to medicine, of Joannitius (or to give him his Arab name, Hunin), which explains the technical terms used by mediaeval writers. Dr. Cholmeley's work is a well ordered storehouse of learning and a solid contribution to the history of medicine.

THE GLUT OF OPIUM IN CHINA.

In an article which appeared in the *JOURNAL* on September 14th, 1912, it was pointed out that a crisis was to be expected, in the near future, in the opium traffic between India and China. We indicated that, paradoxical as it might appear, the opium merchants, the anti-opiumists, and the Chinese reformers were at one in desiring a cessation of poppy cultivation in India for purposes of the Indo-Chinese opium trade. Unfortunately, the Indian Government, which has pocketed large surpluses in past years from opium sales to merchants trading with China, was not disposed to reduce the present area of 200,000 acres under poppy cultivation in India. The result is a present glut of opium in the warehouses of the treaty ports in China, to the estimated value of £11,000,000. There is a growing disproportion between demand in China and the supply from India. The latter has been almost forced upon the merchants by the sales at auction conducted by the Government of India with an eye to revenue. The demand in China has been reduced by the fact that during the unsettlement consequent on the revolution the home production of the drug was illegitimately augmented, while more recently a recrudescence of energy on the part of the Republic has cancelled licences to smoke opium and conducted a vigorous anti-opium campaign.

It is true that by agreements made with the Imperial Government of China in 1907 and 1911 the Indo-Chinese trade was to terminate in 1916, but it was also rather illogically arranged that until that date Indian opium should be permitted to enter those provinces of China which themselves continued to produce the drug. While it appears to be the sincere desire of the wisest heads among the Chinese authorities to bring to an early and complete termination a trade which they are convinced is demoralizing and degrading their people, there is also little doubt that there are keen business men who desire that so long as opium fetches highly remunerative prices the large profits should go into the pockets of the Chinese growers rather than into those of the British merchants, with rather un-British names, who are anxious to unload upon the citizens of the Republic the product of the Indian Government's poppy fields.

In a debate which took place in the House of Commons just before Christmas it was pointed out, on behalf of the Government, that we were under no obligation to secure a profitable market in China for Indian opium merchants. The question to be answered, it was said, was whether the planting of the poppy was going on in China under the sanction of the Republican Government; if this was the case and the import of Indian opium was being obstructed, the agreement of 1911 was being infringed and the consequences might be serious. If, on the other hand, as recent reports appeared to show, the new Government of China was making real endeavours to restrict the growth, consumption, and trade in this perilous drug, no question of cancellation of our agreement could arise.

This policy, as stated by Mr. Acland for the Government of India, is, we believe, in accord with

public opinion—at any rate, in this country—though it may create an unpleasant position for the Indian merchants, and not be altogether free from embarrassment to the Government of India. We agree with the *Times*, which, in a recent article on the subject, indicated that a war to insist upon the fulfilment of these opium agreements with China would be “regarded as indefensible.”

We read of the burning of seven chests of Malwa opium at Anking, and the dispatch of H.M.S. *Flora* thither with a British consul-general on board. If, as is alleged, this opium was in the hands of a Chinese purchaser when destroyed, it is not clear that any case for British intervention has arisen, since a recent dispatch from Delhi states that the Indian Government, after next April, will suspend opium sales for China, and reduce the amount to be sold for consumption outside China by 4,200 chests. This, it is hoped, will unload some of the accumulations in the treaty ports of the opium, which has become in very truth a “drug in the market.”

Meanwhile the date fixed by the Hague Convention for a fresh step in the way of practical performance of the International Opium Convention of 1912—namely, December 31st—has passed. We understand that some Powers have not yet signed the convention, and, according to the protocol, it will be forthwith the duty of the signatory Powers to meet at the Hague and consider how practical force can be given to the International Convention without waiting any longer for the laggards.

We are aware, of course, that the Anglo-Chinese treaties were ruled out of consideration at the Hague Conference, but we look to the coming into force of this International Convention as the means for bringing enlightened public opinion to bear upon the extinction of the opium vice as well as the abuse of morphine and cocaine all the world over.

MEDICAL INSPECTION OF SCHOOLS.

ELSEWHERE in this issue will be found the conclusion of our summary of the latest report of the Chief Medical Officer to the Board of Education. Like its predecessors, this fourth report is full of details of an interesting character; but, also like its predecessors, it sometimes, indeed often, fails to supply any summing up giving precise information as to the position of matters and as to the line of action the Board would commend to education authorities. It is clear, however, that a considerable number of school medical officers throughout the country are giving attention to the consideration of matters of principle, despite the preoccupations of a large proportion of them by the ordinary duties of a medical officer of health. On one point Sir George Newman's views are very plainly set forth:—that is, the right performance of the duty of medical inspection. He points out that the main purpose of medical inspection is preventive, and that to be effective it must be sufficiently thorough and clinical. Its value for each individual child depends upon the degree to which the medical officer brings to bear his medical skill, knowledge, and experience combined with powers of observation and judgement. He must thoroughly appreciate disease as a crippling agent, even when present only in minor degrees. The whole life and condition and circumstances of the child in relation to disease must come within his purview. The sum total of physical data taken in relation to the child's environment must be thought of, not as an abstract proposition, but as it concerns the present welfare and the future development of the child. Some of the factors on which his success will depend are his medical

knowledge, his accuracy, caution, thoroughness, and the avoidance of besetting fallacies in his examinations, and in his deductions and interpretations. The work calls for imagination as well as for clinical ability, exact observation, and experience. The sequelae of even minor morbid conditions must be understood. All this is admirable, but obviously its attainment demands a high degree of clinical acumen and intimate knowledge of the family to which each child belongs. The work requires, in short, a combination of qualities which can hardly be expected except in family practitioners of lengthy experience. It is probably in view of this circumstance that not only in the United States but also in Germany, which rightly or wrongly has for some years past been regarded as the true leader of thought in regard to the State application of medical knowledge, the school medical service has been staffed almost exclusively by part-time medical officers, that is to say, by general practitioners who are prepared to devote a portion of their energies to school work. Sir George Newman records this fact in his notes on the two countries, but does not point out how different is the policy it represents from that which the Board of Education in this country appears to have adopted. The medical inspection of school children in this country is mainly in hands other than those of family practitioners. In 243 areas out of 302 the school medical officer is the medical officer of health. Many of them, no doubt, possess considerable clinical experience, but this can hardly be the case in regard to their 212 whole-time assistants. These, for the most part, must be young men who have specialized early in the direction of public health work, and no amount of organization will enable them to obtain that intimate knowledge of the home circumstances of a child which comes to a family practitioner in the course of his ordinary work, and which often enables him to give sound advice to its parents as to its educational career. Yet this is what Sir George Newman deems to be necessary if the real objects of medical inspection are to be attained. There are many other points in the report which afford room for thought, notably Sir George Newman's suggestions as to the establishment of sanatorium schools, and sundry passages which indicate a desire to bring children under a continuous official control, which will begin on the day of their birth and only end on the day when they come under that of the managers of the great labour organizations of the country.

STATE INSURANCE SICK CLUBS IN GERMANY.

DURING the period of five years from 1907 to 1911 the total number of sick clubs under the State Insurance in Germany (*Krankenkassen*) fell from 23,232 to 23,103, but the number of members rose from 12,138,966 to 13,619,048. In 1911, 5,772,382 cases of illness with inability to work were dealt with, as against 4,956,383 in 1907. In respect of these, sick “benefit” and treatment in some form of institution was paid for 115,328,905 days in 1911, as against 97,148,780 in 1907. The ordinary income of the clubs rose from Mk. 319,592,187 in 1907 to Mk. 412,290,611 in 1911, and the expenditure from Mk. 300,379,186 in 1907 to Mk. 388,442,459 in 1911. The excess of assets over liabilities for 1911 was about Mk. 312,000,000. The average cost per member in 1911 worked out at Mk. 24.83. The amount of money paid to the doctors for attendance on sick insured persons was Mk. 63,325,782 in 1907 and Mk. 83,754,224 in 1911; the cost of drugs, etc., rose from Mk. 40,157,749 in 1907 to Mk. 53,171,234 in 1911. In 1911 the doctors' bill came to Mk. 6.15 per member and the drug bill to Mk. 3.90. It will thus be seen that the average number of days during which members were in receipt of benefits was eight and a half, while of the 24s. which each member cost the clubs about 10s. went for

the doctor and medicines. A further significant fact may be deduced from the current figures—namely, that while the clubs, taken as a whole, received about £20,600,000 from the members as contributions and spent £19,400,000 in sick pay, etc., the actual excess of assets over liabilities amounted to the huge sum of £15,600,000. Unfortunately we cannot state the number of days' illness for which ordinary medical attendance was given, and therefore we cannot gauge the average remuneration received by the doctors in comparison with the work done.

VOLVULUS, DIET, AND RACE.

Two interesting articles, making together a monograph on pathological torsion of the large intestine, appeared at the end of last year in a French contemporary.¹ M. Duroux, the author, finds that volvulus of the large intestine is very rare in France and western and southern Europe, whilst it forms an appreciable proportion of all cases of intestinal occlusion registered by surgeons and pathologists in Scandinavia, Finland, Russia, and Poland. Duroux quotes half a dozen authorities who work in these northern and eastern lands, and finds that they have sufficient material at their disposal to determine with some accuracy averages of the relative frequency of volvulus in different portions of the large intestine. Whilst in France only 18 authentic cases of volvulus of the caecum have been reported, Leichtenstern, Philipowicz, and others have made out that this, the rarest form of volvulus, is much more frequent in Slavonic and Scandinavian countries. Taking statistics in which volvulus of the small intestine is included, these writers estimate that the caecum is the seat of volvulus in no less than 10 per cent., the ileum in 34 per cent., and the sigmoid colon in 50 per cent., isolated volvulus of the transverse colon making up the remainder. The relative frequency of volvulus of the caecum as compared with the same lesion in the small intestine, in the north and east of Europe, will surprise surgeons and pathologists in the United Kingdom. It would be interesting to draw up an "all-British" table of volvulus. The French *cuisine* and the dietary of the other Latin nations is more delicate than ours. Plenty of poor folk in this country eat very little meat, and the potato-eating Irish peasant must be taken into account, though the diet in the south and west of the sister isle is not so unvaried as it was before the famine. The modern Norseman and Slav are vegetarians on the whole. According to Tarentsky, Dreike, and Rolssen there are no differences in the morphology of the intestine in different races. But Hyrtl found that when one cat was kept for a year on a vegetarian diet and a second cat on animal food for the same space of time, the intestine of the former became 3 in. longer than that of the flesh-fed animal. It is doubtful, however, if elongation of the bowel becomes marked in vegetarian races. Duroux admits that there is no evidence that such is the case. On the other hand, he points out that badly-cooked vegetable food of inferior quality undoubtedly causes dilatation of the bowel and, what is directly to the point, that well-known clinical symptom, atony of the colon, so closely associated with volvulus. This atony is increased by the dyspepsia and other ailments due to the hardships of life and the rigours of climate prevailing in northern Europe. No doubt where one case of torsion occurs there must be hundreds of persons suffering from loaded colon, which implies evil effects far more frequent.

PSYCHOLOGICAL AND PHYSIOLOGICAL STUDIES ON APES.

The idea of prosecuting a scientific study of the psychology of the anthropoid apes is not new, but hitherto this

study has been limited to artificial surroundings. The observations of military officers and of other persons not trained in psychological technique cannot, in Professor M. Rothmann's opinion,² be relied upon, and too much importance should not be attached to the mentality of apes kept in captivity in the various zoological gardens, or to those trained animals which perform at circuses. On the other hand, some exceedingly important work has been conducted on the physiological processes of apes by well-known neuro-physiologists. Professor Rothmann briefly sketches some of the available information in regard to the psychology of gibbons, chimpanzees, orang-outangs, and gorillas, and after reviewing the physiological investigations claims that there is urgent need for the institution of an "observation station" for anthropoid apes. The suggestion that such a station should be organized in Germany has been abandoned on account of technical and financial difficulties. A suggestion to establish the station in the Cameroons was found to be fraught with many difficulties owing to the long journey and to the climate. It was therefore decided to find an intermediate home for the apes, and Teneriffe has been chosen. The Governor of the Cameroons and the German Colonial Office have lent assistance to the scheme by providing animals, and the Woermann Line has generously consented to carry them free of charge; the initial expenses have been met by the Sclenka Trust and the Plaut Trust. The management has been placed in the hands of a committee, of which Professor Waldeyer is president. Two chimpanzees have already arrived and are reported to be doing well. If the climate proves suitable to the animals it is proposed to send out a young investigator next year to study in a methodical manner the sounds uttered by the apes, their gesticulations, their comprehension of spoken language, their comprehension of numbers, the power of differentiation of colour, the development of the hands, and other matters of primary importance. Later, it is suggested that psychological studies should be extended to orang-outangs.

MEDICINE IN THE ENCYCLOPAEDIA OF RELIGION AND ETHICS.³

REFERENCE has on a previous occasion (vide this JOURNAL for February 24th, 1912, p. 452) been made to the medical interest which is excited by the perusal of this remarkable *Encyclopaedia*; and, although there are not in this volume (the fifth) articles which are so distinctly medical as several which appeared in the earlier ones, yet there are many which deal with subjects closely related to the practice of the physician and surgeon. The only purely medical article is that on *Drunkness*, written by Dr. J. F. Sutherland. There are some very interesting paragraphs in this contribution regarding the degeneracy of the offspring of drunkards, a degeneracy "about which until quite recently there has never existed a doubt." Dr. Sutherland deals very carefully with the question, but he sums up quite decidedly: "As far as the controversy has gone, there can be no doubt that the authorities who believe that alcoholism, not gross alcoholism—about that no doubt exists—but that fairly general kind of free indulgence which takes place daily, with frequent 'week-end' bouts, does lead to the physical and mental impairment of the offspring, are in the right, and can produce unquestioned evidence in support of their view." It may be mentioned, in this connexion, that the subject of *Eugenics*, which should in alphabetical order have been taken in this volume, has been postponed, and will be considered along with *Marriage*; we shall then see whether Professor Pearson and his co-workers have succeeded in weakening the generally accepted opinion on the degeneracy of the drunkard's child. An article in

¹ Les torsions pathologiques du gros intestin et leur traitement chirurgical. I. Volvulus du caecum. *Rev. de gynéc. et de chir. abd.*, October, 1912. II. Torsions du colon transverse et de l'S-Iléum. *Ibid.*, November, 1912.

² *Berl. Klin. Woch.*, October 14th, 1912.

³ *Encyclopaedia of Religion and Ethics*. Edited by James Hastings, M.A., D.D., Fellow of the Royal Anthropological Institute. Vol. V. Pravidians—Fichte. Edinburgh: T. and T. Clark.

which there is a marked medical substratum is that on *Dwarfs and Pygmies*, and in it there is evidence of the marked shifting of anthropological opinion during recent years regarding these curious peoples: for according to Kollmann and Schmidt (and they have many followers) the pygmies are "the oldest of peoples on the earth—the child-race of mankind," and it is possible that the belief Leland reached by an intuitive process years ago—namely, that "mankind was originally a dwarf"—may soon be accepted as the verdict of anthropology and ethnology. In this connexion it is to be noted that this volume also contains an article on *Ethnology* from the pen of Dr. A. H. Keane; it is a most condensed but at the same time valuable contribution, and by its bibliographies throws open the way to further research on the part of the interested reader. In the various articles which fill the nine hundred pages of this instalment of the *Encyclopaedia* there are constant references to the medical side of things, and we may name, in particular, the papers on *Dreams and Sleep*, on *Dress*, on the *Emotions*, on *Enthusiasm* and the *Enthusiasts*, on *Ecstasy*, on *Environment*, on *Euthanasia*, on *Evolution*, on *Fasting*, on *Fear*, on *Feeling*, and on *Fetichism*. Further, the chief contribution, that on *Ethics*, occupying over one hundred pages and written by some twenty authors, has many allusions to and bearings upon matters which cannot fail to interest every doctor, be he general practitioner, alienist, or specialist. The subject of *Eunuchs* is treated by Dr. L. H. Gray, who also writes on *Duelling*, *Eskimos*, *Expiation*, and *Fate*; castration, its mental and physical effects, its birthplace, its ethical bearings, and the strange question of the status of the eunuch-priest are all fully discussed. The *Evil Eye*, as a strange widespread belief, has a most interesting story, and it is well told in these pages; the phallic and other protections against its baleful influence lead the inquirer into a most curious region of medical folk-lore. The theory that the baby's coral and bells is a modern form of the ancient amulets against the evil eye is accepted. Two other articles call for notice. The one is on what is called the *Female Principle*, and deals with the relation between femininity and religion, with sexless deities, and other curious phenomena of a psychological kind in this department; the other is devoted to a careful presentation of *Faith-healing*, containing quotations from Sir Henry Morris's article in this JOURNAL in 1910. The author (W. F. Cobb, D.D.), under the term "faith-healing" includes mental healing, magnetic healing, spiritualistic healing, and spiritual healing; in all of them, he says, "suggestion plays a leading part," and he adds, "the most widely spread subspecies of mental healing is that known as Christian Science, and the strongest form of suggestion is that called hypnotism." Dr. Hastings is to be congratulated on having completed the first half of his gigantic task in the editing of this unique encyclopaedia, always supposing, however, that his original estimate of ten volumes is not to be overpassed.

SEX OF INFANTS AND AGE OF MOTHERS.

We must take nothing for granted, especially statistics, and above all statistics which appear to prove questions about fertility, decadence, and determination of sex. Such is the moral of a recent communication¹ by Professor Ahlfeld, well known for his works on teratology and obstetrics. There is a notion prevalent that to elderly primiparae male children are born in an unusually large proportion. Ahlfeld himself made out some time ago that whereas 100 females to 106 males was the general proportion, in the case of elderly primiparae the males amounted to 137. He warned his pupils at the time that some accidental factor might lie hidden in the series on which these statistics were based, but other long series of births analysed after Ahlfeld's tended to confirm his evidence.

Then Eckhardt set to work and brought out a somewhat different result. The proportion of males was high in primiparae from 30 to 34, and higher between 30 and 39; but in women who conceived for the first time after 40 excess of females over male children appeared to be the rule. More recently, in scrutinizing a series of 8,000 births at Marburg, Ahlfeld himself obtained actually opposite results. Out of 280 primiparous mothers aged from 30 to 49, 151 gave birth to girls and only 129 to male children, or 85.4 males to 100 females. This reversed Schramm and Ahlfeld's proportion of 132.8 males to 100 females collected at Leipzig. Ahlfeld still doubts whether all the statistics above noted, lumped together, would be sufficient to warrant a confident conclusion. Believing that not thousands, but millions, carefully collected and scrutinized, would be necessary, Ahlfeld has combined these already known statistics and publishes them in tables which obstetricians and publicists may study with interest and possibly with advantage. It seems pretty well established that young primiparae give birth to more males than females. Bidder made out 133 males to 100 girls in primiparous mothers from 14 to 18 years of age, but in primiparae between 18 and 30—that it is to say, women in the prime of sexual life—the proportion was 109.3 males to 100 females, the lowest proportion of all. On the other hand, in primiparae over 40, the proportion was 130.3 males to 100 females, the excess of boys being less than in child-mothers. Bidder held that the female, as members of that sex are very prone to believe in the present day, is the higher sex, physically at least, and that consequently women in their prime bear more female children proportionately than do young girls or women approaching the menopause. Thus the weaker women bear the most male children. The one fact the statistics seem to show is that, as a total, more males are born than females. One point quite unsolved, Ahlfeld reminds us, remains to be settled: Is the sex already determined in the ovum before impregnation? Experiments on tadpoles have led to the belief that the sex may be influenced by the temperature of the water in which they are reared. Ahlfeld says nothing of these experiments, but remarks that scientists have distinguished male from female ova in *Dinophilus apatris* and *Phyllocera vastatrix*. He urges registrars, midwives, and others to gather more information.

MEDICAL STUDENTS IN OLD PARIS.

G. J. DE BOYER DE CROISY, in a thesis presented to the University of Paris some time ago, gave an account of the medical students of Paris in the sixteenth century, and showed that they came from the upper ranks of the bourgeoisie, and from the families of magistracy. For admission to the Faculty the degree of Master of Arts was necessary. In the colleges the students, like the professors, were obliged to speak Latin, even out of class. Latin was also spoken in the Faculty of Medicine. It was not Ciceronian, but was a useful means of communication among the learned all over the world. Readers of Rabelais will remember the Limousin and his amazing jargon. The normal period of medical study for the degree of Bachelor was four years. Two further years of study led on to the licence which gave the right to practise. Finally came the degree of doctor. The total cost of the degrees was about 2,000 livres. Marino do Cavalli, in 1546, reported to the Doge that the University of Paris was attended by sixteen to twenty thousand students, most of them miserably poor, living in the colleges founded for that purpose. A curious description of the toilet of a student in 1555 is given by Victor Gay from the colloquies of Mathurin Cordier. "As soon as I awoke I got up, put on my doublet and my tunic. I sat down on a stool, put on my breeches and stockings, then took my shoes, fastened my breeches to my doublet with

¹ Die Einfluss des Alters der Mutter auf das Geschlecht des Kindes. *Monatsf. f. Geb. u. Gyn.*, September, 1912, p. 271.

hooks, fastened my stockings with garters above the knee. I took my belt, I combed my head, I took my cap, which I shook well. I put on my gown, and then going forth from the room I went downstairs, made water in the court against a wall, took some water out of a bucket and washed my hands and face, drying them with a towel." The students in the Middle Ages had to work under less comfortable conditions than those of the present day. The class-rooms had only a stool for the professor and a little straw strewn on the ground for the students to sit upon. They wrote on their knees. This position was justified by a decree of Pope Urban V in 1366, in which he says that that position was intended to remove from them the temptation of pride. The medical students went to lecture at six o'clock in the winter and at five in summer. In the sixteenth century a change came over academic life. The literatures of antiquity were studied and imitated, and grammar and rhetoric gradually took the place of logic. The professors read the works of masters, and dictated lectures in which discussions were summed up. Although the literary side of education became greatly developed, medical teaching was still very narrow. Anatomy, for instance, could not be properly learnt, as only the bodies of executed criminals were available for dissection; the professor never handled the scalpel, but was assisted by a prosector, usually a bachelor, who summed up the lesson of the master. But the true prosector was the barber surgeon, who was strictly confined to dissection. Clinical studies were almost entirely neglected. The students were only asked to be present at the lectures in the school and public debates. They attended hospitals only after they had taken the bachelor's degree, and then but very little. Young men intending to be surgeons were apprenticed to a master. Some of them were admitted to the hospitals, as we know from the life of Ambroise Paré, who was companion, or as we should now say, *interne* or house-surgeon, in the Hôtel-Dieu, Paris, for two years. Apprentices apparently discharged the duties of dressers. The lodgings of the students in the Latin quarter were not, as a rule, luxurious. Many lived under the same roof, and there was not much furniture. One room, with a single bed, was usually occupied by two students. The works of Hippocrates and Galen, and some books of medicine and philosophy and Greek and Roman literature, constituted the library of the medical student. Meals were taken where they could be got, but there were places of entertainment suited for every purse. In his leisure hours the student of medicine gave much time to the worship of the *divine bouteille*, especially on feast days. It was a time of great eating, and banquets were given on the least pretext. After every examination there was a dinner at the expense of the candidate, in which wine figured largely. Care was taken that the dinners should be good, for we find that by a special decree dated February 11th, 1546, it was ordered that thenceforward several doctors should be deputed to taste the wines, and see the victuals were good. The professors and students often dined at the same table, took part in the same games, and shared in the same debauches. We are sorry to say that often students were convicted of theft and murder. It may be not inappropriate here to recall the fact that Dr. Routh, of Magdalen, who died in 1854, could remember the hanging of two undergraduates for highway robbery. An order of Parliament dated August 20th, 1544, was issued to stop the acts of violence and excess every day committed in Paris, especially in the University and the adjoining quarters. The University held sway in the Latin quarter, and would not suffer the authority of the police. When students were so clumsy as to get themselves put into prison the masters would go and claim them. There were town and gown riots, especially at the feast of the Landit, which dated from the twelfth century, and was in reality a religious pro-

cession in honour of the true cross, of which the cathedral of Paris had received a fragment in 1109. Although turbulent and licentious, the medical students were for the most part workers. Their examinations were numerous, and required laborious preparation. To say they were occasionally riotous and dissipated is only to say that they were young men of their age.

TOXICITY OF THE URINE IN MEASLES.

It has long been recognized that the diagnosis of measles in its early stages is important from a public health point of view. Even the recognition of Koplik's spots in the buccal mucosa does not permit the disease to be diagnosed early enough for preventive measures. Any method of determining the existence of measles infection at a very early period is, therefore, worthy of attention. Drs. Hans Aronson and Paul Sommerfeld,¹ in the course of their experiments on the urine in connexion with their study of anaphylaxis, have found that the urine of patients suffering from measles contains a thermostabile, dialysable poison, which, when injected intravenously, rapidly kills guinea-pigs and rabbits; as a rule, 2 c.cm. of urine are lethal. They further found that this or a similar poison is present in the urine of anaphylactic animals, and that the urine of patients suffering from what is probably the "fourth disease" and from serum exanthems also acts toxically. The urine of patients suffering from typhoid fever, tuberculosis, diphtheria, whooping-cough, and scarlet fever does not contain any such poison. It is of importance to note that the appearance of the poison does not coincide with the acutest period of the illness nor with the onset of the rash. It is detectable at a very early period, and lasts for a considerable time. It would seem that this urinary toxin is in some manner associated with a hypersensibility of the organism toward certain proteins. In measles there may be some peculiar anaphylactic condition, as is indeed suggested by the fact that during the period of the illness, as von Pirquet has shown, an individual susceptible to tuberculin becomes temporarily insusceptible. So far the test must be made in animals, but it may become possible in future to recognize the toxin chemically. In any case, this quality of the urine of the patient suffering from measles in the earliest stage may prove of practical value.

THE CONVEYANCE OF POLIOMYELITIS BY INSECTS.

The infection of poliomyelitis can often be referred to direct or indirect contact with cases in the acute stage of the disease, but not infrequently it occurs sporadically, apparently in the absence of any acute source. The virus of poliomyelitis has several times been demonstrated in the tonsils and naso-pharyngeal secretion of persons suffering from the disease, and the disease has been reproduced experimentally by swabbing the nasal mucous membrane with the virus. The presence of the virus in dust has also been established, for it can withstand drying and low degrees of temperature. Evidence has recently been brought forward to indicate that healthy people in contact with acute cases may act as carriers of the infection, the virus having been found in their nasal secretions. The fact that the seasonal incidence of poliomyelitis roughly corresponds with the annual prevalence of insects suggested to Howard and Clark² the possibility of transmission of the infection by common insects. Experiments were conducted with flies, such as *Musca domestica*, with the bed-bug (*Cimex lectularius*), and lice, and with mosquitos. Flies have access to contaminated products, and may convey whatever virus they pick up therefrom to food and other objects, owing to the fact that they regurgitate in order to moisten and dissolve the stuffs on which they feed. In the experiments the flies

¹ *Deut. med. Woch.*, September 12th, 1912.

² *Journal of Experimental Medicine*, December, 1912.

were allowed to feed on infected cords or on materials containing cord emulsion; they were afterwards isolated, and after varying periods were killed with ether, ground up with sand and saline solution, and filtered through a Berkefeld bougie, and the filtrates were injected into the brain of monkeys. The experiments showed that the virus of the disease was retained on or in the bodies of flies for at least twenty-four to forty-eight hours. The viscera were also removed with aseptic precautions, and it was found that the virus existed in the digestive system for at least six hours. In the case of mosquitos the filtrates in no case produced poliomyelitis in monkeys. It has been shown by Flexner and Lewis that the virus exists only in minute quantities in the blood stream of experimentally infected monkeys, so that the conveyance of the disease from this source by biting insects would not seem at first sight to be very probable. Howard and Clark's experiments with lice were entirely negative, but when they allowed bed-bugs to feed on infected monkeys they found that the filtrates on one occasion (in sixteen experiments) produced poliomyelitis when injected into a normal monkey—a remarkable finding in view of the exceedingly dilute condition in which the virus exists in the blood stream. In this case the virus must have been carried by the bugs for at least seven days. More direct experiments have been reported by Rosenau, and by Anderson and Frost,¹ on the conveyance of poliomyelitis by the biting stable fly, *Stomoxys calcitrans*. The flies were allowed daily to bite infected monkeys, and were then transferred to healthy monkeys with the result that the latter all developed the disease seven to nine days after the first exposure.

THE LUNACY LAWS IN GERMANY.

At the opening sitting of the German Reichstag this winter a debate was raised on the administration of the lunacy law. It appears that some believe that there are many unjust detentions of persons in lunatic asylums, and certain members of the Reichstag sent a petition to the Commissioners, calling for fresh legislation for the regulation of the treatment of the insane. The Commissioners preferred to refer the petition to the Imperial Chancellor. In the debate it was urged that the existing law had proved insufficient to safeguard the interests of the public in respect of frequent incarceration of sane persons into asylums. Dr. Gerlach, in reply, pointed out that the charges of a highly sensational character, which found their way into the daily papers, emanated from patients discharged from asylums who had been obsessed by imaginary grievances during their detention; these grievances continued to obsess them after their discharge. He urged that the medical men who conducted the asylums and the professional members of the Commission were quite capable of protecting people against unjust detention. Dr. Struve also spoke against the folly of this organized campaign against asylum doctors. The matter will be brought up again, it is said, on the discussion on the Budget.

THE UTILIZATION OF SEWAGE SLUDGE.

Two cases of death from sewer gas poisoning occurred in Dublin last week. The accident happened at the Pigeon House Fort, where sewage tanks were erected a few years ago in connexion with the new drainage system of Dublin. A man was overcome by gas in a culvert, and a comrade who went to his rescue was also overpowered; they were both rescued by another workman. The first man was dead when his body was recovered, but the second man, though unconscious, was alive, and was taken to the nearest hospital; he died seven days afterwards, death being due, according to the doctor's evidence given at the

inquest, to septic pneumonia. The fatal results are attributed to the inhalation of sulphuretted hydrogen, the presence of which in large quantities is explained by the fact that a large amount of sludge had been stored in one of the tanks since last summer. It had fermented, and the officials at the place had observed a very bad smell for some time and had to make arrangements for the escape of the large quantities of gas that had formed. In connexion with the disposal of the solid part of sewage, an experiment has been carried on for the last twelve months in Yorkshire with an invention of a Dublin man. The solids are collected and compressed into cakes, which are put into large retorts and burned by the combustion of the contained hydrocarbons. The results of this combustion are drawn off and dealt with so as to collect the products evolved. From the cake, which hitherto cost a considerable sum to dispose of, an oil suitable for lubricating and other purposes is obtained, and also sulphate of ammonia, thousands of feet of gas, and a valuable residue in the ashes. The cost is said to be very small, as the necessary heat is got by combustion of the material itself. The amount of gas generated is said to be sufficient to enable a town or city consuming its own sewage cake in this manner to run all the electric machinery for the municipality with the power derived from the gas.

OTTAWA WATER SUPPLY.

For some time past the water supply of the capital of the Dominion of Canada has been causing considerable anxiety, and in the hope of finding out the cause and a remedy for the trouble the Government has decided to get the aid of two experts from the Mother Country. We understand that Lord Strathcona, who represents the Dominion in this country, has asked Sir Alexander Binnie, formerly chief engineer to the London County Council, to help the Canadian Government on the engineering side of the problem, and on the bacteriological side he has approached the Metropolitan Water Board for the services of Dr. Houston, Director of Water Examinations. We understand that the Board has felt it its duty to render what help it could to Canada in this important matter, and has allowed Dr. Houston to undertake the work. In a few days these two gentlemen will be on their way to Ottawa, and we feel sure that every Britisher sincerely hopes that they will be successful in suggesting some scheme that will give to the capital of the Dominion a plentiful supply of pure water.

Medical Notes in Parliament.

[FROM OUR LOBBY CORRESPONDENT.]

Isolation Hospitals and Small-pox.—Mr. Black asked the President of the Local Government Board on January 9th whether he was aware that in a report recently issued by the Department on isolation hospitals, Dr. H. Franklin Parsons stated that there was no near prospect that local authorities would find it unnecessary to be provided with hospital accommodation for the isolation of infectious diseases other than small-pox, though the scale on which such accommodation might be needed would vary in different districts; whether he agreed with the view therein expressed; and, if so, why he considered there was a near prospect of further hospital accommodation for the isolation of small-pox being unnecessary. Mr. Burns, in reply, said that the paragraph in Dr. Parsons's report to which reference was made was one dealing with the case of hospitals for diseases other than small-pox. The following paragraph dealt with the question of small-pox hospitals, and there was no suggestion in it that small-pox hospitals were as yet unnecessary.

[FROM OUR SPECIAL CORRESPONDENTS.]

SMALL-POX AND VACCINATION AT KIRKCALDY.

A RECENT report of the outbreak of small-pox in Kirkcaldy and Dysart gives details of 43 cases. Of these, 31 were known to have been vaccinated and 12, including an infant infected prior to birth, were either unvaccinated or showed no vaccination scars. There were 13 deaths. Six were patients who showed evidence of vaccination. Of these 2 were females, aged 50 and 52 years respectively, not vaccinated since infancy, one male aged 47, vaccinated in infancy, and another male aged 37, who had been revaccinated twenty-three years previously. The remaining 2 cases were females who both died in puerperium, 1 aged 23 with two vaccination scars, the other aged 33 with one vaccination scar. Seven deaths occurred in persons who showed no evidence of vaccination. Of these, 2 males, aged 47 and 46, were registered as having been vaccinated in infancy, but no vaccination scar was found. An infant now known to have been infected with small-pox before birth was vaccinated when two days old and died six days later after the small-pox rash had appeared.

Excluding 3 cases revaccinated within nine days of infection with small-pox, only 1 revaccinated case (and that revaccinated over twenty years before) occurred during the outbreak. A number of persons were infected who refused the offer of vaccination or revaccination. An analysis of the vaccinated cases reveals the striking fact that in no single instance were there four scars. Of the 31 vaccinated cases, 13 showed only one scar, 16 only two, and 2 showed three scars. A higher standard of vaccination is distinctly indicated than that obtained in the bulk of these cases. Very careful observations have been recorded regarding the vaccinal condition of the cases in the Kirkcaldy outbreak. The antivaccinators have agitated for this, but the details fully maintain the claims advanced for vaccination. It is unfortunate that certificates of "successful" vaccination should be issued, as has frequently happened, since the consequences tend to produce an altogether erroneous impression in the minds of antivaccinators and others. There exists a uniformity in the certificates, but by no means a uniformity in the vaccinations. There are many cases recorded in which certificates have been given without inspection, and the ease for vaccination suffers by this, and there are other indications of laxity in regard to vaccination certificates. If certificates are to be taken as proof of vaccination the greatest possible care is essential. It has been suggested that the certificate should contain a statement as to the number of insertions made and the number of vesicles obtained. In the case of public vaccination this information is recorded in the register, but these details are not provided in private vaccination. The Kirkcaldy outbreak was of a severe type, as reflected in the mortality-rate. If the two doubtful cases—registered as having been vaccinated but showing no scars, and who refused the offer of vaccination—are added to those showing definite evidence of more or less imperfect vaccination, the mortality in that class was 8 in 33. The mortality in the unvaccinated class (including the infant born with small-pox) was 5 in 10. The extensive vaccination and revaccination of contacts and of large numbers of the general population in Kirkcaldy has proved to be a valuable weapon in the hands of the authorities in combating the outbreak, which, it is hoped, has now been effectively checked.

THE WEATHER OF 1912.

The total amount of bright sunshine recorded during 1912 at the Royal Observatory, Edinburgh, by the Campbell-Stokes instrument was 1,071 hours, or 29.3 per cent. of the possible. This shows a deficit of 308 hours when compared with the average of twelve years, and of 474 hours when compared with 1911. June and August were remarkably sunless, and only aggregated 135 hours, or 40 per cent. of the normal, while December could only muster 16 hours. April was the sunniest month, with 176 hours, but all the others, with the sole exception of September, were below the average, and the year has

no parallel during the twelve years over which records extend.

The total rainfall for the year measured 26.91 inches, as against an average for seventeen years of 25.22. April was by far the driest month, the total being only 0.24 inch, but the fall during January, May, October, and November was below the average. August was the wettest month, with 4.75 inches, but Edinburgh was fortunately too far north to share in the phenomenal floods which devastated East Anglia on August 25th, when nearly double the Edinburgh fall for the whole month came down in twenty-four hours. On two days—August 4th and September 30th—the fall exceeded 1 inch, as against one day in 1911 and six days in 1910. There were eighteen consecutive days without rain in April, and twenty in September.

The mean shade temperature for the year was 46.8° F., which is the exact average for the past seventeen years. All the summer months were cooler than usual, and August and September were the coldest on record at this observatory. July was the warmest and January the coldest month. The shade temperature only once exceeded 70° (74.6° on July 12th).

Snow fell on fourteen days during the year, but in no case to any considerable depth, nor did it ever lie for more than a few days.

Ireland.

[FROM OUR SPECIAL CORRESPONDENTS.]

EMIGRATION FROM IRELAND IN 1912.

ALTHOUGH over 29,000 emigrants left Ireland last year there was a reduction of over 1,200 compared with 1911. In fact, with only two exceptions—that is, 1903 and 1909—the number for 1912 is the smallest recorded in any year since 1890, before which date such statistics were not kept. In spite of this distinct reduction in the numbers there were six months of the year during which they exceeded those of the corresponding months of 1911. Though no fewer than 20,466 of the 27,477 who emigrated to foreign countries and the colonies went to the United States, there has been a distinct increase in the number going to the colonies. The decrease was distributed over the four provinces, but Ulster, where the decrease is smallest, is still responsible for about 60 per cent. of the total number of emigrants.

Victoria.

MEDICAL INSPECTION OF SCHOOL CHILDREN.

THE report of the school medical officers for 1911 has lately been issued, the second since inspection has been instituted. The number of children examined was 9,601. The inspectors state that the year's results amply support the statement in the last report, that a large amount of unsuspected defect and disease exists in the apparently healthy children of the schools. About one child in every six has some defect of vision, one in seven defect of hearing, and one in four defect of the nose and throat, while deformities of posture are frequent, and dental decay almost universal, not one in twenty having a clean mouth. Only about one-third of the children in metropolitan and one-half in country schools escape notification to parents for defects of vision, hearing, nose and throat, and general defects (heart, lungs, etc.). As a result of the notification, the immediate response of parents has been only a moderate one, one in four of all children visiting a doctor, oculist, or dentist. As all Australian boys are, under the Defence Acts 1903-11, required to serve as junior and senior cadets, and as it is necessary to submit each boy to medical examination on his entrance to the service, the question arises whether it would not be more economical and more effective to utilize the school medical inspectors for this purpose. An interesting and unique feature of the work for 1911 was the examination of the aboriginal children at the Lake Tyers State School, sixteen in all. Physically the girls were well developed, and appeared

well above the average in height and weight. Of the defects found the most marked was the presence of enlarged tonsils and of post-nasal growth. Amongst the girls no skin disease was found, but one very bad case came under notice among the boys. Contrary to expectation the teeth were found to be very defective, caries being almost as common as amongst white children.

Correspondence.

ANTIVIVISECTION IN GLASGOW.

SIR,—In my letter which you published on December 14th, 1912, I stated, with regard to the antivivisection lecture given here by Dr. Hadwen, that "another part was devoted to the immorality of drinking alcohol, and the uselessness and danger of vaccination." Dr. Hadwen states in his letter you published on December 28th:

This assertion is simply amazing and almost unpardonable; not one word about alcohol drinking or vaccination escaped my lips the whole evening.

The following gentlemen were present at the lecture besides myself: Dr. Cathcart, Dr. J. Mill Renton, Dr. William Campbell Mackie, Dr. Charles Bennett, and Dr. H. E. Whittingham. I have spoken to all of them, and they allow me to state that they all agree with me that the following is accurate and true in substance with regard to what Dr. Hadwen said about alcohol and vaccination. He said that the opinion of the public and of the profession had changed with regard to the use of alcohol. He quoted the story of a man who many years ago was refused by an insurance office because he was a total abstainer, and pointed out that now some offices gave specially advantageous terms to abstainers. He said that vaccination was useless and dangerous, and in support of this he said that he had never been vaccinated, that he had frequently been exposed to contagion, but that he had never caught small-pox. He spoke at length upon both these subjects, and said a great deal more than I give here, but that he said these particular things we are all agreed. I have not the slightest doubt that if I knew who had been at the meeting I could produce many more witnesses who would remember these things.

Now this is positive and not negative evidence. One reputable person who is prepared to swear that a certain thing was said upon a certain occasion is worth any number who will swear that it was not.

In view of the fact that Dr. Hadwen actually spoke at length upon subjects with regard to which he declares not one word escaped his lips during the whole evening, it is perhaps unnecessary for me to say that other statements in his letter are made in such a manner as to be entirely misleading. Dr. Hadwen did ask a question regarding the centrifuge. Dr. Hadwen did imply that though Sir Frederick Treves had practised vivisection formerly, he now disapproved of it. This is perfectly obvious from the report in the *Glasgow Herald* which Dr. Hadwen says is almost verbatim. His attack upon Sir George Beatson occupied a large part of his lecture; it occupies more than half the report in the *Glasgow Herald*. I have the report before me and have just measured that part devoted to the lecture, excluding the discussion. Yet Dr. Hadwen refers to this report as supporting the statement that he only made two references to Sir George.

That Dr. Hadwen should consider the recovery of a micro-organism from the body of an individual inoculated with this organism as an astounding feat is more surprising than the feat itself, which any one with any experience in a pathological laboratory must have seen performed hundreds of times as a matter of routine. But then we must remember that Dr. Hadwen considers that Pasteur was "a French charlatan" and that to him the greatest surgeons here and abroad are "Lister and his fatuous school." He regards the peerage conferred upon Lister as "one of those ironies of history which should be a warning to 'science' in the future." Finally, he declines to put what he professes to believe to the proof. He is prepared to risk nothing to demonstrate either that he really believes his own statements, or to prove by demonstration that there is any justification for the cause he advocates, otherwise he

would accept my challenge and allow himself to be inoculated with some of those micro-organisms in which he says he does not believe, the organisms having been washed thoroughly free of the "environment" in which he says he does believe.

I have said enough, and more than enough, about Dr. Hadwen and his lecture, but I should be glad if you would permit me to say a few words with regard to an offensive statement in Dr. Hadwen's letter which does not refer to myself only. In writing of me he says:

He had two or three hundred students at his back, howling, yelling, and gesticulating like dancing dervishes.

This implies that the students were there on my account, came to back me, and behaved disgracefully. As a matter of fact, I had nothing to do with their being there, and was not known to them even by sight. I am not connected with the university. The lecture had been freely advertised, and one of the well-known and disgusting antivivisection exhibitions had been in the town for some time. With regard to the behaviour of the students, speaking as one who has had a good many years' experience in official capacities of university students, I have no hesitation in saying that they were extraordinarily good tempered under considerable provocation. The tub-thumping, gesticulating, and posturing type of oratory is irresistibly funny to the healthy male youth, which Dr. Hadwen evidently did not realize. Had I, as he did, waved my arms and body about in the course of any of the lectures I have had to give in different universities I should have expected, and doubtless should have got, at least the same treatment as he did. However, they gave him a perfectly fair hearing in spite of the interruptions, and received his grossly offensive remarks about themselves with perfect good humour. They evidently regarded his exhibition of temper as being as funny as his oratorical methods. They came to see fair play, and they achieved their object admirably. Every one who spoke was subjected to interruptions, just as Dr. Hadwen was, but every one was allowed to say what he wanted to say as far as the students had anything to do with the matter.—I am, etc.,

Glasgow, Dec. 27th, 1912.

CHARLES WALKER.

HUMAN AND BOVINE TUBERCULOSIS.

SIR,—In the letter of Dr. T. Readman, published in the *BRITISH MEDICAL JOURNAL* of January 11th, occurs the following remark: "The poorer classes in China do not suffer from tuberculosis, whereas among the dominant Tartar class (milk and meat consumers) the disease is prevalent." China is a large country, and European medical men who have had experience of disease amongst the Chinese must be comparatively few. It would be interesting to learn something of the nature of the experience of the medical man who gave rise to the above statement. A relative of mine, who is medical officer to a mission hospital in China, has told me that the only cattle in the district in which his hospital is situated are draught animals. Children never under any circumstances are given milk from the cow, yet all the forms of tuberculosis met with in England are admitted into the hospital for treatment.

Preconceived ideas often determine the character of observations, and it is justifiable to doubt whether any of the statements quoted by Dr. Readman would bear careful investigation. Amongst these statements is one which says that "tuberculosis is unknown in Morocco, where there are no European dairy cows." Of medical experience in Morocco I know little, but a medical man—also a relative—resident for twenty-three years in districts in Central Africa, where the natives possess no domestic cattle, has informed me that tuberculosis is by no means unknown.

We are asked to await with equanimity the publication of the full reports of the Edinburgh investigation upon questions connected with infection from bovine tuberculosis. Edinburgh justly holds a high reputation throughout the world for soundness of judgement, but even in Edinburgh it is possible for preconceived ideas to influence observations and conclusions of the mind. Although the interest of some medical men in Edinburgh in various aspects of tuberculosis is stimulating, certain

teaching which emanates from there is, it seems to me, likely to give rise to difficulty.

In another part of the same issue of the *BRITISH MEDICAL JOURNAL* is a reference to the last annual report upon medical inspection of school children by Sir George Newman. It is suggested that the school children might with advantage be referred to specialists when the question of the presence of pulmonary tuberculosis arises. In a previous report respect has been expressed for the teachings of Edinburgh in the matter of tuberculosis in children. To refer children to specialists who hold Edinburgh views upon the diagnosis of pulmonary tuberculosis in children, I believe, would be unfortunate. It is my contention that the teaching which is becoming widely spread from Edinburgh displays little knowledge of morbid affections of the lungs, of chronic nature, occurring in children as seen in the *post-mortem* room, and that reliance upon methods of diagnosis without this knowledge will militate against successful dealing with the disease.—I am, etc.,

January 13th.

THEODORE FISHER.

THE SPHYGMOGRAPH, REFERRED PAIN, AND SOMERSAULTS.

Sir,—There are three articles in the *JOURNAL* of January 11th which deserve to be specially noticed: (1) "Dynamical Diagnosis of the Pulse." I am old enough to remember when neither the sphygmograph nor thermometer were used by physicians even in the Edinburgh School of Medicine. By working with these two instruments, while resident physician in the University clinical wards of the Royal Infirmary in Edinburgh, I made observations and experiments which, owing no doubt to their originality, being made the subject of my graduation thesis, were awarded the gold medal. The thermometer is now regarded as an indispensable instrument in the diagnosis of disease, chiefly, I believe, through the improvements on the old instrument, but the sphygmograph, in spite of its imperfections is a far more reliable guide, not only in diagnosis but in treatment, than the thermometer. Both require skill and care in their use, for both may do more harm than good in unskilled hands. Few would think of trusting to a nurse to take a sphygmographic tracing, but a reliable observation with the thermometer is almost as difficult; nevertheless, the nurse too often has to record the temperature of the patient. I have seen temperature charts, used to illustrate febrile diseases by physicians, whose falsity was apparent to any one who had used the thermometer in such diseases with care and intelligence. By its use I was able to show that in every infectious disease there is a primary and a secondary fever, before any bacillus had been discovered to account for them; but I found that the sphygmograph gave a much earlier indication of a favourable or fatal issue than the thermometer, and I feel sure that in time it will be considered as necessary as the thermometer in the diagnosis and treatment of disease. As to the "plentitude" and "intensity" of the pulse beat, without the previous study of sphygmographic tracings they can have no meaning. Hippocrates himself without a sphygmograph would have had no chance with the average modern practitioner, who understands the indications that instrument is capable of giving. I would therefore urge my professional brethren, in spite of the Insurance Act, to take to the study of the sphygmograph and they will get a rich reward, were it only for their surpassing skill in prognosis. The sphygmomanometer is, so far as I have seen, a comparatively useless instrument, and owes its popularity more to the ease with which it can be used, and the little skill required in its use, than to the value of any indications it gives.

2. "The Sensory Phrenic and Its Organs." That article I look upon as an acknowledgement of our ignorance of the sensory nerves, and the need there is for more knowledge as to their relation to those of motion. I have little doubt that every ache and pain will in time be discovered to be "referred." Toothache and neuralgia in the region of the teeth is an example deserving of study. With a decayed tooth we will have toothache every time we make the saliva acid by sugar for example, and if we continue for three days to take too much sugar we will have neuralgia all round the decayed tooth proceeding

from the nerve centre, and owing to the over-acidity of the lymph. The toothache as well as the neuralgia is "referred," but neither occurs without some decay. Such is with every ache. A solution of continuity, or some degenerative change in a spot on the skin, or on the mucous membrane of any part of the intestinal tract, will cause first an ache and then neuralgia, all "referred," but perhaps far from each other. Thus a wrong meal may cause angina pectoris, apoplexy, or heart failure in those suffering from the Russian physician's new disease, "idiopathic anasarca"—just another name for the "plethora" of Hippocrates.

3. "Somersaults at Sixty." This article rightly understood emphasizes the fact that it is not years that make us stiff and unable to turn somersaults, but the bad habit of eating for pleasure and by the clock. If the Romans could conquer the world, eating only one meal in the twenty-four hours, what excuse can we have for eating oftener? If we do, need we wonder that we require doctors, of whom Rome in her best days would have none within her walls.—I am, etc.,

Denholm, Hawick, Jan. 11th.

JOHN HADDON, M.D.

NAPOLEONIC RELICS.

Sir,—With reference to the interesting address by Dr. A. Keith, on the alleged *post-mortem* relics of Napoleon, the question is raised as to the whereabouts of the molar extracted by Dr. O'Meara, and sold at the sale of the latter's effects for 7½ guineas. This tooth is without doubt in Madame Tussaud's Museum, and has the following label attached:

Tooth of Napoleon, extracted by Dr. O'Meara. It is said that the Emperor suffered much, and had three extracted by him. On visiting Italy the doctor gave one to Madame Mère, one to the ex-king of Spain—Joseph—and the last he kept."

The relic is an upper third molar. In the same museum, among several other personal belongings of the Emperor, is also exhibited a toothbrush which has no apparent signs of wear.

In *Napoleon, the Last Phase*, by Lord Rosebery (p. 231), it is stated:

His digestion endured for a life-time, hearty meals, devoured in a few moments, and at odd times. His first tooth was extracted at St. Helena, and then it appears unnecessarily. But this operation was the only one he ever under-went.

In the *BRITISH MEDICAL JOURNAL* (March 2nd, 1912), the following remarks with reference to his rapid feeding appear:

Napoleon ate very fast, remaining at the table only from eight to twelve minutes—a bad habit, which caused continual indigestion. This haste led to neglect of ordinary decencies of the table, the Emperor often using his fingers in place of a fork or a spoon. He even drank out of the dish, and steeped his bread into the sauce. He followed no order in his feeding, passing from side dishes to the *hors d'oeuvres* and back again to the roast. He would not be trammelled by the order of a classic meal.

According to the recent work by Dr. Chaplin, *The Illness and Death of Napoleon Buonaparte*, there is a strong possibility that the cancerous condition of Napoleon's stomach arose from chronic gastric ulceration, and when we consider the peculiar habits of Napoleon when feeding, it is not startling that his gastric apparatus broke down from the abnormal strain, and this would naturally predispose to malignant growth.

I do not know of any available information as to Napoleon's back teeth, but in Lord Rosebery's work are quoted the following observations on Napoleon's appearance (p. 254): "Teeth are bad and dirty but he shows them very little"; and also, "Good white, even teeth, but small (he rarely showed them)."—I am, etc.,

CYRIL H. HAWKINS, M.R.C.S., L.D.S.

Birmingham, Jan. 15th.

UNDER the will of the late Mrs. Annie Maria Jones, of Rusholme, the Victoria University and Manchester Royal Infirmary each receive a donation of £1,000. Other bequests include sums of £500 to the University College of Wales at Aberystwyth, and £300 each to the Children's Hospital at Pendlebury, Manchester, the Christie Cancer Hospital, the Manchester Surgical Aid Society, and the gynaecological department of St. Mary's Hospital. The testatrix was the widow of the late Mr. Thomas Jones, who until his death some fifteen years ago was Professor of Surgery at Owens College.

Obituary.

WILLIAM HOWSHIP DICKINSON, M.D. CANTAB.,
F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO ST. GEORGE'S HOSPITAL.

THE announcement of the death on January 9th of Dr. William Howship Dickinson will be received with deep personal regret by all old students of St. George's Hospital who are approaching or who have now reached middle age, as well as by many others who knew him at the Hospital for Sick Children in Great Ormond Street and as an active member of the medical societies of London.

William Howship Dickinson was born at Brighton in 1832 and educated at Caius College, Cambridge, of which he was at the time of his death an honorary fellow. He entered St. George's Hospital in 1851 when J. A. Wilson, Nairn, Page, and Bence Jones were physicians and Pitman and Fuller assistant physicians. He graduated M.B. Cantab. in 1859 and M.D. in 1862. His first appointment at St. George's Hospital was that of curator of the museum. At that time there was a strong company of Cambridge men at St. George's Hospital with Timothy Holmes and Dickinson at their head, and included Reginald Thompson, Robert James Lee (son of Dr. Robert Lee, for many years obstetric physician to St. George's Hospital), and Sir William Dalby. He became assistant physician to St. George's Hospital in May, 1866, physician in 1874, and became consulting physician on his retirement in January, 1894.

Dr. Dickinson was appointed assistant physician to the Hospital for Sick Children, Great Ormond Street, in 1861, physician in 1869, and consulting physician in 1884.

He became a Member of the Royal College of Physicians of London in 1858, and was elected a Fellow in 1865. He held many offices in the College; he was an examiner for three periods between 1872 and 1884, he served on the Council from 1879 to 1901, was a Censor in 1885-86, and Senior Censor in 1892. He delivered the Croonian Lectures in 1876; the Lunnleian, on the tongue as an indicator of disease, in 1888; and the Harveian Oration in 1891. He was an examiner in medicine to the Royal College of Surgeons of England at various periods, and to the universities of Cambridge, London, and Durham. As an examiner he was strict but courteous, and in oral examinations put the candidate at his ease by giving him the impression that the object was to ascertain what he knew and not so much what he did not know.

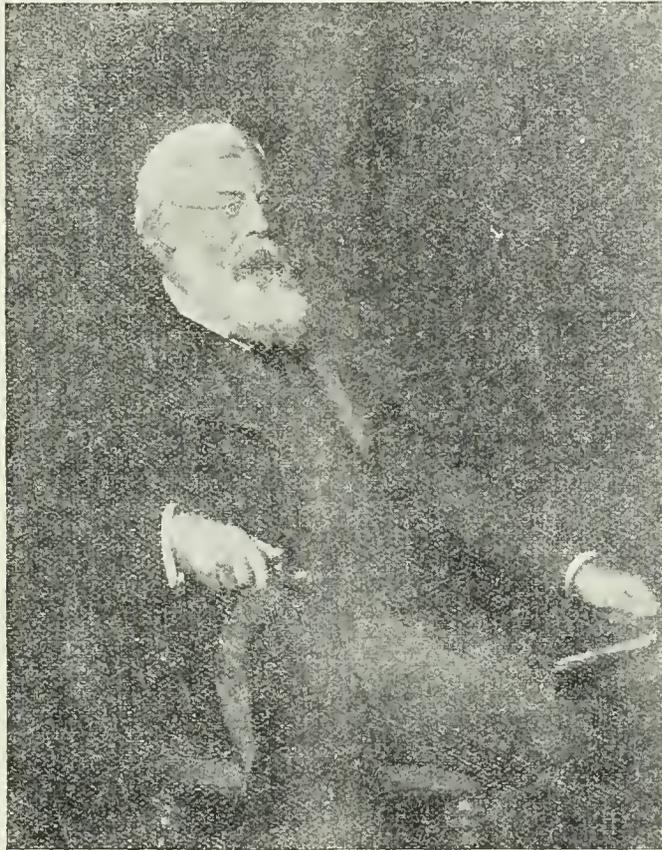

Dr. Dickinson was vice-president of the Section of Pathology and Bacteriology at the annual meeting of the British Medical Association held at Cambridge in 1880, and president of the same Section at the annual meeting at Bournemouth in 1891. He was president of

the Section of Diseases of Children at the annual meeting at Bristol in 1894.

We are indebted to a colleague of Dr. Dickinson's for the following estimate of the value of his contributions to clinical medicine:

Dr. Dickinson was an all-round physician and wrote on nearly all branches of medicine. His advice was most often sought in consulting practice for diseases of the kidney and of children on account of the book (1875-85) on renal and urinary affections and because of his long connexion with the Hospital for Sick Children; but his contributions to diseases of the nervous, cardio-vascular, and digestive systems were numerous and always worthy of attention both for the matter and for the purity of his Addisonian English. With the exception of a now forgotten *Experimental and Pathological Inquiry into the Functions of the Cereb. Trunc.* (1865), which entailed operations upon snakes, frogs, and fish), his work was based on

hospital cases observed during life and carefully checked by the *post-mortem* results, the statistical method being largely used in arriving at conclusions. It is difficult to decide how far medicine of the present is indebted to writers of a past generation; for a few years after a fresh point is established the observer's name accompanies the statement; but except on epoch-making advances the name soon drops out of the current textbooks. In order to form a just impression of his influence on contemporary medicine, reference will now be made to some of Dr. Dickinson's more important contributions, most of which are referred to in the first edition of *Fagge's Principles and Practice of Medicine* (1886). He attacked the embolic hypothesis of chorea, and described arterial haemorrhages and peri-arterial degeneration in the brain and cord (1875). From his experience at the Hospital for Sick Children, Great Ormond Street, he wrote

W. Howship Dickinson

on the visceral changes in rickets and on hepatic cirrhosis in children. In a statistical paper on the morbid effects of alcohol as shown in persons who trade in liquor (1872) he showed that alcohol favours tuberculosis of all sorts, but contended that the injurious effect of alcohol on the kidney had been exaggerated, on the ground that the incidence of renal changes was practically equal in 149 persons exposed to alcohol and in a corresponding series not so handicapped. His observation of hereditary albuminuria in four generations of a family has not, perhaps, attracted its due share of attention. Although Treitz had long before described uraemic ulceration of the intestine in chronic renal disease, and ascribed it to the irritating effects of ammonium carbonate, Dickinson's account of albuminuric ulceration was entirely independent; he examined 22 cases, including three of gastric ulceration, and brought forward evidence to show that the ulceration was due to previous haemorrhage in the intestinal wall. By a long series of observations and drawings made by his own hand of sections he showed that the media of the larger arteries is hypertrophied in chronic renal disease. His *Harveian Oration on Dropsy* (1891) and an elaborate

paper on this same subject in the *Medico-Chirurgical Transactions* for 1892, in which he concluded that the dropsy was truly cardiac though not cardiac *ab initio*, were based on prolonged examination of the cardiac vascular system in renal disease. Influenced no doubt by Fuller's results at St. George's Hospital, he was a strong advocate of the alkaline treatment of rheumatism, and later brought forward statistical evidence in favour of the view that the incidence of cardiac complications is lowered by adding full doses of alkalis to salicylates. In 1897, when President of the Royal Medical and Chirurgical Society, he gave an account of some cases of pure aortic stenosis in which the only murmur was a musical apex bruit due to mitral regurgitation.

During its periods of greatest activity, when morbid anatomy constituted progressive pathology and was advanced by the younger clinicians, Dr. Dickinson was a prominent figure at the Pathological Society of London, of which he was successively Secretary (1869-71), Vice-President (1872), and President (1889-90). He contributed numerous papers and took part in several important debates, such as those on diseases of the lymphatic system, including leukaemia and lymphadenoma (1870), on lardaceous disease (1879), which he introduced, and on the morbid anatomy of diabetes (1883).

On the last two subjects he had previously expressed very definite opinions, which, though they have not met with the sanction of general opinion, are of some historical interest. In 1867 he read a paper before the Royal Medical and Chirurgical Society, in which he argued that lardaceous or amyloid disease was due to the presence of dealkalized fibrin in the affected organs, and that this infiltration was caused by the removal of potash which occurred in the suppurative processes responsible for the change. He therefore proposed, as a more accurate title, "depurative disease." When, twelve years later, he opened the discussion at the Pathological Society on this subject, his views met with considerable criticism and opposition. In 1870, at the Royal Medical and Chirurgical Society, he described as "the morbid changes in the nervous system in diabetes" empty spaces around the blood vessels, especially the arteries, in the central nervous system. The significance of this change, which was soon widely copied into textbooks, was subsequently challenged at the discussion at the Pathological Society by Dr. F. Taylor and Dr. Hale White, and a committee appointed to report on the question came to the conclusion that the nervous system does not present any constant lesion in diabetes, and that some of the appearances are due to artefacts.

He was a student of disease rather than of medical literature, and until the time limit necessitated his retirement from the active staff of the hospital was constantly engaged on some clinico-pathological problem or research. Entering in collecting his data, he stuck to his conclusions against all opposition, and made a vigorous fight for his beliefs. This was exemplified by the controversy on what he termed "the presystolic murmur falsely so called." Though a notable physician and pathologist in his generation, it seems unlikely that his name will be specially connected with any important advance in the science at which he worked so vigorously.

Dr. Dickinson retired some years ago to his house at Tintagel, where he eventually died.

Dr. Dickinson married a daughter of Dr. James Arthur Wilson, and had four daughters and two sons, one of whom, Dr. William Lee Dickinson, a man of much promise, died at an early age in 1904; the other son entered the Church.

We are indebted to another colleague of Dr. Dickinson for the following appreciation:

With Dr. William Howship Dickinson there passed away a most remarkable individuality, a man of great originality of thought, who brought to bear upon any subject which occupied his attention ideas peculiarly his own and oftentimes somewhat at variance with the opinions of his contemporaries. He held strong views on many subjects, and always made a gallant fight in supporting them.

Whatever he did, whether it was a walk from London to Brighton in the days of his youth or the strenuous advocacy of a theory in his later years, he always threw

his whole soul into the work, and, though he used to proclaim himself to be a man of peace, he seemed in reality to enjoy the amenities of controversy.

Dr. Dickinson was a great reader, and in consequence his conversation was always interesting and attractive. He had a quaint way in expressing himself and a great sense of humour. As an instance of this may be a remark which he made once to the writer on being told that an ardent student had had engraved on the stage of his microscope the words, "All thy works praise thee, O Lord." "I should have thought," said Dickinson, "We magnify thee, O Lord," would have been more appropriate." This sense of humour contributed greatly to his popularity; it was one of his chief characteristics and one of the main attractions of his daily visits to the wards of the hospital, where his audience was always a large and appreciative one. His contributions to medical literature were many and various and well known. It is only necessary to mention in this notice his early work on the kidney, to which his reputation as a pathologist was due.

A certain abruptness of manner, probably the result of shyness, was often liable to repel a first acquaintance, and those who were not fortunate enough to be able to improve that acquaintance often credited him with a coarseness which he never intended. As soon as the ice was broken one knew the man for what he was—genial, witty, and well informed. He delighted in the society of men, and was never happier than at a gathering of a dining club or when entertaining friends at his own house. Many of his sayings are still household words at St. George's Hospital, and many of those who listened to them are now asking sadly: "Where be your gibes now . . . your flashes of merriment that were wont to set the table in a roar?"

Mr. G. R. Turner, senior surgeon to St. George's Hospital, has written the following note at our request:

Dr. Dickinson in the Seventies and Eighties of last century was a great character—in the best sense of the word—at St. George's Hospital, and his practice was followed by crowds of students anxious not only to acquire medical lore and knowledge but to have the opportunity of appreciating the quiet humour with which he abounded. He believed very thoroughly in the surpassing importance of his art and made others believe it. He was in earnest and made others earnest. He regarded a hospital physician as the noblest work of God, but had a wholesome, and not unmerited, dislike of the surgery of his early days. He was always a little behind the triumphs of Listerism and spoke "of those dismemberments and eviscerations that surgeons regard with such complacency, their patients with such inquietude." He constantly advocated "the safer processes of nature," even when mechanical intestinal obstruction existed; indeed, to him surgery was a *dernier ressort*, and the surgeon but a bradawl or other occasionally useful tool. He was a masterful man in his diagnosis, to which he would hear no objection—indeed, it was irreverently said that if the required dullness was not present his stiffened finger made it. He disliked a diagnosis being made for him by his house-physician. On one occasion, on being taken to a patient suffering, he was told, from gout, he said, "A more typical case of rheumatism I never saw." Yet next day it was "typical gout" and treated as such. The interest of the patients was ever his first care, and though sometimes afraid of they were always fond of him. This too was the way students, terming him affectionately "Old Dick," also regarded him. As a lecturer he always held his audience, and cultivated even the dullest details of pathology by apt illustration and story. Of his stories he enjoyed none more than those that told against himself and his habit of sometimes thinking aloud. He was a man of backbone and character, upright, cultured, and honourable—a good friend and a bitter enemy. His picture hangs in many an old St. George's man's consulting-room, and his memory will long be affectionately treasured by them.

An old colleague and contemporary writes:

I believe no more honourable, straightforward man could be imagined, and no more true friend could any man have. His watchword was *truth*. Through a somewhat rough exterior could be detected a tender heart by those who knew him.

Dr. S. RUSSELL WELLS, who was at one time house-surgeon, house-physician, and medical registrar to St. George's Hospital, writes:

Dr. Howship Dickinson was an excellent representative of a type of physician formerly far more common than at present. Cultured, skilled, possessing considerable literary attainments and a pungent wit, he rather prided himself upon a certain brusqueness and on the freedom with which he stated his opinions.

The writer well remembers how profoundly he influenced the St. George's students of some twenty-five years ago; his aphorisms, his strong and freely expressed views and criticisms of men and things, burnt themselves into one's mind and remain as lasting impressions. Some feared and rather disliked him, but those who got to know him well admired and were devoted to him.

His intolerance and contempt for all that savoured of pretentiousness, sham, or incompetence manifested itself on many occasions. A student who was asked what he thought of the tension of a certain patient's pulse, and who tried to conceal his ignorance by saying it was "a little tense and a little soft," was promptly told that he was "a little wise and a little fool." A drunken valet, an in-patient of the hospital, who hoped to obtain extra privileges and consideration by sycophantically informing Dr. Dickinson that he was in the service of Lord So-and-So, and was in fact his lordship's most confidential servant, received as answer: "I don't know and I don't care who is your master; I know what you are, you are a drunkard, a beer drunkard;" and on the man protesting that he was almost a teetotaler, he was told, "You are a drunkard, and, what is more, you are a liar."

He encouraged an independence of mind, and taught that because a view or theory was popular at the moment it should not be accepted on that account alone. Medical writers and speakers he divided into two classes: those "who spoke because they had thought and had something to say," and those "who spoke because they thought they had to say something." If a student entered the lists with him and acquitted himself well he accounted it to the student's credit. The capping a quotation, a clever rejoinder, or a really apposite criticism pleased him. On one occasion he informed his clerks that he had been at a dinner of the College of Physicians the night before, and that there had been a man with an appropriate Shakespearian quotation to each item, and asked them if they could give him a suitable one from Milton for the wine, say the port; one of the clerks replied, "You said, sir, it was a dinner of the College of Physicians: might I suggest, 'Souls of Belial flown with insolence and wine.?' " Dickinson chuckled, and confessed that he thought it was better than the one that had occurred to him—namely, "The memory of that heavenly port."

He was intensely proud of his hospital and its traditions; woe betide the student who spoke of the digitalis, squills and mercury pill as Guy's pill, he would immediately be told that that combination was first devised by Matthew Baillie, a former St. George's physician—"Guy's pill, indeed, they stole our pill." The great Thomas Young, who was at one time physician to St. George's Hospital, was one of his heroes, and he surprised many by showing from the old records of the hospital that the average mortality in cases of pneumonia treated by Young was distinctly lower than the present mortality in that disease. *Apropos* of pneumonia, it may be mentioned that he was never tired of impressing on the students the harm that may be done by lengthy examination of such cases. "Make sure of your diagnosis, and then do not examine a pneumonia patient again until he is better, unless there is some very real occasion for it; more than this is gratifying an idle curiosity on the part of the physician at the expense of the patient."

Howship Dickinson was essentially a clinical physician, and had high ideals of the duties and responsibilities of his vocation; he taught that whenever a patient died one should if possible obtain a *post-mortem* examination, and afterwards ask oneself three questions—first, "Have I done anything that can have hastened the end?" Secondly, "Could I have done anything to have delayed or averted it?" Thirdly, "In light of what I now know how should I treat a similar case in future?" He constantly impressed upon us that we should endeavour to place ourselves in the position of the patient we were seeing, and then adopt that

line of treatment we should desire to have employed on ourselves under like circumstances.

That all his views and opinions on matters medical should subsequently have been proved to be correct is hardly to have been expected, but the majority of his former pupils must feel, like the writer, that they owe an incalculable debt to his sane, robust, and stimulating teaching.

The portrait here reproduced is from the autotype print of the oil painting by the Hon. John Collier, which hangs in the board room of St. George's Hospital.

W. R. DUGUID, M.A., M.D.,
BUCKIE.

WE regret to have to announce the unexpected death, on January 10th, of Dr. Duguid, a highly respected Banffshire practitioner: it occurred with startling suddenness when he was attending one of his patients at a farm in the country. He was going about in his ordinary health at his duties the previous day, and when he received a call to a patient at Williamstown, about three miles out of town, he motored there. The sympathy felt in the community was expressed in the tolling of the town bell for the passing of one who for half a century was prominent, not only in Buckie, but throughout the North of Scotland. As President of the Banff, Elgin, and Nairn Division of the Association, he has been attending regularly all meetings in connexion with the National Insurance Act. As the Representative for his Division he attended the last Representative Meeting, and had a few words to say on the conditions of practice in his area, while only a week or two ago, as the Representative of his area on the Scottish Medical Insurance Council, he attended the last meeting in Edinburgh. Professionally, he was well known and highly esteemed by his brethren, and exceedingly popular, especially among the fishing community. Dr. Duguid, who was 72 years of age, and was born at Uduy, was educated at Green of Uduy School, Aberdeen Grammar School, and Aberdeen University. He took the M.A. degree as long ago as 1858, he graduated M.B. and C.M.—both with honours—in 1862, and took the M.D. degree some years later. Dr. Duguid went to Buckie over fifty years ago, and opened up a practice at a time when Buckie was merely a collection of fishing hamlets. His first appointment was that of parish medical officer, which he held all along. He was at various times during his career Provost of Buckie, Chairman of Rathven School Board, President of the Moray Firth Fisheries' Association, and Surgeon-Lieutenant-Colonel of the Banffshire Volunteers. He was also an Honorary Sheriff-Substitute of Banffshire, and a Justice of Peace for the county. He served as a member of the Scottish Fishery Board for fifteen years. He had for the past few weeks been giving sittings to Mr. Allan Sutherland, of Aberdeen, who is staying in Buckie, for a public presentation portrait that was subscribed for over a large area, in commemoration of the completion of his professional jubilee. Fortunately the portrait is in a sufficiently advanced state to make its completion an easy matter. Dr. Duguid was a widower, his wife having died some years ago. One of his sons has been associated with his father in the practice.

JOHN LOUIS CHAMBERS, L.R.C.P. EDIN.,
M.R.C.S. ENG., L.S.A.

Ox December 21st, 1912, passed away at his residence, 249, Hackney Road, Dr. John Louis Chambers, at the age of 65. His practice was one of the oldest in the north-east of London, having been founded more than a century ago by his uncle, the late Dr. Frederick Chambers, who practised there for many years, subsequently retiring to Margate, where he was twice mayor. He was succeeded by Dr. John Chambers, the father of the subject of our notice. John Louis Chambers received his medical education at the London Hospital, took the diploma of L.S.A. in 1869, that of L.R.C.P. Edin. in 1870, and that of M.R.C.S. Eng. in 1871. He was born in the house in which he died, had lived all his life in Shoreditch, and was one of the senior practitioners in that borough. His familiar figure will be sadly missed in the locality and his loss lamented by a large circle of patients. He attended the meeting of the

City Division at the Shoreditch Town Hall, on December 13th, and voted with the majority. He seemed then in his usual health, but on December 15th he had a slight fit and developed symptoms of heart failure. In spite of unremitting care and attention, he gradually became worse and died, as stated, on December 21st.

WE regret to record the death of Mr. ALBERT HENRY HUGHES, of Brunswick Terrace, Plymouth, at the early age of 40. It took place on December 10th, 1912, after a very brief illness, due to appendicitis. A Bristol man by birth, Mr. Hughes received both his general and professional education in that city; he became L.S.A. in 1905, and settled two years later in Plymouth. There he enjoyed much popularity, especially among the poorer classes in the east end of the town, among whom his practice chiefly lay. He also held an appointment under the Poor Law guardians. He had begun to take interest in public affairs, and contested an election for the town council of Plymouth a year or two ago. His funeral was attended by a large gathering of his friends, including representatives of various public bodies and of his professional colleagues. Mr. Hughes, who was a member of the Plymouth Division of the British Medical Association, married some six years ago, and is survived by his wife and a daughter.

DEATHS IN THE PROFESSION ABROAD. Among the members of the profession in foreign countries who have recently died are: Dr. L. Wille, professor of psychiatry in the University of Basel, aged 78; Dr. Alfred Genzmer, extraordinary professor of surgery in the University of Halle, aged 61; Professor Jules Felix, of Brussels, formerly physician to the household of the King of the Belgians, well-known as a hygienist, and one of the founders of the Belgian Society of Hydrology; Dr. Eduard Clason, sometime professor of anatomy in the University of Upsala; Dr. Caesar von Ramdohr, formerly professor of obstetrics in the New York Post-Graduate Medical School and Hospital; and Dr. J. Wood McLane, emeritus professor of obstetrics in the Medical Department of Columbia University, New York, aged 73.

The Services.

HEALTH OF THE NAVY.

The *Statistical Report of the Health of the Navy for the Year 1911* has recently been issued.

Summary of Returns for Total Force.

The returns for the total force for the year 1911 show a continuous improvement in the general health of the fleet as compared with the preceding five years. The case, invaliding, and death ratios for the year under review are again lower than the average ratios for the last five years, and the average loss of service for each person compares favourably with the five years' ratio and with that of 1910. The total force, corrected for time, in the year 1911, was 117,100, and the total number of cases of disease and injury entered on the sick list was 76,465, which gives a ratio of 652.97 per 1,000, a decrease of 25.96 as compared with the average ratio for the preceding five years.

The number of entries per man for disease and injury was: Home Station, 0.76; Home Fleet, 0.56; Atlantic Fleet, 0.63; Mediterranean, 0.67; North America and West Indies with Fourth Cruiser Squadron, 0.56; China, 0.64; East Indies, 0.27; Australia, 0.78; Cape of Good Hope, 0.67; Irregular List, 0.73. The average for the total force was 0.65, which is identical with the average for 1910. The average number of men sick daily was 3,170.33,

giving a ratio of 27.07 per 1,000, a decrease of 1.00 in comparison with the previous five years. The total number of days' sickness on board and in hospital was 1,157,172, which represents an average loss of service for each person of 9.88 days, a decrease of 0.36 as compared with the average for the preceding five years. The ratio per 1,000 of men sick daily on the various stations was: Home Station, 35.85; Home Fleet, 23.36; Atlantic Fleet, 23.7; Mediterranean, 25.11; North America and West Indies and Fourth Cruiser Squadron, 19.84; China, 24.43; East Indies, 31.3; Australia, 23.39; Cape of Good Hope, 22.54; and the Irregular List, 40.32. For the total force the ratio was 27.07. The North America and West Indies Station, as in 1910, shows the lowest sick rate, and, as usual, the Irregular List the highest, but this is due to the inclusion of sickness of invalids on passage from foreign stations.

Invalidings.

The total number invalided was 2,110,² which gives a ratio of 18.01 per 1,000, a decrease of 1.81 in comparison with the average ratio for the preceding five years. The total number of persons finally invalided was 1,876, of whom 71 were invalided after refusing operative treatment. The ratio per 1,000 of final invalidings was 15.94, a decrease of 0.5 as compared with the average for the previous five years. Of the 2,110 invalidings, 1,970, or 16.82 per 1,000, were for disease, and 140, or 1.19 per 1,000, for injury.

Deaths.

The total number of deaths was 366, giving a ratio of 3.12 per 1,000, a decrease of 0.23 in comparison with the average ratio for the last five years. Of this number, 260, or 2.22 per 1,000, were from disease, and 106, or 0.9 per 1,000, from injury.

General Diseases.

The following is a summary of the returns under the head of general diseases:

Small-pox.—One case from the Atlantic fleet, and occurred in the *Formidable*. The disease, it is stated, was probably contracted at Gibraltar where that ship was undergoing a refit, and was of moderate severity.

Cow-pox.—845 cases, 714 of which were from the Home Station.

Chicken-pox.—15 cases, 13 of which were contracted in Home Wafers, and 2 in the Mediterranean.

Measles.—227 cases, with 4 deaths.

Tuberculosis.—279 cases; 194 from the Home Station, 48 from the Home Fleet.

Scarlet Fever.—120 cases, with 1 invaliding.

Dengue.—2 cases, both from Australia.

Mumps.—101 cases. The Home Station contributed 43, the Home Fleet 36, and the Australian Station 11.

Other Infective Diseases.—1,598 cases (including all the preceding cases). The total includes 5 cases of septicaemia, 2 of osteomyelitis, and solitary instances of ulcerative endocarditis, pyaemia, and plague. Five deaths resulted from septicaemia, 2 from ulcerative endocarditis, 1 from osteomyelitis, and 1 from pyaemia. A case of sequelae of osteomyelitis was finally invalided. The discrepancy between the number of entries for ulcerative endocarditis and the number of deaths is due to a case which was entered originally under another heading.

Influenza.—1,364 cases, with 2 deaths, giving a decrease of 12.82 in the case ratio as compared with the average. The disease was, on the whole, of a very mild type.

Diphtheria.—172 cases.

Fatigic Fever.—137 cases, with 2 final invalidings and 30 deaths. The case and death ratios per 1,000 were 1.16 and 0.25 respectively, as compared with 1.47 and 0.22, the average ratios for the previous five years.

Mediterranean Fever.—6 cases, with 1 final invaliding. The case ratio is 0.05 per 1,000, as compared with an average of 0.5. Five fresh infections are reported from the Mediterranean, three Englishmen and two Maltese being affected, in three of whom the vehicle of infection was undoubtedly unboiled goat's milk partaken of on shore.

Pyraemia.—350 cases, giving a decrease of 0.63 in the ratio as compared with the average. The Mediterranean contributed 144 of the total, but the report states that many of these were probably "sand-fly" fever.

Dysentery.—55 cases, showing a decrease in the case ratio.

Pneumonia.—455 cases, with 5 final invalidings and 30 deaths.

¹London: Published by His Majesty's Stationery Office. To be purchased, either directly or through any bookseller, from Wynman and Sons, Limited, Peter Lane, E.C., and 32, Abingdon Street, S.W.; or His Majesty's Stationery Office (Scottish Branch), 25, North Street, Edinburgh; or F. Ponsonby, Limited, 116, Grafton Street, Dublin; or from the Agencies in the British Colonies and Dependencies, the United States of America, the Continent of Europe, and Abroad of T. Fisher Unwin, London, W.C. Printed by Eyre and Spottiswoode, Limited, East Herring Street, E.C. Printers to the King's Most Excellent Majesty, 1912. Price 1s.

²This number includes men temporarily invalided from foreign stations, many of whom are again able to join the active force. The number finally invalided represents the waste of the Service during the year.

Malaria.—413 cases, with 1 final invaliding and 2 deaths, giving a decrease of 1.51 in the case ratio as compared with the average. The East Indies contributes 162 cases, of which the majority of instances of fresh infection were contracted at Bombay, while many were recurrent attacks for short periods in men who had acquired the disease during the landing at Lingah in 1910. On the whole 1911 can be regarded as a good year for malaria on the East Indies Station. The highest case ratios were furnished by this station, 70.43; North America and West Indies, 14.83; China, 9.38; Australia, 9.27; and the Irregular List, 4.58. The total, as usual, includes a large number of relapses, and does not imply that 413 individuals were affected.

Septic Diseases.—34 cases of erysipelas are returned under this heading.

Tuberculosis.—286 cases, with 237 invalidings and 38 deaths. The case, invaliding, and death ratios per 1,000 were 2.44, 2.02, and 0.32 respectively, as compared with 2.73, 2.02, and 0.27, the average ratios for the previous five years. Of the whole number, pulmonary tuberculosis contributed 245 cases, of which 25 proved fatal; joints, 9; testicle, 8; meninges, 4; glands, 4; peritonium, 3; kidney, 2. There were 6 cases of miliary tuberculosis, all fatal. The remainder were single instances of tuberculous growth of the intestine (which proved fatal), disease of bone, skin, and bladder respectively. The East Indies contributed the highest case ratio and the Home Fleet the lowest.

Veneral Diseases.—The total number of cases recorded is 13,461—namely, chancreoid, 2,349; primary syphilis, 658; secondary syphilis, 2,959; gonorrhoea and its sequelae, 7,495. There were 120 final invalidings—namely, 1 for chancreoid, 61 for secondary syphilis, and 58 for gonorrhoea and its sequelae. Four cases ended fatally, 3 being due to constitutional syphilis and 1 to sequelae of gonorrhoea. The case, invaliding, and death ratios per 1,000 were 114.92, 1.01, and 0.02 respectively, as compared with 121.23, 1.45, and 0.05, the average ratios for the previous five years. The total number of days' loss of service was 308,917, while the average daily number of men ineffective from these diseases was 846.34—a ratio of 7.21 per 1,000, as compared with 8.01, the average for the preceding five years. The China Station shows the highest case ratio per 1,000 with 147.45, and the Home Station 131.24, while the Cape of Good Hope Station, with 67.57, shows the lowest. The total days' sickness for primary and secondary syphilis is less by 10,477 days than that of 1910, so that the reduction, says the report, anticipated by the use of salvarsan as a treatment is already felt to an appreciable extent.

Rheumatic Fever.—892 cases, with 5 final invalidings and 1 death. The case and invaliding ratios per 1,000 were 7.61 and 0.04 respectively, as compared with 5.83 and 0.56, the averages for the preceding five years. The increase in the case ratio is partly due to the concentration of the Fleet in Home Waters, and to more accurate classification, rheumatic fever and muscular rheumatism being formerly classed as one in the returns. Corresponding with the increase in the case ratio under this head, there is a substantial decrease under "Organs of Locomotion."

Parasitic Diseases.—3,306 cases, of which 3,152 were scabies. The ratio shows a decrease, as compared with the average, of 5.81 per 1,000.

Alcoholism.—83 cases, with 1 final invaliding and 2 deaths, an improvement upon 1909 and 1910, and also as compared with the average for five years.

Poisons.—218 cases, with 5 final invalidings and 7 deaths. Lead poisoning was responsible for 26 cases, and ptomaine poisoning for 150, with 2 of the deaths. Of the remainder, carbon dioxide was the cause in 9 (of which 3 were fatal), coal gas 8, carbon monoxide 4, tobacco (including 3 of tobacco amblyopia) 5, morphine 2, *Jatropha Caracas* or the "physic nut" of Jamaica 2, iodoforn 2, and single cases of poisoning by zinc fumes, cordite fumes, mercury, copaiba, cocaine, turpentine, iodine, corrosive sublimate, chloroform, and jelly-fish sting.

Other General Diseases.—464 cases: 189 of gonorrhoea, 166 non-malignant and 19 malignant new growths, 10 of diabetes, 57 of anaemia, 8 of beri-beri, 5 of osteo-arthritis, 5 of climatic debility, 2 of leucocythaemia, and solitary cases of splenic anaemia, Hodgkin's disease, and pernicious anaemia. There were 14 deaths from malignant and 1 from non-malignant new growth, 2 from diabetes, 2 from beri-beri, and 1 from pernicious anaemia.

Local Diseases.

Diseases of the Nervous System.—916 cases, with 328 final invalidings and 13 deaths. The case, invaliding, and death ratios are 7.82, 2.79, and 0.1 per 1,000 respectively,

as compared with 7.66, 2.44, and 0.12, the average ratios for the preceding five years. "Nervous Diseases" accounted for 835 cases, with 282 invalidings and 12 deaths; and "mental diseases" for 81, with 46 invalidings.

Diseases of the Eye.—908 cases, with 162 final invalidings, mostly errors of refraction.

Other Organs of Special Sense.—830 cases, with 117 invalidings and 6 deaths. Diseases of the ear accounted for 749 cases, 113 of the invalidings, and all the deaths; diseases of the nose for 81 cases, and 4 of the invalidings.

Diseases of the Circulatory System.—728 cases, with 329 final invalidings, and 38 deaths. The case, invaliding, and death ratios are 6.21, 2.8, and 0.32 per 1,000 respectively, as compared with 5.75, 2.00, and 0.33, the average ratios for the preceding five years. Organic heart disease accounted for 253 cases, with 265 final invalidings, and 29 deaths; functional heart disease 195, with 29 final invalidings; aneurysm for 22, of whom 8 died; diseases of veins, 244; and 14 other diseases, of whom 1 died.

Diseases of the Respiratory System.—8,108 cases with 92 final invalidings and 8 deaths. The case ratio shows a decrease of 0.36 per 1,000, as compared with the average for five years. Catarrh furnished 6,867 of the cases; the remainder include 138 of diseases of the larynx, 629 of bronchitis, 304 of pleurisy, 66 of asthma, and 104 of "other diseases."

Diseases of the Digestive System.—13,445 cases, with 141 final invalidings and 29 deaths, giving case, invaliding and death ratios of 114.81, 1.2 and 0.24 per 1,000 respectively, as compared with 104.14, 2.08, and 0.2, the averages for the previous five years. The increase of 10.67 in the case ratio is mainly due, says the report, to the large number of entries returned for minor diseases, sore throat, tonsillitis, and enteritis being exceptionally prevalent on the Home, Mediterranean, and Australia Stations. "Mouth and teeth" diseases accounted for 848 cases, with 3 invalidings; sore throat and tonsillitis for 6,388; gastric and intestinal diseases for 1,388 and 3,504 respectively; hernia for 669, with 86 invalidings, 27 of whom refused operative treatment; haemorrhoids for 440; hepatitis for 54; other diseases of the liver, chiefly catarrhal jaundice, 154. Among the cases under intestinal diseases there are notes of 302 cases of appendicitis, 122 of which were operated upon. The highest case ratios were furnished by the Home Station, East Indies, and Irregular List; the lowest by North America with the Fourth Cruiser Squadron, Home Fleet, and Atlantic Fleet.

Diseases of the Lymphatic and Glandular System.—592 cases with 1 final invaliding and 1 death. Non-venereal bubo accounted for 412 cases. The East Indies, the Cape of Good Hope, and the Irregular List show the highest ratios.

Diseases of the Urinary and Generative System.—906 cases, with 89 final invalidings and 14 deaths. Renal diseases, mainly various forms of nephritis, accounted for 13 of the deaths and a majority of the invalidings, but a considerable number of persons were also invalided for incontinence of urine.

Diseases of the Organs of Locomotion.—1,516 cases with 72 final invalidings. The case ratio is 12.94 per 1,000, as compared with 17.31, the average for the preceding five years, the decrease corresponding with the apparent increase under the heading "rheumatic fever." Diseases of joints accounted for 15 invalidings, but the majority were called as "other diseases," the commonest cause being flat-foot.

Diseases of the Connective Tissue and Skin.—8,923 cases, with 14 final invalidings and 2 deaths. The case ratio varied from 140.86 in the East Indies to 63.61 and 65.19 in the Home Station and Home Fleet respectively.

Injuries.

(a) **General.**—331 cases, with 3 final invalidings and 68 deaths, the case and invaliding ratios being nearly identical, and the death ratio slightly decreased as compared with the averages. The deaths were due to: Drowning, 43; burns and scalds, 2; heat-stroke, 4; caisson disease, 1; asphyxia, 4, 2 of whom were due to the inhalation of vomited liquid when drunk ashore; suffocation, 2. Three cases of caisson disease were recorded, and 211 of heat-stroke.

(b) **Local.**—15,950 cases, with 111 final invalidings and 26 deaths, giving case, invaliding and death ratios of 136.2, 0.94, and 0.22 per 1,000 respectively, as compared with 142.06, 1.17, and 0.16, the average for the previous five years. Under the heading, "Burns and Scalds," 1,280 cases are classed, and 14,670 under "Injuries."

(c) **In Action.**—Three wounds in action are recorded. Two of the entries, however, refer to one man, who was wounded when a punitive party was landed from the

Torch in the Solomon Islands, and the other occurred in the Persian Gulf during the operations against gun-runners.

Suicide.

Twelve deaths are returned under this heading, 4 each by cut-throat and by drowning, 2 by gunshot, 1 each by hanging and by jumping into a dry dock.

Papers.

An appendix to the report contains an interesting communication on Yangtze Fever, by Surgeon W. Harold Edgar, M.B. A case of bullet wound of posterior tibial artery is recorded by Staff Surgeon J. Martin. Fleet Surgeon P. W. Bassett-Smith, C.B., R.N., contributes a paper on the serum diagnosis test for syphilis at Haslar during 1911. Fleet Surgeon R. H. J. Browne reports a case of plague at Shotley. The Royal Navy is to be congratulated on the continuous improvement in the health of the force shown by the report, and the papers are a proof of the professional efficiency of the medical officers.

ARMY MEDICAL SERVICE.

The Secretary of the War Office announces that the appointment of Director-General, Army Medical Service, will in future be tenable for four years, as in the case of other staff appointments at army head quarters, instead of for three years, as hitherto. Surgeon-General Sir W. L. Gubbins, K.C.B., whose tenure was due to expire on March 6th, will, therefore, continue in his appointment of Director-General, Army Medical Service, until March 6th, 1914.

Medico-Legal.

WORKMEN'S COMPENSATION.

Appendicitis and Accident.

In the case *Brewster v. Bradford and Co.* (Stafford, December 6th, 1912) it appeared that the deceased workman had been employed by the respondents, and had visited the County Asylum to obtain particulars prior to his firm submitting a tender to do certain work. While there he fell from a ladder a distance of 13 ft., and afterwards complained of having received an injury. The question at issue was the connexion between this fall and the man's death, which took place some time later. An operation was performed on the deceased at Leeds Infirmary for appendicitis, and a tin-tack was found in the appendix. Medical evidence was called on behalf of both applicant and respondent.

His Honour said that both he and the medical referee agreed that it was a case of appendicitis caused by a foreign body being in the appendix, but they were not satisfied that death was brought on by the fall "lighting up" the tin-tack. Judgement would therefore be for the respondents. Costs were not asked for.

Medical News.

DR. PERCY E. ADAMS has been presented by his patients and friends with a handsome pair of silver candlesticks suitably inscribed and a cheque on leaving Hartley Wintney, where he was in practice for eleven years.

THE Gresham Professor of Physic, Dr. F. M. Sandwith, will continue his lectures on the relief of the sick and wounded in war on Tuesday, January 28th, and the three following days. The lectures will be given at the City of London School, Victoria Embankment, at 6 p.m. each day, and are free to the public.

At the request of the Council of the Pharmaceutical Society of Great Britain, Professor R. T. Hewlett, M.D., will give a course of three lectures on microbiology and pathological chemistry and micro-copy in relation to the pharmacist in the lecture theatre of the Society at 8 p.m. on Wednesdays, January 22nd, February 19th, and March 19th.

MR. E. HURRY FENWICK, F.R.C.S., Professor of Urology, and Consulting Surgeon to the London Hospital, will give a course of three lectures on the haematogenous infections of the kidney in the clinical theatre of the hospital on Monday, Wednesday, and Friday, January 20th, 22nd, and 24th, at 1.30 p.m. The attendance of members of the medical profession and medical students is invited.

THE *Times* states that the executive committee of the Liberal Association of the Harborough Division of Leicestershire has decided to recommend the name of Sir Victor Horsley for adoption as Liberal candidate on the retirement of Mr. J. W. Logan, which will take place at

the next general election. Sir Victor Horsley contested London University in 1910, when he was defeated by Sir Philip Magnus. He was adopted for North Islington in 1911.

THE Metropolitan Asylums Board, on January 11th, received a letter from the Local Government Board approving the arrangements proposed to be made at the Downs School for the conversion of the premises into a tuberculosis sanatorium in co-operation with the London County Council. It was announced that in future the institution would be known as the Darenth Sanatorium. The cost of alterations to the premises was stated to be £1,645: this will be borne by the London County Council.

WE are informed by the Imperial Merchant Service Guild that it has drawn the attention of the Board of Trade to a letter from Dr. Edridge-Green which appeared in our issue for January 4th, and has expressed a hope that a previous omission will be rectified by the Board taking advantage of an offer made by Dr. Edridge-Green at the time the committee on colour blindness was sitting. The Board of Trade at present proposes to classify colour blindness by measuring the luminosity of the colour sensation by the flicker method, but Dr. Edridge-Green is prepared to show by actual cases that this method may result in a colour blind person being returned as normal and a normal person as colour blind.

THE Local Government Board has issued a circular to port and riparian sanitary authorities calling attention to the fact that cholera is now prevalent in and around Constantinople and in a number of districts and ports in Asia Minor and Syria, and is severely epidemic in Mecca and Hedjaz, from which pilgrims are now returning to Turkey, Egypt, and Southern Europe. It is hoped that the statement issued weekly by the Board to medical officers of health of port and riparian sanitary authorities, which contains information as to such cholera occurrences as come under notice, will be of assistance in enabling them to keep themselves informed as to the spread of the present outbreak of cholera. Reference is made to the General Order issued on September 9th, 1907, relating to cholera, yellow fever, and plague on ships arriving from foreign ports.

A CURIOUS case has just been decided in the Saxon medical ethical courts. A certain specialist for skin and venereal diseases had employed a lay assistant for a number of years. This man was sentenced to imprisonment for an unnatural offence in 1910. A complaint was lodged against the specialist for continuing to employ the man after having become aware of the nature of his habits. The local court dismissed the charge, but the matter was referred to the court of appeal, which reversed the findings of the lower court, holding that, inasmuch as the man was brought into close contact with patients in carrying out injunction and other forms of treatment, the patients were exposed to an unwarrantable risk, and further that the knowledge of the facts would tend to lower public respect for the profession. The court of appeal, however, holding that the specialist only continued to employ the man out of pity, did not pass any sentence and did not require the defendant to pay costs.

A QUARTERLY court of the directors of the Society for Relief of Widows and Orphans of Medical Men was held on January 8th, the President, Sir Thomas Boor Crosby, in the chair. Sixteen directors were present. Two gentlemen were elected members of the society, and it was reported that three members had died since the last court. The sum of £514 was paid in December, 1912, as a Christmas present to the widows and orphans in receipt of grants, each widow receiving £10, each orphan £5, and each orphan on the Copeland Fund £10. This grant is in addition to the usual half-yearly grants. The invested funds of the society now amount to £101,600; £1,313 10s. was voted for the payment of the half-yearly grants. An application for relief was received from the widow of one of the members on behalf of herself and five orphans: her late husband had paid in subscriptions £16 16s. The court voted a grant at the rate of £50 per annum for the widow and £20 per annum for each orphan, making a total grant of £150 per annum. In addition, the widow will probably receive at Christmas £10, and each orphan £3, bringing the total amount she will receive from the society up to £175 per annum. A more striking example of the advantages of joining the society can hardly be shown. Membership is open to any registered medical practitioner who at the time of his election is resident within a twenty-mile radius of Charing Cross. The annual subscription is two guineas. Special terms for life membership. Further particulars and application forms for membership may be obtained from the Secretary at the offices of the Society, 11, Chandos Street, Cavendish Square, W.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

THE following candidates have been approved at the examinations indicated:

D.T.M.H.—A. B. Arora, F. D. Bana, J. A. Beattie, G. Browne, de Vere Condon, A. da Gama, S. H. Daukes, G. E. Dodson, P. J. S. Dunn, A. E. A. Ismail, R. K. Mhatre, A. Moore, A. K. Sinha, W. C. P. Winter.

UNIVERSITY OF LONDON.

Examinations.

THE following candidates have been approved at the examinations indicated:

FIRST M.B. G. C. Agarwala, G. N. Anderson, K. N. G. Bailey, J. R. Banks, Grace M. Beaven, J. H. F. G. Berncastle, A. B. Bond, G. W. J. Bousfield, T. Carlyle, P. C. L. Carrier, O. C. Carter, P. S. Clarke, C. G. Coombs, R. C. Davenport, G. Day, *†J. D. Dyson, G. W. Elkington, C. F. Eminson, G. H. FitzGerald, L. B. Goldschmidt, Iris Harding, G. W. Heckels, *W. A. Hewitson, E. A. Holmes, C. A. Hutchinson, J. W. D. Hyde, J. Joffe, D. M. Jones, V. E. Jones, M. H. K. Kane, G. E. Kidman, E. E. Lightwood, Marguerite F. J. Lowenfeld, Ethel M. McCartney, R. G. Mack, T. E. Malins, H. I. Marriner, P. N. Menon, J. O. R. Montecchio, A. Morford, M. Munir, †N. Olivier, Irene G. Parsons, V. J. E. C. del S. Perez, y. Marzan, E. S. Phillips, Sybil M. G. Pratt, T. D. Pratt, S. H. de G. Pritchard, C. N. Read, J. B. Reed, F. E. Rendel, P. G. Rigga, H. B. Russell, M. Shimberg, Ellen Sykk, A. A. Thiel, N. B. Thomas, K. R. Traill, K. T. K. Wallington, R. E. S. Webb, A. D. Weeden, A. W. Wells, Effie A. Wharton, G. S. Wilson, W. F. P. Wilson, Sik To Wong, C. Young.

* Awarded a mark of distinction in Inorganic Chemistry.
† Awarded a mark of distinction in Physics.
‡ Awarded a mark of distinction in Biology.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN.

Scholarships and Bursaries.

A bequest has been received from the late Miss Mabel Sharmar-Crawford to found a scholarship to bear her name. The scholarship, offered annually, of the value of £20 a year for four years, will be awarded for the first time in July, 1913, on the result of an examination in biology, chemistry, and physics. Other scholarships to be awarded in July, 1913, are the Isabel Thorne Scholarship, value £30, and the St. Dunstan's Exhibition, value £60 a year for three or five years. The Agnes Guthrie Bursary for Dental Students, value £60, and the Mabel Webb Research Scholarship, value £30 a year for one, two, or three years, will be awarded in September, 1913. The Dr. Edith Peehey-Phipson Post-graduate Scholarship of the value of £40 will be awarded in June, 1913. Full particulars can be obtained from the Secretary of the Medical School, 8, Hunter Street, W.C.

Gifts.

Valuable gifts have recently been received for the Library from the Worshipful Company of Clothworkers and Sir Montagu Turner, for apparatus from Mr. Alfred Langton and Dr. Florence Stoney, and for bursaries from Mrs. Anstruther and Dr. Eleanor Lowry.

UNIVERSITY OF EDINBURGH.

ANNUAL REPORT FOR 1912.

Numbers of Students.

DURING the past year the total number of matriculated students (including 572 women) was 3,404. Of these, 466 (including 25 women) were enrolled in the Faculty of Science, 1,330 (including 6 women) in the Faculty of Medicine. The numbers in the Faculties of Arts and Medicine show a small reduction, but the number of students in the Faculty of Science is the best ever reached, exceeding by 40 that for 1911, and by 84 that for 1910. Of the students of medicine, 591, or over 44 per cent., belonged to Scotland; 228, or over 17 per cent., were from England and Wales; 95 from Ireland; 102 from India; 265, or 20 per cent., from British colonies; and 49 from foreign countries. The number of women attending extra-academical lectures, with a view to graduation in medicine in the university, was 69.

Degrees Conferred, Etc.

The following degrees were conferred during 1912: Bachelor of Science (B.Sc.), 71 (the highest number ever reached); Doctor of Science (D.Sc.), 4; Bachelor of Medicine and Master in Surgery (M.B., C.M.), 2; Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.), 201; Doctor of Medicine, M.D., 55. The General Council of the University now numbers 11,941. The Diploma in Tropical Medicine and Hygiene was conferred on one candidate; the Diploma in Psychiatry on four candidates.

Scholarships, Etc.

The total annual value of the University Fellowships, scholarships, bursaries, and prizes now amounts to about £19,420, and includes: In the Faculty of Science, £1,190; in the Faculty of Medicine, £5,230. A number of bursaries are in the gift of private patrons, but the great majority of the university bursaries, prizes, etc., are awarded by the Senatus after competitive examination. In addition to the above, a sum of upwards of £660, being the income of the Earl of Moray Endowment Fund, is annually available for the encouragement of original research.

Lectureships, New Courses, Etc.

During the year six new lectureships have been instituted by the University Court, and the courses are being delivered in the current session. Of these there are as follows: Neurology—J. J. Graham Brown, M.D.; Physical Methods in the Treatment of Disease—Harry Rainy, M.A., M.D.; Physical Optics—J. R. Milne, D.Sc. A second Lecturer upon Diseases of the Skin has also been appointed in the person of Dr. Frederick Gardiner.

New Ordinances, Etc.

Early in the year the sanction of His Majesty in Council was given to the Ordinance of the University Court of the University of Edinburgh, No. 13 (Institution of Degrees in Veterinary Science, and relative Regulations). The Court's Ordinance, No. 14 (Foundation of Chair of Bacteriology), has been submitted to the King in Council and laid before Parliament. The foundation of the new Chair is due to a munificent bequest, intimated several years ago, by Mr. Robert Irvine, of Royston, Granton, for this purpose. The sum in the hands of the trustees has been allowed to accumulate until it has reached £30,000, and it is available not only for the founding of the Chair, but also for the equipment of a class-room and laboratory connected therewith. A draft Ordinance has also been framed for the foundation of the Moncrieff Arnott Chair of Clinical Medicine.

New Buildings.

The year just closed has seen the completion of a portion of the western annexe of the physical laboratory, a suite of rooms having been so fitted up as to provide accommodation both for the laboratory work of the Medical Physics Class and for the tutorial work of the Natural Philosophy Class.

Benefactions, etc.

As in former years, the university has to make grateful acknowledgement of numerous benefactions. Among others may be noted a sum of about £1,200, being the residue of the estate of the late Mr. John Bruce, M.P., C.M., of Kirkwall, for the foundation of a bursary in the Faculty of Medicine, to be called the "Whiteside Bruce Bursary"; and a sum of £337s. 2d. subscribed by medical practitioners in the Straits Settlements to provide a medal in the subject of tropical diseases. A highly interesting and much-prized donation has also come to the university by the bequest of the late Lord Lister (at one time Professor of Clinical Surgery in the University), of his orders and medals, the caskets presented to him in connexion with the conferring upon him of the freedom of London, Edinburgh, and Glasgow, and the numerous diplomas and congratulatory addresses received by him at various times from British and foreign learned societies, together with his portrait, painted by Mr. J. H. Lorimer. All of these have been placed in the university library.

Miscellaneous.

Inclusive fees have been instituted in the Faculty of Arts, in the Faculty of Science (Department of Pure Science), and in the Faculty of Law, to apply to those who are studying with a view to graduation in these faculties.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY Council was held on January 9th, Sir Rickman J. Godlee, Bart., President, in the chair.

Votes of Thanks to Donors.

The thanks of the Council were given to Mr. Harold Peake, of Westbrook House, Newbury, Berks, for his gift of a collection of skulls and skeletons of Anglo-Saxons of the seventh century, found near Newbury. Likewise to Mr. H. E. Juler, for a gift of 150 specimens illustrating injuries and diseases of the eye, and to Dr. T. Colcott Fox for presenting a series of cultures of ringworm fungi.

CONJOINT BOARD IN ENGLAND.

FIRST COLLEGE (Part I and Part II)—*A. Arias, J. R. S. Bowker, V. H. Butcher, R. Calvo, H. H. Castle, *A. V. S. Davies, D. A. Dyer, A. M. El-Mishad, E. S. Gonda, P. Green, F. J. Harrington, E. G. Harris, W. R. G. Hoarnden, F. H. Hyland, Mabel M. Ingram, †T. W. Le Mesurier, †P. Lloyd-Williams, *A. N. McMillan, A. Mishriky, *R. Moser, W. I. F. Powell, D. S. Pracy, R. H. C. Pryn, †D. R. Reynolds, E. N. Reynolds, A. Rodd, J. H. E. Sandford, G. E. L. Simons, B. L. Skeggs, †T. F. Zerolo. (Part III): E. B. Alabaster, P. Banbury, W. J. Colborne, Jane Crawford, A. M. El-Mishad, J. H. Ewen, A. Fair, N. E. Fasken, P. Y. Hassaballa, W. R. G. Hoarnden, M. Ibrahim, J. Macadam, A. N. McMillan, W. I. F. Powell, R. H. C. Pryn, A. Rodd, J. H. E. Sandford, B. C. W. Simpson, A. H. Talaat, C. Vincent-Brown. (Part IV): H. L. Addison, C. S. Atkin, C. L. Balkwell, G. A. Batchelor, S. S. Beare, H. S. Bryan, A. A. K. C. Doyle, W. Farquharson, H. H. Fisk, H. J. Grimshaw, D. M. Hanson, S. P. Harris, O. R. Horwood, W. G. Johnston, D. W. Jones, J. V. Lambert, F. G. Liescher, J. A. Liley, J. Lloyd, C. H. G. Penny, J. Precocoules, C. W. Roe, B. E. P. Sayers, A. D. Stammers, R. Stansfeld, E. W. Twining, G. L. Wilkinson, C. W. Wilson. † Passed in Part I only. ‡ Passed in Part II only.

SECOND COLLEGE (Anatomy and Physiology)—H. S. Baker, K. L. Bates, J. H. Bayley, S. C. Biswas, J. P. Bracken, A. S. Carter, J. E. Clark, S. W. Coffin, S. A. Cornelius, R. Curle, Delphine Gertrude D'Abreu, C. W. Dias, C. L. Donne, W. A. Easton, J. E. Evans, A. G. B. Fenwick, S. W. Fisk, H. P. Gabb, S. C. Ghosh, C. C. G. Gibson, G. D. Gripper, C. G. W. Habr, R. B. Hick, R. A. Holmes, W. A. Hosson, H. B. Hyde, V. C. James, S. D. Lodge, G. Lynden-Bell, A. J. V. McDonnell, J. M. Madariaga, R. P. S. Mason, I. Morfada, E. W. Mottam, R. V. Powell, J. N. Puri, K. R. Rao, H. B. Fisk, J. Rowland, S. F. Rookitt, R. L. Robinson, L. C. S. Roche, A. F. Rook, J. Rowland, S. F. Simpson, R. C. W. Staley, J. G. Stevens, V. Sunderland, H. J. H. Symons, R. C. Thomas, C. P. G. Wakeley, F. L. Webster, N. J. Wigram, H. Whyte.

Letters, Notes, and Answers.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 429, Strand, London, W.C.; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Office, 429, Strand, London, W.C.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C., on receipt of proof.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Artiology, Westrand, London*. The telegraphic address of the BRITISH MEDICAL JOURNAL is *Articulate, Westrand, London*.

TELEPHONE (National):—
2631, Gerrard, EDITOR, BRITISH MEDICAL JOURNAL.
2630, Gerrard, BRITISH MEDICAL ASSOCIATION.
2634, Gerrard, MEDICAL SECRETARY.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

PINKLAND asks for the details of Van Noorden's treatment of constipation, or for reference to some work in English giving these details.

MAM asks for suggestions in the treatment of a lady of 70 who has lost appreciation of touch in her fingers. On taking hold of an object it feels as if it were something else or that something has been introduced between the finger and the object. No neurotic element is present. Treatment for gout ineffectual. Would, he asks, constant current be of any use; if so, how should it be applied?

A. M. asks for suggestions in the treatment of the two following cases: (1) A multipara is much troubled with severe after-pains, so severe as to be agonizing every few minutes for the first few days; no clots are passed; she is dreading another confinement because of this. (2) A female patient, aged 37, has been troubled for about twenty years with excessive sleepiness at the wrong time; the total amount of daily sleep is not too much, but sleep commences about seven o'clock each evening, then she is unable to sleep in the early hours of the morning.

X RAYS AND PRURITUS ANI.

SHERWOOD asks for experience regarding the treatment of pruritus ani by means of the x rays and whether there is danger of any of the surrounding organs becoming atrophied. He has under treatment a case of ten years' standing.

DAILY DRUGGING.

FINCH asks if any unpleasant symptoms are known to be associated with the daily taking of a small dose of liquid paraffin for constipation.

JUNUS asks if injurious effects have been known to follow the taking of sodium bicarbonate in 30-grain doses every four hours over a prolonged period in a case of gastric hyperacidity. He wishes to know whether the alkalinity of urine so produced has any bad effects on the urinary system, and whether some form of magnesia would not be better, and, if so, what preparation.

INCOME TAX.

CHITLES has recently secured an appointment at a salary of £500; previously he was earning about £30 a year. He desires to know whether he is entitled to be assessed on the average of three years.

If the appointment represents our correspondent's sole source of professional income, the average does not apply, and he should be assessed for the current year on the amount of salary receivable for the period up to April 5th next, with an addition for his earnings during the period from April 5th last to the date of appointment. The usual allowance of £160 will be due from the total assessment if his income from all sources be under £470.

ANSWERS.

DR. W. LOW-WORTH WAINWRIGHT (Henley-on-Thames) writes: "A." will find that a dose of 1 or 2 grains of potassium permanganate in a glass of soda water is a simple and certain cure if taken on an empty stomach.

DR. BRAMWELL (Liverpool) writes: In answer to "A." a probable cause of offensive breath is offensive secretion blocking crypts in the tonsils. This secretion is sometimes so deeply placed as to be quite out of sight of an ordinary examination. Slight loss of tone in the soft palate will sometimes cause food to lodge behind it, in the neighbourhood of the posterior nares, and so undergo decomposition. Also powerful cructations from the stomach will sometimes drive up small particles of food to lie in the same position. Loss of muscular tone may also cause food to lodge in either sinus pyriformis at the upper extremity of the oesophagus. Attention to such causes might result in cure. Emaciation, tonics, strychnine, electricity, etc.

IODINE AS A SKIN ANTISEPTIC.

MR. J. LIONEL STRETTON (Senior Surgeon, Kidderminster Infirmary and Children's Hospital) writes: In reply to Mr. Vaughan-Pendred, I would point out that the deep suppuration he mentions had probably no connexion with the condition of the external skin. From his brief account it appears that the skin healed. There are so many other sources of infection that it is hardly fair to describe occasional cases of suppuration as failure of the iodine method as originated by me. In ventrifixation operations it is easy to get an infection from the sutures in the uterus. I am preparing a further contribution on the subject of iodine sterilization in which I deal with this question.

LETTERS, NOTES, ETC.

POISONING BY ARSENIC IN CARPETS.

IN a note upon cases of poisoning traced to arsenic in carpets published in the BRITISH MEDICAL JOURNAL, November 30th, 1912, p. 1570, founded upon observations made in Germany by Dr. Kuttner and reported by him to the Hufeland Society (*Berl. Klin. Woch.*, 1912, No. 45) it was stated on his authority that arsenic was used in the manufacture of cheap linoleum. We have received from Messrs. Barry, Ostlere, and Shepherd, Ltd., of Kirkcaldy, a letter stating that this statement is incorrect, either as regards cheap or dear linoleum, except in so far as some of the raw materials employed may contain the merest trace of that substance. Messrs. Barry state that some time ago analyses were made by the Edinburgh city analyst, Mr. J. Falconer King, and in their own laboratories on standard samples of their goods, and the result was to show that the amount of arsenic present was not more than 0.17 mg. of metallic arsenic per 50 sq. cm., a quantity which it is considered would be quite incapable of exercising a deleterious influence on the users of an apartment in which the linoleum was laid.

"GLUTEN BREAD."

MESSRS. CALLARD AND CO. (Regent Street, London, W.) write: We notice in your review of a French "manual on nutrition" (January 11th, p. 76), that a statement is made in reference to the starch-content of gluten bread. The reference to a statement by our late principal prompts us to explain that the term "Gluten Bread" has ceased to be applied to any standard preparation. All bread made from wheat flour contains some gluten, and this fact seems to justify the name of "Gluten Bread" being applied to any white bread. Many so-called gluten breads contain as much as 55 per cent. of starch, and are, therefore, no better than ordinary bread for the use of diabetic patients, although much more expensive. We have made for many years a gluten bread, containing not more than 7 per cent. of starch, but it is not palatable, although eatable. Gluten bread of any kind is out of date; it has been superseded by the newer breads made from casein, eggs, and butter, which are palatable and absolutely free from carbohydrate. Our experience shows that physicians prefer to treat their patients with these starch-free breads, and give a definite weight of potato or ordinary bread at each meal when they desire to administer carbohydrate. This is more accurate than ordering any so-called palatable "Gluten Bread" which may contain any proportion of starch from 50 to 55 per cent.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

| | £ | s. | d. |
|-----------------------|-----|-----|--------|
| Eight lines and under | ... | ... | 0 4 0 |
| Each additional line | ... | ... | 0 0 6 |
| A whole column | ... | ... | 2 13 4 |
| A page | ... | ... | 8 0 0 |

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Wednesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restantes* letters addressed either in initials or numbers.

A Report of the Work

CARRIED OUT AT

THE RADIUM INSTITUTE

FROM AUGUST 14TH, 1911, TO DECEMBER 31ST, 1912.

BY

A. E. HAYWARD PINCH, F.R.C.S.,
MEDICAL SUPERINTENDENT.

(Published with the Authority of the Committee.)

This report deals with all the cases which have presented themselves for treatment at the Radium Institute during the period extending from August 14th, 1911, to December 31st, 1912. For its correct appreciation it is necessary to state at the outset that the cases treated were in no instance selected. Ever since the opening of the Institute applications have been received for the treatment of patients many of whom have exhausted all the known resources of medicine and surgery, their condition being almost hopeless.

The only cases refused have been those in which the patients were practically moribund, or where the disease was of a kind for which radium therapy was manifestly unsuitable.

It has been the purpose of the Committee to give equal prominence to the cases in which radium has appeared to be useful, as well as to those in which it has been useless or possibly harmful.

It is one object of this report to point out the conditions under which radium is therapeutically of no service.

The repute of radium therapy has suffered severely from that irrational enthusiasm and that unthinking expectation which often attend the debut of a new remedy. These distorting influences have been especially marked in the present instance, for radium has astounding physical qualities, and it seems to have been assumed that its therapeutic powers must be equally penetrative and marvellous.

It is important to note that no examples of malignant disease—rodent ulcer alone excepted—have been treated, other than those in which operation had been declared to be unjustified or in which operation had been absolutely declined by the patient.

The term "apparent cure," used in relation to cases of malignant disease, must be interpreted as representing a condition in which all trace of the original lesion or lesions has disappeared, in which there is no sign of any recurrence, and in which the patient is, so far as can be determined by a thorough and careful examination, free from any indication or symptom of the disease.

With reference to the figures appearing in the column headed "abandoned treatment," it must be explained that in not a few instances treatment was given up because the patient had been obliged to leave London or was unable to defray the cost of repeatedly travelling from the country to the Institute.

THE APPARATUS.

APPLICATORS.

The method by which the apparatus is prepared is explained more fully in the appendix on the work of the Chemico-Physical Laboratory by Mr. W. L. S. Alton. Here it will be sufficient to give the following particulars:—

The apparatus employed in treatment is of several types:

(a) *Flat varnished applicators*, rectangular, square, and circular; the superficial area of the various applicators ranging from 0.7 sq. cm. to 28 sq. cm.

They are either—

1. Full strength, containing an amount of radium sulphate equivalent to 10 mg. of radium bromide to each square centimetre.

2. Half strength, containing an amount of radium sulphate equivalent to 5 mg. of radium bromide to each square centimetre.

3. Quarter strength, containing an amount of radium sulphate equivalent to 2.5 mg. of radium bromide to each square centimetre.

The smallest applicator contains ... 7 mg.

The largest " " " " ... 150 mg.

(b) *Capillary glass tubes, filled with radium sulphate*, closely packed so as to prevent any movement of the salt.

Their length varies from ... 2 to 4 cm.

Their diameter " " " " ... 0.2 to 0.3 cm.

The amount of radium sulphate contained is the equivalent of 25, 30, 50, 60 or 100 mg. of radium bromide.

(c) *Radium emanation*. This may be—

1. Collected in glass tubes or metal containers, and used with appropriate screens, exactly as the radium salts themselves are used, due regard being paid to the gradual fall in radio-activity resulting from the decay of the emanation.

2. Dissolved in distilled water or a weak saline solution, and administered by drinking or injection.

SCREENS.

The screens employed as filters for the different rays are:

(a) *Aluminium*—0.01, 0.02, 0.04, 0.08 mm. thick. These are principally used with short exposures in the treatment of capillary naevi, pruritus, leuro-dermatitis, and superficial skin lesions.

(b) *Silver*—0.5 and 1 mm. thick. These are most useful as shields for the glass tubes of radium when introduced into tumours, and also in the treatment of keloid and vicious cicatrices.

(c) *Lead*—0.1, 0.2, 0.4, 0.5, 1, 1.5, and 2 mm. thick. Screens less than 0.5 mm. in thickness are valuable in the treatment of flat superficial epitheliomata, leucoplakia fibromata, and granulomata.

Those exceeding 0.5 mm. are used when it is desired to employ the hard beta and gamma rays only, and to give prolonged applications without causing any surface irritation.

METHODS OF APPLICATION.

DURATION OF APPLICATIONS (EXPOSURES).

Very short exposures of half a minute to three minutes' duration, according to the age of the patient and the character of the lesion. Principally used in the treatment of superficial skin troubles. The apparatus is applied without any screen beyond that afforded by a covering of thin rubber sheeting.

Short exposures of five minutes to one hour's duration. Most frequently resorted to when treating warts, senile keratoma, some forms of naevi, shallow ulcers, lupus erythematosus, etc. The screening in these exposures rarely exceeds 0.04 mm. of aluminium.

Moderately long exposures of one to eight hours, adopted when it is desired to obtain the destructive action of the rays. Used in cases of rodent ulcer, rapidly growing epithelioma, lupus vulgaris, etc. No screening beyond thin rubber sheeting is employed, and a total exposure of three to eight hours is extended over two, three, or four days.

Prolonged exposures of twelve to one hundred hours, or longer. These are employed in the treatment of deep-seated malignant growths, in cancer of the rectum, uterus, breast, etc. Lead screens are always employed, usually of 2 mm. thickness. Exposures are given in periods of six to twelve hours, with an interval of at least twelve hours between successive exposures.

SCREENS AND APPLIANCES.

A varnished applicator is always covered with a thin layer of rubber sheeting, thus effectively protecting it from contact with any excretions or moisture, and avoiding the necessity of repeatedly cleaning the apparatus.

When silver or lead screens are used, the passage of the gamma rays through these metals gives rise to secondary rays, which are very irritating, though their action is superficial only, and it becomes necessary to absorb these rays. With this object, from six to twenty-four sheets of black photographic paper and one or two layers of lint are interposed between the metal screen and the outer rubber covering. When tubes shielded with lead or silver screens are introduced into the vagina, rectum, uterus, etc., they are enveloped in rubber tubing of 3 mm. thickness for the same purpose. These secondary rays vary greatly in amount according to the nature of the metal and the thickness of the screen employed.

The lesion to be treated is gently cleaned and dried, and all crusts or flakes of secretion are removed. The healthy skin and tissues surrounding the lesion must be carefully protected by a layer of lead-rubber sheeting—similar to that used in x-ray work—an aperture being cut in the sheeting the exact size and shape of the lesion. For external lesions the apparatus is best fixed in position with some non-irritant adhesive rubber plaster.

To retain tubes in the vagina or uterus the employment of a tampon is generally necessary. In the rectum, nasal and buccal cavities the apparatus is attached to

a handle of thick silver wire, which can be easily bent and fastened to the gluteal fold, cheek, or ear by adhesive plaster.

THE REACTION.

All tissues when treated with radium respond in some manner, but the nature and extent of this response vary very greatly, and depend upon:

1. *The apparatus, screening and dosage employed.*
2. *The nature of the tissue treated.*
3. *The condition of the tissue treated.* If x rays, ionization, CO₂ snow, etc., have been previously used in the attempts to bring about a cure, the reaction in such cases is frequently atypical, and repair is exceedingly slow.
4. *The extent of the area treated.* The reaction is dependent not only upon the strength of the applicator, but also upon its superficial area. For example, the reaction from an applicator of half strength applied over an area of 4 sq. cm. is often not more intense in degree than that obtained with an applicator of quarter strength over a surface area of 16 sq. cm.
5. *Personal idiosyncrasy.* This is most important and often productive of curiously puzzling results. In this respect factors to be considered are age, sex, and temperament, susceptibility to actinic rays generally—for example, as in persons who suffer much from freckling or solar eczema—hyperidrosis, exalted vasomotor sensibility, etc.

Nature of Reaction.

The reaction usually appears between the seventh and fifteenth days and may vary in character from a slight erythema to a destructive ulceration.

Four degrees may be clearly distinguished:

1. Simple erythema.
2. Erythema followed by desquamation.
3. Vesication with superficial ulceration.
4. Deep ulceration; sometimes accompanied by the production of an eschar.

With some patients the time of reaction is much delayed, with others the response is exceedingly prompt, and it is difficult, if not impossible, to say why this difference should be. It is particularly noticeable in the treatment of capillary naevi, and cases have been seen in which, instead of the reaction appearing on about the seventh or eighth day, it has been evident three days after the exposure. In others a period of four weeks has elapsed before any effect has been perceptible, though in all of these cases the applicators employed, the screening, and the times of exposure have been identical.

The increased susceptibility to changes of temperature over areas that have been treated with radium is very remarkable, and many patients who have had rodent ulcers and superficial skin lesions cured with radium state that they experience great discomfort at the site of the old lesion when very cold or very warm air plays upon it. This susceptibility, however, gradually returns to the normal in two or three months.

A very marked condition of lethargy is frequently, it might almost be said invariably, noted in patients receiving prolonged exposures with large quantities of heavily screened radium. It generally makes its appearance about the fourth day of the treatment, and passes off within a few days of the cessation of the exposures.

RESULTS OF TREATMENT OF DISEASE.

The results of treatment in 578 cases treated by radium or its emanation at the Radium Institute are given in the following tables. It will be noted in Table I, which contains a summary of 657 cases, that 38 were examined but not treated, and that in 41 the treatment is too recent to enable any conclusion as to the results of treatment to be stated. In Table II the cases are arranged according to the nature of the disease and its site. The tables are followed by a general discussion in which typical cases of the various conditions are reported in detail.

TABLE I.—SUMMARY OF CASES.

| | | | | | | | | | | |
|--|-----|-----|-----|----|---------------------|-----|-----|-----|-----|-----|
| Examined but not treated | ... | ... | ... | 38 | Improved | ... | ... | ... | ... | 245 |
| Recently treated and results not yet noted | ... | ... | ... | 41 | Not improved | ... | ... | ... | ... | 70 |
| Received prophylactic irradiation only | ... | ... | ... | 39 | Abandoned treatment | ... | ... | ... | ... | 88 |

CARCINOMATA.

Squamous-celled (Epitheliomata) of the Skin.

Very different results are obtained with epitheliomata affecting the glabrous skin as opposed to those involving mucous surfaces.

Epitheliomata of the face, trunk, or extremities, if flat and superficial and accompanied by little or no ulceration, give satisfactory results when treated with quarter or half strength apparatus, screened with 0.2 mm. of lead, the exposures varying from six to twelve hours' duration, spread over a period of three or four days. The retrogression of the growth is quickly brought about and little or no scarring results.

Ulcerating epitheliomata without much subjacent infil-

tration, require treatment with quarter or half strength apparatus applied unscreened for a total exposure of two to six or eight hours, spread over a period of four or five days, and repeated after an interval of six weeks if necessary. A destructive reaction follows, but the result is usually quite good, and there is but little cicatricial contraction.

Ulcerated epitheliomata with great infiltration, require prolonged treatment with heavily-screened apparatus emitting "ultra-penetrating" rays. Exposures of thirty to sixty hours given during one week, and repeated in five or six weeks' time are best; but if the growth shows signs of rapid extension the borders should be given a vigorous treatment with unscreened apparatus.

CASES.

Epithelioma of Cheek.

M., aged 82 (Case No. 47). The growth began as a small warty nodule six months before the patient was seen at the Radium Institute. It had grown steadily in size until October, 1911, when it was submitted to radium treatment. It was then an oval tumour measuring 2.7 by 2 cm., and projected 0.5 cm. above the surface of the skin. The whole mass was wartlike, with an ulcerated apex, situated over the zygoma, and surrounded by a zone of infiltration. The infiltration reached to the ear; the pre-auricular gland was enlarged and hard. The nature of the disease had been verified by microscopical examination. The patient had refused operation.

He was treated for two hours with a half-strength apparatus screened by aluminium foil 0.01 mm. in thickness, and a similar treatment of one and a half hours was given a month later.

In January, 1912, the patient's medical attendant reported that no sign of the carcinoma remained.

Epithelioma of Right Hand.

M., aged 53 (Case No. 231). The patient's skin had always been peculiarly susceptible to the influence of light. When he was examined in May, 1912, the exposed parts of his body (face and hands) were deeply freckled and had several small warty growths upon them. The condition strongly resembled an early case of xeroderma pigmentosa. Eighteen months previously a small tumour was removed from the back of the patient's right hand, and proved to be carcinomatous on microscopical examination. He came for the treatment of a circular ulcer 1.5 cm. in diameter, with everted edges and indurated base, which had originated at the extremity of the scar of the previous operation. It was situated over the centre of the middle metacarpal bone of the right hand. No pain was associated with the growth.

A full strength apparatus without a metal screen was applied to the ulcer for fifty minutes.

In July the patient reported that there had been a very sharp reaction, but that the ulcer had healed completely and that no sign of the lesion remained.

Epithelioma of Hand.

F., aged 67 (Case No. 5,034). The patient had for ten years a small wart on the back of the right hand. In April, 1911, it commenced to grow rapidly and became very painful. The growth was excised, but recurred, and subsequent treatment with caustics and ointments produced no improvement. In September, 1912, an oval tumour, 3 cm. by 2.5 cm. and 1 cm. in height, was situated on the back of the right hand. Its raised centre was covered by a dry irregular crust. It was immovable, and the site of almost constant severe pain. The axillary glands were not enlarged. The patient refused operation. Seven treatments of two hours each were given with a half-strength apparatus, an interval of one month intervening between the applications. No screen was employed.

The growth steadily improved from the beginning, and in April, 1912, no sign of it remained except a smooth cicatrix.

Epithelioma of Neck and Sculp.

M., aged 65 (Case No. 39). Disease of ten months' duration. Its nature had been determined by microscopical examination.

The patient was first seen on October 10th, 1911. He then had an enormous ulcerated epithelioma extending from a point 2 in. above and behind the tip of the left ear to 3 in. below the mastoid process. There was a deep and wide fissure just behind the ear cleaving the growth in a vertical direction, with which a cavity left by a previous mastoid operation communicated. The whole auricle was greatly swollen and infiltrated with carcinomatous deposit. There was a profuse and offensive purulent discharge. The patient complained of constant and intense pain.

He was treated with 250 mg. of radium, both tubes and flat applicators being used, with screens of silver of 1 mm. and 1.5 mm. respectively, and received in all an exposure of twelve hours on October 10th and 11th. There was a slight reaction about a fortnight afterwards; the ulceration commenced to heal and the pain was considerably lessened.

On October 28th, in compliance with the urgent request of the patient's friends, the injection of Coley's fluid was commenced by the surgeon in charge of the case, and half a minim was injected every second day until December 7th.

Under the action of either the radium or the Coley's fluid, or perhaps the combination of the two remedies, the patient's condition slowly but steadily improved, and when seen on December 12th a remarkable change was apparent.

The greater part of the ulceration had healed, and much of the surrounding carcinomatous infiltration had disappeared. The vertical fissure behind the ear had closed at its lower extremity, was much shallower and covered with epithelium, save for one small ulcerated area at the spot where it communicated with the mastoid cavity. The auricle was much less swollen. Discharge was scanty and non-offensive. During the last four weeks the pain had returned with increasing severity, and the patient desired a further application of radium with the object of relieving the pain. On December 16th and 17th he received a further treatment of twelve hours' duration in all, with 460 mg. of radium screen 1 with 2 mm. of lead.

On January 17th, 1912, his surgeon reported that the wound had completely healed, and that the whole of the previously ulcerated area now presented an almost keloidal appearance. The pain had been much lessened but not entirely abolished.

The patient was, however, suffering from vomiting, which was found to be due to acetonaemia.

The patient died on February 6th, 1912, from acetonaemia.

EPITHELIOMATA IN RELATION WITH MUCCOUS MEMBRANES.

Epitheliomata of the tongue, buccal, gingival, and pharyngeal mucous membranes are almost uniformly disappointing in their ultimate response to radium-therapy.

Temporary improvement is infrequently seen, and this sometimes goes as far as disappearance of the original lesion; but the treatment has practically no effect in preventing or delaying the appearance of metastatic deposits in the cervical glands and elsewhere.

The rate of growth of the infected glands can often be retarded by the prolonged and persistent use of the "ultra-penetrating" rays. If the dose given be a large one, the glands sometimes break down and discharge a milky-white fluid through a small sinus, and it is remarkable that ulceration of glands thus treated rarely occurs.

Considerable difficulty is experienced in giving satisfactory exposures within the oral cavity, as patients are often unable to tolerate the presence of applicators in their mouth for the necessary length of time, and should the reaction be at all pronounced the congestion of the tissues occasions great discomfort. There is the further danger that a severe reaction may act as a stimulus to the original growth, increase its size, and hasten metastasis.

CASES.

Epithelioma of the Lower Jaw.

M., aged 72 (Case No. 87). A malignant epulis was removed from the right side of the lower jaw of this patient, together with a portion of the mandible, in March, 1911. The microscopical diagnosis was squamous-celled carcinoma. The incision healed well save at one small spot, which closed up under radium treatment. The glands became enlarged on the right side of the neck, and were removed in May, 1911.

A recurrence took place in the jaw at the beginning of November, 1911. Later in the month a small circular nodule, 1.5 cm. in diameter, was evident in the mucous membrane over the lower jaw, immediately to the right of the middle line. It was ulcerated, bled freely when handled, and had a sinus at its centre leading to the bone. The left submaxillary glands were enlarged and hard. A tube of 50 mm. of radium unscreened was placed for two hours in the middle of the growth. In a month the tumour had disappeared, leaving an oozing cavity. The glands of the right side of the neck had much increased in the meantime.

In January, 1912, three half-strength applicators containing 250 mg. radium were placed over the enlarged glands of the right side of the neck with 2 mm. of lead interposed, and an exposure of thirty hours given. In February the enlargement of the glands had made steady progress, but the nodule on the gum had disappeared entirely. The patient died in March, 1912.

Epithelioma of Left Superior Maxilla.

F., aged 69 (Case No. 391). The history of this case was very indefinite, but the first symptom which attracted the patient's attention was a persistent muco-purulent discharge from the left nostril. This was first noted in August, 1912. At the end of September the left nostril was becoming obstructed. She consulted a leading hospital surgeon, who diagnosed a malignant growth in the left superior maxilla, and advised operation, but this the patient refused.

She was seen at the Institute on October 15th, 1912. Transillumination showed great opacity of the left antrum extending up to the orbital margin. The left cheek was much swollen and the left naso-labial fold obliterated. Complete occlusion of the left nostril and slight epiphora were noted. The left half of the palate was pushed downwards, so that the patient was unable to wear her upper dental plate. There was one hard, enlarged gland just below the left mandible.

On the evening of October 15th an incision was made through the mucous membrane over the socket of the first bicuspid in the left upper jaw, and a silver tube, 1 mm. in thickness, containing radium emanation equivalent to 95.6 mg. radium bromide, was inserted into the antrum and left there for twenty-four hours. The patient was again examined on November 5th. The swelling of the cheek was no longer appreciable externally, and the naso-labial fold was distinct. The epiphora had disappeared. She could breathe easily through her left nostril and wear her upper dental plate with comfort. The gland under the left jaw had increased considerably in size and was becoming fixed. Transillumination showed the opacity of the antrum to be much diminished, but still existent.

The treatment was therefore repeated on November 6th. An emanation tube of the initial activity of 114.8 mg. in a screen of 1 mm. silver was inserted into the growth for twenty-four hours.

At the urgent solicitations of her friends the patient consented to have the gland excised a few days later. The gland

was examined microscopically, and the growth found to be a squamous-celled carcinoma.

The patient's doctor reported on December 13th that the patient had no pain or trouble in her face, and was in excellent health.

Epithelioma of the Mucous Membrane of the Right Cheek.

M., aged 68 (Case No. 5,025). In this case three operations had been performed to eradicate an epithelioma of the angle of the mouth on the right side, but after the last operation, in which a piece of the lower jaw had been removed, recurrence again took place.

When examined, the patient was capable of only very limited movement of the lower jaw. A small ulcerated surface, 1 by 0.5 cm., could be seen far back on the buccal mucous membrane in the angle between the cheek and the mandible. It was hard on palpation and fixed. A large mass of hard immovable glands was present in the right submaxillary and sublingual regions.

The ulcer was treated for three hours with two tubes, each of 25 mg., of radium screened with 1 mm. of lead, and over the glands were placed two full-strength applicators (80 mg.) screened with 2 mm. of lead for six hours on five successive days.

In a month the glands were scarcely palpable and the buccal ulcer was smaller and less indurated. Two similar treatments were repeated, with the result that the ulcer steadily improved. No fresh enlargement of glands took place. The patient died from an unrelated illness.

EPITHELIOMATA OF THE VAGINAL AND UTERINE MUCOSA.

These conditions are more amenable to the action of radium, and some distinctly encouraging results have been obtained:

Small primary growths of the vaginal mucosa unaccompanied by much deep infiltration of the vaginal tissues may be completely eradicated by treatment with full strength or half strength apparatus and an unscreened exposure of one to three hours.

With larger ulcerated and deeply infiltrating growths radium is best applied heavily screened, and with prolonged exposures of from thirty to sixty hours extending over a week or ten days. This frequently checks the rate of growth, heals the ulceration, and lessens the amount of infiltration.

Secondary non-ulcerated deposits in the cellular tissue of the vagina often respond extremely well to treatment with the "ultra-penetrating rays," and in some instances the deposits completely disappear.

CASE.

Epithelioma of Vulva.

In March, 1912, the patient, aged 73 (Case No. 258), had a squamous-celled carcinoma removed from the region of the clitoris. In May it recurred near to the urinary meatus. Further operation was refused.

When she came to the Institute for treatment, there was a hard malignant ulcer, 1.7 cm. in diameter, extending into both labia, and surrounded by a dense zone of infiltration. Its surface bled easily, and it was tender to the touch. On two successive days a tube of 50 mg. of radium was applied for one and a half hours without metal screen. The improvement was marked in a month. The same treatment was then repeated for two hours. Two months later no sign of the growth remained.

CARCINOMA OF THE UTERUS.

In cases of inoperable malignant disease in this situation radium will often bring about results which cannot be attained by any other known method of treatment.

The haemorrhage is arrested, the discharge is diminished in amount and rendered inoffensive in character, the ulceration is healed, and the pain is greatly relieved.

The rate of growth is checked, sometimes completely arrested, and the surrounding infiltration and induration are so much lessened that in a few instances cases previously declared to be inoperable become operable.

The treatment is best carried out by the introduction of a tube containing 50 to 100 mg. of radium, screened with 2 mm. of lead and 3 mm. of rubber into the cervical canal, or, if this be not practicable, into the posterior fornix, a large flat strong applicator screened with 2 mm. of lead being placed on the abdominal wall over the fundus of the uterus. The exposures should be prolonged, and should be from thirty to sixty hours' duration, spread over a period of from five to ten days.

The series of exposures should be repeated at intervals of not less than six weeks.

The action of radium is, however, only local, and though it may, and often does, check the rate of growth,

yet in most cases dissemination will sooner or later occur, and the disease spread to parts beyond the effective range of radium.

CASES.

Carcinoma of Uterus.

The patient, aged 63 (Case No. 14), had been married forty years, and had had six pregnancies, the last child being still-born.

The duration of the disease was three years. The first symptom was a slight vaginal discharge which slowly increased in amount through a period of two years, finally becoming profuse and purulent. In June, 1911, she had a sudden severe haemorrhage followed by others of less degree.

On examination on September 7th, 1911, the cervix uteri was found to be surrounded by a fungating mass which bled when touched, and the vaginal walls were indurated almost to the vulva on the right side and anteriorly. The uterus was enlarged and fixed. The patient complained of pain and a feeling of weight in the lower abdomen, increased frequency of micturition, and an offensive vaginal discharge.

She had one series of treatments for twelve days of sixty-six hours in all, a tube containing 50 mg. in a screen of 2 mm. of lead being inserted daily into the cervical canal for five and a half hours.

Three months later she reported that all the symptoms had so lessened in degree that she could perform all her duties in comfort. Her general health was much improved, and she went to Australia.

Carcinoma of Uterus (Recurrent).

This patient, aged 61 (Case No. 167), had had a subtotal hysterectomy performed fifteen years before coming for treatment, her previous trouble having been increasing menorrhagia for nearly eleven years. She remained well until September, 1910, when she noticed a slight vaginal discharge, which after continuing some months became sanguineous. She consulted a well-known surgeon, who refused to operate, as he found carcinoma of the cervix with implication of the bladder wall. Treatment with x rays was begun, and some improvement followed. She was then advised to try radium.

On examination on March 18th, 1912, the cervix uteri was found to be enlarged, hard, and ulcerated. The anterior fornix was obliterated, and the posterior fornix very shallow, the walls of the vagina being much indurated. The growth projected into the rectum about 7 cm. from the anus, but the mucous membrane covering it was normal. The patient complained of sacral pain, constipation, and vaginal haemorrhages, the last of which occurred on any slight exertion.

She had one series of treatments, five days of six hours each, a tube containing 100 mg. of radium screened with 1.5 mm. of lead being placed in the vagina. During four of these sittings an emanation tube, initial activity 73 mg., screened with 2 mm. of lead, was fixed opposite the tumour in the rectum.

Three months later she reported that no haemorrhage had occurred since a week after the treatment ceased. The pain had lessened very much, and the constipation was less troublesome. Her general health was much improved.

Carcinoma of Uterus.

The patient (Case No. 178), aged 56, was perfectly well until within eighteen months of coming for treatment, when she noticed a slight occasional discharge from the vagina. A sudden profuse haemorrhage led to examination in February, 1912, and a leading provincial surgeon pronounced her to be suffering from inoperable carcinoma. The cervix was enlarged, indurated, and ulcerated, and the uterus was fixed. The anterior wall of the vagina was ulcerated, and both the fornices were full and infiltrated. She had frequent uterine haemorrhages and was quite unable to get about.

On March 25th, 1912, an emanation tube, initial activity 85 mg., with a screen of 2 mm. of lead, was passed into the cervix and left in for two periods of eighteen hours, with twenty-four hours' interval. This produced diminution of the induration.

Two months later the cervical canal was dilated and the uterus curetted, and an emanation tube, initial activity 80.5 mg., with a screen of 1.5 mm. of lead, was placed in the cervix for thirteen and a half hours, and after an interval of one day, in the uterus for thirty-two hours.

A month later the os was contracted almost to normal size, and covered with healthy epithelium. There was much less induration. Pain, haemorrhage, and discharge had ceased, and the patient had resumed her usual duties.

Carcinoma of Uterus (Recurrent).

The patient, (Case No. 180), aged 53, had hysterectomy (Wertheim's operation) performed on November 19th, 1911, for carcinoma uteri. She made an excellent recovery, and kept well until the end of February, 1912, when recurrence took place in the upper part of the recto-vaginal septum. The condition was declared to be inoperable.

She was seen on April 1st, 1912. Examination per rectum revealed a definite ridge-like growth stretching transversely across the recto-vaginal septum 5 cm. from the anal orifice.

She was treated with two tubes of radium containing 75 mg., and screened with 1.5 mm. lead, one tube being placed in the rectum and one in the vagina; she had in all twenty hours' treatment—five hours for four consecutive days.

She was examined by her surgeon on June 7th, who reported

that all trace of the growth had disappeared and that the patient looked and felt perfectly well. She wrote at the end of October, 1912, saying she was in excellent health.

Carcinoma of Uterus.

The patient (Case No. 291), aged 62, had no symptoms, save a slight vaginal discharge during the three months before coming for treatment. The appearance of blood in the discharge so alarmed her that she consulted a surgeon in August, 1912, who found inoperable carcinoma of the cervix. The uterus was quite fixed, both rectum and bladder were implicated, and the induration at the right side extended up almost to the iliac vessels. The growth was curetted and the thermo-cautery applied.

The patient received two treatments. A 100-mg. tube in a screen of 1.5 mm. of lead was inserted in the vagina for six hours daily for five consecutive days. This led to slight general improvement, and five weeks later the treatment was repeated, a screen of 2 mm. of lead being used.

Seven weeks later the patient was almost free from pain, the discharge had nearly ceased, and the cervix uteri was covered with healthy epithelium externally. Her general condition was much improved. She expressed her intention to continue the treatment at a later date.

Carcinoma of Uterus (Recurrent).

In this patient (Case No. 5,109), aged 53, the disease was of four years' duration. Hysterectomy (Wertheim) had been performed in July, 1908. The patient made a good recovery and kept well until the end of 1911, when she began to suffer from a purulent vaginal discharge. She again consulted her surgeon, who detected a recurrence (inoperable) and advised radium.

The patient was first seen on February 7th, 1912. The scar at the vaginal roof was healthy. There was a hard, rounded lump the size of a walnut above and a little anterior to the scar on the right side, and there was a similar but smaller swelling the size of a muscat grape just behind the left angle of the scar.

The patient had three series of treatments, the first of ten days' duration in February, six hours each day; the second of five days' duration in April, six hours each day; the third of five days' duration in May, six hours each day; 60 mg. of radium in a screen of 1.5 mm. lead were used throughout.

The nodules of recurrence gradually decreased in size and the discharge ceased.

Her surgeon wrote on June 11th saying that he had examined the patient and that the nodules had completely disappeared. The patient reported herself for examination at the Institute on June 28th. She expressed herself as feeling perfectly well. No trace of the nodules in the vagina could be felt or seen.

Carcinoma of Uterus.

The patient (Case No. 5,037, aged 46) had suffered from intermittent haemorrhages from the vagina for nearly four years, but did not consult a surgeon until six months before coming for treatment on September 8th, 1911. She was then found to have inoperable carcinoma of the cervix. The uterus was fixed and the cervix ragged and ulcerated; induration extended laterally almost to the pelvic wall, and filled up the fornices of the vagina. In the anterior vaginal wall was a hard mass continuous with the cervix, extending to the ostium vaginae. The patient suffered from very severe pain and much discharge.

The first treatment was with a tube containing 60 mg. of radium in a screen of 2 mm. of lead inserted for six hours daily for twelve days. For the first four days a plate containing 40 mg. with a similar screen was placed on the abdomen. This caused a rapid cessation of pain, and a month later the induration and ulceration were appreciably less. A second treatment of five days, six hours each, with a 60 mg. tube and screen of 2 mm. of lead followed; and similar treatments, eleven in all, have been carried out at intervals of about five weeks, a screen of 1.5 mm. being sometimes used instead of 2 mm. As a rule the symptoms increased at the end of the interval, and lessened at once after each treatment. The ulceration returned after the fifth treatment, and the hard mass in the anterior vaginal wall ultimately gave way, leaving a vesical fistula.

The patient is now slowly going downhill, and her general health is failing, but at no time has her pain been as constant and severe as it was before she was treated. It is sixteen months since she first came, and she is still under observation.

Carcinoma of Uterus (Recurrent).

The patient (Case No. 5,199), aged 52, had suffered from occasional haemorrhages for some time before the disease was diagnosed. Abdominal hysterectomy was performed in April, 1909, and four months later two recurrent nodules were removed from the vagina. In the spring of 1912 she noticed some vaginal discharge, and had abdominal pain with occasional vomiting in June.

Examination on June 28th, 1912, revealed a large, hard, movable tumour in the upper abdomen, and in the anterior vaginal wall were two almond-sized swellings which bled when touched, surrounded by much induration. She was very weak and cachectic. She was treated by two 80 mg. plates, with a screen of 2 mm. of lead, placed on the abdomen over the tumour, and a 100-mg. tube in a screen of 2 mm. of lead inserted in the vagina. She did not come back for further treatment as arranged, but on September 16th, 1912, the surgeon wrote to say that all sign of growth in the vagina had disappeared.

Two months later the patient died from intestinal obstruction.

CARCINOMA OF THE RECTUM AND ALIMENTARY CANAL.

Rectum and Intestine.

Radium therapy not infrequently proves of considerable value in the treatment of these carcinomata, but it is extremely difficult to say what are the factors which determine or contribute to the success of the treatment.

Speaking in general terms, the application of radium results in the arrest of haemorrhage, the healing, partial or complete, of any ulcerated surface, a diminution of the amount of the discharge, less pain, and a retardation of the rate of progress.

In some instances more striking changes manifest themselves. The growth shrinks in size, undergoes a fibrous transformation, and becomes much less fixed to the underlying tissues, so that a carcinoma which before radium treatment was regarded as inoperable can be easily and completely removed.

A few patients manifest an unusual degree of susceptibility to radium when applied within the rectum, and a relatively short treatment of eighteen to twenty-four hours with heavily screened radium is followed by a severe though transient proctitis.

The routine method of treatment in rectal cases is the introduction—through an operating sigmoidoscope, if necessary—of 50 to 100 mg. of radium screened in 2 mm. of lead and 3 mm. of rubber. It is maintained in position by a stem of soft silver wire, which is bent at an acute angle at the anal orifice, and fastened by strapping and a T bandage in the fold between the buttocks. Each exposure is from six to twelve hours in duration, and is repeated daily until a total treatment of thirty to sixty hours has been given. The series should be repeated after an interval of six weeks.

CASES.

Carcinoma of Rectum.

The patient (Case No. 35), M., aged 53, on account of severe rectal haemorrhage, sought the advice of a leading London surgeon; he diagnosed carcinoma of the rectum, but refused to operate, and suggested radium.

When first seen, on October 9th, 1911, there was a craggy, hard, annular ulcerated growth, the lower margin of which was 3 cm. from the anal orifice, while the upper margin was 9 cm. above the orifice. It was moderately fixed, its chief attachment being posteriorly. It bled on examination.

The patient was treated with a tube of 60 mg. radium screened with 2 mm. of lead, and received an exposure of sixty hours' duration, spaced over ten days.

He was examined six weeks later; the growth was found to be much reduced in size, and no longer ulcerated. It was much less fixed to surrounding tissues.

He was examined by his surgeon again on December 6th, who declared the condition to be so greatly improved that it was quite operable, and performed Kraske's operation.

On March 4th, 1912, the patient returned to the Institute for a course of prophylactic irradiation, and received thirty hours' treatment with 60 mg. of radium screened with 2 mm. lead.

He reported himself on June 18th, 1912, as being perfectly well and in excellent general health. No sign of recurrence could be detected after a most thorough examination.

Carcinoma of Rectum.

In this case (No. 48), M., aged 61, there was a six months' history of alternating diarrhoea and constipation. Immediately before coming to the Radium Institute he had been examined by a well-known surgeon, who declared him to be suffering from an inoperable carcinoma of the rectum.

The patient complained of "pressure" in the rectum, with difficulty in defaecation, and the passage of a mucoid discharge. No bleeding had taken place. On rectal examination a growth could be felt 5 cm. above the anus. It was firmly fixed, annular, and ulcerated, and affected chiefly the anterior wall of the rectum. The lumen of the growth admitted the tip of the little finger. Fifty mg. of radium in a tube, covered by a screen of 2 mm. of lead, were applied in the lumen of the growth for six hours a day for ten days.

A month later considerable improvement was noted. The growth was much smaller and covered with smooth intact mucous membrane. Above the stricture could be felt one or two nodules. Treatment as before was repeated for five days.

Five months later no infiltrating growth could be felt, and only what was apparently an easily dilatable fibrous stricture remained.

Carcinoma of Rectum.

The patient (Case No. 108), M., aged 55, was first seen on December 15th, 1911, and found to be suffering from recurrent carcinoma on the posterior wall of the rectum, which had appeared five years after a Kraske's operation. Colotomy had been performed on November 24th, 1911.

The rectal opening was close to the sacrum, and extremely contracted by malignant infiltration, so that no digital examination could be made. One or two nodules were visible at the

posterior border of the orifice of the bowel. The patient complained of much persistent pain in the rectum and left thigh and of frequent bleeding.

The first treatment consisted of thirty hours' application in the rectum of a 50 mg. tube of radium in a screen of 1.5 mm. of lead.

Two months later the patient felt better; all haemorrhage had ceased, the pain had nearly disappeared, and the induration round the anus was much less.

The patient remained in this condition for some months, but the bleeding and pain reappeared, a rectal discharge developed, and the buttocks on either side of the anus became infiltrated. The patient was treated with the same tube three times, but in May, September, and November, 1912, flat half-strength applicators containing 180 mg. radium were screened with 2 mm. of lead and placed over the infiltrated buttocks. This resulted in considerable improvement. The induration appreciably diminished, the discharge became less, the pain was alleviated.

The patient's general condition is good. He attends business at his office. He is still under treatment.

Carcinoma of Rectum.

This patient (Case No. 117), M., aged 68, who was the subject of advanced mitral disease, had suffered from persistent diarrhoea for six months. He was examined by a leading provincial surgeon, who diagnosed carcinoma of the rectum, but considered operation inadvisable by reason of the patient's age and ill health.

He was first seen on December 29th, 1911. Sigmoidoscopic examination revealed a flat hard carcinomatous plaque ulcerated at its upper part. It was confined principally to the posterior rectal wall, and its lower border was 16 cm. from the anal orifice. The patient experienced constant pain, which was very severe on defaecation.

He was treated by inserting a tube of 50 mg. of radium screened by 2 mm. of lead into the lumen of the bowel and received an exposure of thirty hours' duration, spread over five days.

Following the treatment the patient slept well, ate well, the diarrhoea ceased, and all pain disappeared. Seven months later he died, but his medical attendant stated that the freedom from pain persisted right up to the day of his death.

Carcinoma of Rectum.

This patient (Case No. 185), F., aged 56, was seen in April, 1912. She had an indefinite history of abdominal pain and obstinate constipation. A surgeon examined her and declared her to be suffering from an inoperable carcinoma of the rectum.

Examination revealed a hard, annular growth of the bowel 16 cm. above the anus. It was slightly ulcerated anteriorly, bled readily on examination, and invaded the surrounding tissues. The lumen was very small and irregular, the size of a crow quill, and a very offensive discharge was continuously present. There was constant rectal pain. The patient was very weak and emaciated.

On April 3rd, 1912, an emanation tube, initial activity 83 mg., screened with 1.5 mm. of lead, was placed in the lumen of the growth and left there for twenty-four hours. Six weeks later a severe reaction was reported, but afterwards the patient's health improved much, the discharge ceased to be offensive and the pain was only slight. The lumen of the bowel was much larger and the ulceration had disappeared.

On June 5th the patient was again treated with an emanation tube, initial activity 63.2 mg., placed in a screen of 2 mm. of lead, and an exposure of twenty-four hours was given. In October the patient had no discharge and no pain, was having natural actions of the bowel, attending to her household duties, and improving much in general health. She had gained nearly 2 st. in weight. She declined examination on the ground that she was perfectly well.

Carcinoma of Rectum.

This patient (Case No. 5,088), M., aged 37, had suffered from tenesmus and the passage of blood-stained mucus from July, 1910. He steadily became worse. In July, 1911, inoperable carcinoma of the rectum was diagnosed and the nature of the growth verified microscopically. A month later colotomy was performed.

In December, 1911, the patient was examined at the Radium Institute. He was in constant pain, had much bleeding and discharge, and was thin, worn, and anxious. On rectal examination an annular growth could be felt 2.5 cm. from the anus. It was hard, craggy, ulcerated, and firmly fixed. The lumen was small and tortuous.

Treatment consisted of the insertion of a tube, containing 60 mg. of radium screened by 2 mm. of lead, into the lumen of the growth for periods of six hours for five days. This was repeated five weeks later, and in March, 1912, the patient's weight had increased. He slept well, and the discharge was much diminished. The pain had gone. The growth was still large and hard, but the ulceration had disappeared. The same treatment was then given for four days.

In November, 1912, the patient again presented himself for examination. He looked in good health and had been doing four hours a day of manual labour. During the last few weeks he had some return of pain. The growth was harder and smaller. Treatment is being continued.

CARCINOMA OF THE STOMACH.

A few inoperable cases of cancer of the stomach have been treated by radium, not in the hope of cure, but with the object of checking the growth and alleviating the symptoms.

Some slight degree of benefit has resulted from the application of powerful apparatus screened with 2 mm. of lead over the gastric region, the pain being lessened, the frequency of vomiting decreased, and the general health improved.

CARCINOMA OF THE BREAST.

The results of radium therapy in the treatment of cancer of the breast are, on the whole, encouraging, and this is especially the case when the primary growth is of the sclerotic rather than of the medullary type, when the secondary deposits occur in the skin lymphatics and lymphatic glands, and there are no internal metastases.

Radium should never be used as a substitute for operative interference, but when the case is inoperable it will do much to relieve pain, promote the healing of ulcerated surfaces, and check the growth of the secondary deposits. In not a few cases it will bring about the almost complete absorption of superficial carcinomatous nodules and infected glands. Instances have been noted in which the physical signs were strongly suggestive, if not positively indicative, of carcinomatous deposits in the lungs, and the prolonged application of from thirty to forty hours of a large quantity of radium screened through 2 mm. of lead has brought about an apparent resolution. In rapidly growing cancers of the encephaloid type radium can do little but relieve pain. The post-operative lymphatic engorgement of the arm on the affected side is sometimes distinctly benefited by the application of a heavily screened tube of 50 to 100 mg. of radium placed at the apex of the axillary cavity, an exposure of twenty-four to thirty hours spread over five days being given.

CASES.

Carcinoma of Breast.

In this case (No. 89), F., aged 46, the disease had existed for five years before the patient consulted a surgeon. The condition was then quite inoperable.

In December, 1911, she came for treatment. The right breast was densely indurated, firmly fixed, and surmounted by a superficial ulcer 6 by 4.5 cm. in area, which had completely destroyed the nipple. The right axillary, supraclavicular, and infraclavicular glands were all enlarged and hard. She complained of a cough and pain in the right side of the chest, where the expansion was relatively much diminished. She had also pain in the right arm, and the movements of the shoulder-joint were much restricted.

The first treatment consisted in placing a half-strength plate containing 50 mg. of radium over the ulcer, with a 30 mg. tube in the axilla. The screening was 2 mm. of lead; the exposure was six hours daily for five consecutive days. This produced a local improvement, but at the end of January her respiration was much embarrassed and the cough much more troublesome.

In February a second treatment was given, the screening and time being exactly the same as at first, the apparatus employed being two quarter-strength plates containing 40 and 70 mg., two full-strength plates containing 30 mg. each placed directly over lesions, and a tube of 30 mg. in the axilla. This was followed by local and general improvement.

In April, during a third treatment, a half-strength plate containing 150 mg. was also used, with the view of acting on the implicated pleura and lung tissue.

In May the air entry to the lung was free, the pain and cough were gone, and the induration of the breast was much less. A fourth treatment was then given, resembling the third, and in July the ulcer had healed completely, the induration was almost gone, and all the glands were smaller. Unmistakable signs, however, pointed to an extension of disease within the chest below the axilla, and a fifth treatment was undergone.

In September the superficial lesions were all negligible, but the dullness below the right axilla had increased, and respiration was hurried and embarrassed, the patient having to use oxygen. She then had a sixth similar treatment, and at the end of November was feeling better and breathing more comfortably, whilst the physical signs were no worse. She is to come again early in 1913.

Carcinoma of Right Breast (Recurrent).

In March, 1910, the patient's right breast and right axillary glands (Case 129, F., aged 52) were removed for carcinoma, and a recurrence which appeared in August, 1911, was not shown to the surgeon till the end of the year, when the condition was inoperable.

In January the patient came for treatment with many nodules and a diffuse induration around the operation scar, the latter extending to both folds of the axilla. The right supraclavicular and infraclavicular glands were enlarged, hard, and fixed. At

the centre of the scar was an ulcer 2 cm. in diameter. The left breast was hard, and some glands could be felt in the left axilla.

She was treated with a 30 mg. tube in each axilla, and five flat applicators containing 200 mg. of radium placed directly over the affected parts. The screening was 2 mm. of lead throughout, and the period of exposure six hours daily for five consecutive days.

Two months later the ulceration had healed, and all the enlarged glands, as well as the mass in the left breast, were reduced in size. The induration was less, except in the anterior axillary fold, where it had increased slightly.

A second similar treatment, using only 180 mg. radium, was then given.

Later in the year the medical attendant reported that the condition was quiescent, that the patient was feeling very well, and attending to all her duties.

Carcinoma of Right Breast (Recurrent).

The patient (Case No. 151), F., aged 64, had the left breast removed and the axilla cleared in June, 1911, for carcinoma. In February, 1912, some progressive induration appeared at the upper end of the scar incision, and the left arm began to swell.

She was treated by three applicators containing 150 mg. of radium and a tube of 30 mg. placed in the axilla. The screens were 2 mm. of lead throughout, and the duration of exposure six hours daily for five consecutive days. By the end of April much of the induration had disappeared and the swelling of the arm was greatly reduced.

A second treatment by one 30 mg. applicator and the 30 mg. tube was repeated with the same screen and exposure.

The patient was seen last in November. There was then no induration perceptible, the swelling of the arm had disappeared, and her health was excellent.

Carcinoma of Left Breast (Recurrent).

The patient (Case No. 191), F., aged 49, had the left breast and left axillary and supraclavicular glands removed in July, 1907. A recurrent nodule was excised from the scar in November, 1909. A second recurrence early in 1912 was considered inoperable.

When she came for treatment in April a nodule of 1.5 cm. diameter was adherent to left fifth rib, the overlying skin being ulcerated, and the tissues over the fifth and sixth costal cartilages were much indurated. Some small hard glands were felt behind the left sterno-mastoid. She was losing weight.

Applicators containing 160 mg. with a tube of 60 mg. radium were applied for six hours daily for five consecutive days, all screens being 2 mm. of lead. Six weeks later the nodule had disappeared, the glands and induration were less, and she had gained in weight.

After a further six weeks fresh induration appeared over the third and fourth left costal cartilages, and there was considerable dyspnoea on exertion. Applicators containing 300 mg. and a tube of 60 mg. of radium were applied, time and screens being as before. Three months later all the induration had disappeared and the glands were as small as swan shot; there was no longer any dyspnoea.

In October a gland was discovered at the apex of the axilla with some redness over the fifth rib. She was again treated for the same period as before, with the same screens, with applicators containing 300 mg. She is still under treatment, steadily improving in general health, and gaining weight.

Carcinoma of Right Breast.

In this case (No. 295), F., aged 55, the disease had existed for one year before the patient consulted her medical attendant in September, 1912. The whole of the right breast was then indurated and firmly fixed to the underlying tissues, and in the upper and outer quadrant was a rounded mass of 6 cm. in diameter, bright red in colour, and ulcerated. On the inner side of this and extending to the edge of the sternum was a leather-like area of "cancer en cuirasse," while numerous small nodules could be felt at the lower border of the breast. In the right axilla, supraclavicular fossa, and posterior cervical triangle enlarged glands were felt. The patient complained of excessive pain.

A tube of 30 mg. was placed in the axilla and three half-strength plates, containing 50, 80, and 150 mg., applied over breast and glands. The screening was 2 mm. lead, and the exposure five consecutive days of six hours each.

Two months later the mass on the breast was much reduced in size and the ulcer had healed. The infiltrated area by the sternum had become quite soft, and the glands and affected areas were smaller. The pain was quite gone and the patient had gained in weight.

The same treatment was given a second time, and the improvement continued. She is still under treatment.

Carcinoma of Right Breast (Recurrent).

In this case (No. 5,100) F., aged 60, the disease was of five years' duration. An operation had been performed by a leading hospital surgeon in January, 1906, when the breast was removed and the axilla cleared. Recurrence took place in June, 1910, with several small nodules arranged in the form of a circle 6 cm. in diameter having its centre at the middle of the breast incision. These nodules were treated with a rays for some time, but steadily increased in size.

The patient was first seen on February 1st, 1912. She then had six hard nodules arranged as above described, each the size of a small walnut and very tender on pressure.

She was given two series of treatments, with half-strength applicators screened with 2 mm. lead—the first of five days' duration, six hours each day, February 1st to 7th; the second of five days' duration, six hours each day, April 22nd to 26th. The nodules steadily decreased in size and the tenderness disappeared.

She came for examination on June 4th. All the nodules had gone. There was no longer any tenderness, and she was in excellent general health. She was afterwards seen by the surgeon who operated on her, who expressed his great satisfaction at the result of the radium treatment.

Carcinoma of Breast (Left).

In Case No. 5,216, M., aged 72, the duration of disease was about three years. The nipple of the left breast became hardened and retracted, and finally ulcerated. The patient was not considered a suitable subject for operation.

Examination revealed an oval tumour of 5 cm. diameter surmounted by an indurated ulcer 1.7 by 1.5 cm., which occupied the site of the nipple. In the skin towards the inner side five hard nodules could be felt.

He was treated in July, 1912, with applicators containing 110 mg. of radium with screens of 2 mm. of lead. Over the ulcer a screen of only 1 mm. of lead was used. The time of exposure was five hours daily for five consecutive days.

In September, 1912, the ulcer was smaller and the swelling less. A fresh treatment for a similar period was carried out, the screens being 1.5 mm. of lead and applicators containing 190 mg. of radium being used for the same time as previously.

In October the ulcer was much softer, and a similar treatment was carried out. In November the tumour had disappeared, the ulcer was healed over, and the nodules were scarcely perceptible. The patient is still under treatment.

Carcinoma of Right Breast (Recurrent).

This patient (Case No. 5,008), F., aged 53, came in August, 1911, for treatment of some small hard nodules in and below the right axilla. The right breast had been removed with the glands of the right axilla in June, 1904, and two earlier local recurrences had been excised in 1908 and 1910. She had much pain in the axilla and right arm, and was taking morphine.

Screens of 2 mm. of lead were used throughout. The nodules were treated with an applicator containing 30 mg. of radium daily for three hours on four consecutive days.

Three weeks later these nodules had disappeared, and the pain was quite gone. Some fresh nodules, however, could now be felt just below the clavicle; the same apparatus was used again for three hours daily for four consecutive days in September, and again for three hours daily for seven days in October. In December she wrote saying all the nodules had disappeared, and she had no pain.

In April, 1912, some thickening appeared in the scar in two places, and a nodule was found at the posterior border of the right sterno-mastoid. Applicators containing 110 mg. were used, with a 50 mg. tube in the axilla, all being applied for six hours daily on five consecutive days. An applicator of 40 mg. was put over the nodule on the sterno-mastoid for the same period; it became much smaller, and the induration disappeared.

In September the patient came again with pain in the arm, stiffness of the shoulder, dyspnoea, and thickening in the anterior axillary fold. She was weak and very thin. A tube of 60 mg. and applicators were again used as before for six hours on four consecutive days, and a month later a similar treatment with somewhat larger apparatus was carried out. Eight weeks after this the dyspnoea had become less, the pain was gone, and the patient could move her arm freely again. She is still under treatment.

PAGET'S DISEASE.

Two patients afflicted with this condition have been treated with radium.

The first, an unmarried woman of 35, had a patent urachus, and the disease had commenced at the umbilicus. It readily yielded to radium, and an apparent cure was effected.

The second, a married woman aged 58, had the left breast affected. She came under treatment quite recently, but a very great improvement has already been brought about, though the case is not yet finished.

In both instances treatment was carried out with a quarter strength applicator, unscreened, and an exposure of one and a half hours' duration.

CASES.

Paget's Disease of Umbilicus.

The disease (Case No. 5,010, F., aged 35) was of three years' duration. It had been subjected to a variety of treatments without effect, and was slowly but steadily increasing in size.

The patient was first seen on August 21st, 1911. There was then a roughly circular patch 5.5 cm. in diameter, with its centre at the umbilicus, covered with a flaky, yellowish crust, which, when detached, left a reddish, slightly ulcerated surface underneath. There was no bleeding, no infiltration, and no rolled edge. The diagnosis of Paget's disease had been made by a leading dermatologist. The patient had a patent urachus.

A quarter strength applicator of sufficient size to cover the lesion completely was applied without screen for one and a half hours on August 21st, 1912.

She was examined on September 13th. There had been a fairly vigorous reaction. The inner portion of the ulcer nearest to the umbilicus was covered with new healthy epithelium, but the outer portion was still red and inflamed. She came again a fortnight later, when the lesion was found to be completely healed.

A slight recurrence took place early in September, 1912. The same treatment was adopted with an equally good result. The patient has since kept perfectly well.

CARCINOMA OF THYROID.

In Case No. 5,127, F., aged 35, the disease was of six months' duration. The symptoms were cough with occasional hæmoptysis, dysphagia, and dyspnoea; marked stridor accompanied any exertion or excitement. She consulted a leading hospital surgeon in March, 1912, who diagnosed carcinoma of the thyroid (inoperable), and advised radium.

She was first seen on March 26th, 1912. Examination showed distinct enlargement and hardness of the thyroid, most marked inferiorly. The percussion note was impaired over the apex of the right lung, and vocal resonance and fremitus were increased in the same area. X-ray screening showed a faint shadow just below the inner end of the right clavicle.

The patient had three series of treatments with half-strength apparatus containing 120 mg. radium screened with 2 mm. lead. The first, of four days, six hours each day (March 27th to 30th); the second, of five days, six hours each day (April 29th to May 3rd); the third, of five days, six hours each day (June 3rd to 7th).

She reported herself for examination on September 23rd, 1912. The enlargement and hardness of the thyroid had disappeared. Her general condition was good, and she had gained weight. She no longer had any dysphagia and experienced only a very slight degree of dyspnoea on great exertion. There was no stridor. The physical signs at the apex of the right lung were unaltered.

The patient has returned to her work as schoolmistress, but still reports herself every two months. No further treatment has been necessary.

RODENT ULCER.

This is of all forms of malignant disease the one which is most amenable to the action of radium. Untreated rodent ulcers not exceeding 2 cm. in diameter, and not affecting mucous membrane, cartilage, or bone, almost invariably yield to one exposure of one to three hours' duration with a full-strength applicator unscreened.

If the ulcer occupy a large superficial area—say, 20 sq. cm. and upwards—an unscreened application over the whole area at the same time is inadvisable in view of the severe systemic disturbance which would follow such a procedure, and the lesion should be treated by two, three, or four applications made in rotation to different parts of its surface, at intervals of three weeks or a month.

When a mucous membrane is affected rodent ulcers prove much more refractory, though exception should perhaps be made in regard to the palpebral mucosa, as small rodent ulcers in this situation often respond well to exposures of strong unscreened apparatus of fifteen to twenty minutes' duration given consecutively for three days.

If the rodent ulcer has attacked bone or cartilage, great care must be exercised not to give too heavy an exposure, or a very acute, painful, and prolonged inflammation may be produced.

When the extent, position, or character of the ulcer precludes the possibility of strong unscreened exposures, the best results will probably be attained by prolonged exposures with heavily-screened apparatus using the "ultra-penetrating" rays only. This method is followed by little or no active inflammatory change, and, in addition, often alleviates the pain of the ulcer in a very definite manner. The action of radium in these cases can be greatly aided by judicious skin grafting as soon as the base of the ulcer has assumed a healthy appearance.

Many of those ulcers which have received treatment extending over a period of many years with x rays, zinc ionization, CO_2 , etc., respond badly to radium treatment, and it is unwise to attempt to make any pronouncement as to the probable result. Quite frequently the previously treated tissues break down to an extent which far exceeds the existing ulceration, and repair is very slow and imperfect.

More than half of the cases of rodent ulcer which applied for treatment at the Radium Institute during the past year were of this character, and the destruction of

tissue was so great that no hope of satisfactory repair could be entertained.

CASES.

Rodent Ulcer of the Neck.

In Case No. 102, F., aged 53, the disease was of twenty-five years' duration. All kinds of treatment had proved ineffective, and during the last three years the ulcer had steadily grown larger.

The patient was first seen on December 12th, 1911. There was a flat, roughly oval, shallow ulcer in the right lumbar region, measuring 4.2 by 2.7 cm. The patient was given one treatment with a half-strength applicator containing 70 mg. of radium, unscreened, for one and a half hours, on December 29th, 1911.

She reported herself for examination on February 2nd, 1912, when the ulcer was found to be almost healed and to measure only 2.6 by 1.3 cm. No further treatment was given, but the patient was asked to come again in two months.

She returned on May 14th, 1912, when the ulcer was seen to be completely healed.

Rodent Ulcer.

The patient (Case No. 66, M., aged 59, had an oval ulcer measuring 1.5 by 1 cm. situated just below the inner canthus of the left eye. It had begun two and a half years before and was steadily increasing in size.

A full-strength applicator was placed in contact with the lesion, without a screen, for two hours on November 9th, 1911. On February 24th, 1912, nothing of the lesion remained. In September a nodule the size of a millet seed appeared at the site of the former lesion. This was again treated as before and after a few weeks nothing save a faint scar was left.

Rodent Ulcer.

The patient (Case No. 133, M., aged 75, had been treated during three years by zinc ionization, carbon dioxide snow and radium, with temporary success, for a small rodent ulcer on the right ala nasi. Each new treatment had brought about an apparent cure, but recurrence took place within two months. On January 24th, 1912, a full strength applicator was placed in contact with the ulcer without a screen for one and a half hours. The reaction was slow, but by April nothing remained of the lesion but a small white depressed scar. There has been no trace of recurrence.

Rodent Ulcer of Ala Nasi.

In Case No. 175, M., aged 65, the disease was of three years' duration. He had been treated with x rays, high frequency, fulguration, and thoradin, but without any good result.

He was seen and treated on March 27th, 1912. He then had an almost circular ulcer, 1.3 by 1.4 cm., on the centre of the right ala nasi. The floor of the ulcer was very thin, being composed of but little more than nasal mucous membrane. The edge of the ulcer was much infiltrated, especially at its upper part. He was given one treatment with a full-strength apparatus applied for fifty minutes to the floor, and one and a half hours to the edge of the ulcer.

He was examined on May 23rd, 1912, when the ulcer was found to have healed perfectly, and to be covered with a smooth and supple cicatrix.

The patient, who lives in Canada, wrote at the end of August saying there was no sign of recurrence.

Rodent Ulcer.

Case No. 242, male, aged 49, had had a rodent ulcer on the left side of his neck for eighteen years. It had been treated by many applications of x rays, and three times by excision, but never healed completely.

When he came to have radium applied in June there was an ulcerated area of 10 by 7 cm. on the side of the neck. The whole of the area was covered by half-strength applicators with screens of $\frac{1}{8}$ mm. of lead, for four hours on each of four consecutive days. This treatment was repeated three weeks later. The upper part of the ulcer rapidly healed, while the edges became much thinner. Two similar treatments were given at longer intervals, and the physician reported towards the end of the year that the ulcer was nearly healed, and that the patient had left England.

Rodent Ulcer.

This patient (Case No. 5,137), F., aged 69, had been treated through nine years by many methods, including the cautery, carbon dioxide snow, and x rays, but never with complete success.

When she came she had an ulcer with raised margin measuring 2 by 1 cm., situated close to the inner canthus of the right eye. A half-strength applicator was placed over the ulcer without any screen for one and a half hours on May 1st.

On June 12th the ulcer had healed, but a nodule remained close to the inner canthus. This was treated by a small full-strength applicator, applied for one and a half hours without a screen; the nodule subsequently broke down. When the wound healed in July there was a smooth, soft, healthy scar.

Rodent Ulcer.

The patient (Case No. 5,044, F., aged 50, had a circular ulcer of 1.8 cm. diameter situated high up on the left cheek. It was of four years' duration and had recently increased in size more rapidly. She had had no previous treatment excepting with ointments.

On September 16th, 1911, a half-strength apparatus was placed directly over the ulcer for one and a half hours. On October 27th following she came to show herself, and a smooth white scar occupied the site of the former ulcer.

Rodent Ulcer.

Case No. 5,227, M., aged 60, when seen had a roughly circular lesion 2 cm. in diameter on the left eyebrow. It had existed for sixteen years in spite of treatment with lotions and ionization. The base was indurated, the margin was thick and irregular, and the floor red and tender.

A full strength applicator was put on the growth for one and a half hours without any screen on July 27th, 1912. The ulcer rapidly cleared up, and the induration slowly disappeared. When seen in November there was a perfectly smooth, healthy scar.

SARCOMATA.

Whenever possible sarcomata are best treated by the insertion into their centre of a tube containing 50 to 100 mg. of radium, with a screen of 0.5 or 1 mm. of silver; it is left in position for twenty or thirty hours; the application is repeated after a month.

This frequently proves most effective; the tumour steadily shrinks in size, and becomes replaced by a dense fibrous nodule which shows little or no tendency to grow.

If this method be impracticable, prolonged exposures with flat applicators screened with 1 or 2 mm. of lead, and placed so as to cover as great an extent of the growth as possible, and to produce a "cross-fire" action of the rays, will often do much to check the growth; but this procedure is not nearly so promising as the preceding one. In either case it is essential to give as vigorous a treatment as possible, as the great vascularity of these growths, and their rapid and wide dissemination by the blood stream, are factors which militate very strongly against the chances of success.

CASES.

Sarcoma of Superior Maxilla.

The patient (Case No. 148), M., aged 72, was first seen on February 20th, 1912, when the disease was stated to be of three months' duration. The growth was rapidly increasing.

Little or no alteration in the size of the maxilla was appreciable externally, but there was marked bulging downwards of the left half of the hard palate, and the left nostril was occluded by the pushing of the antral wall over to the nasal septum. The patient had epiphora and diplopia.

On February 20th an emanation tube (initial activity 44.5 mg.) in a screen of 1 mm. of lead was inserted into the growth, and left there for twenty-four hours. A portion of the growth was removed at the time of operation and submitted to microscopic examination. It proved to be round-celled sarcoma.

The patient was examined on April 25th. The bulging on the left half of the palate was much less, and the left nostril was no longer occluded. There was no diplopia and no epiphora. Transillumination, however, showed that there was still some abnormal opacity of the left antrum, and the patient was advised to have a second treatment.

On April 26th an emanation tube (initial activity 30 mg.) in a screen of 1 mm. of lead was inserted into the antral cavity and left there for twenty-four hours.

The patient's doctor wrote on July 20th, 1912: "I have again seen our patient, and he is wonderfully well. There is nothing in the nostril now, nor is there any pain. The swelling in the mouth has gone. His general condition is excellent."

Sarcoma of Pharynx.

At the beginning of 1912 the patient (Case No. 232), M., aged 56, experienced a choking sensation at night with a sharp pain in his neck. He consulted a surgeon, who found a swelling in the posterior pharyngeal wall, and, after a biopsy which showed the growth to be a sarcoma, excised the tumour, cutting down to the bone, which was found to be roughened. After this the patient's neck remained very painful and stiff, and, though it improved with massage, it still caused great suffering and inconvenience. Shortly after the operation a mass of granulation tissue in the posterior pharyngeal wall was treated with the cautery, but the wound never healed and there was continuous suppuration.

When seen on May 29th, 1912, the posterior pharyngeal wall was bulging forward. A rectangular area of ulceration, measuring 3 by 1.5 cm., covered with granulations, was situated on the centre of the prominence, with pus exuding from its lower end. Deep palpation behind the angles of the jaw revealed a swelling, more marked on the right side. The patient was very weak, had considerable dysphagia, and suffered from constant pain in his neck. The first treatment lasted through five consecutive days. Three applicators, containing 310 mg. of radium screened with 2 mm. of lead, were fastened externally below and behind the angles of the jaw, so as to cross-irradiate the affected areas. This was done five hours daily for five consecutive days. The exact situation was altered slightly from day to day. A small circular applicator, containing 30 mg. of radium screened with 1 mm. of silver and arranged with a thick lead case to protect the mouth, was held by a silver wire against the ulcer for an hour each day. Before this treat-

ment had been completed the patient reported that he had been able to sleep well for the first time for many months.

On July 16th he came to be treated again. He had then no pain or dysphagia. The suppuration had ceased and the pharyngeal ulceration had completely healed. The swelling in the pharynx was reduced to an oval prominence about 3 cm. long, and no definite tumour could be detected by external palpation. The patient was back at his ordinary work and feeling well. The treatment was then repeated, and the patient returned to his home. He has not reported since.

Lympho-sarcoma of Neck.

In Case No. 50, M., aged 41, the disease commenced in December, 1910, as a growth just below the right mastoid. An operation was performed in April, 1911; the growth on microscopic examination proved to be sarcoma. It recurred in June, 1911, and a second operation was performed on August 14th, 1911. There was recurrence again in September, 1911. The patient then consulted a leading hospital surgeon, who declared the condition to be inoperable and suggested radium.

The patient was first seen on October 24th, 1911. There was an oval swelling at the level of the angle of the jaw behind and below the right ear. It measured 6.5 by 4 by 1.3 cm.; it was hard and firmly fixed to the underlying tissues. The skin over its most prominent part was glazed and hyperaemic. The growth was the seat of occasional severe lancinating pains.

He had fourteen treatments between October 24th, 1911, and January 16th, 1912, with full-strength applicators containing 260 mg. radium screened with 2 mm. of lead. The growth steadily decreased in size and all pain disappeared.

When examined on February 16th, 1912, no trace of the growth could be found, and the patient expressed himself as feeling quite well.

He was seen again on June 29th, 1912. He was then in perfect health and had gained 9 lb. in weight.

Sarcoma of Thigh.

The patient (Case No. 211), M., aged 18, had an injury to the right thigh at the junction of the middle and lower thirds in March, 1912, and shortly afterwards an increasing swelling appeared at the site of the injury. The tumour was smooth and oval, with ill-defined edges, and slightly tender on pressure. Careful examination led an eminent surgeon to pronounce it to be periosteal sarcoma, and he advised operation, but the patient refused to submit.

On May 10th, 1912, an emanation tube with initial activity equivalent to 100 mg. of radium bromide, in a screen of 1 mm. of lead, was embedded in the tumour and left for twenty-four hours. A portion of the growth was removed at the time of the operation, and microscopic examination showed it to be spindle-celled sarcoma. Seven weeks later an emanation tube of initial activity equivalent to 75 mg., in a 1 mm. lead screen, was inserted for twenty-four hours. After the first treatment the tumour ceased to enlarge, after the second it became somewhat smaller, and the patient was able to walk with comparative ease.

The surgeon reported in November that no signs of dissemination had made their appearance, and that the original tumour was not causing the patient any trouble whatsoever.

NAEVI.

FLAT SUPERFICIAL NAEVI, CAPILLARY NAEVI—"PORT-WINE" STAINS.

These are the most difficult of all naevi to treat, and much care and patience must be exercised in order to bring about a satisfactory result.

The factor of personal idiosyncrasy is always prominent, and it is exceedingly difficult to lay down any definite rules as to strength and duration of exposure. It is best to proceed with great caution, giving a short, unscreened exposure, and if necessary gradually increasing the same until a satisfactory reaction has been obtained. As a general rule, apparatus of quarter or half strength should be used, the screening should not exceed 0.02 mm. aluminium, and the exposures should range from ten to sixty minutes' duration.

The best results can be looked for when the naevus is quite superficial, and shows no tendency to infiltration. If much infiltration exist the treatment will have to be much more vigorous, and a destructive reaction of slight degree produced. A smooth, supple, and white scar will be left.

CASES.

Capillary Naevus.

In Case No. 174, F., aged 19, the naevus was congenital; it was roughly circular, dark, plum-coloured, and about 3 cm. in diameter. It was situate in the centre of the right cheek. No previous treatment had been tried. On March 27th, 1911, a half-strength applicator screened with 0.01 mm. of aluminium was placed in contact with the naevus for forty minutes. A fair reaction followed.

On May 9th a quarter-strength applicator with the same screen was used for one hour. On June 20th the first treatment

was repeated. The patient was seen in September, when the naevus was so light in colour as to be scarcely noticeable, and the overlying skin was perfectly smooth.

Capillary Naevus.

The patient (Case No. 229), F., aged 4 months, was brought on May 29th, 1912, with a raised blue circular naevus 2 cm. in diameter over the middle of the left parietal bone. A full-strength apparatus screened with 0.04 mm. aluminium was applied to cover the lesion for seventeen minutes.

When seen a month later only the posterior margin remained discoloured, and the patient was treated with a half-strength applicator, screened as before, for twenty minutes.

On September 13th the naevus had almost disappeared, the tissues felt normal, and the hair was covering the slightly red area which remained.

Capillary Naevus.

The patient (Case No. 5,040), F., aged 16, came on September 11th, 1911, for treatment of a very disfiguring purple superficial naevus occupying the upper half of the left cheek. It dated from birth, and electrolysis and other treatment had brought about very little improvement. It was treated, a portion at a time, with a large quarter-strength or smaller half-strength applicators screened with 0.01 mm. of aluminium, the exposures varying from forty minutes to one hour. An interval of a month was allowed for each reaction. The patient emigrated in September, 1912, and the colour then was reduced to a fairly uniform pale pink tint, except close to the eyelids, where it was somewhat deeper.

CAVERNOUS NAEVUS.

These lesions are frequently particularly suitable for treatment by "cross-fire," and in such cases good results can generally be expected.

Half-strength applicators should be used with screens of 0.1 mm. of lead and exposures of from twenty minutes to one hour's duration, given daily for three consecutive days, and the series repeated in a month's time. Under this method of treatment the naevus slowly and steadily shrinks, and the process is unaccompanied by any surface irritation.

CASES.

Venous Naevus of Finger.

Case No. 19, F., aged 11, presented a venous naevus of the right middle finger, which was congenital but had slowly increased in extent in spite of two operations.

When seen in September, 1911, she had a large blue, pulpy, subcutaneous mass occupying the dorsal palmar and outer surfaces of the right middle finger. Two half-strength applicators, containing 60 mg. screened with 0.04 mm. of aluminium were used to cross-fire the naevus, the exposure being twenty minutes. A sharp reaction followed.

On November 16th the naevus was smaller, and the treatment was repeated for a thirty minutes' exposure.

In January, 1912, and again in March the same applicators were used for forty-five minutes with a screen of 0.1 mm. of lead. Finally in May this treatment was repeated for thirty minutes on two consecutive days.

When seen in September the finger was normal in colour, and though some slight thickening remained it was not sufficient to trouble the patient either by its size or appearance.

Cavernous Naevus.

In Case No. 5,021, F., aged 1 year, a small naevus was present on the tragus of the left ear at birth, and rapidly increased to the size of a large orange in spite of treatment by electrolysis and carbon dioxide snow.

When first seen, in August, 1911, the cavernous tissue involved the lower part of the ear and the side of the neck, while a scarred swelling rested on the clavicle, dragging the child's head down to the left.

Four half-strength applicators containing 30 mg. each, with a screen of $\frac{1}{16}$ mm. of lead, were used throughout the treatment; the exposures were made at first for four, and later for three, consecutive days, beginning with sittings of fifteen minutes each, gradually and carefully increasing the time to thirty minutes. The intervals allowed for reaction were slightly over a month. When seen in November the patient had had nine treatments in all. The naevus was reduced to the size of a pigeon's egg, occupying the posterior portion of the pinna and lobe of the ear. Some bluish capillary areas were present in the soft relaxed skin, but the scarring had almost completely disappeared, and the child's head was no longer displaced by the size and weight of the tumour.

Cavernous Naevus.

Case No. 5,104, F., aged 18 months, was brought to be treated for a large hemispherical pulpy naevus of 4.5 cm. diameter occupying the upper part of the left cheek. The condition had developed from a congenital red flat birth-mark, in spite of treatment with carbonic snow and electrolysis. The child's mouth and nose were distorted, and the swelling projected upwards in front of the left eye.

The exposures for this treatment were always given on three consecutive days with two half-strength applicators of 30 mg. each screened with 0.1 mm. of lead. The time of each sitting

was twenty minutes during the first treatment in February, 1912, increased by five minutes each time up to three-quarters of an hour. The treatments were given at intervals of slightly over a month, and the child has had eight in all.

When seen in December the lesion was reduced in size sufficiently to relieve the dragging on the mouth and nose, and there was no obstruction to vision.

This patient is still under treatment.

KELOID.

The results obtained in the treatment of this condition with radium are admirable. Keloids of recent formation and occurring in young subjects are the most easily cured. Applicators of half strength should be employed with screens of 1 mm. of silver and an exposure of from fifteen to twenty hours extended over three successive days. The series should be repeated at intervals of one month.

By this method of treatment a steady and gradual return of the tissues to the normal is produced without any surface irritation.

Small elevated and rapidly growing keloids may be safely treated by a single exposure of one to one and a half hours' duration with a half-strength apparatus un-screened. The resultant scar is usually quite smooth and supple, and shows no tendency to further keloidal formation.

CASES.

Keloid of Face and Hands.

Case No. 13, F., aged 27, was severely burnt on the face and hands with petrol on March 30th, 1911. Healing was not complete until the middle of June, and shortly afterwards all the scars became keloidal and rapidly increased in size.

The patient was first seen on September 11th, 1911. At that date there was a large, very dense, bright red keloid covering the nose and both cheeks, and occupying the position usually picked out by lupus erythematosus. Both lower eyelids were drawn down, and there was epiphora. There were other keloids over the forehead (most marked on the right side) while in front of each ear there was a dense keloidal band 0.3 cm. in height and running from the level of the external canthus to the angle of the jaw. Another small keloid was present on the left side of the upper lip. The face was like a mask, rigid and expressionless. The dorsal surfaces of both hands were covered with darkly pigmented keloidal masses which also implicated the thumb and the first and second fingers of the left hand, so that the finer movements of the hands were performed stiffly and with much difficulty.

The patient was under treatment from September 12th, 1911, to May 20th, 1912, receiving six series of treatments, each series being of five days' duration, with exposures ranging from two to six hours each day. The applicators used were of half strength, and screened with 1 mm. of silver.

The improvement was steady and uninterrupted, and when seen in September, 1912, scarcely any facial bluish was appreciable, the epiphora had disappeared, and the texture of the skin over the greater part of the face was normal.

All the keloidal tissues had disappeared from the hands, though the skin was still slightly pigmented.

Keloid of Chin and Cheek.

This child (Case No. 158), F., aged 14, was severely burnt about the neck and chin on April 17th, 1911. Keloid formation was first noted in the scar in September, 1911; since that date it had steadily increased.

The patient was first seen on April 17th, 1912. There were then two extremely dense keloidal bands passing from the under surface of the chin to the right sterno-clavicular articulation and exercising so much traction that she was unable to close her mouth. There was another dense band running along the lower border of the right jaw from its angle to the symphysis menti, and all the skin between the right jaw and the clavicle was keloidal.

The case was treated with large-size, quarter-strength applicators screened with 1 mm. of silver; the exposures were of six hours' duration, and the patient received in all twenty treatments between March 11th and October 11th, 1912.

The child is still under treatment, but great improvement has already been effected. She can close her mouth perfectly, there is no longer any traction on the chin, the keloidal tissue on the right side of the neck has disappeared, and the dense bands leading from the chin to the sternum are much smaller and softer.

Keloid of Cheek and Chin.

In Case No. 5,060, F., aged 5, there was a very dense and highly coloured keloid, following on a burn received fifteen months previously.

The patient was first seen on October 30th, 1911. There was then a wide, ribbon-shaped band of keloid running from the right temple down the descending ramus of the jaw and spreading out so as to invest completely the right half of the chin on its inferior and lateral aspects.

The patient received in all thirty-two treatments between October 3rd, 1911, and October 15th, 1912. Half-strength applicators were used with screens of 1 mm. of silver, and each exposure was of three hours' duration.

Steady and uninterrupted improvement resulted from the treatment, and when the patient was examined on December 16th, 1912, scarcely any keloidal tissue was noticeable except at the right angle of the mouth, and this, the patient's mother stated, was rapidly disappearing.

Keloid Lesion.

In Case No. 5,103, M., aged 37, the duration of disease was five years and all treatment had been ineffective. The patient suffered from intense irritation at the back of his neck, and a thick keloid patch 5 by 2 cm. had slowly developed, surrounded by an area of red, roughened skin.

The first treatment consisted in applying a quarter-strength applicator over the lesion for two hours on two consecutive days. The reaction was fairly sharp, with hyperæmia and tenderness, but the patch was much softer at the end of a month.

The second treatment was by a half-strength applicator for one hour, and this was repeated every five weeks till in December only a very small nodule remained in the centre of the part treated, and the patient was free from irritation.

No screen was used in treating this patient.

PAROTID TUMOURS.

These growths appear to be peculiarly susceptible to radium, and in almost every instance distinct improvement, frequently going on to apparent cure, is observed.

The treatment must, however, be lengthy, and much patience and perseverance are needed to bring about a successful result. Applicators of half or full strength should be employed and screened with 2 mm. of lead, the tumour should, if possible, be covered over its whole extent, and the exposure should be of not less than thirty hours' duration extended over five days.

The series of exposures should be repeated at intervals of four to six weeks so long as is necessary.

CASES.

Parotid Tumour.

The patient (Case No. 185, M., aged 55, was sent by a leading surgeon who had found him to be suffering from inoperable malignant tumour of the parotid. He had a hard oval tumour measuring 6 by 3.5 cm. firmly fixed to the ascending ramus of the right jaw. It was not tender on pressure, and occasioned very little discomfort, but it was growing rapidly.

The patient was treated on four occasions at intervals of six to eight weeks, the screen used being 2 mm. of lead throughout, and the exposure being four hours daily on alternate days for six, five, or four sittings; three to five full-strength and half-strength applicators, containing each from 20 to 80 mg. of radium bromide, were employed to cover the whole surface of the tumour, cross-firing it as much as possible, about 240 mg. being used on each occasion. After each treatment the swelling grew less, till only a hard nodule, measuring 3.2 by 2.4 cm., was left behind the angle of the jaw.

He is to report again if any further activity should become evident.

Parotid Tumour (Recurrent).

In Case No. 5,105, F., aged 18, the tumour was of four years' duration. It was removed by operation, July, 1910, but recurred in December, 1910. The growth steadily though slowly increased, and had not been checked by rays.

The patient was first seen on February 5th, 1912, when there was a definite hard, fixed growth immediately below the lobule of the right ear. It measured 4.5 by 3 cm., and was distinctly tender to the touch. The patient complained of intermittent acute lancinating pains in it.

She received in all thirteen treatments between February 8th, 1912, and May 10th, 1912, with half-strength applicators screened with 2 mm. of lead, and the growth gradually decreased in size, and became far less tender.

When the patient came for examination on June 21st, 1912, the growth had completely disappeared. She no longer had any pain, and was in excellent health.

Parotid Tumour.

The patient (Case No. 5,159), F., aged 39, had a tumour excised from behind her right jaw in September, 1909; recurrences were removed from the same area in January, 1910, and February, 1911. A further recurrence was considered inoperable, and the disease was held in check for a time by x-ray treatment.

In May, 1912, the tumour was situated below, and anterior to, the right ear, filling up the fossa behind the jaw. It was oval, firm to the touch, and quite fixed, measuring 7 by 4 cm., and causing partial obstruction of the external auditory meatus. There was an enlarged gland to be felt near each end of the hyoid bone.

The patient was treated with five applicators, containing 260 mg. of radium, placed so as to "cross-fire" the tumour thoroughly, screened with 2 mm. of lead, for five hours daily for five consecutive days.

Two months later the tumour was reduced to half the size, and a further similar treatment with three applicators of 30 mg. each was carried out. In September, no tumour could be felt, and the glands were shot size.

In November a very small nodule could be felt at the edge of the masseter. This was treated by a 20 mg. plate, screened with 1.5 mm. of lead, the time of exposure being as before. The nodule rapidly disappeared, and the patient was in excellent health when seen late in December, 1912.

FIBROMATA.

Two cases of fibromata of the penis have been treated and both cured. In both instances all previous treatment had proved quite ineffective.

CASES.

Fibroma of Penis.

In Case No. 74, aged 56, the disease was of seven months' duration. No cause was ascertainable. The patient was awakened every night about 4 a.m. by painful erection, which occasioned him great discomfort and annoyance. He was impotent.

He was first seen on November 16th, 1911. There was then a small oval fibroma, 1 by 0.5 cm., situate on the dorsum of the penis in the middle line immediately behind the corona.

The patient was given eighteen hours' treatment six hours a day on three successive days, with a full strength applicator screened with 2 mm. of lead.

He reported himself on January 23rd, 1912. He stated that he had had no trouble or discomfort from painful erections since November 28th, and that he was no longer impotent. Palpation revealed the presence of an extremely dense nodule about the size of a BB shot at the site of the original tumour. It occasioned the patient no pain or annoyance. He has since remained perfectly well.

Fibroma of Penis.

The patient (Case No. 5,154, aged 51, had complained of a hard lump on the dorsum of the penis for nine months. It was not painful, but it caused slight retraction and impotence.

When seen in May, 1912, the tumour was the size of a walnut, and was situated in the corpus spongiosum at the root of the penis.

The patient had four treatments at intervals of about six weeks. On each occasion two full-strength applicators of 50 mg. each, screened with 2 mm. of lead, were fixed at right angles over the tumour for six hours daily for three consecutive days. There was a steady diminution in the size of the lump till in December it was no larger than a pea, and gave rise to no symptoms whatever.

FIBROID DISEASE OF THE UTERUS.

Only four patients suffering from this condition have as yet been treated with radium, and of these two only have been under observation long enough to enable any opinion to be formed as to the benefit which may be obtained. In both instances distinct improvement has resulted, but the cases are still under treatment.

CASES.

Fibroid Disease of Uterus.

In Case No. 237, aged 26, the disease was of three years' duration. The dysmenorrhœa and menorrhagia had steadily increased in severity. In May, 1911, she consulted a leading gynaecologist, who curetted the uterus; this was followed by slight but transient benefit. In April, 1912, she again saw her surgeon, who told her she had fibroids, and advised hysterectomy. This was declined and the patient determined to try radium.

She was first seen on June 3rd, 1912. She stated that her menstrual period lasted for seven days, the flow being excessive and the pain very severe, especially during the first three days, so that she was unable to leave her bed. Per vaginam the uterus was the size of a three months' pregnancy and nodular. The cervix was hypertrophied, elongated, and oedematous.

This patient had two series of treatments, each for five consecutive days, six hours each day—the first June 3rd to 7th, the second July 22nd to 26th—with a tube containing 100 mg. of radium with a screen of 2 mm. of lead.

She reported herself on September 11th. Her last period, which occurred during the first week of September, lasted but four days; pain was only experienced on the third day, and then was but trifling. She estimated that the loss of blood had been reduced to one-eighth of the former amount. Vaginal examination showed no increase in the size of the uterus. The cervix was much firmer, shorter, and not oedematous.

The case is still under treatment.

Fibroid Disease of Uterus.

The patient (Case No. 5,093), aged 43, had suffered from menorrhagia, gradually increasing in severity for six years, till the period now lasted for a fortnight at a time and was accompanied by intense pain. She had also a constant mucoid discharge from the vagina, and was very thin and pale. She had some difficulty in walking.

Examination on June 6th, 1912, revealed a large irregular tumour reaching to the umbilicus, and by its size fixing a nodular and anteverted uterus in the pelvis. The anterior lip of the cervix was enlarged and oedematous.

The first treatment in January, 1912, was conducted by inserting a very small tube containing 50 mg. of radium bromide (screened by 1.5 mm. of lead) into the uterine cervix for six hours daily for ten days. This produced sufficient

amelioration of symptoms to make the patient wish for further treatment. In March a tube of 60 mg. was used as on former occasion for five days, and in May the 50 mg. tube was used as before for five days. By the end of the year the patient had had normal menstruation without much pain, and there was no vaginal discharge. She was looking and feeling well.

LICHENIFICATION OF SKIN.

This peculiarly intractable form of skin lesion is quickly cured by short exposures to half-strength applicators unscreened, or screened with the thinnest aluminium, and the relief afforded to the intolerable irritation is often marked within twenty-four hours. Cases so treated show little or no tendency to relapse.

Lichenification of Neck.

In Case No. 236, F., aged 31, the disease was of ten years' duration and had resisted all attempts at cure. There were two lesions—one, triangular in shape, with sides of 6 cm. in length, was situated at the lower part of the left posterior cervical triangle; the other, a circular patch 3 cm. in diameter, over the anterior surface of the left axillary fold. The patient complained of a frequent and almost intolerable irritation in the spots, which was aggravated by warmth and was exceptionally severe during menstruation.

She was treated on June 3rd, 1912, receiving a ten minutes' exposure with an applicator of half strength, screened with 0.01 mm. aluminium.

She reported herself for examination on July 15th. The lesions had completely disappeared, leaving normal and healthy skin, and she stated that she no longer experienced even the slightest irritation.

She has since kept perfectly well.

Lichenification of Skin.

Fourteen years previously the patient, M., aged 58 (Case No. 278), was attacked by eczema on which lichenification developed. For several years itching had been a very marked feature of the case. When seen there were superficially seared red patches over each clavicle. Between the shoulders at the back was a quadrilateral patch of skin with numerous scattered red papules. Similar lesions were present on the inner side of each knee and the sock area from the ankle upwards.

Five areas on the back were treated each for ten minutes with an unscreened quarter-strength apparatus. Three months later all the treated areas had responded well and the irritation had ceased. Six more patches were treated, and all cleared up in the same manner. There was no tendency to recurrence.

PRURITUS.

Radium is undoubtedly of great use in this condition, especially if it be of long standing and associated with leucoplakia or hyperkeratosis. When no actual lesion exists and the trouble is purely nervous in character the results are not so satisfactory, and often little benefit follows the application.

No definite rules can be laid down for treatment, as the local conditions vary so greatly, but the screening and exposures must be adjusted in relation to the character of the lesion.

CASES.

Pruritus Vulvae.

In Case No. 122, aged 62, the disease was of twenty-six years' duration. She had had every possible kind of treatment with lotions, ointments, baths, and high-frequency currents without success. The irritation at times was intolerable, and she was unable to get any rest.

She was first seen on January 5th, 1912. On examination two small hyperaemic and inflamed but non-ulcerative patches were found immediately within the ostium vaginae just above the fourchette, one on each labium, the right being the larger. She also complained of great irritation immediately above the clitoris, but there was no visible lesion at that site. Between her first visit and April 26th, 1912, she received in all nine treatments, each of five minutes' duration, with a half-strength applicator unscreened.

Slight but quite definite and persistent improvement followed on each treatment, and on May 9th she came to report herself as completely cured.

She has since kept perfectly well.

Pruritus Ani.

In Case No. 236, M., aged 57, the disease was of more than thirty years' duration. The patient was operated on by the late Mr. Allingham for a condition of hyperkeratosis of the anal orifice in 1897. He had, however, never been wholly free from pruritus since that date, and during the past two years the condition of hyperkeratosis had returned, and steadily increased, while the itching had become intolerable. All remedies had proved utterly futile.

He was first seen on May 24th, 1912. The anal orifice was cone-shaped and covered with a dense pearly epithelium, which was hard to the touch and traversed by numerous radiating fissures which showed the vascular corium at their base. The condition of hyperkeratosis extended upwards towards the

spine and forwards to the perineum, and was surrounded by a zone which was hyperaemic and eczematous.

The patient had three series of treatments between May 28th, 1912, and September 26th, 1912; each series occupied four days, with exposures of three hours' duration each day. Half-strength applicators were used with screens of 1 mm. of silver.

When examined on November 14th, almost the whole of the hyperkeratosis had disappeared, except for a small circular patch close to the anal orifice. There was no longer any induration; the itching was but slight, was of an intermittent character, and easily bearable.

Pruritus with Leucoplakia Vulvae.

In Case No. 5,137, F., aged 50, the condition was of five years' duration. She was in a bad neurasthenic condition, due to the insomnia, loss of appetite, and loss of weight, which had followed on the almost ceaseless irritation.

She was first seen on June 25th, 1912, at which date there was a condition of hyperkeratosis in the angles between the folds of the labia minora, all round the ostium vaginae, and spreading backwards towards the anus. On the inner surface of the right labium was a rectangular patch of leucoplakia 2 by 3 cm. The patient complained greatly of the irritation, which she declared to be almost intolerable.

She had seven treatments between June 25th and September 5th, with the result that all the hyperkeratosis and leucoplakia disappeared, and the intolerable irritation became reduced to a very slight, inconstant, and quite easily bearable itching. She reports that she is still improving.

CHRONIC ECZEMA: PSORIASIS.

These conditions generally yield readily to short unscreened exposures with quarter-strength apparatus applied for two to three minutes on three successive days, the exposure being repeated after a week or fortnight if necessary.

With chronic eczema the cure may be permanent, but in psoriasis the patches tend to recur sooner or later, and require further treatment.

CASES.

Chronic Eczema.

Case No. 4, F., aged 52. This patient had been treated by routine methods for eighteen months for a widespread chronic eczema, but a number of intractable patches on the abdomen remained. Four of these were treated by an unscreened half-strength applicator applied to each spot for three minutes on three successive days.

In a month no sign whatever of the rash remained on the areas treated. Several other patches were treated in a similar manner, and all cleared up in the same remarkable way. Eight months later no recurrence had taken place.

Psoriasis.

In Case No. 5,148, F., aged 12, four small scaly patches of psoriasis were present eighteen months before the radium treatment was undertaken, one on each knee and on each elbow. The spots on the elbows had yielded to ichthyol, but no treatment had availed to clear the knees.

Quarter-strength plates were applied unscreened to the knees for periods of three minutes on three successive days. One month later the left knee showed only slight signs of the rash. The treatment was repeated to the left knee, and to a fresh patch that had arisen on the left elbow. In two months the elbow was free of disease, but the left knee still showed a small scaly area.

One month following the above date the knees and elbows were quite free from psoriasis, but two months later slight recurrences had taken place on each knee. The same treatment was repeated. The patient has not yet returned for examination.

LUPUS VULGARIS.

Treatment with Finsen light is to be preferred to radium in cases of this disease, and whenever possible it should always be adopted.

If radium be used, however, half-strength or full-strength applicators should be employed without screen, and a destructive reaction produced.

LUPUS ERYTHEMATOSUS.

This very intractable condition, which so often defies all treatment, is usually greatly improved by radium. Care must be taken not to give too strong a dose, and the best results usually follow the use of a quarter or half strength applicator sufficiently large to reach well beyond the borders of the lesion unscreened or screened with 0.01 mm. aluminium, and an exposure of forty to sixty minutes' duration.

CASES.

Lupus Erythematosus.

In Case No. 177, F., aged 31, the disease was of six years' duration, and began as a small spot just outside the outer

canthus of the right eye, whence it rapidly extended to the left cheek, nose, right cheek, and right upper eyelid. She had been treated with arsenic, quinine, iron, and mercury internally and salicylic acid, resorcin, and carbon dioxide snow locally, without benefit. Hyperaemia was a marked feature of the condition.

The treatment adopted was the application of unscreened quarter strength plates for an hour over various portions of the lesion. This was continued at intervals of a month for four months. The disease steadily retrogressed from the beginning. In October, 1912, the left wing of the lesion was hardly noticeable. Two small active patches were present, one on the left side of the nose, and one near the inner canthus of the left eye. Most of the right wing of the affected area was healthy, the lower edge alone remaining somewhat scaly.

The patient is coming at long intervals for treatment, and there is little doubt that her condition will eventually be cured.

Lupus Erythematosus.

In Case No. 5,129, M., aged 24, the condition began as a small whitish patch on the left cheek. It grew steadily, and a few months later a similar lesion arose on the right cheek. No vasomotor phenomena were present, except that both ears were scarred and somewhat purple in colour. Just before treatment there were three slightly raised red patches, one on the right cheek (2.5 by 3.5 cm.) and two on the left (2.5 by 1.3 cm. and 1.7 by 1.7 cm.). There was no rash on the nose. The red areas itched and smarted.

Treatment consisted of the application of a quarter-strength plate without metal screen for one hour over each patch. The reaction was smart, and the disease became less marked. All subjective symptoms ceased, and a month later the same treatment was repeated. This apparently cured the disease. Examination six months later showed the patches to be covered by smooth, supple, healthy scars, and no sign of activity had manifested itself.

TUBERCULOUS ADENITIS.

Prolonged exposures of from twenty to thirty hours' duration in all, with heavily screened radium apparatus emitting only the ultra-penetrating rays will generally bring about a steady diminution in size of the infected glands without causing suppuration or surface irritation.

CASES.

Tuberculous Adenitis.

The patient (Case No. 34), F., aged 24, came in October, 1911, to be treated for two enlarged tuberculous glands below the left jaw. She had had several operations previously for the removal of similar glands.

Two applicators of 20 and 30 mg., screened with 2 mm. of lead, were placed so as to cross-fire the glands, and applied for four hours daily for three consecutive days. This led to a considerable diminution in size, and the treatment was repeated in November. The glands shrank to small hard nodules and caused no further trouble.

Tuberculous Adenitis.

The patient (Case No. 103), F., aged 16, came in December, 1911, to have treatment for an enlarged tuberculous gland fixed to the skin by scar tissue, the remains of an old sinus. Two full-strength applicators, containing 30 mg. each, were applied, with screens of 2 mm. of lead, for three consecutive days, that over the scar remaining for three and a half hours and that over the gland for seven hours each day. When seen four months later the gland had shrunk to the size of a BB shot, and was movable under the skin; the scar was scarcely noticeable.

ARTHRITIS DEFORMANS.

This extremely obstinate, progressive, and crippling malady is not infrequently strikingly benefited by the daily drinking of 250 c.cm. of radium emanation solution of a strength of 1 to 2 millicuries per litre. The treatment must, however, be persisted in for quite a long time, and at least six weeks are likely to elapse before any change is noted.

In a favourable case the articular and muscular pains are lessened or disappear, the movements of the affected joints become much freer and are accompanied by less grating, the muscles controlling the joints regain much of their lost tone, and the general health of the patient is greatly improved.

With the majority of the patients the emanation solution produces a definite diuresis, and with a few it acts as a slight laxative, though free purgation has never been noted.

Up to the present time only twenty-one patients have been treated, but the results obtained are sufficient to warrant the hope that radium emanation solution will prove a most valuable addition to the routine medical treatment.

CASES.

Arthritis Deformans.

In Case No. 197, M., aged 39, the disease was of twenty-five years' duration, the joints chiefly affected were the wrists, elbows, ankles, and knees.

The patient was first seen on April 25th, 1912. He complained of great pain, especially in his knees, elbows, and shoulders. He was unable to stand upright without sticks. He walked very slowly and with extreme difficulty, and could not cross his knees. The movements of his upper extremities were greatly restricted so that he was unable to brush his hair or shave himself.

The patient was put on a course of radium water, and took 250 c.cm. of radium emanation solution daily, except on Sundays, for eighteen consecutive weeks.

He was seen and examined on September 3rd, 1912, and very general improvement was noted. Pain in the affected joints was so slight as to be practically negligible, and he slept well. He was able to flex his knees and cross them one over the other. He could stand and put on his overcoat without supporting himself with a stick, and he stated that he felt much more secure when walking. The movements of his upper extremities were much freer and more exact, and he could now brush his hair and shave himself. Appetite was good, and the general health excellent.

The patient is still under treatment, and is steadily improving.

Arthritis Deformans.

In Case No. 220, M., aged 56, the disease was of four years' duration and commenced with synovitis of the right knee. The attack lasted for eighteen months, and was accompanied by much swelling and grating of the joint on movement. In January, 1912, the left knee-joint became affected and painful so that the patient was unable to bear his weight on his left leg.

He was first seen on May 17th, 1912. The left knee-joint was slightly swollen, and a little free fluid was present. Movement of the patella over the articular surface of the femur with the quadriceps tendon relaxed elicited slight grating, principally on the external aspect. The patient complained chiefly of a feeling of weakness and insecurity in the joint. The pain was not very severe and was most acute when he walked upstairs.

He received a six weeks' course of radium emanation water — from May 20th to June 29th. He was examined on July 11th, when he expressed himself as feeling much better, and said that the feeling of weakness in the knee-joint had disappeared, and that he was able to run a little. Examination of the joint showed a considerable diminution of the swelling, no free fluid was present, and passive movement no longer elicited grating. In October the improvement was still maintained.

Arthritis Deformans.

In Case No. 222, M., aged 35, the disease was of nine years' duration. It commenced in May, 1903, with synovitis of the right knee following an injury. The knee was kept in splints for two years under the assumption that the disease was tuberculous. At the end of that period the joint was firmly ankylosed. The right elbow and right wrist became affected in June, 1904, complete ankylosis of these joints was noted in June, 1909. The left hip and ankle were attacked in September, 1908, the hip becoming almost completely ankylosed at the end of 1910. The disease made its appearance in the right hip in the year 1908, but this never became so severely affected as the left one. The patient had been treated with hot air, peat, pine, and electric baths, high frequency, massage, etc., and had had 5 gr. of guaiacol three times a day for three years; nothing had served to arrest the progress of the disease.

He was given two courses of treatment with radium emanation solution. Each course lasted for six weeks and the patient drank 250 c.cm. of radium emanation solution every day except Sundays. The first course was from May 20th to June 10th, the second from October 14th to November 25th.

He was examined on December 12th. Very great improvement had taken place. All his movements were freer. He could walk much better, and no longer had pain in any of the affected joints. He stated that he could now dress himself completely without any help, except putting on his shoes, a thing which he had not been able to do for more than four years. His general health was excellent.

The improvement is still being maintained.

Arthritis Deformans.

The disease in Case No. 5,084, F., aged 52, was of twelve years' duration. The first symptoms were limitation of flexion at the hip-joint and pain under the gluteus maximus of an intermittent character. These symptoms gradually increased in severity for ten years, but in November, 1910, the patient had an acute exacerbation, and all movements at the hip-joint became restricted, and were attended with intense pain. In September, 1911, this pain was so severe and constant that she was unable to sleep for more than half an hour at a time, and became extremely worn and emaciated. Every possible form of treatment—dietetic and medicinal—had been tried without effect.

The patient commenced to take radium emanation solution on October 9th, 1911, and continued until December 21st, 1911. Slight improvement was noticed about six weeks after the treatment commenced, and from that time progress was both steady and rapid. The patient was examined on December 28th, 1911. The pain at the hip-joint had disappeared and all

the movements could be accomplished with ease. She stated that she was able to button her boots, which had been impossible for the last ten years. She slept well every night, and was able to lie in any position without discomfort. The patient was seen again in November, 1912, and was quite well.

Arthritis Deformans.

In Case No. 5,194, M., aged 54, the disease was of eighteen months' duration; it had commenced in January, 1911, with severe synovitis of the left knee which left the joint swollen. All movements of the knee became painful and were accompanied by coarse grating. Wasting of the left thigh muscles was very marked. The left hip became affected in February, 1912. The patient had tried all forms of medicinal treatment, electric and hot air baths, but without much effect.

Treatment was commenced on May 14th, 1912, and the patient drank 250 c.c.m. of radium emanation solution of a strength of 6 millieuries per litre daily, Sundays excepted, until July 26th, 1912.

He was examined on September 3rd. There was then scarcely any restriction of movement at the left knee and hip, and all movements could be accomplished without pain. The wasting of the thigh muscles was no longer so pronounced, and the muscular tone was greatly improved. The patient stated that he was able to walk for three or four miles at a time without experiencing any discomfort.

This improvement has been steadily maintained.

GRANULOMATA.

Granuloma of Bridge of Nose.

The patient (Case No. 185), M., aged 16, struck his nose against a lamp-post on January 21st, 1912, splitting his skin in a vertical direction. The wound was sutured, but did not heal, and pus formed. It was then treated by fomentations, etc., and the split closed, but left a very marked thickening, which resisted all attempts to bring about its absorption. The thickening was confined entirely to the epidermis and subjacent connective tissue, and did not involve the periosteum. It was not tender, and only slightly painful on pressure, but occasioned the patient much annoyance by its unsightliness, as it gave him a Roman nose of an extremely pronounced type.

He was first seen on April 3rd, 1912, and received two treatments, each of six hours' duration, on April 4th and April 11th, with applicators of half strength, screened with 2 mm. of lead.

The mother of the patient wrote on June 3rd, 1912, saying that he had returned to school, that his nose was perfectly well, and there was no longer any distortion of its shape.

PAPILLOMATA.

Warty Growth.

The patient (Case No. 240), F., aged 30, was first seen on June 5th, 1912. A small, flat, warty growth was found on the

dorsal surface of the metatarso-phalangeal joint of the left great toe, 1 cm. in diameter, surrounded by a zone of marked hyperaemia.

It was of six months' duration, and had steadily grown in spite of all kinds of treatment. It was very tender on pressure and acutely painful. The patient could not wear a boot, walked with great difficulty, and was taking morphine in order to get sleep at night.

She was given one treatment with a full-strength applicator unscreened for one hour on June 5th, 1912. She reported herself on July 8th, when the growth was found to have completely disappeared. The patient was wearing a boot, and could walk perfectly well. All pain had gone.

PROPHYLACTIC TREATMENT.

During the period between September, 1911, and December, 1912, thirty-nine patients who had recently undergone operation for malignant disease received post-operative prophylactic irradiation. Only seven recurrences had been reported at date January 1st, 1913.

In the treatment of these cases full and half-strength applicators with screens of 2 mm. of lead and containing from 50 to 500 mg. of radium were used. The length of exposure varied between twenty and sixty hours spread over a period of three to ten days, according to the nature of the disease.

It would be utterly futile at so early a date to make any statement as to the precise value of radium treatment in preventing or minimizing the danger of recurrence, but as the majority of these patients had suffered from extensive, severe, and rapidly progressive malignant disease, and the operators had expressed grave doubts as to the probability of their remaining free from the disease for more than a few months, the relatively slight percentage of recurrences so far noted does much to justify the routine adoption of post-operative irradiation. It should prove of especial service in those cases of malignant growth in which it has been found impossible to operate well beyond the appreciable area of the disease.

In the compilation of this report much valuable assistance has been rendered by my assistants, Dr. J. E. A. Lyham and Dr. A. Burrows, who have been associated with me in the treatment of the majority of the cases described.

APPENDIX.

REPORT OF THE CHEMICO-PHYSICAL LABORATORY.

By W. L. S. ALTON,

FELLOW OF INSTITUTE OF CHEMISTRY; DIRECTOR.

THE Laboratory has been concerned since the foundation of the Institute with measurements in connexion with the purchase of the radium salts acquired. Not only have the available amounts of radio-active material been excessively uncertain, but until the recent preparation of International Radium Standards, the use of various methods of determining the activity proved that the real value of the term "radium bromide" differed as much as the methods themselves.

The laboratory has prepared, with a few exceptions, all the applicators now in use, and in fact was engaged in this work during the building and equipment of the Institute; so that at the time of opening, there were twenty-four pieces of apparatus ready for use. Since then, with the acquisition of more radium salts, eleven applicators have been added, which, with their maintenance and the additional applicators still to be made, will keep the staff constantly employed.

In addition, work and experiments with radium emanation have developed steadily; the increasing utility of this form of treatment, both by means of applicators and by means of radio-active solutions, has necessitated the setting aside of a very large amount of radium salts to provide the emanation required. The Laboratory is solely responsible for the preparation of radio-active applicators and screens in accordance with the prescriptions of the medical staff for work within and without the Institute.

The total activity of the emanation produced for this purpose, and for radio-active solutions, exceeds that of 5,900 mg. of radium bromide.

The preparation of a continual supply of radio-active water has now gone beyond the experimental stage, and has resulted in the construction of a new type of apparatus which appears to be highly efficient. The amount of radio-active water prepared since the opening of the Institute exceeds 400 litres.

Finally, the Laboratory is called upon to perform all the determinations of the activity of the apparatus employed, and, in the case of all emanation applicators, the dosage during the period of application.

APPLICATORS.

Radium applicators may be of two kinds:

(a) Applicators containing radium salts, which may be further subdivided into two classes—(1) those in which the radium salts are fixed by means of varnish, and (2) those in which the radium salts are contained in capillary glass tubes.

(b) Applicators containing radium emanation.

Before describing the varnished apparatus, it will be well to point out that consideration must be paid to the concentration of the radium salt per unit area, as well as to the purity of the salt. It is obvious that a different therapeutic result will be obtained from 10 mg. of radium bromide spread over 1 sq. cm. of surface, than from the same amount spread over twice the area.

For this reason a unit of concentration has been adopted. This consists of a centigram of radium bromide spread over a square centimetre. Applicators containing radium salts to this extent of concentration are said to be "full strength" applicators; similarly, "half" and "quarter" strength applicators contain respectively 0.5 and 0.25 cg. of radium bromide respectively to each sq. cm.

Radium bromide has been accepted by the medical profession as the unit of measure for describing the content of radium applicators. This salt was the first salt of radium prepared, and happens to be most unsuitable for fixing to applicators by means of varnish, or for filling tubes.

In all probability all the apparatus at the Institute will be remeasured during the course of the coming year, and its radium content stated in terms of the element radium; not only will this procedure be more exact, but the applicators containing emanation can be more closely compared with those containing radium salts.

1. Varnished Applicators.

Flat varnished applicators have been made in three shapes:

- (a) Squares, measuring 0.7, 1.5, 2.0, and 4.0 cm. across.
- (b) Rectangles, measuring 2.0 by 3.0 cm.
- (c) Circular plates of 6 cm. diameter.

The general method of making these flat varnished applicators has consisted in carefully weighing out the required amount of radium bromide or chloride, converting it to radium sulphate by means of sulphuric acid, and transferring the dried, ignited radium sulphate to the applicator: a flat shallow tray made of German silver, previously prepared by being coated with one or two carefully dried layers of varnish. The radium sulphate mixed with the third coat of varnish has then been evenly distributed over the prepared area and also carefully dried. Three more layers of varnish are added, care being taken to dry each one, and the applicator has been given a finishing coat of another type of varnish which gives it a glass-like surface. The temperature best suited for drying has been obtained in an electrically heated oven kept constant at 120 C. In addition, cylindrical surfaces and rods have been coated with varnish and radium salts by a similar method, except that these latter have been rotated in the electrical oven when drying, so as to obtain an even distribution of the varnish and radium.

The time taken to prepare an applicator by this method has been on the average about six weeks. Apparatus of this type has been found in general to be very durable. It is all-important that each coat of varnish should be thoroughly dried before adding the next, if the applicator is to be in permanent use, otherwise the surface of the varnish becomes uneven and covered with bubbles, and the applicator very soon breaks down. "Full-strength" applicators need remaking every two years, but "half" and "quarter" strength apparatus may be kept effective for a much longer period by means of an occasional coat of varnish.

The destructive power of radium emanation (which produces the rays of radium) towards organic matter is responsible for the relatively short life of the "full-strength" applicators, but experiments have been made which satisfactorily prove that, in spite of this drawback, no other varnish resists as well as the one that is used.

These applicators may be exposed to a temperature of 120 C., and, if need be, may be sterilized by means of alcohol, mercuric chloride, or ether. But they may not be

treated with dilute phenol solution, nor is it advisable to dip them in boiling water for more than a few seconds.

2. Tube Applicators.

The second type of radium applicators containing radium salts consists of capillary glass tubes filled with radium sulphate, closely packed so as to prevent any movement of the salt. This type of applicator is a great improvement on the one frequently met with, in which the tube is relatively large, and in which the radium salt shifts from place to place whenever the patient moves. It also has the advantage that it can be employed with screens of varying material and thickness, which advantage has not been the case with metal tubes packed with radium. Further, on account of their small size (they vary from 2 to 4 cm. long, and are no larger than 3 mm. in diameter), they can often be employed in quite small cavities. The capillary walls are quite thin, and are protected by means of a second glass sheath; in case of a breakage, fortunately rare, the capillary tube remains unharmed.

Emanation Applicators.

Applicators containing radium emanation may be divided into two classes: (1) Flat applicators; (2) tubes.

The activity of all radium salts or solutions depends principally upon the emanation they contain. If they are heated or subjected to a vacuum, they lose nearly all their activity, which may be collected in the form of gas by suitable means. This gas, radium emanation, glows in the dark, can be condensed at the temperature of liquid air, and produces a series of radio-active bodies, radium A, B, C, etc., from which are derived the alpha, beta, and gamma rays of radium salts. The activity of the gas, at first about 90 per cent. of the total activity of the original salts or solutions, decays gradually, falling to half value in 3.85 days, ceasing to be active in about a month, and finally yielding helium, an inert gas. Conversely, the salts or solutions regain their lost activity at the same rate as the activity of the emanation obtained from them has decayed.

It was obvious that this emanation could be of therapeutic use, for not only was it possible to make applicators or tubes for special cases, and to impart to them either a high or a low activity, but these applicators could be sent to most places in the United Kingdom, while the parent stock of radium remained at the Institute to furnish in a short while emanation for further needs.

The stock of radium salts at the Institute which had been set aside to produce radium emanation is divided into convenient amounts and introduced in aqueous solution into small bulbs.

These small bulbs, in sets of five, are so distributed between several mercury vacuum pumps that each pump shall deal with the emanation produced from about 250 mg. of radium bromide. From time to time the mixed gases containing radium emanation (for aqueous solutions of radium salts evolve oxygen and hydrogen) are pumped off, collected, and transferred into applicators in the following manner:

1. Flat Applicators.

These are simply hollow boxes, made of German silver, with one of the faces turned down on the lathe to about 0.3 mm.; it is not desirable to screen off too many of the rays, as additional screens can be added at will. The boxes are fitted with a lead tube having a capillary bore; they can be made in both circular and rectangular form and of large or small area.

To fill an applicator it is attached to a mercury vacuum pump and pumped empty; the mixed gases from the emanation apparatus, after having been sparked in an eudiometer tube to get rid of the oxygen and hydrogen, are drawn into the evacuated box by means of a special apparatus in connexion with the vacuum pump. When all the emanation has entered the applicator, the capillary lead tube is firmly pinched with a pair of pliers in order to make a hermetical seal; the box is then detached from the pump, and is ready for use.

2. Tubes.

Large glass tubes, with a capacity of 0.2 cm. and upwards, can also be filled by a similar method; the tubes are somewhat constricted at one end, and when filled are

sealed at this constricted end with a mouth blow-pipe. They can be used alone, or introduced into metal tubes which act as screens.

Capillary glass tubes, suitable for use in the smallest cavities, need a somewhat more elaborate method in their preparation. A tube of this kind, sealed on to a small glass bulb, is filled, by means of the vacuum pump and the apparatus spoken of above, with mixed gases from the emanation apparatus. The bulb and capillary tube are then cooled by means of liquid air to a low temperature (about -200°C .), when the emanation is condensed, but the other gases, oxygen and hydrogen, remain in the gaseous condition. These are pumped off and the bulb completely exhausted; the liquid air is removed, and the purified emanation again becomes a gas. Mercury is now allowed to enter the bulb, and, rising, forces the emanation into the capillary tube. Like the larger tubes, this can be hermetically sealed, and used with or without metallic screens.

Measurement of Activity.

The activity of these applicators and tubes is compared with a standard of radium bromide; they have varied in strength from 40 to 200 mg.

During the year eleven applicators and thirty-three tubes have been made. The total activity of all the emanation applicators and tubes made has been equivalent to 3,403 mg. of radium bromide.

RADIO-ACTIVE SOLUTIONS.

The coincidence that nearly all the well-known spas in Europe, whose waters are efficacious for gouty and rheumatic troubles, contain radium emanation in solution, has led to the preparation with some success of artificial radio-active waters.

These solutions can be made either with distilled water, or water containing the same kind of saline constituents as the majority of spa waters.

These liquids when violently agitated with gas from the emanation apparatus become radio-active. This is due to the solubility of radium emanation, and the radio-activity depends on the amount of gas introduced and on the volume of liquid present.

The apparatus at the Institute is designed to give solutions with an activity from 1 to 2 millicuries per litre, an activity much greater than the best of the radio-active waters from natural sources.

MEASUREMENTS.

All determinations of the radio-activity of specimens of radium salts or of applicators are made by direct comparison with a standard specimen of radium chloride. An International Standard has been acquired, and comparisons of the gamma-ray activities are made with an electroscopie by Rutherford's method. The walls of the electroscopie must be made of lead at least 3 mm. thick, and the readings obtained for the standard, and for the specimen measured, must be obtained under the same conditions of distance, screening, etc.

Emanation applicators and tubes must be measured after four hours, in order that the gas may have reached its maximum activity, which is attained when it has produced its equilibrium quantity of radium A, radium B, and radium C. The value of the applicators at any time can be found by calculation from the decay curve of radium emanation, and, consequently, the dosage over any particular period obtained.

Measurements of the activity of the radio-active water used at the Institute are made from time to time. Since the water has a relatively high activity, it can be directly compared with a small standard tube of radium chloride, the measurements being made by the gamma-ray method.

When the activity of a solution is small, such as that of natural waters, or of artificial waters containing only a small amount of emanation, the gas must be expelled from solution by boiling, and introduced directly into a gas electroscopie. The standard emanation in this case is obtained either from a dilute solution of radium salt, or, better, from a small amount of pitchblende whose radium content has been determined. These determinations of the radio-activity of solutions are given in milli-

curies, a millicurie being the amount of emanation in equilibrium with a milligram of radium.

SCREENS.

The screens used to filter off the different rays given out from the radium apparatus are:

- (a) Aluminium: 0.01, 0.02, 0.04, and 0.08 mm. thick;
- (b) Silver: 0.5 and 1.0 mm. thick;
- (c) Lead: 0.1, 0.2, 0.4, 0.5, 1.0, 1.5, and 2.0 mm. thick.

Radium salts, when in equilibrium with the emanation produced from them, give out three kinds of ray: the alpha, beta, and the gamma.

The alpha ray is particulate—that is to say, it consists of actual particles emitted from the source. These particles lose their velocity and therefore their activity in a few centimetres of air, and since the absorption of all the radium rays has been found to be directly proportional to the density of the screen, it is obvious that the alpha rays will be completely absorbed by a very thin screen of aluminium (about 0.1 mm.). Since the layer of varnish in most applicators is more dense than this amount of aluminium, it follows that the alpha rays are completely stopped, but the coats of varnish gradually become permeable, due partly to minute cracks, which spread throughout the layers, and partly to the absorption of emanation by the varnish, so that in course of time an applicator emits alpha rays.

The beta rays are far more penetrating than the alpha rays, and consist of negatively charged bodies projected with velocities of the same order as the velocity of light. They vary considerably as to their velocities, and are distinguished by the terms "soft beta" and "hard beta." For this reason a considerable variety of screens are used, depending on the nature of the radiation required.

Again the rule that the absorption varies directly with the density applies, and since the coefficients of absorption of aluminium, silver, and lead to the beta rays are 14.0, 75, 122, it follows that very much more aluminium than lead must be used to absorb all the beta rays.

The gamma rays are extremely penetrating, and are somewhat analogous to very penetrating Roentgen rays. When all the beta rays are absorbed by 5 mm. of lead, the radiation escaping is nearly all of the gamma-ray type; it is therefore obvious that with the screens used at the Institute, none of the gamma rays are absorbed.

Secondary Rays.

The use of thick screens of heavy metal is, however, accompanied by the production of secondary rays, which are capable of causing considerable surface irritation. This secondary radiation is screened somewhat by the use of many layers of black paper or black rubber tubing.

The whole subject is one of great interest, as the ideal screen should be capable of cutting out the primary beta rays during a long period of exposure, while at the same time giving rise to very little secondary radiation. Screens of different metals will be under trial during the coming year, and it is hoped that some progress will be made in this difficult question.

EXTERNAL WORK.

The laboratory has undertaken from time to time the preparation of applicators and radium apparatus for medical men; four applicators have been made. It has also performed eleven determinations of the radio-activity of various specimens of radium salts, including minerals and natural waters.

AT the annual meeting of the Liverpool Medical Institution held on January 16th, the following office-bearers and members of council were elected. Those marked * did not hold the same office last year: *President*, Mr. Robert Jones; *Vice-Presidents*, *Thomas Bushby, *W. B. Warrington, C. J. Macalister, J. Lloyd Roberts; *Treasurer*, R. J. Hamilton; *General Secretary*, *Frank Hugh Barendt; *Secretary of Ordinary Meetings*, Alexander Stokes; *Secretary of Pathological Meetings*, W. Blair Bell; *Librarian*, *Nathan Raw; *Editor of the Journal*, John Hay; *Council*, T. R. Bradshaw, T. B. Grimsdale, Edward W. Hope, W. S. Henderson, N. Percy Marsh, C. E. Solomon, *R. E. Harcourt, *M. T. Stack, *A. W. Riddell, *D. Moore Alexander, *J. A. Howard, *W. B. Bennett; *Auditors*, W. S. Henderson and *A. P. Hepe Simpson.

A Lecture

ON

THE DIAGNOSIS AND TREATMENT OF
CANCER OF THE RECTUM.DELIVERED AT THE CANCER HOSPITAL, BROMPTON,
ON JANUARY 22ND, 1913.

BY

W. ERNEST MILES, F.R.C.S.

SURGEON TO THE CANCER HOSPITAL AND TO THE GORDON HOSPITAL
FOR RECTAL DISEASES, ETC.

THE rectum is conveniently divisible into three parts :

1. The *anal canal*—that portion embraced by the external and internal sphincters and by the horizontal fibres of the levatores ani.

2. The *ampulla*, consisting of a lower part below the peritoneal reflection and an upper part covered by peritoneum in front and at the sides only; and

3. The upper portion joining the terminal part of the pelvic colon at the level of the middle of the third piece of the sacrum about $4\frac{1}{2}$ or 5 in. above the muco-cutaneous junction of the anus.

Above this the bowel is pelvic colon. Anatomists formerly described as part of the rectum the portion of bowel extending from the left sacro-iliac synchondrosis to the middle of the third piece of the sacrum, but nowadays they relegate this portion to the pelvic colon, and we shall avoid a great deal of confusion if we follow them.

Cancer may occur in any of the three parts of the rectum. You see before you sixty specimens of the lower bowel removed for cancer, and an examination of them will convince you that in no single case is the lowermost border of the growth at a greater height than 5 in. from the anal margin. It is obvious, therefore, that a cancerous tumour of the rectum can always be reached by digital exploration, and that if the growth is beyond reach it is not in the rectum at all, but in the pelvic colon.

Now, the position of the growth has a considerable bearing on its appearance and on the symptomatology when the case first comes under observation. If it is situated in the upper portion it generally involves the whole circumference of the bowel and tends to produce invagination; if in the ampulla it usually encompasses from a half to four-fifths of the circumference, and in nearly all cases is found to have infiltrated the posterior wall; if it has arisen in the anal canal the anterior wall is generally the site of election, and from a third to a half of the circumference is involved.

SYMPTOMS.

It is of the utmost importance that the earliest symptoms indicative of the presence of a malignant tumour in the rectum should be known and recognized. The disease is insidious in its inception and early progress, and may exist for six months or longer before giving rise to symptoms which may induce the patient to seek advice. For this reason many cases do not come under observation until the disease is far advanced and beyond the limits of useful operation. About 25 per cent. of the cases under 60 years of age that I see are probably beyond operation. Let us see how the position of the growth affects the symptoms. If the neoplasm involves the anal margin, a situation where the mucous membrane is particularly well supplied with sensitive nerve terminals, pain is an early manifestation. If the growth is situated in the upper portion of the rectum, owing to the great tendency there to circular infiltration of the gut, a stenosis is produced and an attack of mechanical obstruction may ensue quite early. In both these cases the patients seek advice while the disease is still in an early phase of development. When the lesion occurs in the ampulla the case is different. Here the mucous membrane is much less sensitive, and the lumen of the bowel is so large that a considerable time must elapse before the entire circumference has been encompassed by the growth. Under these circumstances the patient, until he begins to lose blood from the rectum, or notices a discharge, is not aware that there is anything of a serious nature amiss with

him. There is a considerable latent period during which there are no objective symptoms at all, the growth being still in the pre-ulcerative stage. So soon as surface disintegration commences, bleeding from the rectum makes itself manifest, and this is generally the first objective symptom that causes the patient to seek advice. The symptoms indicative of the presence of a cancerous growth in the ampulla of the rectum may be conveniently considered during the successive phases of its progress, as follows:

(a) *Symptoms Prior to the Disintegration of the Surface of the Growth.*

From what I have already said it is obvious that the growth has existed for several months prior to the onset of the first objective symptom that impelled the patient to seek advice. But I want to call your attention to a particular sign which is always suggestive of cancer of the rectum in this situation, and the two patients here to-day are illustrative of its importance. Careful inquiry as to the habits of life during the year or two preceding the onset of objective symptoms will nearly always reveal the fact that a prolonged and well marked attack of constipation occurred several months beforehand. This attack of constipation is not of the ordinary kind which is speedily relieved by aperients, but is of the nature of a temporary functional inertia persisting for several days or weeks at a time and not yielding to treatment. Aperients appear to have little effect beyond producing small ineffective motions and the passage of flatus. After a period varying from three to six weeks, diarrhoea, slight at first but showing a tendency to become more marked, supervenes and persists. It is important, therefore, that a thorough examination of the rectum be made in every case in which diarrhoea supervenes upon a prolonged attack of constipation and persists in an otherwise healthy patient, since the possibility of carcinoma being the cause is very great and should not be lost sight of. The temporary inertia of the bowel is not associated with abdominal distension, indicating an absence of mechanical obstruction.

(b) *Symptoms During the Process of Surface Disintegration.*

The growth having become ulcerated, local symptoms of a more definite and objective character appear. The rectum becomes irritable and intolerant of the presence of faeces. Hence there is a desire to evacuate frequently, the bowels acting from twelve to twenty times during twenty-four hours. As a rule, the first and second evacuations consist of faeces, the remainder consisting almost entirely of mucus mixed with blood and pus. Bleeding, though occurring with each action of the bowels, is seldom copious, but is more marked in cases of papilliferous cancer than in the infiltrating adenocarcinoma. If the bleeding is free, the blood generally comes from coexistent internal piles. The appearance of an increased quantity of mucus in the stools is characteristic of ulceration of the growth taking place. This mucus is peculiarly offensive in odour. Local pain in the rectum from the contact of the faeces with the ulcerated surface is usually present, though not severe, as long as the growth does not extend into the anal canal. When the anal canal becomes involved, the pain is acute at each movement of the bowels, and persists for some time afterwards. During this stage of the disease the patient begins to lose flesh in a decided manner. The loss of weight generally begins to show itself in from six to twelve months after the initial attack of constipation, and becomes progressive. If bleeding is free, and especially if suppuration is profuse, emaciation sets in, and is frequently rapid.

(c) *Symptoms when the Growth has Infiltrated the Perirectal Tissues and Perforation of the Rectal Wall has Taken Place.*

When the disease has reached this stage the symptoms are pronounced, and usually indicate the implication of neighbouring viscera. They consist of haemorrhage, which is often free; pus in considerable quantity on account of pelvi-rectal suppuration and the development of ischio-rectal fistulae; deep-seated pain in the pelvis, over the sacrum, and extending down the thighs from

implication of the sacral plexus by extramural spread of the disease; and the supervention of general cachexia from chronic septic absorption.

(*b*) *Symptoms when almost Complete Occlusion of the Lumen has Supervened.*

This stage is generally reached in eighteen months or two years after the onset of the earliest symptoms, and the disease is then too far advanced for removal. The attendant symptoms are: (1) Obstinate constipation alternating with diarrhoea; (2) local pain and intermittent attacks of abdominal pain; (3) intermittent hæmorrhage; (4) increasing abdominal distension; (5) rapid emaciation; and finally (6) an attack of absolute obstruction.

EXAMINATION OF A CANCEROUS TUMOUR OF THE RECTUM.

A thorough exploration of the whole of the rectum in a systematic manner is the most reliable way of detecting the presence of malignant disease. The finger should be introduced to its full extent, so that the highest possible point can be reached. With an ordinary length of finger the promontory of the sacrum can nearly always be felt. The finger should then be swept round the entire circumference and gradually withdrawn as each encircling movement is made. In this way even a small nodule in the rectal wall can scarcely be missed. If a tumour be felt the following points should be noticed. Is the growth sessile or pedunculated? Is the surface smooth, lobulated, or excoriated? How much of the circumference is implicated by the growth; is the lumen of the bowel at the site of the growth stenosed? if so, can the finger be introduced through the stenosis? Is the growth movable or fixed to the muscular coat? if so, is the diseased part of the bowel movable or fixed? Finally, does the growth extend upwards beyond the reach of the finger?

Additional information as to mobility and possible extramural permeation may be obtained by bimanual examination, under an anaesthetic if necessary. The sigmoidoscope should always be used in order to verify the findings of the digital examination. You will have the opportunity of examining the condition in these two cases by the sigmoidoscope.

DIFFERENTIAL DIAGNOSIS.

From the clinical point of view the conditions which are most likely to be mistaken for carcinoma are polypus, villous papilloma, benign stricture, invagination of the rectum, gummatous deposits, and tuberculous ulceration. Polypi are very rare in adults. They are soft, pedunculated, free from induration, and seldom of a large size. Villous papilloma is fairly common. It is pedunculated, and may reach a large size. Its surface is soft and irregular, and as it secretes a large quantity of watery fluid it produces frequent evacuations of the bowels, but no induration exists anywhere. In benign stricture the margin is firm and regular; it does not bleed, and it is freely movable and generally accompanied by a purulent discharge. Invagination of the rectum may, when advanced, simulate carcinoma, but it is distinguishable from cancer by its even contour, the regular outline of its lumen, and the absence of induration. Gummata of the rectum are rare, and they may be distinguished from cancer by their smooth, round, elastic feeling, by the history of antecedent syphilis, and by the result of a Wassermann reaction. Tuberculous ulceration is not very common. It is difficult of diagnosis owing to the swelling produced and the chronic inflammatory thickening accompanying it, as you will see from the specimen shown; but in tubercle the ulceration is generally superficial, and the edges of the ulcer are not everted. Evidence of tuberculosis in other parts is often found.

THE EVOLUTION OF THE GROWTH.

An early adeno-carcinoma of the rectum forms a sessile, rounded, or oblong tumour, involving the mucous and submucous coats of the bowel. The growth increases in size in all directions, though apparently more rapidly in a transverse than in an upward or downward direction. Though at first freely movable on the subjacent muscular coat, it sooner or later becomes adherent to it. This adherence denotes that infiltration has commenced, and gradually the whole tumour becomes firmly fixed to the wall of the bowel. It is impossible to determine how long

infiltration of the muscular coat occurs after the primary appearance of the growth as a definite tumour, as cases vary in the rapidity of their evolution, but from a calculation based on the time of onset of the first symptoms I should say that six months is a rough average. As the growth increases in size the oldest part of the surface, probably owing to malnutrition, disintegrates and a definite ulcer appears—superficial at first, but gradually becoming deeper. The ulcer exhibits the well-known malignant characteristics of an irregular indurated margin, an uneven, excavated surface, and an indurated base. The lateral extension of the growth is not rapid, and when one-half of the bowel has been encroached upon the disease has probably been in existence for about a year; when three-fourths or five-sixths have been involved the growth is from eighteen months to two years old. These are rough averages. As the growth encompasses more and more of the circumference the wall becomes correspondingly rigid, and marked narrowing of the lumen results. Concurrently with the increase in size the spread of the disease is taking place partly by infiltration and partly by permeation of the lymphatics. Spread occurs both intramurally and extramurally. Intramurally the cells grow along the submucous lymphatics only to a very slight extent longitudinally in the majority of cases. They tend more to permeate by radial intramuscular channels to a deeper lymphatic plexus, where the area of spread may be of considerable extent, and from this they are conveyed by collecting channels running extramurally to the lymph glands. The clinical fact that recurrence may take place in the cut end of the bowel at a distance of several inches from the site of original growth strongly supports the view that cancer cells may permeate the intramural lymphatics for a considerable distance. It is impossible to state how soon after a cancerous tumour has developed extramural spread occurs. It is quite wrong to suppose that it takes place very late in the course of the disease. I have seen several small and freely movable growths, clinically early, which had given rise to widespread lymphatic involvement and to deposits of cancer in the pelvic mesocolon and pelvic peritoneum at a distance of several inches from the site of primary growth. Visible spread like this can only be recognized when the abdomen is opened and cannot possibly be detected by the ordinary methods of rectal examination. The invisible spread is much more subtle. From clinical observations of post-operative recurrences, I am quite convinced that cancer cells, even in comparatively small and early growths, invade the lymphatic channels to a distance far beyond the limits of the visible spread, and consequently all the tissues contained in the lymphatic areas leading from the primary growth to the lymph glands must be regarded as invaded territory. I divide these areas into three—the zones of downward, lateral, and upward spread. There is a free intercommunication between the lymphatics of the rectal wall and those contained in the ischio-rectal fat, perianal skin, and the external sphincter. Involvement of this area does occur even when the primary growth is situated in the upper part of the rectum. The lateral zone comprises the levatores ani, retrorectal lymph glands, internal iliac glands, the prostate, the base of the bladder, and, in the female, the cervix uteri, and the base of the broad ligament with Poirier's gland. Situated between the upper surface of the levators and the pelvic diaphragmatic fascia there is an extensive lymphatic plexus which freely communicates with the intramural lymphatics. In several cases I have observed small plaques of growth located either in the substance of the levators or upon their upper surface close to the rectal wall, and, in one instance, in the substance of the muscle close to the origin of the muscle from the pelvis. The levator ani muscle is therefore exceedingly vulnerable to the spread of rectal cancer, and should in all instances be freely removed. The zone of upward spread is the most important of the three. The structures in this lymphatic area are—the peritoneum of the floor of the pelvis, the whole length of the pelvic mesocolon, the paracolic lymph glands, and the glands grouped at the bifurcation of the left common iliac artery. Spread occurs into these very rapidly.

I have gone very briefly into the pathology of the spread in order to show you that any operation on cancer

of the rectum that is useful at all must remove certain areas of highly dangerous tissue. The facts of surgical pathology alone are sufficient to damn all such restricted operative procedures as perineal excision and resection with end-to-end anastomosis. I cannot speak of the end results of perineal operation in the hands of others. I only know that I gave them far too long a trial, extending their scope as far as possible, limiting my selection of cases more than I do now, and faithfully following my results. I did 53 such operations; I had 55 recurrences; and I am convinced.

TREATMENT.

The failures of restricted operations and the observations clinically on the areas of recurrence led me to devise the radical abdomino-perineal operation. I shall not now describe my operation, but you will have the opportunity to-morrow of seeing one of these cases operated upon by the method; the other will be operated upon on Thursday, January 30th. Briefly, the operation consists in removing nearly the whole of the pelvic colon, the whole of the mesocolon, the whole of the levatores ani, and the whole of the rectum and anus and ischio-rectal tissues, and making a permanent inguinal colostomy. You will see the results in those patients who have been good enough to return to us to-day for examination after three and more years since the operation, and you will find that they have practically complete sphincteric control of the abdominal anus, and that this artificial anus is neither uncleanly nor unsightly, nor is it a source of discomfort. The operation is a severe one. I do not think that it should be performed on those over 60 years of age; of 10 such cases all died. With regard to the remainder, of whom there were 36, 8 died from the effects of the operation, 4 have had recurrence, 2 died of intercurrent disease, while 22 are to-day alive and well after periods varying from six months to six years.

Memoranda :

MEDICAL, SURGICAL, OBSTETRICAL.

THE TREATMENT OF OBSTINATE SCIATICA BY PHENAZONUM INJECTIONS.

The treatment of obstinate sciatica is attended with so many difficulties that success by 'Tubache's method' may be of interest.

A. V., aged 66, of robust constitution, weight 15 stone, came under my care on August 30th, 1912. He had had a sharp attack of sciatica in 1886, and was quickly cured by the baths of Hammam R'Irha, Algiers; again, in 1905, he was apparently cured of another attack by visiting the same baths. An attack in September, 1911, was greatly relieved by three weeks of Harrogate treatment, baths, massage, electricity, etc., and in June, 1912, after a sharp attack of lumbago, a more severe trouble arose from a return of the sciatica. Three weeks at Droitwich; baths, massage, and Aix douche made the patient's condition steadily worse. He returned home and took to his bed on September 3rd. The daily application of an electric light bath was tried, and blisters along the course of the sciatica nerve, salicylates, potassium iodide, and other remedies, but he continued to experience the most acute pain on the slightest movement. He could only lie on his left side, the sciatica affecting his right leg from thigh to foot.

On September 21st I commenced the deep hypodermic injections of the following: Phenazonum, 5ijss; cocain. hydrochlor., gr. ijss; aq. destill. steril., ʒijss; 1 c.cm. (mxx) being injected into the upper part of the thigh over the nerve. The injection was repeated at different places along the course of the nerve on September 23rd, 25th, 27th, and October 3rd, 7th, 9th, 13th, 17th. They caused no pain at the time, but invariably about 6 hours after a great deal was experienced, which lasted some hours, and sometimes necessitated an injection of morphine. There was no great relief from the treatment until October 12th, but the nearer the injection got to the nerve the greater

the relief seemed to be. For instance, the injection over the external popliteal behind the head of the fibula gave great relief, and another injection, on October 13th, on the dorsum of the foot completely removed the pain after four hours, and it has not returned.

After October 12th the patient rapidly improved: the pain ceased and movement became easy. About this time some anxiety was felt because of some slight cardiac trouble, causing a slow and intermittent pulse; but a mixture of strychnine and digitalis put this right again. Since October 28th the patient has gradually resumed his usual habits, and experiences only a considerable stiffness in his right leg. The power of walking is gradually improving.

High Wycombe.

LEWIS W. REYNOLDS, M.R.C.S. Eng.

RUPTURE OF THE PLEURA WITHOUT FRACTURE OF RIBS CAUSED BY A BUFFALO.

W. R., a German hunter aged 27, was attacked by a buffalo on October 7th, 1912, near Kasisi Camp, on the Anglo-Belgian frontier, about 40 miles from Fort Portal, Toro, in the Uganda Protectorate.

The buffalo first attacked a native porter, going him in the abdomen from one side to the other as it tossed him. The man died on the spot. It next turned its attention to W. R., threw him on his back, and tried to crush him by pressing his chest with its head. With great presence of mind W. R. then pushed two fingers of each hand into the animal's eyes, which made it start back suddenly. Before he could get hold of his rifle (which lay by his side) the buffalo made a second rush at him and tried to crush him as before, the hunter trying to relieve the pressure by seizing both the animal's horns. In the meantime one of the other porters succeeded in killing the buffalo after three shots.

In the struggle the following injuries were sustained:

1. General bruising of the whole body and limbs.
2. A lacerated wound of the neck on the right side, and a double wound of the middle of the right arm, caused by penetration with the horn, and another lower down.
3. The principal injury, however, was rupture of the pleura between the fourth and fifth rib just outside the nipple line for 4 to 5 in.

The patient was first seen by me on October 11th, four days later. He was very anaemic, and there was a well marked mitral bruit. At each expiration the lung protruded from the aperture above described to the size of a large walnut. There was extensive emphysema of the chest wall up to the sixth rib in front and to the fourth in the axillary line. No pleuritic rub could be heard, being probably masked by the crepitations. The base of the lung was clear. The temperature was 101° F., the pulse 100, and the respirations 32.

A pleuritic rub was heard reaching to the base of the left lung on October 14th. The temperature was 98.6° in the morning, and 102.4° at 8 p.m.

The patient made a rapid recovery, and on October 18th the temperature was 98.2°, the pulse 84, and the respirations 26. The treatment was then stopped at the patient's request, but there was still dyspnoea and pain on November 2nd.

Note by DR. CROPPER, late of the C.M.S. Hospital, Toro.

I saw this patient on November 2nd and three following days. He was very anaemic, and I diagnosed malaria; this was confirmed by the microscope, which showed well marked benign tertian rings. Quinine in doses of gr. xv quickly put an end to the fever. The wounds were nearly healed. Pain in the left chest was diminishing, but there was still dullness at the left base, probably due to effused blood still unabsorbed. The rent in the pleura was closing, but on forcible expiration there was still a small protrusion of the lung nearer to the shoulder-joint than the nipple, and apparently more external than just after the injury. This could be controlled by a well fitted pad strapped on.

S. R. BHAGWAT, L.R.C.S.E.,

Government Surgeon, Fort Portal, Uganda.

Reports

ON

MEDICAL AND SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF THE BRITISH EMPIRE.

ROYAL NAVAL HOSPITAL, MALTA.

THREE CASES OF INTEREST.

(Reported by G. T. BISHOP, Fleet Surgeon, R.N.)

THE following notes of three cases occurring at the above hospital have been forwarded for publication by the Director-General of the Medical Department of the Royal Navy:

1. *Two Inguinal Herniae on the Same Side.*

P. R., 28, A.B., a Maltese. Admitted for operation with a right inguinal hernia, which he sustained about two years before. Examination showed a bubonocoele, which extended down to the external ring. When the parts were exposed, two well-developed sacs were found, a direct (which was empty) coming through the conjoined tendon, and an oblique, containing some non-adherent intestine. Both sacs approximated towards their distal ends, and they were nearly touching at the external ring.

REMARKS.—I have previously seen a similar case, but it was not reported. Perhaps in all cases of direct hernia a sac of the oblique variety should be looked for, which may not be so apparent as in the above patient.

2. *Salvarsan in Locomotor Ataxy.*

E. H., 36, leading seaman, admitted with locomotor ataxia. Has two circular punched out ulcers on plantar surface of right foot about the size of a split pea and a threepenny piece respectively. Pupils do not react to light, knee-jerks absent. Romberg's sign very marked. Gait unsteady. The patient is very thin, and looks ill. Shooting pains down both thighs and legs. No cutaneous anaesthesia could be made out. Wassermann's reaction positive. Urine contained a trace of albumen, otherwise normal.

On August 10th 0.3 gram of salvarsan administered intravenously. This was followed by some slight pyrexia and an increase of shooting pains; subsequently also by some girdle pains.

On August 26th 0.6 gram of salvarsan was given as before. This time there was more pyrexia, temperature reaching 103°. It became normal, and remained so after August 29th.

On October 1st the patient was discharged for passage to England. He walks quite well and speedily. Romberg's sign is negative. No albumen in urine; one ulcer has healed, and the larger practically so. Pupils react sluggishly to light. Has had no lightning pains for a month. Knee-jerks still absent. Most marked was the improvement in general health. The careworn look the patient had on admission was replaced by a cheerful expression, and his face filled out considerably.

REMARKS.—It is of course impossible to say whether this general improvement will be maintained, but the case certainly shows what salvarsan can do in an early case of tabs. The patient could not say when the various symptoms commenced, but he thought he had had unsteadiness for two months at least before admission.

3. *Iodine in Corneal Ulcer.*

J. Q., 23, stoker, was admitted with a history of ulcer of the cornea for three weeks past, which showed no inclination to improve.

Examination showed a crescentic, unhealthy-looking ulcer below the pupil, accompanied with much pain, circumcorneal inflammation, slight chemosis, photophobia, and lachrymation. The patient was treated for four days with boracic fomentations and irrigation, with just sufficient atropine to keep the pupil dilated. This resulted in no improvement.

On October 9th, after some 2 per cent. solution of cocaine had been dropped in the eye, tincture of iodine was applied to the ulcer by means of either a probe or camel-hair brush. This treatment was continued twice a day (with an occasional drop of atropine solution) until October 14th, when it was discontinued. The ulcer was then quite clean-looking, although much circumcorneal injection remained. This inflammation soon cleared up and the eye was well on October 20th, there being only slight opacity at the seat of the ulcer.

REMARKS.—I hasten to report this case, for I am not aware that iodine has been applied to corneal ulcers, and its effect here was very striking.

A fine camel-hair brush was found the best means of applying the tincture. It was possible that the treatment was not required for so long a period as five days, for the surrounding inflammation persisted while the application was being made and rather masked the improvement in the ulcer. Cocaine was required after instillation as well as before.

Reports of Societies.

MEDICAL SOCIETY OF LONDON.

Monday, January 13th, 1913.

Sir W. WATSON CHEYNE, President, in the Chair.

The General Practitioner-Surgeon.

MR. T. NORTH read a paper on the rise and possibilities of the general practitioner-surgeon. The object of the paper was to show the possibilities of operative surgery in general practice. Patients who required operative treatment might be divided into three classes. First, the rich, who could afford whatever might be necessary in treatment. They would go, as before, to surgeons whom they knew or had heard of as being pre-eminent in the class of operation they required. At the other extreme were the very poor, who would continue to receive treatment, in the future as in the past, from the hospitals. Between these two and merging into each was a class who could afford moderate fees or some fee for surgical treatment, but who could not find any one willing to operate for fees within their reach, or, if willing, capable of doing it. This condition of affairs would soon pass and there would be soon men capable and willing to operate for moderate fees. The extent to which operative procedures should be carried on in general practice could only be answered by the individual who undertook them. The advantage to the consulting surgeon would be great, as it would leave him more time for original work, and he could become a pure consultant. His aid would be sought more frequently if the patient remained under the general practitioner's care. The opinions expressed in the paper were based on between 700 and 800 operations of all kinds performed in general practice.

Treatment of Recent Injuries by Massage.

DR. J. B. MENNELL, in a paper on this subject, recounted the good results which attended massage if properly applied. Most of the dissatisfaction which had arisen as to the treatment was due to the fact that it was not practised as described by its originator. Dr. Menzell demonstrated the correct methods both of massage and movement in cases of recent fracture.

ROYAL SOCIETY OF MEDICINE.

SURGICAL SECTION.

Tuesday, January 14th, 1913.

Mr. MAKINS, President, in the Chair.

Actinomycesis.

DR. A. G. HAYNES LOVELL recorded a case of actinomycesis primarily affecting the inferior maxilla. The disease commenced in the tooth sockets followed by an inflammatory mass attached to the jaw; after teeth extraction an exploration was made and a vaccine of actinomycesis prepared from the culture of the pus obtained. The vaccine was given every ten days and potassium iodide administered. The patient was quite cured at the end of sixteen months. The speaker claimed that actinomycesis of bone was usually secondary to infection of the overlying soft parts. Osteoporosis took place without bony thickening; the neoplastic form was rare in man but common in animals. He thought that an early diagnosis was an essential to successful treatment and that surgical interference should not be attempted until the vaccine and potassium iodide has been tried.

MR. T. H. KELLOCK, in a paper read by Mr. PEARCE GOULD, said that actinomycesis was ubiquitous, and divided the cases into two classes, the clean and the septic; in the latter it was difficult to grow cultures. The disease usually occurred in the alimentary and respiratory tracts, especially in the salivary glands and the appendix. It was common in the lower jaw but rare in the upper, and when it did occur it started at the orifice of the parotid duct. He thought that the liver became infected directly from the duodenum. Actinomycesis of the lung spread to the chest wall; the spot in the lung was often very small and so easily overlooked. He had seen cases diagnosed as

gumma, streptococcal infection, tubercle, sarcoma, and carcinoma. The spread by direct continuity resembled malignant growths. The characteristic signs were painlessness, linear puckering, the degree of infiltration, and the small amount of pus; also the fact that the growth usually started in the openings of ducts on mucous surfaces and that it was followed by very little deformity.

Mr. A. G. R. FOULERTON compared the age and sex incidence, site of infection, and the mortality of the 76 cases of this disease that had come under his notice with the statistics given on the Continent and in Allbutt's *System of Medicine*. He found that they substantially agreed—65.4 per cent. occurred in males, 70 per cent. from the age of 15 to 35, 51.2 per cent. occurred in the mouth, tongue, and neck, 25.6 in the appendix, and 17.2 in the lungs. He divided the cases according to the kind of parasite present; most of them belonged to the mould type and spread by direct continuity; the others were a rapid blood infection leading to secondary abscesses. Actinomycosis attacked the workers amongst vegetable products; 5 of his own cases were due to passing infected cotton through the mouth. None of the cases had been diagnosed before operation and examination of the pus. Cases were often overlooked even after examination of the pus owing to the varying morphology of the parasite. He illustrated some of the forms by a series of photomicrographs, in which the coccal form was indistinguishable from tubercle.

Mr. BARKER said he had found great improvement from the injection of iodepin in one case.

Mr. WILSON reported 6 cases occurring in the appendix; 3 resembled acute appendicitis and 2 local peritonitis. In these two residual abscesses developed after appendicectomy. One formed a tumour in the caecal region and spread into the walls of the caecum without causing ulceration.

The PRESIDENT thought that everybody was liable to the disease; his experience was that the abdominal and pulmonary cases died; vaccines might in the future be able to save them.

Mr. BERLY thought that the diagnosis was extremely difficult and that the deeper forms were usually fatal. He did not agree with Dr. Lovell that surgical treatment should be postponed; the early isolated infection was the ideal for removal; scraping operations were bad.

Mr. FOULERTON, in a reply, said that up to the present only 4 cases had been reported in which a vaccine had been tried.

SECTION OF LARYNGOLOGY.

At the meeting on January 10th, Mr. HERBERT TILLEY, who was in the chair, exhibited the chart of a patient, aged 10, with a continuous evening temperature of 100° F. for fourteen days, with slight tonsillitis and enlarged glands, which had subsided under *facial treatment*. A swab culture from the tonsil revealed *Streptococcus longus* with staphylococci. Dr. EYRE also isolated a similar streptococcus from a bladder specimen. The opsonic index was 0.72, when an autogenous vaccine from the tonsil was injected. This was followed by a reaction; 10 c.cm. of polyvalent antistreptococcal serum was injected (Lister Institute), and next day 1.25 million of autogenous bladder streptococci. The temperature, which had mounted to 103° F., subsided before the third injection of vaccine prepared from the bladder streptococci had been used. The marked improvement after the last vaccine was the feature of the case. Mr. DE SANTI suggested that the symptoms were due to a general streptococcal infection. Mr. F. J. STEWARD related similar cases with recurrence of fever. Dr. JOHNSON HORNE did not attribute benefit to the vaccine. The PRESIDENT showed, in a healed condition, a case where galvanic puncture had been used in a *Tuberculous ulcer of the cord* by the direct method under cocaine. Evidence of lung trouble with tubercle bacilli in the sputum was adduced. The PRESIDENT also showed a case of *Granular congestion of the cord* the result of an ulcer which had healed under potassium iodide. In connexion with Mr. C. I. GRAHAM's case of *Cyst of the pituitary fossa*, operation by the nasal route was discussed. The patient was admitted under Dr. Wilfred Harris with failing sight, temporal headaches, drowsiness, slow mental reaction and incontinence of urine for several months. A skiagram showed the pituitary fossa to be flattened out and

enlarged. An incision was made in the middle line from the tip of the nose into the lip, splitting the columella; the greater part of the septum was removed. The mucous membrane over the sphenoid was raised, and then the anterior wall and interseous septum removed till the pituitary fossa was opened (Cushing's method). Two drachms of fluid escaped. During the first twenty-four hours there were thirst and polyuria. The patient still suffered from defective sight, but this was improving. Dr. WILLIAM HILL said that in Cushing's operation the upper lip was turned up, and pointed out the advantage in the use of Killian's long speculum. Mr. F. J. STEWARD asked that full notes might be inserted in the *Proceedings*, as this was the first case dealt with by this procedure in England. Dr. DAN MCKENZIE said that Hirsch of Vienna had found that the advantage of this route was the diminished danger of sepsis. Mr. L. COLLEGE exhibited two cases of *Laryngeal paralysis* due to central lesions in the vagus area, probably tuberculous in nature. The PRESIDENT recalled a case of syringomyelia in which similar signs were present. Mr. F. A. ROSE related a somewhat similar case which recovered. Dr. HERMINGTON PEGLER ascribed the lesion to pachymeningitis. Mr. S. W. BADGEROW's case of *Congenital web of the larynx*, in which a white web was attached to the anterior two-thirds of the cord in a boy aged 6, was the subject of a prolonged discussion. The PRESIDENT described a case in which coloboma iridis was also present. Mr. C. HORSFORD recommended excision by the indirect method, but said that it was well to be prepared for tracheotomy. Dr. WILLIAM HILL recommended laryngo-fissure, kept open for one month, during which time a splint was inserted. A case of his could not do without a tube, but could speak quite well. Dr. A. S. HITCHCOCK questioned the advantage of operation unless good articulation were obtained. Dr. FITZGERALD POWELL considered that such cases were best left, though Lack's tubes used after laryngotomy gave good results. Dr. DUNDAS GRANT was of opinion that such a condition would call for tracheotomy during one of the exanthemata. Dr. E. A. PETERS's case of *Extraordinary mobility of the tongue*, which could be passed into the post-nasal fossa, was discussed. Mr. BADGEROW indicated that irritation of the pharynx was the immediate cause of the use of the tongue. Dr. DONELAN related that suicides in slave ships were caused by passing the tongue in this manner. In commenting on a case of *Multiple papillomata of the larynx*, shown by Dr. E. A. PETERS, Mr. JOHNSON HORNE suggested that it should be dealt with by the direct method, and repeated removals, if necessary, once a month. Mr. F. J. STEWARD also recommended this method, and considered the difficult age was about 2 years. At the age of 9 the tendency to recur had diminished. Mr. C. W. M. HOPE supported this view, though the resulting oedema sometimes made intubation necessary. Dr. FITZGERALD POWELL mentioned that tracheotomy alone cured some cases. Mr. F. A. ROSE had used magnesium sulphate without improvement. Dr. WILLIAM HILL said that he saw such a case every fortnight. Dr. DUNDAS GRANT said that he removed the growths as they appeared, and rubbed alcohol and salicylic acid into the base. The PRESIDENT mentioned a case of his which sprouted with papillomata even in the tracheotomy wound. This patient had undergone forty-three operations, and was seen every two to three months. Dr. WILLIAM HILL took the chair, and a case of *Soft bony growth of the antrum* in a girl of 14 years was shown by Dr. E. A. PETERS. It was opaque to transillumination, and the walls, except the palatal, bulged slightly. An artificial antrum had been scooped out of the solid mass nine months ago, and the condition was stationary. Dr. W. H. KELSON referred to similar cases in which the condition was bilateral. Mr. F. H. WESTMACOTT had met with cases which were due to a hyperplasia, instead of vacuolation of the superior maxilla; he advised gouging out of all the soft material contained in the bone, and considered the prognosis in a case so treated to be good. Mr. C. W. M. HOPE exhibited a case of unusual form of *Syphilitic laryngitis* incident during residence in Norway. The uvula, arytenoids, and superior ventricular bands were occupied by white solid swellings. The palate was not anaesthetic, but healed scars were present. Wassermann's reaction was positive, and 0.6 gram of salvarsan was given with marked reaction and subsequent

local improvement. Another similar intravenous injection was followed by another reaction. Dr. LUEVEN of Aix considered that in tertiary syphilis, owing to the diminished number of spirochaetes, 0.5 gram, or in a small patient 0.3 gram, was the correct dose. These reactions were dangerous, and had probably caused the death of many patients. In one series of early cases in which there was no glandular enlargement Wassermann's reaction became negative in 5 per cent., but this was rarely observed. Relapse in secondary cases treated by the salvarsan method were uncommon; he considered that only a few of the fatal cases had been published. Dr. JONSON HORNE showed a case of *Dysphagia* with pain running up into the right ear, and lasting one month. The tongue was protruded to the right side and there was a fullness at the base of the tongue. A course of potassium iodide resulted in cure of the condition, which was probably due to a gumma at the base of the tongue.

SECTION OF OTOLOGY.

THE meeting of this Section on January 17th, under the presidency of Dr. DUNDAS GRANT, was devoted to a discussion on *The treatment of meningitis of otitic origin*. Dr. WILLIAM MILLIGAN, of Manchester, in opening the debate, referred to the difficulty of diagnosis and the disappointment met with in treatment in many cases of the disease. The march of surgery in conquering septic organisms gave him hope of greater success in connexion with this disease. The symptoms were headache, vomiting, stiffness of neck muscles, and increased arterial tension. The disease was not necessarily fatal provided it was diagnosed early and prompt treatment instituted. One must have courage to operate when the full series of textbook symptoms were not present. Meningitis could be divided into two groups: (1) Localized, (2) diffuse. When the infective organism reached the subdural spaces the tendency was for suppuration to be generalized. The most formidable form was purulent lepto-meningitis, that is, when the meshes of the pia arachnoid membrane were involved, and here there was often brain abscess or sinus thrombosis also. But the fact that it remained for a time localized afforded hope for operation even in this form. Increase of temperature he held to indicate the invasion of fresh areas. When the full range of textbook symptoms was present the patient was usually beyond the hope of surgery. Diminished alkalinity of the fluid denoted bacterial invasion, while an acid reaction showed that purulence had become established. Dr. Milligan proceeded to discuss the mechanism of the condition and the methods of operation, pointing out that bacteria were not found in films or cultures in the early stages of the disease. Oedema or fluffiness at the edge of the optic disc he regarded as a very important sign of the disease, and too much significance could not be attached to progressive increase of intracranial tension, which was usually accompanied by cerebral anaemia. Lumbar puncture as a therapeutic agent was of the greatest use when the fluid, though possibly turbid, was still alkaline and reduced Fehling's solution, but lumbar puncture he considered to be more a diagnostic than a therapeutic agent. When the labyrinth was the chief focus of serous meningitis he favoured a decompression operation in the posterior fossa, at some distance from the original focus, so as to avoid the risks of infection. An autogenous vaccine he regarded as merely an adjuvant. The internal ear was the most frequent avenue of infection to the meninges and the most dangerous. Dr. Milligan concluded with a historical survey and a description of the various operative procedures now employed, with especial regard to the prevention of herniation of the brain. His own records showed 37 cases of meningitis serosa with 29 recoveries and 8 fatalities. In the latter the cerebro-spinal fluid was purulent, and the decompression operation did not succeed. THE PRESIDENT remarked that a similar hopeful tone was manifest concerning this grave condition at a discussion held by the German Otological Society, and there the best results were said to have followed excision of dura mater. Mr. C. E. WEST expressed his objection to the terms "meningitis serosa" and "pachymeningitis externa." In the latter case why call it meningitis at all? One did not speak of peritonitis when the seat of suppuration was

outside the peritoneum. His results were not so good as those which Dr. Milligan was able to produce, probably largely because the cases were not seen early. He considered inferior vestibulotomy adequate for drainage; labyrinthectomy was an operation of unnecessary severity. Mr. SIDNEY SCOTT was not satisfied with the term "subdural"; the words "intradural" and "extradural" expressed all that was needed. He spoke highly of the operation of translabyrinthine drainage. Dr. DAN MCKENZIE emphasized the diagnostic value of pain in meningitis, as well as occipital headache in association with some rigidity of the neck. The great aspect which required attention and study was the treatment of purulent meningitis when the disease had passed the incipient stage and had entered the realm of the desperate. An important operation was multiple trephining and drainage in the neighbourhood of the base. Dr. MILLIGAN replied, and was accorded the hearty thanks of the Section.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

Wednesday, January 15th, 1913.

Mr. J. M. COTTERILL, President, in the Chair.

Endemic Febrile Illness in a Boy's Industrial School.

Dr. C. McNEIL and Dr. J. P. MCGOWAN described peculiar outbreaks of endemic febrile illness in a boy's industrial school near Edinburgh which had occurred periodically for over ten years. The illness had assumed three types: Cases of acutely fatal illness terminating within forty-eight hours; a total of 20 such cases occurred in the period. Cases of irregular pneumonia; total, 51 cases. Cases of uncomplicated fever; total, 175 cases. The common features of the three types, their occurrence together in groups, their identical onset, and their similarity of clinical phenomena showed that they constituted a single morbid entity, and that an atypical or distorted pneumonia. *Post-mortem* evidence in the acutely fatal illnesses confirmed the suggestion of pneumonia. There still remained to be explained the irregular type of the pneumonia and its prevalence in epidemic and endemic character. The authors advanced the hypothesis that this was due to the pre-existence in the boys of an abnormal constitution or diathesis. A clue as to the nature of this diathesis was found in the appearances of status lymphaticus found in certain of the *post-mortem* records. This might explain the fulminant character of the fatal cases, and its existence in a less marked degree might produce the irregular features of the other non-fatal illnesses.

Professor LITTLEJOHN discussed the subject of status lymphaticus, and Dr. SHENNAN observed that his remarks emphasized the difficulty of this investigation, a difficulty which, from what Dr. McNeil had said, had evidently been deeply felt by the authors. He and several of his colleagues had conducted *post-mortem* examinations of several of the earlier cases referred to. He had examined four or five cases himself, and had concluded that the only explanation, and that not altogether a satisfactory one, was that they were probably of the nature of acute pneumococcal toxæmias. He had in several cases noted the persistent enlargement of the thymus gland and the hypertrophy of the lymphatic tissues, but had not attached the importance which the authors did to these changes, as conducing to the fatal result. This was the additional and highly important contribution made by the authors to the possible pathology of these cases. In none of his cases had he seen evidences of pneumonia sufficient to justify his classing them as cases of that disease, and supposed that the intoxication had been so profound that the patients had died before the anatomical lesions had become pronounced. He suggested that if it had been possible to employ specific agglutinating reactions the question of food poisoning could have been more definitely excluded. Dr. J. GREEN, Dr. R. J. JOHNSTONE, Mr. WADE, Dr. GOODALL, and Dr. FRASER also took part in the discussion, and Dr. McNEIL replied.

Tuberculosis of Bone.

Mr. J. FRASER said that in differentiating human and bovine types of tubercle bacilli obtained from bone lesions the best method was the inoculation test, performed

by injecting intravenously into rabbits 0.01 gram of the culture of tubercle bacilli. Rapid emaciation and death denoted a bovine infection; continuation of health indicated a human infection. Employing the above test in 100 cases of bone and joint tuberculosis in children, the results showed a proportion of 62 per cent. due to bovine infection, of 35 per cent. to human infection, and 3 per cent. to a mixed infection of human and bovine types. With regard to the question of infected milk, in those children showing a bovine infection 73 per cent. were under 3 years of age, and had been brought up on unboiled cow's milk, while in the cases showing a human infection 71 per cent. gave a family history of tuberculosis. As to the paths of infection, it was very difficult to experimentally infect a bone with tubercle unless the marrow was first made to undergo a fibro-myxomatous degeneration; and such a marrow degeneration might result from an endarteritis of the nutrient vessel, or a tuberculous infection of the neighbouring joint. Tubercle might attack a bone as a pure diaphysitis, as an epiphysitis or as a metaphysitis. The question of epiphysitis or metaphysitis depended on whether the synovial membrane extended only as far as the epiphysis, or beyond it into the diaphysis. The stages of the pathological process in the bone began with the development of a tubercle follicle in the bone marrow. Following this, changes took place side by side in the periosteum, in the bone lamellae, in the marrow, and in the blood vessels; a thickening of the periosteum from the deposit of cancellous bone, either rarefaction or hyperostosis of the bone lamellae, fibrosis of the bone marrow, and a tuberculous endarteritis in the blood vessels. The gross pathological varieties of bone tubercle might be classed as follows: Encysted, infiltrating, atrophic, and hypertrophic. The paper was illustrated by numerous lantern slides.

Mr. STILES highly complimented the author on his paper, which was the outcome of two years' work, and only contained a fragment of that work. In almost every particular he agreed with the conclusions of the paper. The beginning of tuberculous infection in bone was a chronic endarteritis in a nutrient vessel, due to a chronic toxæmia derived from a tuberculous focus elsewhere and most probably in a gland. Tubercle rarely began in the epiphysis, and when it did so was nearly always secondary to synovial tubercle; but there were many cases of primary disease in the metaphysis. It was important to distinguish cystiform from infiltrating tubercle in the metaphysis, for the method of treatment was different, rest and immobilization being demanded in the former, and operative interference in the latter. But the great value of the paper was that it had established the source of the great majority of bone infections—tubercle-infected milk. The inspection of dairies in Scotland was scandalously inadequate; indeed, in many rural districts it was totally absent. Further discussion was postponed to the next meeting.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

AT a meeting on January 8th, Dr. WALTER SWAYNE, President, in the chair, Dr. A. J. NIXON gave a demonstration on the technique of the *Intravenous administration of neo-salvarsan*. He stated that it was necessary in syphilis to give doses at intervals of a week or less until Wassermann's reaction had become negative, and remained so for at least four weeks, four or five doses being usually required. Dr. C. W. J. BRASHER, in a paper on *Intermittent swelling of the parotid gland*, related the case of an adult female who had had attacks of acute parotid swelling at intervals for more than ten years. A vaccine of the *Micrococcus catarrhalis* grown from the interior of Stenson's duct gave a year of freedom from attacks, but the condition had since recurred. Dr. J. O. SYMES said that he had seen a boy with bilateral parotid swelling occurring every evening for some weeks following an attack of mumps, and Dr. CAREY COOMBS said that he had seen a similar condition affecting the submaxillary glands. Dr. R. S. S. STATHAM showed a specimen of primary *Rupture of the pregnant uterus before labour*. When the patient, who was eight months pregnant, was first seen it was thought to be a case of concealed accidental hæmorrhage, but laparotomy

revealed an extensive rupture of the uterus and the child free in the peritoneal cavity. She had been curetted a year previously for a septic abortion, and no other cause could be found. Dr. F. H. EDGEWORTH related a case in which *Phosphaturia and oxaluria* alternated, the latter condition being accompanied by renal colic and hæmaturia. The condition was cured by more complete mastication, the patient having previously bolted his food. Dr. BRASHER mentioned a case of oxaluria accompanied by hæmaturia and renal colic.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

AT a meeting on January 17th, the PRESIDENT (Dr. Dobson) in the chair, Mr. ALEXANDER D. SHARP showed a number of *Skigrams of the mastoid area*. A bismuth plug had been placed in the external auditory meatus before sending the patient to the radiographer. A very distinct outline of the canal appeared on the negative. This formed a useful guide to the mastoid antrum, lateral sinus, etc., and simplified the interpretation of the plate. In some cases it might be more useful to smear the drum-head only with the bismuth paste. Mr. HAYES showed a case in which there had been a five months' history of *Oesophageal obstruction*. A diagnosis of oesophageal epithelioma was made, and this was confirmed by the oesophagoscope. An operation was performed by Mr. J. F. Dobson, and the growth, which was an extensive one, successfully removed, the upper end of the cut oesophagus being sutured to the skin. The specimen was also shown. Mr. J. F. DOBSON exhibited some cases showing the advantage of "block" dissection in the *Removal of cervical glands* for malignant disease. Cases were also shown by Dr. VINING, Dr. BRONNER, Mr. WALTER THOMPSON, Mr. BASIL HALL, Mr. LITTLEWOOD, Dr. TELLING, Dr. GRIFFITH, and Dr. OLDFIELD. A paper was read by Dr. CARLTON OLDFIELD on *Obstetric surgery, its uses and limitations*. He discussed the treatment of eclampsia, comparing the surgical methods of simple induction of labour and of vaginal and abdominal Caesarean section with expectant and therapeutic measures. Pernicious vomiting of pregnancy he regarded as a neurosis, and advocated treatment by full feeding and suggestion. As a rule, surgical interference was not indicated in this condition, nor was it in fibroid tumours or in pyelitis complicating pregnancy. The necessity in some cases for cranioclasty and decapitation was deplored. The need for these could usually be avoided by examination during pregnancy, when Caesarean section would be indicated.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting on January 9th, Mr. ROBERT JONES, President, in the chair, Mr. C. A. ADAIR-DIGHON, in a paper on *Cavernous sinus thrombosis*, reported two cases. The first was a girl, aged 13, who had had a mastoid abscess on the right side. After the radical operation on the mastoid the girl did well for a week. Then her temperature ran up, she had rigors, with exophthalmos, drooping of the eyelids, with haziness of the cornea and optic neuritis. The right internal jugular vein was ligatured close to the clavicle and dissected up to the mastoid. The lateral sinus was exposed, curetted, and a current of fluid passed through it. Multivalent serum was administered. She made a good recovery, after showing signs of septic synovitis in several joints. The second case was a boy, aged 6. In this case the trouble arose from the nasal region, the right orbit being affected. The superior bony wall of the orbit was removed, the frontal lobe elevated, the cavernous sinus curetted, and a rubber drain introduced. The child died of acute meningitis. Mr. R. E. KELLY showed a case of *Suture of the crucial ligaments of the knee*. The patient, a carter, aged 33, had been kicked on the outer side of the knee while the joint was extended, a portion of the skin on the inner side being caught as a fold between the ends of the tibia and femur. There was extreme mobility of the joint, which could be dislocated backwards and replaced easily. The leg was put up in a Thomas's knee splint for five days. Then Mr. Kelly opened the joint by a long horizontal incision. The crucial ligaments and the internal lateral ligament were sutured with thirty-day catgut. The wound was closed and the leg kept at rest on a

Thomas's splint for three months. The PRESIDENT, after congratulating Mr. Kelly on the result, said he had seen several cases of this injury recover without operation when fixed on a splint at once. Mr. RUSHTON PARKER also thought that though the result justified the operation in this case, in most cases immediate fixation was the most important point in treatment. Mr. G. C. E. SIMPSON related a case where he had started treatment four months after the injury, with the result that after six months of splint treatment there was still a flail joint. Mr. G. C. E. SIMPSON, in a paper on *Congenital anomalies of the umbilicus*, described 3 cases of laparotomy for congenital exomphalos. In one the major part of the liver was included in the sac. The other two cases were successful. In 2 cases of ectopia the trigone of the bladder had been implanted into the sigmoid portion of the large intestine. The one lived for four months, dying from pyelitis. The other died from the shock of the operation. The anomalies of the urachus were discussed and a case of urachal umbilical polypus was described. Cases of umbilical polypi due to abnormalities of the Vitelline duct were considered. Four had been treated with success. The results of a Meckel's diverticulum was illustrated in various forms.

Rebivctus.

RADIO-ACTIVE SUBSTANCES.

ANY person who, though not engaged in the pursuit of pure science, yet has a grasp of the principles of scientific method, experiences keen intellectual pleasure in following an account given by a master of his subject of the way in which a new field of science has been entered, explored, and, as to its broad features at least, mapped out. Such a pleasure is in store for such persons who possess themselves of Professor RUTHERFORD'S new volume, *Radio-active Substances and their Radiations*.¹ We refer in particular to Chapter I, on radio-active substances, to Chapter VIII, on the continuous production and decay of radio-active matter, to Chapter XI, on the theory of successive transformations, to Chapter XVIII, in which the general results and relations are summed up, and to Chapter XIX, in which the radio-activity of the earth and atmosphere are discussed. These contain the general map of the new world which is being explored. The general methods of the exploration are explained in chapters on the ionization of gases and on methods of measurement, and details are filled in by others on the alpha, beta, and gamma rays respectively, on the properties of radiations, on radio-active gases and active deposits, and on uranium, ionium, and the origin of radium. Two chapters are given to radium and its emanation and active deposit, and these are followed by others on actinium and thorium and their products, and on the production of helium and the emission of heat.

In dealing with each subject the historical method is followed. That is to say, an account is first given of the manner in which the knowledge of the subject has been developed, and the data are then discussed in all their bearings.

Professor Rutherford's style is in general so perspicuous that the reader is left with the conviction that where some ambiguity or uncertainty seems to exist it is due not to any defect of expression, but to the circumstance that the facts have not yet been fully ascertained, or brought into relation with others which have been fully established.

It is true that the mathematical discussions which fill many pages in almost every chapter may present a formidable appearance to such as are not endowed with the mathematical faculty. But if they are content to accept these discussions as beyond suspicion, as safely they may, and pass on to the conclusion of each matter, they will find no difficulty in understanding the significance of the results and their relations.

The book, therefore, attains the rare success of appealing both to the specialist and to the generality. The detailed description of methods of experiment, the full mathematical discussions, and the copious references will make it

¹ *Radio-active Substances and their Radiations*. By Professor E. Rutherford. Cambridge: University Press, 1913. (Demy 8vo. pp. 766; figs. 121. 15s. net.)

invaluable to the former, while the clearness of statement and the logical sequence observed in the development of the subject and each of its parts will fascinate the latter.

The book is a masterpiece, and we would strongly commend its study to all those who desire to gain an intelligent appreciation of a new department of science intensely interesting in itself, and possessing for medical men the special attraction that one of its technical applications may have an important influence on the development of their art. The science itself is still young. The radio-activity of uranium was only discovered by Becquerel in 1896. The existence of radium was established by M. and Marie Curie two years later, and since then an enormous amount of work has been done by an army of workers, one of the chief of whom has been the author of this work. But the therapeutic application of radio-active matter is still in its infancy. The theory of radio-activity is complex and not yet fully elucidated; the theory of living matter and its disorders is even more complex, and still less understood, and Professor Rutherford refrains from more than the briefest reference to the physiological action of radio-active substances.

THE BLOOD IN DISEASE.

THE volume on *The Blood*,² by Drs. GULLAND and GOODALL of Edinburgh forms a notable addition to the list of monographs dealing with diseases which influence the blood in such a way as to render their detection certain in some cases and probable in others. The research and learning of its two authors and the richness of the clinical opportunities from which they have drawn their conclusions justify the opinion we express that it will for a long time be an authoritative guide to a most difficult but important medical subject.

It is divided into five parts, and concerns itself with those studies which have to do with every departure of the blood from the normal, with one exception. That exception is the bacteriological aspect of blood diseases and all that its study implies, such as the investigation of the effects of bacterial antigens, of the immune and anaphylactic reactions to such agents, and with the curative methods which have been devised to combat infection, through the mechanism of various antibodies. Only half a page is given to the bacteriological examination of the blood, and this closes with a reference for further information to bacteriological treatises. Lest this remark should damp the reader's inclination to peruse the work, it is only necessary to say that the rest of the volume is packed full of information on problems connected with the blood, which no student of medicine, however much impressed with the importance of infection, can ignore. All that can be hoped for is that the authors some day will give the medical profession another such volume dealing with those changes in the blood which are intimately connected with bacteriological study, and on lines as thorough, as scientific, and as useful as are followed in this work.

The first 46 pages deal with the examination of the blood by methods which have been thoroughly tested and approved by experience, and include those which are of far-reaching importance, as the methods of Haldane and Lorrain Smith for estimating the haemoglobin content, and the colouring methods advocated by Pappenheim, Leishman, and others. The second part of the volume is devoted to a study of the formed elements of the blood, and if the reader would like to test the reserve and practical-mindedness of the writers we would commend this section to his notice, for they have made the descriptions as simple as possible, and have avoided the excesses of differentiation and nomenclature in which German workers, who are the chief offenders, have indulged. Chapters XI, XII, and XIII (dealing with the blood in animals, with the histology of the marrow, and with the development of the cells of the blood) will serve to show the thorough-going and broad-minded attitude of the

² *The Blood: A Guide to its Examination and to the Diagnosis and Treatment of its Diseases*. By G. Lovell Gulland, M.A., B.Sc., M.D., F.R.C.P.E., Physician to the Royal Infirmary and to the Royal Victoria Hospital for Consumption, Honorary Physician to Chalmers Hospital, Lecturer on Medicine at Surgeons' Hall, Edinburgh; and Alexander Goodall, M.D., F.R.C.P.E., Lecturer on Physiology and on Practical Medicine at Surgeons' Hall, and on Diseases of the Blood in the Edinburgh Post-Graduate Courses in Medicine. Edinburgh and London: William Green and Sons, 1912. (Roy. 8vo. pp. 358; figs. 16. coloured plates 16. 15s. net.)

authors towards problems which will almost certainly find their full solution only in comparative pathological study and in embryology. The third part is devoted to a study of the blood, of the bone marrow, and of the lymphoid tissues in disease, and, as we have already said, in some of these the blood examination yields results which make diagnosis possible; whereas in others it fails, or succeeds only when taken in conjunction with other data independent of blood examination. The chapters dealing with hæmophilia and congenital family cholaemia are of special interest and importance, containing as they do reference to recent work on these subjects. The condition known as status lymphaticus, which presents so serious a stumbling-block to the clinician and the pathologist, receives adequate treatment so far as is possible in the present uncertainty of opinion even as to its existence. Part IV is devoted to a study of the cytological changes of the blood in special infectious diseases, and is the least satisfactory of the volume, for it is wanting in that pointedness which would have been given had it been accompanied by what we have already expressed we hope will follow, a study of the bacteriological side of the questions discussed. The fifth and final part is devoted to a study of the animal parasites of the blood, such as cause malaria, kala-azar, sleeping sickness, relapsing fever, and filariasis. There is a very complete index, and the excellent coloured plates deserve high praise.

AFTER-RESULTS OF ABDOMINAL OPERATIONS.

In collecting and reprinting his papers on the *After-results of Abdominal Operations*,³ contributed to the *Journal of Obstetrics and Gynaecology of the British Empire*, Dr. ARTHUR GILES has rendered a service to surgery of no little importance. During ten years he has spent much time and trouble in following up the whole of the cases operated on before July, 1909. The statistics refer to operations upon the female generative organs only; 80 per cent. of all cases have been traced and investigated. It is notable that the operative mortality is only 4 per cent., but the detailed inquiry into the after-history of all these cases—revealing as it does somewhere about 60 or 70 per cent. of complete restoration to health—should enable both surgeon and patient to take heart of grace. Moreover, the 30 per cent. of women, previously suffering from the effects of diseased or damaged organs, who recovered without complete restoration to health, were by no means badly off; the majority of them found themselves, and declared themselves, very much better off than they were before operation.

All the conclusions to be deduced from the results of these consecutive inquiries are worth consideration, but it is only possible here to select casually a few. Dr. Giles thinks that "soiling of the peritoneal cavity with the contents of an ovarian cyst favours the occurrence of later disease, and therefore the interests of the patients are safeguarded by the removal of these cysts (however large) intact, without tapping." It would appear that removal of the appendages of one side involves a liability to the occurrence of extrauterine pregnancy. Removal of both tubes and ovaries has no marked detrimental effect on the subsequent health; the influence of the artificial menopause in causing mental depression is relatively small. The fate of the cervical stump after supravaginal hysterectomy need cause no apprehension; amongst 181 cases there was no instance of malignancy and practically no trouble of any sort.

The period of invalidism after this class of abdominal operations is less than three months in 60 per cent. of cases, and very rarely lasts beyond twelve months even in women well on in years. With this class of operations as with those elsewhere, it is found that the severity of the operation itself is not the most important factor in determining the period of convalescence. Dr. Giles has noticed some deterioration of the memory in as many as 20 per cent. of his cases, and thinks it was more marked in proportion to the duration of the operation; it would thus appear to be a result of the anaesthetic intoxication; if this be the case it should be recognizable equally after other than pelvic operations, but is it so?

This is a book that should be in constant requisition in

every library, and one that no surgeon should neglect. It is so liberally documented that even the sceptical public may well accept its reassuring statements; to be operated upon is, after all, not to bid farewell to normal health and happiness!

ENZYMES.

It has been truly said that the fundamental training of a physician should be that course of study which makes of him a good biologist. This newer conception is of comparatively recent date, and some of us can remember when medicine was an affair of chemistry—not of biochemistry, but of that "inorganic" order which sought to cure epilepsy with silver and bronchitis with antimony. Gradually bacteriology came to the front, and we now seem to have reached another period of development—bacteria are not the ultimate recognizable elements of disease, but both bacteria and animal cells are found to exert their influence by means of unorganized agencies which can only be recognized by the product of their activities—ferments or enzymes. Professor COHNHEIM has contrived in the small compass of his book on *Enzymes*⁴ to give a survey of the subject which will provide the reader with much information. The book, which has been presented in English with great skill by Dr. W. B. Cannon, practically divides itself into three parts. The first is concerned with the study of those fourteen or eighteen enzymes, hydrolytic in character, the seat of origin and operation of which is the alimentary canal, including the doubtfully digestive ferment found in the liver and intestine—arginase. To the physiologist concerned in the processes of assimilation such ferments are of the greatest importance, and no doubt in the future more will be heard from the pathologist of those clinical conditions which represent disturbed action of these ferments. A second section, introduced in Chapter XXI, deals with those enzymes the activities of which are directed not to the preparation of foods for mere absorption, but for the far more important function of extracting from such absorbed foods the energy which gives birth to the heat of the body on the one hand, and that power of movement which is an essential in all animal life. The animal body by means of these metabolism-enzymes is rendered the most perfect engine known, for it makes mechanical use of 30 per cent. of the energy represented by the food intake, and the best engineering skill can make use of not more than 10 to 15 per cent. of the total potential energy of the fuel used in steam engines for mechanical purposes. A subsection of the discussion on metabolism-enzymes has to do with the important autolytic enzymes, that is, with ferments which are not yet clearly shown to have any anabolic or katabolic importance, but which come into operation in molar and molecular death of the individual, and are possibly responsible for those wholesale losses of parenchyma seen in cases of arterial occlusion—for example, infarction of various organs.

The third and last section deals with ferments which subserve neither assimilation of food and its internal combustion, nor the removal of tissues no longer capable of surviving. The fibrin ferments represent a group of agencies which in evolution have been found necessary for the protection of the life of the individual. When a blood vessel is opened by accident or by biological activity, here are agents whose function is purely therapeutic, namely, the duty of stopping hæmorrhage. Scarcely less interesting is the discovery by Professor Cohnheim himself of the first-known metabolism-enzyme, namely, the ferment which attacks sugar and is due to the conjunction of two agents derived from two different kinds of tissues—muscle and pancreas. A full index to subjects and authors closes a book which is of first-rate importance to biologists.

THE PROSTATE.

PROFESSOR VON FRISCH's monograph on the diseases of the prostate⁵ is one rather for the genito-urinary expert than

³ *A Study of the After-results of Abdominal Operations on the Pelvic Organs*. By Arthur E. Giles, M.D., F.R.C.S. London: Baillière, Tindall, and Cox. (Med. 8vo, pp. 262. 10s. 6d.)

⁴ *Enzymes*. By Otto Cohnheim, Extraordinary Professor of Physiology, Heidelberg. Six lectures delivered under the Herter Lectureship Foundation at the University and Bellevue Hospital Medical College (1910). First edition. New York: John Wiley and Sons; London: Chapman and Hall, Ltd. 1912. (Cr. 8vo, pp. 180. 6s. 6d. net.)

⁵ *Die Krankheiten der Prostata*. Von Dr. A. von Frisch. Second edition. Vienna and Leipzig: A. Hölder. 1910. (Sup. roy. 8vo, pp. 305. Mk. 6.50.)

for the practitioner. It has a bibliography of thirty pages, and is so fully bedecked in the text with the names of those who have written on the subject, whether exhaustively or casually, that it is a little difficult at times to see the forest for the trees; it is difficult to arrive at the proper views of the author himself. The whole field is traversed, from anatomy, through physiology—including a discussion of the vexed question of the real function of the prostatic secretion, and the even more obscure question of the nature of the internal secretion—to etiology and pathology in their various aspects. One or two points are easily demonstrated. For example, the author confirms the opinion of Sir Henry Thompson that no one of the multitude of etiological factors assumed or asserted as the *fons et origo* of prostatic hypertrophy has any claim to pre-eminence, least of all gonorrhoea: sexual excess no more than continence. Almost positive, too, is the author's assurance that prostatorrhoea is not a constant or even common symptom of chronic prostatitis. It will be gathered that Professor von Frisch is more interested in the pathogeny and the symptomatology of the prostate when it is stated that the pages devoted to total enucleation of the organ are fewer by far than those expended on discussions of the worth and mode of action of the various "indirect" methods of effecting atrophy or regression. There is, of course, an enormous amount of information in the book, ranging over all forms of acute and chronic inflammation to tuberculosis (with no reference, however, that we have detected, to its occurrence in very young children), concretions, and new growths, and, lastly, parasitic affections such as echinococcus cysts. It is a book for reference, not only as to theories of origin, but also as to the manifold methods of instrumental and other forms of treatment which the diseased organ has suffered.

Dr. KARO's book on the pathology and treatment of hypertrophy of the prostate⁶ is a small monograph intended for doctors and students. It contains nothing new on the subject, but what it does contain of facts well known to the specialist is clearly and attractively set out. Only when it comes to deal with hypotheses is it found wanting. It starts with a long exposition of the latest hypothesis which is fashionable in Germany, namely, that the prostate produces a "hormone" which is supposed to activate the bladder nerves (*sic*). It is this hypothesis which dominates the whole essay, but to support it not one single fact is brought forward which appears to us to pass muster. Accepting this hypothesis, the author proceeds to detail certain cases of so-called "prostatism without residual urine and without enlargement of the gland," in which he claims to have obtained a complete cure by injections of testiculin and yohimbin. We fail to see the connexion between the theory and the practice. It would be interesting to know why the average German writer at the present time wilfully refuses to recognize French and English work. To take one instance from many out of this book, Karo enunciates a now well recognized fact that the only part of the prostate which undergoes "hypertrophy" is that part which lies between the urethra and the ejaculatory ducts, and that in prostatectomy a certain part of the prostate is not removed, nor are the ejaculatory ducts torn. We could overlook the fact that this was pointed out a good many years ago in a book by Wallace of St. Thomas's Hospital, but we cannot overlook the fact that these propositions were elaborated in an admirable and very complete article in German by Marion, a Frenchman, in the *Zeitschrift für Urologie*, Bd. 5, No. 8, 1911, exactly one month before the article which Karo calls classical of Tandler and Zuckerkandl in the *Folia Urologica*. Yet Karo overlooks the article of Marion, and writes as if Tandler were the first to point to the facts. Science should know no frontiers.

TEXTBOOKS OF PHYSIOLOGY.

PROFESSOR SCHÄFER has written a little practical book on *Experimental Physiology*⁷ in the same clear style and

with the same excellency of arrangement which characterizes his well known *Essentials of Histology*, a book familiar to every student of medicine. The book before us is illustrated with eighty-three excellent figures and is founded on twelve years' experience of classes at Edinburgh. The electrical circuits and frog muscle and heart preparations are particularly well figured, and the text suffices to give the student a clear and succinct account of the work he has to do in each practical lesson. The exercises chosen are mostly of the old familiar type such as have become traditional in physiological laboratories, but we note among the demonstrations an interesting and novel experiment on the lactating mammae by which is demonstrated the fact that a decoction of corpus luteum or posterior lobe of pituitary body causes a rapid flow of milk.

HERMANN'S *Lehrbuch der Physiologie*⁸ has reached its fourteenth edition and has been revised and enlarged by the learned author. The continued popularity of this work must depend on its containing such a summary of physiological science as can be crammed up by the student or referred to by the practitioner, for the work is remarkable for dullness, and is not written in such a way as to inspire the reader or give him any love for the science. We note very little reference to English work. Thus, in the section on reflex action we look in vain for the fundamental researches of Sherrington. In that on the circulation we find no mention of Bayliss's researches which prove that vaso-dilator nerves to the skin run in the posterior roots, or to the researches of Leonard Hill on the influence of posture on the circulation. In this latter respect an erroneous research carried out by two pupils of the author is alone cited. In the section dealing with speech there will be found an account of Hermann's phonographic records of vowels and consonants. The physics of physiology are dealt with particularly well by the author, and in all the physical sections this work may be consulted with advantage.

HEATING AND VENTILATION.

NOTWITHSTANDING the great amount of attention which has been paid in recent years to the question of the ventilation and warming of dwelling houses and of public buildings there is still a vast amount of ignorance displayed by those who are called upon to carry out practical schemes. A great deal of that ignorance would be dispelled by a careful and intelligent perusal of Mr. A. H. BARKER's work on the *Theory and Practice of Heating and Ventilation*⁹ which deals with the whole subject in an elaborate and masterly manner. The author has studied the many difficult problems, which he admits exist, both scientifically and practically, and he is able to show how many of them may be solved. Although a large portion of the book deals with technical matters of interest primarily to engineers there is still much to be learnt from it by those less expert. For example, the chapter on heating by fireplaces and stoves contains a very clear account of both these methods of warming a room. Among the disadvantages of an open fire as a means of heating Mr. Barker places first its inefficiency, which he considers to be not more than one-fifth or one-sixth of that of a system of heating by radiators for an approximately equal effect. Moreover, it causes an immense amount of labour in carrying fuel and in the removal of ashes, while in addition a great deal of dust is produced. For an ordinary sitting-room he considers that, if no regard is to be had to the initial cost or to the cost of upkeep, the most satisfactory method of warming is by a combination of open fires and radiators. The chapter dealing with the plenum system of ventilation is a very clear exposition of the subject dealt with, and although the author is evidently favourably disposed towards this method of ventilating he has considered it in a very fair and impartial manner.

⁶Die Prostatahypertrophie. Ihre Pathologie und Therapie. By Dr. med. Wilhelm Karo. Berlin: Oscar Coblentz. 1912. (Cr. 8vo. pp. 50. Mk. 1.60.)

⁷Experimental Physiology. By Professor E. A. Schäfer, F.R.S. London: Longmans, Green and Co. 1912. (Med. 8vo. pp. 120; figures 25. 4s. 6d. net.)

⁸Lehrbuch der Physiologie. By L. Hermann. Fourteenth edition. Berlin: A. Hirschwald. (Roy. 8vo. pp. 800; figs. 234. Mk. 18.)

⁹The Theory and Practice of Heating and Ventilation. By A. H. Barker, B.Sc., B.A. London: The Carbon Press. 1912. (Sup. roy. 8vo. pp. 732; illustrations 142. 21s. net.)

NOTES ON BOOKS.

DR. R. C. MACFIE is among the latest contributors to the flood of neo-vitalist speculation, of which Professor Bergson's philosophy is a prominent example. In *Heredity, Evolution, and Vitalism*¹ he deals with "some of the discoveries of modern research into these matters, their trend and significance." He has evidently given considerable study and thought to the subject, and he writes in a style that may be commended as both scholarly and picturesque, though obscure in parts. He deals first with the morphology and chemistry of the cell, development, the various more or less conflicting theories of heredity, and such cognate problems as the transmission of acquired characters and the determination of sex. Medical readers will here find themselves on familiar ground, and will doubtless appreciate the ability of the exposition, as well as the acuteness of the criticism evoked by the consideration of controversial points. But we fear that the un-instructed—and the book purports to make a general appeal—will find the author's treatment too condensed and technical for their powers. In the last few chapters Dr. Macfie comes to grips with his main problem—the bearing of recent discoveries upon the theory of continuous evolution, and especially upon Darwinism. He is pronouncedly anti-Darwinian; for him the publication, or at all events the ultimate acceptance by the scientific world, of the *Origin of Species* was "a spiritual disaster," the victory of the evolutionists "a matter for tears." With Professor Pfüger, he regards vital force as a specially embodied energy of thermal nature and origin, rejecting the view that life has been built up from or is explicable in terms of the inorganic. Dr. Macfie is sceptical as to the common origin of life and the simian ancestry of man. His alternative hypotheses are interesting, but would have been more effectively presented if he had more clearly defined to himself the quality of the audience he wished to address. In any return to the subject it would be well to adopt a method either frankly popular, or taking for granted much of such doubtfully relevant information as he has compressed into this volume.

MR. W. H. WHITE'S *Handbook of Physics*² is one to which unqualified praise can be given. Although it is written avowedly to cover the ground required for the intermediate examinations of the universities, and the author has not thought it *infra dig.* to distinguish by a particular mark those paragraphs with which medical students need not concern themselves if they only wish to do what is required for their examinations, yet it is as far as possible from being a mere cram book. The matter is presented with great economy of words, but the author succeeds in being more and not less interesting from the terseness of his explanations. The subjects of mechanics, heat, light, sound, magnetism, and electricity are dealt with, and each chapter is followed by questions selected from the examination papers of various universities. Mr. White is lecturer on physics at St. Mary's Hospital Medical School, and medical students will find his book an excellent one.

Captain J. W. S. SECCOMBE'S *Bacteriologist's Aid to Memory*³ is a compilation from standard works on bacteriology. It is a large sheet, upon which are arranged in tabular form the chief cultural, morphological, and pathogenic characters of the chief races of micro-organisms. The information is accurate, but most of it would be quite superfluous to any competent bacteriologist. It may be useful to clinical pathologists of little experience, or to those who are preparing for examinations.

The twenty-third volume of the *Transactions of the American Pediatric Society*⁴ relates to its meeting in the summer of 1911. Among the thirty-six papers read and discussed were four dealing with metabolism in children, and five with cases of epidemic anterior poliomyelitis, including a brief report on the subject presented by a special committee which had been appointed to consider the subject on behalf of the society. Among its recommendations was the application of strict quarantine measures for at least a month to every case and the

exclusion of children belonging to infected households from schools. A case of diabetes mellitus in a child aged 7 months was recorded by Drs. P. J. Eaton and E. B. Woods, and a careful clinical and pathological study of amyotonia congenita was presented by Drs. J. P. Crozier Griffith and W. G. Spiller. Three authors, including Drs. Henry Koplik and Francis Huber, dealt with the special problems of ward arrangement and administration created by the needs of children; and Professor E. E. Graham recorded in detail his experience with the vaccine treatment of 24 cases of whooping-cough. It justified, in his opinion, a more extensive trial of vaccine treatment in this disease. The volume is edited by Dr. L. E. L. Fétra.

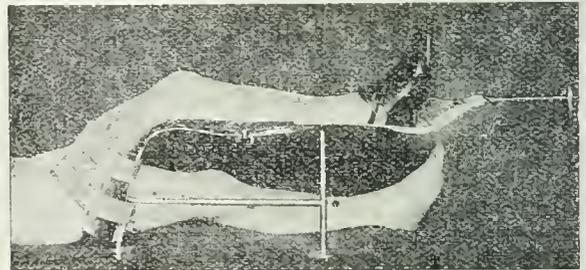

The first English translation of DIEULAFOY'S *Textbook of Medicine*⁵ was based on the fifteenth French edition, and met with considerable success on its publication some two years ago. A further translation by the same workers, Dr. V. E. COLLINS and Mr. J. D. LIEBMAN, Ph.D., LL.D., is based on the sixteenth edition, which appeared only a few days before the lamented death of Professor Dieulafoy in the autumn of 1911. That edition contained a considerable amount of new matter, so that the present volume is more up to date than its predecessor. Vaccines, the opsonic index, the Wassermann reaction, and salvarsan all receive notice, while there are also sections dealing with various syphilitic and parasymphilitic phenomena, gonococcal septicaemia, and haemolytic icterus. Nothing could destroy the attraction of the clarity of thought which helped to win for Professor Dieulafoy his great popularity as a writer, and the translators have at times managed to reproduce something of the charm of the idiomatic phraseology of the original work.

MEDICAL AND SURGICAL APPLIANCES.

Apparatus for the Extension of Fractures of the Tibia during Plating and Screwing Operations.

MR. LAWRIE MCGAVIN, F.R.C.S. (London), writes: The difficulty of bringing into apposition the overriding fragments in fractures of the tibia when operations are undertaken for the screwing or plating of this bone are well known to all surgeons. This difficulty is especially marked in old-standing fractures which, in spite of the manipulative skill which will often overcome the displacement in recent injuries, are frequently impossible to reduce without the exertion of considerable leverage and force. To overcome this difficulty I have recently devised the extension apparatus shown in the accompanying photograph, which I have found of great assistance.

The apparatus is placed upon the operating table, and the patient's knee being flexed, the limb is placed upon it, the thigh being strapped to the thigh piece. The foot,

was padded with wool and bandaged, is placed in the boot, which is laced up, and the straps lying over the malleoli are drawn tight. The ring in the sole of the boot is now placed in the swivel which is attached to the end of the extension screw, the thread of which is very fine, when, by screwing this up tight, the bones are brought into accurate alignment and can be plated with the greatest ease upon the apparatus. The apparatus, covered by sterilized towels, thus takes the place of the operating table, and is adjustable to suit varying lengths of femur and tibia.

This method does away with the irregularity of manual traction, which makes the operation so prolonged and difficult in old cases, as well as with the necessity for introducing levers between the broken ends, which so frequently results in bruising and cracking of the bones and stripping of the periosteum. The apparatus has been made for me by Messrs. Allen and Haubury, who will be pleased to demonstrate its use to any surgeon.

⁵ *A Textbook of Medicine*. By G. Dieulafoy. Second edition, translated from the sixteenth French edition by V. E. Collins, M.D. Lond., and J. D. Liebmann, Ph.D., M.A., LL.D. In two vols. London: Baillière, Tindall and Cox. 1912. (Roy. 8vo, pp. 2180; plates 9, figs. 100. Price 25s. net.)

¹ *Heredity, Evolution, and Vitalism*. By Ronald Campbell Macfie, M.A., M.B., C.M. Bristol: John Wright and Sons, London: Simpkin, Marshall, Hamilton, and Kent. 1912. (Demy 8vo, pp. 302. 6s. net.)

² *A Handbook of Physics*. By W. H. White, M.A., B.Sc., A.R.C.Sc. London: Methuen and Co. 1912. (Crown 8vo, pp. 680; 341 diagrams. 7s. 6d.)

³ *The Bacteriologist's Aid to Memory*. By Capt. J. W. S. Seccombe, R.A.M.C. A handy reference sheet for the laboratory. London: J. Bale, Sons, and Danielsson. 1910. (5s. 6d.; on linen, 4s. 6d.; with rollers, 5s. 6d.)

⁴ *Transactions of the American Pediatric Society*. Vol. xxiii. (Roy. 8vo, pp. 395.)

THE PARLIAMENTARY COMMITTEE ON PROPRIETARY REMEDIES.

The Select Committee appointed to inquire into the sale and advertisement of proprietary medicines resumed its sittings at the House of Commons on January 16th.

The Chairman (Sir Henry Norman) mentioned a case to which the attention of the Committee had been called by a member of the public of an alleged clergyman advertising his willingness to send inquirers a free cure for epilepsy. The method was to forward a prescription, accompanying it with a letter advising the recipient to obtain the principal ingredient from a manufacturing chemist whose premises were in the same town in Cheshire as that in which the "clergyman" resided. Whereas the ordinary price of the ingredient in question was from 2s. to 3s. 8d. per pound, 16s. per pound was charged by the chemist. Inquiries of the local police revealed the fact that the "clergyman's" letters emanated from the address of the manufacturing chemist, and as a matter of fact no clergyman had ever lived there within the knowledge of the police.

PROPRIETARY ARTICLES SECTION, LONDON CHAMBER OF COMMERCE.

Evidence was then given by Mr. E. S. Waring, of Nottingham, a Director of the business of Boots Cash Chemists, who attended at the request of the Proprietary Articles Section of the London Chamber of Commerce. He stated that from his experience, 121 out of the 269 preparations mentioned in *Secret Remedies* and *More Secret Remedies* had no sale whatever; most of them he had never before heard of, and some he knew were dead. Of the remainder, 57 had a very poor, intermittent sale, 12 had a fair sale, 23 a good sale, 25 a very good sale, and 30 a very large sale. He did not consider the prices charged for proprietary medicines to be unreasonable; a chemist would charge 1s. 6d. for making up a box of 56 pills similar to those for which the proprietary medicine vendor charged 1s. 1½d. Proprietary articles which did not impress the public as having real merit died out rapidly. He did not think the interests of the public would be served by the publication on the label of the name of a poison contained in a proprietary medicine; the tendency would be for the victims of certain drugs to buy the medicine for the sake of the drug contained. He was strongly opposed on behalf of the retail trade to any publication of formulæ. It would lead people to purchase the ingredients separately and attempt to compound the medicines themselves—perhaps with disastrous results. Publication of formulæ would lead to unfair competition; a preparation would be advertised as "according to the formulæ" of some well-established remedy.

Sir Philip Magnus: They can do that now from the publication of the formula in *Secret Remedies*.

The Witness: Assuming that it is the correct formula.

Sir Philip Magnus: It is probably as correct as any formula that could be put on the label of a bottle of medicine.

Continuing, the witness said he was in sympathy with any restriction of the improper sale of abortifacients, and he mentioned the steps taken by his firm to prevent abuse in this matter. The witness gave a list of sixteen proprietary articles which, from inquiries at 105 shops of Boots Cash Chemists, he found to be prescribed by doctors.

The list was not fully disclosed, but the Chairman remarked that a good many of them were not secret remedies of the class the Committee had been dealing with.

Mr. Newton examined the witness at some length with regard to preparations manufactured by his firm for female ailments and for gonorrhoea. The witness said this was a legitimate business done by chemists of all classes.

The witness agreed with Mr. Glyn Jones that not much harm would be done if the law prohibited the sale of anything advertised for the treatment in any way of women's functional troubles. He admitted that the traffic in these preparations was large and had serious results.

In reply to Mr. Bathurst, the witness expressed the view that medical men were largely influenced to prescribe

proprietary medicines by the advertisement of these in the medical journals. As to the publication of the name of a poisonous ingredient, the witness admitted that there were not many proprietary preparations containing a sufficient quantity of a deleterious drug to make it worth while for a victim of a drug habit to take the preparation. The witness agreed that the advertisement of preparations purporting to cure incurable complaints should be prohibited by law.

The witness was also questioned with regard to a preparation for gonorrhoea manufactured by his firm, but sold under another name, Messrs. Boots being described as agents.

The Chairman said the witness had used the word "legitimate" several times in the course of his evidence. Did he think it legitimate to sell a medicine bearing on its label a guarantee of genuineness signed in the "facsimile" signature of a non-existent person? The witness replied that he considered it quite legitimate. This was a business that his firm had purchased.

The Chairman: I do not remember any reference by you to the admittedly fraudulent large class of proprietary medicines. You alone of all the witnesses called have not alluded to this.

The Witness: I am sorry I did not say anything about it. There is such a class of medicine; it is advertised through the post mainly. It is desirable that these preparations should be dealt with by legislation.

MOTOR CARS FOR MEDICAL MEN.

SMALL CARS.

THE Clement Bayard Company of Levallois, Paris, has recently opened an agency in London (98, High Street, Marylebone) for the sale of certain cars which are to be known under the title of the Bayard. They appear to have been brought out in answer to the demand for small cars with multiple cylinders, but otherwise of simple construction. The cars now being marketed are in three sizes—8 h.p., 10 h.p., 14 h.p. They all have four cylinders cast in monobloc form, chassis of pressed steel, Bosch magneto ignition, thermo-syphon cooling, automatic pump lubrication, leather cone clutches, and four speeds, including reverse. The transmission is by a Carden shaft enclosed in a torque tube carried back to a bevel-driven back axle. The brakes are foot brakes and act on the back wheels, and the wheels of wire furnished with Michelin tyres. The wheel base of the 8-h.p. car is 5 ft. 5 in., and its total length 9 ft. 5 in., while its cylinders are 60 by 20. The price of this car when fitted with a two-seater torpedo body is £197. The bore and stroke of the 10-h.p. four-cylinder Bayard are 65 and 120 respectively; the price when fitted with a four-seater torpedo body is £241. In the 14-h.p. four-cylinder Bayard the bore is 80 and the stroke 130, the wheel base being 9 ft. 5 in., and the total length 12 ft. 11 in. The price of the chassis alone is £308. We have not yet had an opportunity of trying these cars, but expect to find that they are of a satisfactory character, because the Clement Bayard Company has a very high reputation in France.

IN the course of a paper on acetylene lighting, read before the Illuminating Engineering Society on January 10th, Mr. C. Huddle said that in the United States acetylene is used, not only to light motor cars, but to start the engine. On a recent American tour he saw these motor starters being made by the thousand, and they appeared to work very satisfactorily on the cars fitted with them. A small charge of compressed or dissolved acetylene was pumped into the cylinder by a simple hand-pump and fired by the ordinary electric spark. In this country the use of acetylene for motor cars seemed to be limited to lighting purposes, its great advantage being the convenience with which the tubes containing dissolved acetylene could be carried from place to place. Mr. Huddle stated that acetylene was being employed for miners' lamps to a great extent on the Continent. In France 50,000 acetylene lamps were in use in the mines, and double this number in Germany. The qualities of acetylene lamps for mines had recently been the subject of careful attention, and inquiries into the experiences obtained with open acetylene lamps in the metalliferous and salt mines of Prussia had lately been made by the Prussian Minister of Trade and Commerce, and a corresponding inquiry had been instituted in France.

NOVA ET VETERA.

PROVERBIAL MEDICINE.

PROGNOSIS IN PROVERBS AND FOLKLORE.

Prognosis in disease is proverbially difficult, and so it comes about there are not many proverbs which can be said to yield real assistance in forecasting the future. It requires a very old doctor or a much experienced nurse to foretell a patient's death, and few care to risk their reputation on a guess as to the exact time of the end. "Death defies the doctor"¹ in more senses than one. Further, prognostic proverbs are so closely allied to superstitious beliefs as to be sometimes incapable of separation from them. Nevertheless, there are many interesting sayings of a prognostic kind in common use which are worthy of consideration by the medical man who wishes to be acquainted with popular notions regarding sickness and the signs of approaching recovery or impending death. It is always disconcerting for the doctor to be ignorant of beliefs known to his patients or their friends, even when these are only of the nature of folklore.

Shakespeare's picture² of the prognostics of the approach of death is so well known and so often quoted as almost to have acquired proverbic force. The hostess says to Bardolph, concerning Falstaff's death:

A'parted even just between twelve and one, even at the turning o' the tide, for after I saw him fumble with the sheets and play with flowers, and smile upon his fingers' ends, I knew here was but one way; for his nose was as sharp as a pen, and he babbled of green fields. . . . So a' bade me lay more clothes on his feet. I put my hand into the bed and felt them, and they were as cold as any stone; then I felt to his knees, and they were as cold as any stone, and so upward and upward, and all was as cold as any stone.

Thomas Lupton's description³ contained a few more details:

If the Forehead of the Sick wax red, and his Brows fall down, and his Nose wax sharp and cold, and his left Eye become little, and the corner of his Eye run, if he turn to the wall, if his Ears be cold, or if he may suffer no brightness, and if his Womb fall; if he pulls Straws or the Cloaths of his bed, or if he pick often his Nostrils with his fingers, and if he wake much: these are most certain tokens of death.

In these descriptions the medical reader will recognize many of the symptoms of impending dissolution put into popular language, and other signs are hinted at in some sayings and beliefs as the following. Thus the loss of transparency of the cornea may be the origin of the saying reported by Adams⁴ that

Some physicians maintain that, if looking in a sick man's eyes they see their image, there is hope of life; but the want of this resultance is held an argument of instant death.

Again, there is the adage, "Hunger in sick folks doth foretell death's sad approach," referring to the keen desire for food which is superstitiously explained as the earth or the grave calling for them. The proverbial "death-rattle" is due, of course, to the noise caused by mucus in the trachea which the sick man cannot bring up; and there is the saying, "I shall die, I cannot spit from me," which may point to the same *ante-mortem* inability.

Unusually high spirits in any one are often held to presage an illness or even death; and physiological conditions, such as a rising temperature, doubtless underlie and cause the phenomenon. In some persons an attack of gout or megrim is preceded by a feeling of well-being or of mental brilliancy. In Scotland, principally, this state of mental exaltation is commonly known as *bring fey*, possibly from the Old English *fœge*, fated to die or near to death; and there are such proverbial sayings as "death on the fayest falls," and "there'll nae man die but him that's fe." In Wright's *Dialect Dictionary*⁵ the explanation given of the word is that it was formerly used to express the state of a person who was supposed to be dying, but who would rise from his bed and go about the house, conversing with his friends as if nothing ailed him;

but it was also used of persons in health whose eyes displayed unusual brightness, and who appeared to act and speak in a wild and mysterious manner. This state of feydom or feyness has been illustrated by several examples in *Notes and Queries*⁶ taken from Shakespeare (*Romeo and Juliet*), Casanova's *Memoirs*, Howell's *Letters*, Scott's *Guy Maunering*, and Tytler's *History of Scotland* (death of James I); but the instances chosen were all cases of sudden and violent death. The "lightening before death"⁷ following upon disease has another cause, if, indeed, we can speak of these historical cases of feyness as anything more than mere coincidences brought to mind after the event by superstitious people. It is to be explained probably by changes in the cerebral circulation; and it may very easily deceive the unwary doctor as well as the uneducated relatives into a hopeful prognosis.

It is possible that some of the death warnings so often spoken of by the superstitious may have their origin in the visual and auditory phenomena which result from disturbance of the functions of the liver or kidneys or are due to acute degrees of anaemia. In this group may perhaps be placed "seeing a black dog cross the path," hearing "heavy rumbling sounds" or "strange voices," and dreams, especially of the nightmare type. Even the detection of an unpleasant smell (for example, "smelling the grave to-night will see the corpse to-morrow") may originate in one of the sensory disturbances of the olfactory nerve known to precede some diseases; but the proverb quoted probably refers rather to another's death than one's own.

Osler,⁸ again, writes of the anomalies of vision which may go before apoplexy (the so-called "warnings"), and apoplexy is just the sort of disease which lends itself to the public mind as an instance of mysterious visitation. A blue mark on the skin appearing without known cause and called a *dede-nip* or *witch's nip*, has been regarded as of grave import; may it not in some instances have been purpuric?

Sir Thomas Browne⁹ refers to a curious belief that a dying person "loses his own face" and begins to look like some of his near relations, and alludes to a case in which a young man, dying of consumption, "maintained not his proper countenance, but looked like his uncle, the lines of whose face lay deep and invisible in his healthful visage before"; he reflects that "as from our beginning we run through variety of looks, before we come to consistent and settled faces; so before our end, by sick and languishing alterations, we put on new visages; and in our retreat to earth, may fall upon such looks which from community of seminal originals were before latent in us." Sir Thomas is not referring here to the *facies cadaverica* s. *hippocratica* ("nose as sharp as a pen," etc.), for he calls it that "odd mortal symptom not mentioned by Hippocrates."

Osler has a saying regarding death which may yet become a proverb—namely, "A man rarely dies of the disease from which he suffers." The explanation of this apparently paradoxical statement is, of course, the incidence of terminal infections made possible by the weakened resistance of the tissues occurring some little time before death; the primary disease makes death possible, but the terminal infection gives the *coup de grâce*. In this relation reference may be made to the somewhat commonly remarked coincidence that a physician dies of the disease he has specially studied or has been specially successful in treating. Nearly every one can bring to mind such cases; but it is doubtful whether they are really common, for whilst their occurrence is certain of recognition and comment their non-occurrence passes without remark.

Many proverbs declare the certainty of death—"All men are mortal" (*Mors omnibus communis*) is very true, but "All men think all men mortal but themselves"¹⁰ is the form in which the ordinary man interprets it; "No one can escape death" (*Mortem effugere nemo potest*); "Nothing is certain but death and the taxes"; "Thou know'st 'tis common, all that lives must die, passing through nature to eternity";¹¹ "The first breath is the

beginning of death" (*Nascentes morimur, finisque ab origine pendet*);¹² "Death borders upon our birth, and our cradle stands in the grave";¹³ "Death is common to every age" (Cicero);¹⁴ "A man may not see to-morrow, but he will certainly see the day of his death," and so on, and so on. Death is indeed the ultimate prognosis. Some proverbs, recognizing this universality of the mortal ending of life, put the best face on it and say it is "Better to die quickly than to live sickly," and "*Bona mores est homini, vitæ quæ extinguit mala*" (Death, which destroys the evils of life, is good to a man); others boldly say "*Mortem optare malum, timere pejus*" (To wish for death is bad, to fear it worse), and "*C'est ici que j'attends la mort, sans la désirer, ni la craindre*"; and yet others, with a high hope embedded in them, briefly declare "*Mors janua vitæ.*"

The idea of death "a necessary end" which "will come when it will come"¹⁵ seems to be reflected in such proverbs of a prognostic kind as "If doctors fail, what shall avail?" and "While the doctors consult the patient dies"; and it may possibly be shadowed forth in the proverb quoted by Rabelais that "Happy is the physician who is called in at the end of the illness" (*Heureux est le médecin qui est appelé sus la déclinaison de la maladie*)—meaning, it may be supposed, that then the appointed end of recovery or of decease is no longer dependent upon his skill or lack of it. "There is no remedy against death in the herbarium of the apothecary (*Contra malum mortis non est medicamen in hortis*)" is another such saying. The danger of relapses in disease is well known to the proverbialist, who puts it in such forms as "The relapse is worse than the disease," "The second fall in sickness is ever most dangerous," and "Our sinnes, I fear, will work worse afterclaps, and there's most danger in a re-relapse."¹⁶

The almost invariably fatal result of certain diseases has also been crystallized into proverbs. Thus, Lucretius wrote of the plague in Egypt, which defied the best medical skill of the time: *Mussabat tacito medicina timore* (The art of medicine murmured low in mute fear);¹⁷ and, of the same malady in Sicily, Silius Italicus said, *Succubuit medicina malis*. Then there is the French proverb of the four disastrous states whose names end in *ique*: *Les maux terminant en ique font au médecin la nique*. These were *hectique, apoplectique, paralytique, and léthargique*; and in English we might render the adage, "Diseases ending in ick, give the doctor the kick." With all the advances that have been made, it is still true that consumption (hectic), apoplexy, paralysis, and lethargy (Arbutnot's "lighter sort of apoplexy") are maladies of grave import, and, with some slight readjustment of opinion, are even now reckoned of the worst prognosis. It may be added that "*faire la nique*" means to give a sign of contempt or mockery, as in the expression, "*Un vrai philosophe fait la nique à la fortune, aux richesses*" (A true philosopher turns up his nose at fortune, at wealth); it may be compared with Shakespeare's "Do you bite your thumb at us, sir?"¹⁸

Ague, by which we must suppose that a chill or rigor is sometimes intended, has given rise to some prognostic proverbs. The saying that "a quartan ague is the reproach or shame of physic" (*opprobrium medicorum*) may possibly refer to the risk of relapses and reinfections. There is also the proverb that "quartan agues kill old men and cure young," and there is that other somewhat mysterious adage that "No man dies of an ague or without it";¹⁹ possibly a rigor is all that is here meant. "An ague in the Spring is Physic for a king" may perhaps be explained by the other proverb (a French one) which declares that "From a great illness a man comes to a great health" (*De grande maladie vient en grande santé*); and there is another saying which affirms that "autumnal agues are long or mortal," which is connected, no doubt, with the adage, "Agues come on horseback, but go away on foot," appearing in French as "*Les maladies viennent au cheval retourment à pied.*"

The common cold in the head has given rise to some proverbs of a prognostic kind. Thus we hear it said "A cold must have its course," a form of prognostic fatalism which is probably no more than a reflection of the more widely reaching saying that every disease will have its course. There is greater exactness in the adage which declares that a cold takes "Three days to come, three days to stay, and three more to go away."²⁰ There are other proverbial sayings about colds, such as "A cold begins with the cat and goes through the house," but they are etiological or therapeutical.

Burton, in his immortal *Anatomy of Melancholy*,²¹ has a characteristically rich and entertaining chapter on the "prognosticks" of that dread malady. Notice has already been taken of the proverbial effects of ague, and Burton adds another when he writes that "All melancholy men are better after a quartan"; and then he quotes Jobertus, who "saith, scarce any man hath that ague twice; but whether it free him from this malady, 'tis a question; for many Physicians ascribe all along agues for especial causes, and a quartan ague among the rest." He passes to the evil "prognosticks": "*inveterata melancholia incurabilis*, if it (melancholy) be inveterate, it is incurable, a common axiom, *ant difficulter curabilis*, (or), as they say that make the best, hardly cured. . . . As Lucian said of the gout, she was the Queen of diseases, and inexorable (*Regina morborum et incurabilis*), may we say of melancholy." So Burton discursively but delightfully runs on, "skimming off the cream of other men's wits, picking the choice flowers of their tilled gardens," and furnishing forth adages, axioms, semi-proverbs, and proverbs for the amusement and the edification of all who have fallen under his spell.

Some prognostic proverbs of a miscellaneous kind may be brought together here. Among surgical ones there is the German saying, *Kleine Feinde und kleine Wunden sind nicht zu verachten* (Little enemies and little wounds are not to be despised). There is here, perhaps, a proverbic warning against the infected prick or puncture of sepsis. There is also a Danish form of this proverb²²—namely, *Ingen skal foragte lidet Saar, juttigt Fraende, eller ringe Fjende* (Despise not a small wound, a poor relation, or a humble enemy). Whilst one proverb says "A green wound is soon healed," another gives the bad prognosis that "A wound never heals so well but that the scar can be seen." The busy operating surgeon of the present day will be indisposed, perhaps, to agree with the Latin proverb which says:

Medicus dedit qui temporis morbo curam,

Is plus remedi quam cutis sector dedit

(The physician who allows time for the cure of a disease gives a better remedy than if he used a knife).²³

And there is another Latin adage (from Ovid²⁴), which says:

Principis obsta: sero medicina paratur

Quam mala per longas convalescere moras

(Resist the first advances: too late is a cure attempted, when through long hesitation, the malady has waxed strong).

And there is yet another,²⁵ which states that there is no use asking for hellebore when the skin is dropsical, *Lenienti occurrite morbo* (Meet the approaching disease). The following French adage is probably a reflection of the one already quoted about an ague in spring; it runs thus:

*Qui a la fièvre au mois de May,
Tout l'an demeure sain et gai.*

It is sometimes a little difficult to distinguish between proverbs which have a prognostic meaning and those which are rather to be reckoned as etiological. This observation applies specially to such sayings as "A green winter makes a fat churchyard," "Many sloes, many cold toes," "Often drunk and seldom sober, falls with the leaves in October," etc. Another problematical proverb is, "If the patient and the disease join, then in vain is the physician"; but it may be taken to mean that if the patient is hopeless in his forecast then the physician cannot form a good prognosis, although it

also signify that there is no chance for the sick man to ally himself with his malady by refusing to take his doctor's medicines or submit himself to the surgeon's knife, or who continues to do the things which have caused his disease. These rambles among the prognostic overbills may be brought to an end by the best known of them all, "While there is life there's hope," with its Latin equivalent, *Spes vitæ cum sole redit*, or that Greek one from Theocritus (*Idyll IV*, line 42), ἐλπίδες ἐν ζῶσιν, ἔλπεται δὲ θανόντες ("hopes are among the living, and the dead are beyond hope"). One ought to take heart. *desperandum: dum spiro, spero.*

LITERARY NOTES.

A paragraph published in this column on December 1st, 1912, it was said that there was no documentary evidence that Flaubert, though the son of a famous surgeon in Rouen, had himself ever studied medicine. It was added that there was evidence that before introducing discussions to medical matters he sought the counsel of medical friends, and that he was sometimes coached by his lifelong friend Louis Bonilhet, who had been a medical student. The paragraph has brought us a note from Dr. William Fingland, of Liverpool, reminding us that in the BRITISH MEDICAL JOURNAL of January 31st, 1903, it was stated that M. Charles Fortin, an *officier de santé*, was the trusted adviser of Gustave Flaubert, "not only as to his health, but as to medical matters with which he wished to deal in his writings." The death of M. Fortin had occurred in Rouen shortly before this note appeared, and it would seem that the fear then expressed that he had left no reminiscences was well founded, for as far as we are aware nothing from his pen has been published during the ten intervening years.

The influx of foreign dancers, who for the last few years have taken the hearts of Londoners by storm, has done much to revive the ancient national love of dancing, and has given fresh impetus to the movement which has for its object the resuscitation of the beautiful old English dances. Moreover, it has helped to show dancing in its true colours as one of the most excellent of all forms of physical exercise; even the most ardent devotee of calisthenics or Swedish drill is now beginning to recognize its virtues as a means of promoting health and activity. It seems to have been left to M. Emile Jaques-Dalcroze, the founder of the College for Eurythmics at Hellerau, near Dresden, however, to discover the hitherto unsuspected value of the dancing lesson as an educational factor in the life of school children. The January number of *The Child* contains an interesting account, by Mr. Charles B.ingham, of the Jaques-Dalcroze system, which combined a "natural and graceful physical culture with an assured knowledge of all the complexities of the theory and notation of music and a high degree of sensibility to the basic form or mould of interpretative emotional consciousness, rhythm." The happiest results have already been obtained from this system, whose success was amply demonstrated by the grace and intelligence of the little pupils who accompanied M. Jaques-Dalcroze on his recent visit to this country, and who gave some charming displays of singing and dancing under his direction. It has been said that children, when properly instructed, dance as naturally as they walk; and it might be added with equal justice that many of them act with the same simplicity and lack of self-consciousness. An article by E. Flower on the Village Children's Historical Play Society, which appears in the January number of *The Child*, proves the aptitude of the normal boy or girl to strut and fret his hour upon the stage, and the educational value of this form of amusement. The same number also contains an article on the feeding of infants, by Dr. James Oliver, and another on school hygiene by Dr. Arnold L. Gesell; whilst Dr. A. Gilmore discusses "Measles and Child Welfare," and Lady Henry Somerset has contributed a short account of her home for destitute children at Duxhurst in Surrey.

No one who has ever had the pleasure of reading the letters of Isabella d'Este, Marchioness of Mantua, the

sister-in-law of Lucrezia Borgia, and one of the most brilliant women of her time, can fail to have been struck by the writer's passion for collecting. Books, pictures, jewellery, curios, all were fish that came to her capacious net, so that at one time the palace of the Gonzagas at Mantua must have resembled a museum crowded with rare and beautiful objects, of which, it need hardly be added, their owner was justly proud. This love of collecting, however, was by no means peculiar to the Marchioness Isabella, but was shared by nearly all her contemporaries, both in Italy and other countries. The earliest museums on record, therefore, were really the rooms set apart in the private houses of enthusiastic collectors for the accommodation of the owner's most precious possessions. M. Pierre-Amédée Pichot, writing in the December number of *L'Hygiène*, gives an interesting description of several of these old-world collections. Probably the one that would have appealed most strongly to a modern mind was that of a Liverpool man named Bullock, which from 1809 to 1819 was on view at the building afterwards known as the Egyptian Hall. This collection comprised several authentic relics of the first Napoleon, of which the most important was the travelling carriage captured by the Prussians at Waterloo, and presented by Blücher to the Prince Regent. The First Gentleman in Europe displayed doubtful taste in selling the property of his defeated adversary to Mr. Bullock, who afterwards disposed of it, in his turn, to a Mr. Hopkinson, a coach-builder in Holborn. It may be remarked in passing that this same carriage is now on view at Madame Tussaud's, having found its way there after leaving Hopkinson's hands. Such personal belongings as were found in the berline at the time of capture were sold separately, when Mr. Bullock's collection was broken up and brought under the hammer. They consisted of a small canteen containing a couple of flasks, plate, goblet, china egg-cup, and a silver salt-cellar, pepper-box and mustard-pot, which still held the remains of the condiments with which they had once been filled, a set of chessmen used by the Emperor during the Russian campaign, a flask half full of rum, and two of the imperial toothbrushes. Perhaps the most pathetic reminder of departed glory, however, was the tiny uniform of a miniature colonel of lancers, which had originally been made for the child who afterwards became Napoleon III.* This suit, with all the accoutrements, was knocked down for less than £4, a sad ending for what was probably a source of infinite pride and pleasure to its little owner. The December number of *L'Hygiène* also contains an excellent article by Dr. Maurice de Fleury on the treatment of neurotic patients; whilst Dr. Robert Wurtz has contributed a short account of the present state of the public health in France, and M. Henri Meunisse advises his readers how to keep healthy during the winter months.

* The child referred to was not Napoleon's son, but his nephew, who afterwards succeeded him as Emperor, and was the husband of the Empress Eugénie.

A NURSING Conference and Exhibition will be held at the Horticultural Hall, Westminster, on April 22nd and the three succeeding days. The conference, which will discuss both nursing and midwifery, is being organized by a committee of matrons representative of all branches. Further particulars may be had from the office, 22-24, Great Portland Street, W.

THROUGHOUT the total number of persons who went to Carlsbad last year for treatment showed a fall from 70,935 to 68,269, there was an increase of nearly 100 English patients. There was a decline of 600 in the number of American patients. It is said that most resorts of the kind had fewer visitors than usual last year owing, it is thought, to the bad weather of the summer, and the disturbed political situation in Europe.

THE Woman's Medical Association of New York City notifies that an appointment will be made to the Mary Putnam Jacobi Fellowship of 800 dollars for post-graduate study on June 1st, 1913. Applications must be received by April 1st. The fellowship is open to women graduates in medicine, and will be awarded upon proof of ability and promise of success in the chosen line of work. Further particulars can be obtained on application to Dr. Martha Wollstein, 325, Central Park West, New York.

SCIENCE NOTES.

The final and successful attempt to set up a universal radium standard dates from 1910, when the Congress of Electricity and Radiology, meeting in Brussels, appointed an international committee of physicists to select a well-defined unit in which quantities of radium emanation might be expressed. The result has been the adoption of the unit known as the curie. But as certain other standards, more or less arbitrary, have hitherto been in vogue, and have found their way into literature, it becomes necessary to tabulate their comparative values with the new standard. MM. Jacques and Gaston Daune¹ group the various units employed to express the quantity of radium emanation as follows: (1) Curie, millicurie, microcurie; (2) gram-second, gram-minute, milligram-second, milligram-minute; (3) maché. Without entering fully into the questions involved in the setting up of this new standard, the fact may be recalled that radium emits, spontaneously and continuously, a gas (emanation) which itself is a radio-active substance. The transformation of this gas into another radio-active product follows the law that the quantity of emanation destroyed at each instant is proportional to that which is not yet transformed. While radium has a very slow period of decay, its emanation has a very rapid period, and therefore, owing to the decomposition of the emanation itself, the process of accumulation cannot be carried beyond a certain point. That point is reached when the quantity of emanation produced at each instant is equal to that which is destroyed, and at this moment of radio-active equilibrium the quantity of emanation is the greatest possible for the amount of radium involved. The curie represents the quantity or mass of radium emanation in equilibrium with one gram of radium (element), while the millicurie and the microcurie are quantities in equilibrium with one milligram and one-thousandth of a milligram respectively. The gram-second is the quantity of emanation freed by a gram of radium (element) during one second, and the milligram-minute, by which the greater number of French thermal stations express the radio-activity of their waters, is the quantity of emanation produced by a milligram of radium during one minute. The maché unit, an expression common in this country and in Germany, depends upon the ionizing effect of the radiation emitted by radio-active substances. The ions thus formed may be collected, and the electric current produced in an ionization chamber is easily measurable by means of electrometer or electroscope. The maché unit represents the quantity of emanation, without disintegration products, which produces a current of limited saturation—that is to say, in a receptacle of very large dimensions—equal to one-thousandth of the electrostatic unit of current intensity. It is a very small unit, whereas the curie is a large one. The emanation contained in 10 litres of mineral water moderately radio-active is of the order of 0.1 microcurie, whereas in maché units it would be expressed by hundreds. The table of equivalents is as follows:

| Curie. | Millicurie. | Microcurie. | Milligram-minute. | Maché. |
|--------------|-------------|-------------|-------------------|-----------|
| 1 | 1000 | 1000000 | 7992000 | 250000000 |
| 0.001 | 1 | 1000 | 7992 | 2500000 |
| 0.000001 | 0.001 | 1 | 7.992 | 2500 |
| 0.00000208 | 0.00208 | 2.08 | 16.66 | 5213.5 |
| 0.0001248 | 0.1248 | 124.8 | 1000 | 312812 |
| 0.00000002 | 0.00000208 | 0.00208 | 0.0166 | 5.213 |
| 0.0000001248 | 0.0001248 | 0.1248 | 1 | 312.8 |
| 0.000000004 | 0.000004 | 0.0004 | 0.00319 | 1 |

To find the gram-minute figures, the figures for the milligram-minute are in each case divided by 1,000.

The electric condition of the earth in relation to the atmosphere is forced upon attention during a storm of lightning, and it has been stated that thunder clouds are sometimes negative and sometimes positive towards the surface of the earth. But it is not easy to get any

clear ideas on the general subject from books. From an article Dr. George C. Simpson contributed recently to *Nature* it seems that the physicists have not yet arrived at any certain and comprehensive conclusion. He sums up the present state of knowledge by stating that a flow of negative electricity takes place from the surface of the whole globe into the atmosphere above it, and that this necessitates a constant return current of more than 1,000 ampères, but that nevertheless not the slightest indication of any such current has so far been found, and no satisfactory explanation for its absence has been given. The loss takes place from all regions of the earth, subject to normal or fine weather conditions, so that it would appear that a return current can only exist in regions of disturbed weather; in such regions the potential gradient is often reversed, and the rain charged. Though a reversed field causes a flow of negative electricity into the earth, yet the time during which the field is reversed is only a very small fraction of the time during which it is normal. If the loss were made good in this way the flow of electricity would be so enormous that it could not escape detection. It was believed for many years that the electricity comes to the earth in the disturbed area as a negative charge on rain. But experiments in many widely separated parts of the world show that in all kinds of rain, from that of thunderstorms to a drizzle, more positive than negative electricity is brought to the earth. So that rain only makes the problem more difficult. Nor does it seem probable that lightning discharges from cloud to earth can play an important part. Thus, Dr. Simpson says, the science of atmospheric electricity has come to a deadlock, and there is at present no indication of a way out.

Klausner found that in over 50 per cent. of syphilitic cases and in certain skin diseases a precipitate was obtained if the serum were diluted with three times its volume of water. Further investigation of the mechanism of this reaction has revealed certain very interesting phenomena, which may shed considerable light on the rationale of the Wassermann and kindred reactions. In the *Biochem. Zeitschr.* for November 20th, 1912, Klausner gives the details of his experiments with normal and syphilitic serums, both heated and unheated. He shows that every serum which gives the particular reaction loses that property when it is heated or after extraction with ether. In the latter case the property can be restored; in other words the serum can be reactivated by the addition of an ethereal extract of brain lipoids, but in the former case this addition does not restore the property. A normal unheated serum gains the property of giving a precipitate on dilution with water if the ethereal extract of brain lipoids be added to it, whereas this does not occur with heated normal serum. On the other hand a serum which has been activated by the addition of the lipoids is rendered permanently inactive by heating, but if the lipoids be heated separately their activating properties are not destroyed. The active property is only lost when they are heated in the presence of the serum, and in that case the addition of fresh serum does not restore it. A positive serum rendered inactive by extraction with ether becomes again positive if its extract be restored to it; the addition of the same extract to a normal serum renders it also active, and it is even possible to activate a negative serum by adding to it the ether extract of a normal serum although in this case higher concentrations of the ethereal extract must be employed.

In view of the claim put forward by Neubauer and Fischer, and supported by others, that many cases of cancer of the stomach contain an enzyme capable of hydrolyzing glycytryptophan, and that the detection of this ferment by a simple method was of considerable diagnostic value, Schryver and Singer (*Quarterly Journal of Medicine*, October, 1912), have investigated the gastric contents after test meals in 200 cases of grave stomach disorder for the presence of a peptolytic ferment. Such a ferment was found in 17 of the 200 cases, but gastro-jejunostomy had been performed in 4 of these, and in these instances the ferment was regarded as being of duodenal origin. The remaining 13 formed a well-marked group in which the total acidity was low, free hydrochloric acid was absent, the total and active chloride were below normal, and what the writers term the "peptic

¹ Archives d'électricité médicale, December 10th, 1912.

index" was very low. It is worthy of note that, though the results of gastric analysis of these 13 cases would generally be regarded by the clinician as being indicative of cancer of the stomach, yet only in 4 of them was a malignant growth present, and in one of the latter it was situated in the duodenum and not in the stomach. The presence of the peptolytic ferment is certainly not characteristic of gastric cancer, for in 25 undoubted cases of the disease a positive result was obtained only in one. The writers associate the presence of the ferment with gastric dilatation and atrophy of the walls, and consider that it is of local origin.

THE DEVELOPMENT OF BATH.

VISIT OF LONDON MEDICAL MEN.

ONLY the weather was inhospitable on January 18th, when, by the invitation of the Mayor, a number of leading members of the medical profession paid a visit to Bath. Immediately on arrival the visitors were taken on a fleet of motor-cars to the heights of Lansdown and other beautiful environs of the city: and at night, in the Grand Pump-room, the after-dinner toasts were being drunk only ten minutes before the return train was due. It was stated, by the way, to have been the first time within the memory of the oldest inhabitant that the ancient Tompion clock and the solemn-eyed statue of Bean Nash have looked down upon anything so vulgar as a dinner.

A brief lecture on the city's antiquities was given among the Roman remains, and then, to compare ancient things with modern, the visitors made a tour of the bathing establishment, and also inspected the institute for medico-mechanical treatment, which is one of the most recent additions to the therapeutic equipment of the spa. Still more recent, however, is the "inhalatorium," where, at Sir William Ramsay's suggestion, special apparatus has been installed for the inhaling of the mineral water finely atomized by the "niton" gas or radium emanation. An ingenious spraying arrangement, hitherto fed with air or with air and steam, is now fed also with the natural gas rich in its radio-active properties, and is being used in the treatment of disorders of the nose and naso-pharynx, and in various local affections. The idea is that by this means, not only the radio-activity of the water, but the higher radio-activity of the gas itself, is brought into play.

At a subsequent gathering in the concert hall, the Mayor (Mr. G. T. Cooke) laid stress upon the national character of the asset which Bath possesses in her mineral waters, and expressed the determination of the city to make it realizable to the full. He hinted that the authorities had been approached by those who were prepared to spend from a quarter to half a million upon the baths, but whether this would mature or not, Bath as the premier English spa must go forward.

Sir WILLIAM RAMSAY then delivered an address which was to a great extent a recapitulation of his previous statement as to the radio-activity of the Bath waters.¹ The amount of radium present in the form of emanation, he said, compared favourably with the richest waters on the Continent, such as those of Carlsbad. The emanation had 75 per cent. of the radio-active property possessed by its parent radium in the subterranean depths, and its decomposition, after being given by the mouth or by injection, was followed by similar physiological effects. The fact that the emanation issuing from the gas in the Bath spring was so much greater (perhaps twenty times greater) than the emanation in the water itself, seemed to have a practical bearing upon the therapeutic application of the substance. Therefore he had suggested—and the suggestion had been put in practice in the "inhalatorium"—that the gas from the waters should be bottled up under pressure and used in spraying the water for the treatment of local conditions. It would be an advantage if in such cases, as well as in other treatments in the baths, the patient were insulated and rather strongly electrified negatively, as the absorption of the radio-active particles, which were for the most part positively charged, would then be accelerated. There were three possible methods of applying the emanation therapeutically. One method was to drink the waters saturated with the substance, and this had been carried

out for centuries in the pump-room; the second method was to inject a solution of the gas below the skin, and for this purpose the water was insufficiently charged to produce a result with any practicable quantity; the third method was to inhale the gas, for which special provision had now been made. Sir William added that the use of the emanation in one form or another had a great advantage over any possible means of swallowing or injecting doses of radium, for, apart from the expense of this latter procedure, the slow period of radium decay would mean that very little of it would decompose during the time in which it could remain in the system, whereas the shorter life of the emanation made it therapeutically much more potent.

Sir LAUDER BRUNTON, in a few reminiscent remarks, said that, so far as he knew, Sir William Ramsay was the first to suggest the use of radium in medicine. He came to him (Sir Lauder) seven or eight years ago with the idea that radium might be of service in the treatment of cancer. The suggestion was not put into practice within his own experience until almost two years later, and, although in that particular instance, there was subsequent recurrence, the events were sufficient to demonstrate the potentiality of the radium. In rodent ulcer its effect was remarkable, and in such conditions as sciatica and neuritis he believed radium treatment to have done a great amount of good. From his own experience of radium he had learnt two things—namely, that radium did excite tissue activity, and that extreme care was necessary with regard to dosage.

It was, however, the development of Bath itself in view of its treasure trove that was chiefly discussed. Dr. LEONARD WILLIAMS here revealed himself as the candid friend. He said that, in spite of the smiles of those who talked about the influence of suggestion, it was known that all so-called indifferent thermal waters had a virtue in certain pathological conditions, and among such waters those of Bath were, perhaps, the most efficacious. But when it came to the question of the arrangements at Bath he was less inclined to be laudatory. Comparing the Somerset spa with some of those which were best known on the Continent, he had to reply that the accommodation for bathers and the attractions for visitors were inadequate. He trusted that the English thermal station, in no respect behind its rivals in natural advantages, would develop its resources and bring its establishments up to the high level which its past history warranted.

Further comparisons of Bath with foreign spas were forthcoming at the dinner, when Sir LAUDER BRUNTON, in proposing the toast of "Prosperity to the baths of Bath," said that he had visited almost every health resort of importance in Europe and some out of Europe, but after forty years' wandering his choice was limited to Bath and Aix-les-Bains, the latter suffering, of course, from the disadvantage of distance.

Sir BERTRAND DAWSON, in supporting the toast, said that Bath would have to bid farewell to the evil tradition which had haunted the spas of this country. The tradition might be summarized in the word "haphazard." It was necessary to remember not only the definite treatment of the patient, but the life he had to live. It was useless to bathe a man for his gout in the morning and allow him to nullify the effect with a five-course dinner at night. A stricter regimen was necessary, and he suggested that possibly something might be done in this direction in Bath by means of the hotel owned by the Corporation. Careful organization such as this was the true secret of the success of Carlsbad and other places on the Continent. There a rigorous dieting was enforced, the patient having to do what he was told; he was directed to take graduated exercise, and the distances of his walks were marked out with red posts for the first week and with green posts for the second, and so on. Bath had a band of medical men, progressive, full of knowledge, and up-to-date, but no scheme of organization could succeed without the far-sighted and enterprising layman.

Dr. W. HALE WHITE expressed the thanks of the visitors for the hospitality they had enjoyed. It should be added that no small amount of the success of the occasion was due to the local medical men, whose spokesman, Dr. E. J. CAVE, in a brief speech, said that it was impossible for any man to practise his profession in Bath and remain sceptical as to a specific and potent virtue attaching to its waters.

SATURDAY, JANUARY 25TH, 1913.

THE THERAPEUTICS OF RADIUM.

THE first report of Mr. Hayward Pinch, the Medical Superintendent of the Radium Institute, founded in London in 1911 at the suggestion of King Edward VII, and through the munificence of Sir Ernest Cassel and Viscount Iveagh, is an interesting and in many ways a remarkable document, for the opportunity of publishing which we are indebted to Sir Frederick Treves, Chairman of the Executive Committee of the Institute. It is remarkable, first, for the temperate spirit and scientific caution with which it is drawn up, and it is remarkable also for the striking benefit derived by certain patients in a distressing and hopeless condition from the treatment provided by the Institute. Too often those who have been concerned in the earliest application of a new method of treatment producing effects patent to any observer have been carried off their feet, and in the first flush of enthusiasm, generalizing from insufficient data, have made promises which later experience has not fulfilled. The report now published is free from that defect, and Mr. Pinch takes occasion to utter a warning against the irrational enthusiasm and unthinking expectation which has often attended the introduction of a new remedy and so led to cruel disappointment. He gives a rigid interpretation to the term "apparent cure," which is understood to be a condition in which all trace of the original lesion or lesions has disappeared, in which there is no sign of any recurrence, and in which the patient is, so far as can be determined by a thorough and careful examination, free from any indication or symptom of the disease.

The report deals with the work of the Institute since it was opened in August, 1911, down to the end of last year, a period of a little over sixteen months. Owing to the generosity of the founders, the Institute is in possession of a very large stock of radium, so that practically any quantity considered advisable can be used in the treatment of any case, but Mr. Pinch makes it clear that great discretion must be exercised in determining the amount which should be used, the duration of application, and the amount of screening in any given case. All cases applying to the Institute have been received, except those practically moribund or those in which the disease was of a kind for which radium-therapy was manifestly unsuitable.

Probably most readers will look first at those passages in the report which deal with cancer. Any attempt to form an opinion with regard to them must be governed by the statement in the opening sentences of the report that no examples of malignant disease, with the single exception of rodent ulcer, have been treated unless operation has been declared to be unjustified or the patient has absolutely refused operation; the rigid interpretation given to the term "apparent cure" must also be noted. No useful purpose would be served by a minute analysis of the statistics, and Mr. Pinch does not attempt it. The

stages and extent of the disease vary so much from case to case that only a very large number would warrant use of the statistical method, but some general impression may be obtained from a summary view of certain classes. It appears that the total number of patients suffering from epithelioma who applied for treatment at the Institute was 147; of these, 13 were not treated; in 8 the treatment was commenced so recently that no opinion on its result can be stated, and in 15 the application of radium was prophylactic only. This leaves 111 cases in which the treatment of epithelioma was undertaken, although it was abandoned in 23 patients. Of the 88 cases that remain if these be deducted, 20 are not improved and 22 are dead if to them, on the assumption that the abandonment was due to the patients' disappointment with the result, we add the cases in which the treatment was abandoned, we get a total of 65 failures, or nearly three-fifths. To set off, we have 7 cases in which the patient was apparently cured and 39 in which there was improvement—a total of 46, or about two-fifths. Applying the same system of classification we find that in cancer of the breast the treatment failed in 38 cases and was attended with more or less success in 35, and that in cancer of the rectum it failed in 27 cases, or about three-fourths, and succeeded in 10, or rather over one-fourth. The report is quite definite in advising that radium should never be used in cancer of the breast as a substitute for operation, and the same is true of cancer of the rectum. It seems established, however, that, in inoperable cases of cancer of the breast, radium is often able to relieve pain, promote the healing of ulcers, and check the growth of secondary deposits; in a few instances superficial carcinomatous nodules and enlarged glands disappeared, and reports are given of several such cases in which the results were very remarkable.

In cancer of the uterus the immediate results reported are so satisfactory that it would appear well worth while to submit any patient with inoperable disease to the radium treatment. It has been applied by introducing into the cervical canal a tube containing radium for periods of thirty to sixty hours spread over five or ten days. In a considerable proportion of cases hæmorrhage is arrested, discharge diminished and rendered inoffensive, ulceration healed, pain relieved, and the growth even in some cases stopped. Out of 39 cases treated 3 were apparently cured, while 19 were improved, but the report points out that the action is only local, that in most cases dissemination will occur, and the growth spread to parts beyond the effective range of radium.
